Preface

The Sixth Conference on Machine Translation (WMT 2021) took place on Wednesday, November 10 and Thursday, November 11, 2021 immediately following the 2021 Conference on Empirical Methods in Natural Language Processing (EMNLP 2021).

This is the sixth time WMT has been held as a conference. The first time WMT was held as a conference was at ACL 2016 in Berlin, Germany, the second time at EMNLP 2017 in Copenhagen, Denmark, the third time at EMNLP 2018 in Brussels, Belgium, the fourth time at ACL 2019 in Florence, Italy, and the fifth time at EMNLP-2020, which was held as an online event due to the COVID-19 pandemic. Prior to being a conference, WMT was held 10 times as a workshop. WMT was held for the first time at HLT-NAACL 2006 in New York City, USA. In the following years the Workshop on Statistical Machine Translation was held at ACL 2007 in Prague, Czech Republic, ACL 2008, Columbus, Ohio, USA, EACL 2009 in Athens, Greece, ACL 2010 in Uppsala, Sweden, EMNLP 2011 in Edinburgh, Scotland, NAACL 2012 in Montreal, Canada, ACL 2013 in Sofia, Bulgaria, ACL 2014 in Baltimore, USA, EMNLP 2015 in Lisbon, Portugal.

The focus of our conference is to bring together researchers from the area of machine translation and invite selected research papers to be presented at the conference.

Prior to the conference, in addition to soliciting relevant papers for review and possible presentation, we conducted 13 shared tasks. These consisted of 10 translation tasks: Machine Translation of News, Similar Language Translation, Biomedical Translation, Multilingual Low-Resource Translation for Indo-European Languages, Large-Scale Multilingual Machine Translation, Triangular MT: Using English to Improve Russian-to-Chinese Machine Translation, Translation Efficiency, Machine Translation using Terminologies, Unsupervised and Very Low Resource Supervised Translation, and Lifelong Learning for Machine Translation, two evaluation tasks: Quality Estimation of Translation and Metrics for Machine Translation, and the Automatic Post-Editing task.

The results of all shared tasks were announced at the conference, and these proceedings also include overview papers for the shared tasks, summarizing the results, as well as providing information about the data used and any procedures that were followed in conducting or scoring the tasks. In addition, there are short papers from each participating team that describe their underlying system in greater detail.

Like in previous years, we have received a far larger number of submissions than we could accept for presentation. WMT 2021 has received 49 full research paper submissions (not counting withdrawn submissions). In total, WMT 2021 featured 18 full research paper presentations and 96 shared task presentations.

The event hosted a panel discussion led by Markus Freitag (Google) on evaluation with Nitika Mathur (Univ. Melbourne), Benjamin Marie (NICT), Ricardo Rei (Unbabel), Tom Kocmi (Microsoft).

We would like to thank the members of the Program Committee for their timely reviews. We also would like to thank the participants of the shared task and all the other volunteers who helped with the evaluations.

Loïc Barrault, Ondřej Bojar, Fethi Bougares, Rajen Chatterjee, Marta R. Costa-jussà, Christian Federmann, Mark Fishel, Alexander Fraser, Markus Freitag, Yvette Graham, Roman Grundkiewicz, Paco Guzman, Barry Haddow, Matthias Huck, Antonio Jimeno Yepes, Philipp Koehn, Tom Kocmi, André Martins, Makoto Morishita, Christof Monz, Masaaki Nagata, Toshiaki Nakazawa, Matteo Negri, Aurélie Névéol, Mariana Neves, Martin Popel, Matt Post, Marco Turchi, and Marcos Zampieri

Co-Organizers

Organizing Committee

Organizers:

Loïc Barrault (University of Sheffield)
Ondřej Bojar (Charles University in Prague)
Fethi Bougares (University of Le Mans)
Rajen Chatterjee (Apple)
Marta R. Costa-jussà (Universitat Politècnica de Catalunya)
Christian Federmann (MSR)
Mark Fishel (University of Tartu)
Alexander Fraser (LMU Munich)
Markus Freitag (Google)
Yvette Graham (DCU)
Roman Grundkiewicz (MSR)
Paco Guzman (Facebook)
Barry Haddow (University of Edinburgh)
Matthias Huck (LMU Munich)
Antonio Jimeno Yepes (IBM Research Australia)
Philipp Koehn (University of Edinburgh / Johns Hopkins University)
Tom Kocmi (MSR)
André Martins (Unbabel)
Makoto Morishita (NTT)
Christof Monz (University of Amsterdam)
Masaaki Nagata (NTT)
Toshiaki Nakazawa (University of Tokyo)
Matteo Negri (FBK)
Aurélie Névéol (LIMSI, CNRS)
Mariana Neves (German Federal Institute for Risk Assessment)
Martin Popel (Charles University in Prague)
Matt Post (Johns Hopkins University)
Marco Turchi (FBK)
Marcos Zampieri (Rochester Institute of Technology)

Panelists:

Nitika Mathur (Univ. Melbourne)
Benjamin Marie (NICT)
Ricardo Rei (Unbabel)
Tom Kocmi (Microsoft)

Program Committee:

Tamer Alkhouli (AppTek)
Mihael Arcan (National Universith of Ireland Galway)
Duygu Ataman (New York University)

Eleftherios Avramidis (German Research Center for Artificial Intelligence (DFKI))
Amittai Axelrod (DiDi Labs)
Parnia Bahar (AppTek)
Petra Barancikova (Charles University in Prague, Faculty of Mathematics and Physics)
Rachel Bawden (Inria)
Meriem Beloucif (University of Hamburg)
Bill Byrne (University of Cambridge)
Ozan Caglayan (Imperial College London)
Sheila Castilho (Dublin City University)
Daniel Cer (Google Research; University of California at Berkeley)
Vishrav Chaudhary (Facebook AI)
Boxing Chen (Alibaba)
Pinzhen Chen (The University of Edinburgh)
Colin Cherry (Google)
Vishal Chowdhary (MSR)
Raj Dabre (NICT)
Steve DeNeefe (SDL Research)
Michael Denkowski (Amazon)
Mattia A. Di Gangi (AppTek GmbH)
Shuoyang Ding (Johns Hopkins University)
Miguel Domingo (Universitat Politècnica de València)
Kevin Duh (Johns Hopkins University)
Hiroshi Echizen-ya (Hokkai-Gakuen University)
Sergey Edunov (Faceook AI Research)
Miquel Esplà-Gomis (Universitat d'Alacant)
Angela Fan (Facebook AI Research)
Marcello Federico (Amazon AI)
Orhan Firat (Google AI)
George Foster (Google)
Atsushi Fujita (National Institute of Information and Communications Technology)
Ulrich Germann (University of Edinburgh)
Jesús González-Rubio (WebInterpret)
Isao Goto (NHK)
Cyril Goutte (National Research Council Canada)
Naman Goyal (Facebook)
Jeremy Gwinnup (Air Force Research Laboratory)
Nizar Habash (New York University Abu Dhabi)
Viktor Hangya (Ludwig-Maximilians-Universität München)
Greg Hanneman (Amazon)
Yifan He (Alibaba Group)
John Henderson (MITRE)
Christian Herold (RWTH Aachen University)
Cong Duy Vu Hoang (Oracle)
Mika Hämäläinen (University of Helsinki, Rootroo Ltd)
Kenji Imamura (National Institute of Information and Communications Technology)
Phillip Keung (Amazon)
Yunsu Kim (Lilt, Inc.)

Rebecca Knowles (National Research Council Canada)
Tom Kocmi (Microsoft)
Julia Kreutzer (Google)
Roland Kuhn (National Research Council of Canada)
Shankar Kumar (Google)
Anoop Kunchukuttan (Microsoft AI and Research)
Surafel Melaku Lakew (Amazon AI)
Ekaterina Lapshinova-Koltunski (Universität des Saarlandes)
Alon Lavie (Unbabel/Carnegie Mellon University)
Qun Liu (Huawei Noah's Ark Lab)
Samuel Läubli (University of Zurich)
Andreas Maletti (Universität Leipzig)
Sameen Maruf (Monash University)
Rebecca Marvin (Independent)
Antonio Valerio Miceli Barone (The University of Edinburgh)
Tomáš Musil (Charles University)
Mathias Müller (University of Zurich)
Preslav Nakov (Qatar Computing Research Institute, HBKU)
Jan Niehues (Maastricht University)
Xing Niu (Amazon AI)
Tsuyoshi Okita (Kyushu institute of technology)
Daniel Ortiz-Martínez (University of Barcelona)
Santanu Pal (Saarland University)
Carla Parra Escartín (Iconic Translation Machines)
Pavel Pecina (Charles University)
Stephan Peitz (Apple)
Sergio Penkale (Lingo24)
Marcis Pinnis (Tilde)
Maja Popović (ADAPT, Dublin City University)
Matt Post (Johns Hopkins University)
MatÄ«ss Rikters (University of Tartu)
Annette Rios (University of Zurich)
Elizabeth Salesky (Johns Hopkins University)
Hassan Sawaf (aixplain, inc.)
Rico Sennrich (University of Zurich)
Aditya Siddhant (Google)
Patrick Simianer (Lilt)
Felix Stahlberg (Google Research)
David Stap (University of Amsterdam)
Sara Stymne (Uppsala University)
Katsuhito Sudoh (Nara Institute of Science and Technology (NAIST))
Víctor M. Sánchez-Cartagena (Universitat d'Alacant)
Aleš Tamchyna (Memsource)
Gongbo Tang (Uppsala University)
Tristan Thrush (Facebook AI Research (FAIR))
Jörg Tiedemann (University of Helsinki)
Antonio Toral (University of Groningen)

Ke Tran (Amazon)
Masao Utiyama (NICT)
David Vilar (Google)
Ekaterina Vylomova (University of Melbourne)
Weiyue Wang (RWTH Aachen University)
Taro Watanabe (Nara Institute of Science and Technology)
Guillaume Wenzek (Facebook AI Research)
Joern Wuebker (Lilt, Inc.)
Hainan Xu (Google)
François Yvon (LISN CNRS & Univ. Paris Saclay)
Xuan Zhang (Johns Hopkins University)
Zhong Zhou (Carnegie Mellon University)

Table of Contents

Conference Program

Wednesday, November 10, 2021

9:00–9:10 ***Opening Remarks***

9:10–10:15 Session 1: Shared Task Overview Papers I (Session Chair: Philipp Koehn)

9:10–10:15 *Findings of the 2021 Conference on Machine Translation (WMT21)*
Farhad Akhbardeh, Arkady Arkhangorodsky, Magdalena Biesialska, Ondřej Bojar, Rajen Chatterjee, Vishrav Chaudhary, Marta R. Costa-jussa, Cristina España-Bonet, Angela Fan, Christian Federmann, Markus Freitag, Yvette Graham, Roman Grundkiewicz, Barry Haddow, Leonie Harter, Kenneth Heafield, Christopher Homan, Matthias Huck, Kwabena Amponsah-Kaakyire, Jungo Kasai, Daniel Khashabi, Kevin Knight, Tom Kocmi, Philipp Koehn, Nicholas Lourie, Christof Monz, Makoto Morishita, Masaaki Nagata, Ajay Nagesh, Toshiaki Nakazawa, Matteo Negri, Santanu Pal, Allahsera Auguste Tapo, Marco Turchi, Valentin Vydrin and Marcos Zampieri

9:00–9:25 ***News Translation Task***

9:25–9:35 ***Similar Languages Translation Task***

9:35–9:45 ***Automatic Postediting Task***

9:45–9:55 ***Triangular Translation Task***

9:55–10:05 ***Indo-European Multilingual Translation Task***

10:05–10:15 *Findings of the WMT 2021 Shared Task on Large-Scale Multilingual Machine Translation*
Guillaume Wenzek, Vishrav Chaudhary, Angela Fan, Sahir Gomez, Naman Goyal, Somya Jain, Douwe Kiela, Tristan Thrush and Francisco Guzmán

10:15–10:30 ***Coffee Break***

Wednesday, November 10, 2021 (continued)

10:30–12:00 News Translation Task

10:30–12:00 *GTCOM Neural Machine Translation Systems for WMT21*
Chao Bei and Hao Zong

10:30–12:00 *The University of Edinburgh's English-German and English-Hausa Submissions to the WMT21 News Translation Task*
Pinzhen Chen, Jindřich Helcl, Ulrich Germann, Laurie Burchell, Nikolay Bogoychev, Antonio Valerio Miceli Barone, Jonas Waldendorf, Alexandra Birch and Kenneth Heafield

10:30–12:00 *Tune in: The AFRL WMT21 News-Translation Systems*
Grant Erdmann, Jeremy Gwinnup and Tim Anderson

10:30–12:00 *The TALP-UPC Participation in WMT21 News Translation Task: an mBART-based NMT Approach*
Carlos Escolano, Ioannis Tsiamas, Christine Basta, Javier Ferrando, Marta R. Costa-jussa and José A. R. Fonollosa

10:30–12:00 *CUNI Systems in WMT21: Revisiting Backtranslation Techniques for English-Czech NMT*
Petr Gebauer, Ondřej Bojar, Vojtěch Švandelík and Martin Popel

10:30–12:00 *Ensembling of Distilled Models from Multi-task Teachers for Constrained Resource Language Pairs*
Amr Hendy, Esraa A. Gad, Mohamed Abdelghaffar, Jailan S. ElMosalami, Mohamed Afify, Ahmed Y. Tawfik and Hany Hassan Awadalla

10:30–12:00 *Miðeind's WMT 2021 Submission*
Haukur Barri Símonarson, Vésteinn Snæbjarnarson, Pétur Orri Ragnarson, Haukur Jónsson and Vilhjalmur Thorsteinsson

10:30–12:00 *Allegro.eu Submission to WMT21 News Translation Task*
Mikołaj Koszowski, Karol Grzegorczyk and Tsimur Hadeliya

10:30–12:00 *Illinois Japanese ↔ English News Translation for WMT 2021*
Giang Le, Shinka Mori and Lane Schwartz

10:30–12:00 *MiSS@WMT21: Contrastive Learning-reinforced Domain Adaptation in Neural Machine Translation*
Zuchao Li, Masao Utiyama, Eiichiro Sumita and Hai Zhao

10:30–12:00 *The Fujitsu DMATH Submissions for WMT21 News Translation and Biomedical Translation Tasks*
Ander Martinez

Wednesday, November 10, 2021 (continued)

10:30–12:00 *Adam Mickiewicz University's English-Hausa Submissions to the WMT 2021 News Translation Task*
Artur Nowakowski and Tomasz Dwojak

10:30–12:00 *eTranslation's Submissions to the WMT 2021 News Translation Task*
Csaba Oravecz, Katina Bontcheva, David Kolovratník, Bhavani Bhaskar, Michael Jellinghaus and Andreas Eisele

10:30–12:00 *The University of Edinburgh's Bengali-Hindi Submissions to the WMT21 News Translation Task*
Proyag Pal, Alham Fikri Aji, Pinzhen Chen and Sukanta Sen

10:30–12:00 *The Volctrans GLAT System: Non-autoregressive Translation Meets WMT21*
Lihua Qian, Yi Zhou, Zaixiang Zheng, Yaoming ZHU, Zehui Lin, Jiangtao Feng, Shanbo Cheng, Lei Li, Mingxuan Wang and Hao Zhou

10:30–12:00 *NVIDIA NeMo's Neural Machine Translation Systems for English-German and English-Russian News and Biomedical Tasks at WMT21*
Sandeep Subramanian, Oleksii Hrinchuk, Virginia Adams and Oleksii Kuchaiev

10:30–12:00 *Facebook AI's WMT21 News Translation Task Submission*
Chau Tran, Shruti Bhosale, James Cross, Philipp Koehn, Sergey Edunov and Angela Fan

10:30–12:00 *Tencent Translation System for the WMT21 News Translation Task*
Longyue Wang, Mu Li, Fangxu Liu, Shuming Shi, Zhaopeng Tu, Xing Wang, Shuangzhi Wu, Jiali Zeng and Wen Zhang

10:30–12:00 *HW-TSC's Participation in the WMT 2021 News Translation Shared Task*
Daimeng Wei, Zongyao Li, Zhanglin Wu, Zhengzhe Yu, Xiaoyu Chen, Hengchao Shang, Jiaxin Guo, Minghan Wang, Lizhi Lei, Min Zhang, Hao Yang and Ying Qin

10:30–12:00 *LISN @ WMT 2021*
Jitao Xu, Minh Quang Pham, Sadaf Abdul Rauf and François Yvon

10:30–12:00 *WeChat Neural Machine Translation Systems for WMT21*
Xianfeng Zeng, Yijin Liu, Ernan Li, Qiu Ran, Fandong Meng, Peng Li, Jinan Xu and Jie Zhou

10:30–12:00 *Small Model and In-Domain Data Are All You Need*
Hui Zeng

10:30–12:00 *The Mininglamp Machine Translation System for WMT21*
Shiyu Zhao, Xiaopu Li, Minghui Wu and Jie Hao

Wednesday, November 10, 2021 (continued)

10:30–12:00 *The NiuTrans Machine Translation Systems for WMT21*
Shuhan Zhou, Tao Zhou, Binghao Wei, Yingfeng Luo, Yongyu Mu, Zefan Zhou, Chenglong Wang, Xuanjun Zhou, Chuanhao Lv, Yi Jing, Laohu Wang, Jingnan Zhang, Canan Huang, Zhongxiang Yan, Chi Hu, Bei Li, Tong Xiao and Jingbo Zhu

10:30–12:00 Similar Languages Translation Task

10:30–12:00 *Improving Similar Language Translation With Transfer Learning*
Ife Adebara and Muhammad Abdul-Mageed

10:30–12:00 *T4T Solution: WMT21 Similar Language Task for the Spanish-Catalan and Spanish-Portuguese Language Pair*
Miguel Canals and Marc Raventós Tato

10:30–12:00 *Neural Machine Translation for Tamil–Telugu Pair*
Sahinur Rahman Laskar, Bishwaraj Paul, Prottay Kumar Adhikary, Partha Pakray and Sivaji Bandyopadhyay

10:30–12:00 *Low Resource Similar Language Neural Machine Translation for Tamil-Telugu*
Vandan Mujadia and Dipti Sharma

10:30–12:00 *Similar Language Translation for Catalan, Portuguese and Spanish Using Marian NMT*
Reinhard Rapp

10:30–12:00 *NITK-UoH: Tamil-Telugu Machine Translation Systems for the WMT21 Similar Language Translation Task*
Richard Saldanha, Ananthanarayana V. S, Anand Kumar M and Parameswari Krishnamurthy

10:30–12:00 *A3-108 Machine Translation System for Similar Language Translation Shared Task 2021*
Saumitra Yadav and Manish Shrivastava

10:30–12:00 Automatic Post-Editing Task

10:30–12:00 *Netmarble AI Center's WMT21 Automatic Post-Editing Shared Task Submission*
Shinhyeok Oh, Sion Jang, Hu Xu, Shounan An and Insoo Oh

10:30–12:00 *Adapting Neural Machine Translation for Automatic Post-Editing*
Abhishek Sharma, Prabhakar Gupta and Anil Nelakanti

10:30–12:00 Triangular Translation Task

10:30–12:00 *ISTIC's Triangular Machine Translation System for WMT2021*
Hangcheng Guo, Wenbin Liu, Yanqing He, Tian Lan, Hongjiao Xu, Zhenfeng Wu and You Pan

10:30–12:00 *HW-TSC's Participation in the WMT 2021 Triangular MT Shared Task*
Zongyao Li, Daimeng Wei, Hengchao Shang, Xiaoyu Chen, Zhanglin Wu, Zhengzhe Yu, Jiaxin Guo, Minghan Wang, Lizhi Lei, Min Zhang, Hao Yang and Ying Qin

10:30–12:00 *DUTNLP Machine Translation System for WMT21 Triangular Translation Task*
Huan Liu, Junpeng Liu, Kaiyu Huang and Degen Huang

10:30–12:00 *Pivot Based Transfer Learning for Neural Machine Translation: CFILT IITB @ WMT 2021 Triangular MT*
Shivam Mhaskar and Pushpak Bhattacharyya

10:30–12:00 *Papago's Submissions to the WMT21 Triangular Translation Task*
Jeonghyeok Park, Hyunjoong Kim and Hyunchang Cho

Wednesday, November 10, 2021 (continued)

10:30–12:00 Indo-European Multilingual Translation Task

10:30–12:00 *Machine Translation of Low-Resource Indo-European Languages*
Wei-Rui Chen and Muhammad Abdul-Mageed

10:30–12:00 *CUNI systems for WMT21: Multilingual Low-Resource Translation for Indo-European Languages Shared Task*
Josef Jon, Michal Novák, João Paulo Aires, Dusan Varis and Ondřej Bojar

10:30–12:00 *Transfer Learning with Shallow Decoders: BSC at WMT2021's Multilingual Low-Resource Translation for Indo-European Languages Shared Task*
Ksenia Kharitonova, Ona de Gibert Bonet, Jordi Armengol-Estapé, Mar Rodriguez i Alvarez and Maite Melero

10:30–12:00 *EdinSaar@WMT21: North-Germanic Low-Resource Multilingual NMT*
Svetlana Tchistiakova, Jesujoba Alabi, Koel Dutta Chowdhury, Sourav Dutta and Dana Ruiter

10:30–12:00 *TenTrans Multilingual Low-Resource Translation System for WMT21 Indo-European Languages Task*
Han Yang, Bojie Hu, Wanying Xie, ambyera han, Pan Liu, Jinan Xu and Qi Ju

10:30–12:00 Large-Scale Multilingual Translation Task

10:30–12:00 *The University of Maryland, College Park Submission to Large-Scale Multilingual Shared Task at WMT 2021*
Saptarashmi Bandyopadhyay, Tasnim Kabir, Zizhen Lian and Marine Carpuat

10:30–12:00 *To Optimize, or Not to Optimize, That Is the Question: TelU-KU Models for WMT21 Large-Scale Multilingual Machine Translation*
Sari Dewi Budiwati, Tirana Fatyanosa, Mahendra Data, Dedy Rahman Wijaya, Patrick Adolf Telnoni, Arie Ardiyanti Suryani, Agus Pratondo and Masayoshi Aritsugi

10:30–12:00 *MMTAfrica: Multilingual Machine Translation for African Languages*
Chris Chinenye Emezue and Bonaventure F. P. Dossou

10:30–12:00 *The LMU Munich System for the WMT 2021 Large-Scale Multilingual Machine Translation Shared Task*
Wen Lai, Jindřich Libovický and Alexander Fraser

10:30–12:00 *Back-translation for Large-Scale Multilingual Machine Translation*
Baohao Liao, Shahram Khadivi and Sanjika Hewavitharana

Wednesday, November 10, 2021 (continued)

10:30–12:00 *Maastricht University's Large-Scale Multilingual Machine Translation System for WMT 2021*
Danni Liu and Jan Niehues

10:30–12:00 *Data Processing Matters: SRPH-Konvergen AI's Machine Translation System for WMT'21*
Lintang Sutawika and Jan Christian Blaise Cruz

10:30–12:00 *TenTrans Large-Scale Multilingual Machine Translation System for WMT21*
Wanying Xie, Bojie Hu, Han Yang, Dong Yu and Qi Ju

10:30–12:00 *Multilingual Machine Translation Systems from Microsoft for WMT21 Shared Task*
Jian Yang, Shuming Ma, Haoyang Huang, Dongdong Zhang, Li Dong, Shaohan Huang, Alexandre Muzio, Saksham Singhal, Hany Hassan, Xia Song and Furu Wei

10:30–12:00 *HW-TSC's Participation in the WMT 2021 Large-Scale Multilingual Translation Task*
Zhengzhe Yu, Daimeng Wei, Zongyao Li, Hengchao Shang, Xiaoyu Chen, Zhanglin Wu, Jiaxin Guo, Minghan Wang, Lizhi Lei, Min Zhang, Hao Yang and Ying Qin

12:00–13:00 ***Lunch Break***

13:00–14:15 Session 3: Panel Discussion on Evaluation with Nitika Mathur (Univ. Melbourne), Benjamin Marie (NICT), Ricardo Rei (Unbabel), Tom Kocmi (Microsoft) and moderated by Markus Freitag (Google)

14:15–14:45 ***Mini Break***

14:45–16:15 Session 4: Research Papers on Evaluation (Session Chair: Antonis Anastasopoulos)

14:45–16:15 *On the Stability of System Rankings at WMT*
Rebecca Knowles

14:45–16:15 *To Ship or Not to Ship: An Extensive Evaluation of Automatic Metrics for Machine Translation*
Tom Kocmi, Christian Federmann, Roman Grundkiewicz, Marcin Junczys-Dowmunt, Hitokazu Matsushita and Arul Menezes

14:45–16:15 *Just Ask! Evaluating Machine Translation by Asking and Answering Questions*
Mateusz Krubiński, Erfan Ghadery, Marie-Francine Moens and Pavel Pecina

Wednesday, November 10, 2021 (continued)

14:45–16:15 *A Fine-Grained Analysis of BERTScore*
Michael Hanna and Ondřej Bojar

14:45–16:15 *Evaluating Multiway Multilingual NMT in the Turkic Languages*
Jamshidbek Mirzakhalov, Anoop Babu, Aigiz Kunafin, Ahsan Wahab, Bekhzodbek Moydinboyev, Sardana Ivanova, Mokhiyakhon Uzokova, Shaxnoza Pulatova, Duygu Ataman, Julia Kreutzer, Francis Tyers, Orhan Firat, John Licato and Sriram Chellappan

14:45–16:15 *Extending Challenge Sets to Uncover Gender Bias in Machine Translation: Impact of Stereotypical Verbs and Adjectives*
Jonas-Dario Troles and Ute Schmid

16:15-16:45 ***Coffee Break***

16:45–18:15 Session 5: Research Papers on Data (Session Chair: Mathias Müller)

16:45–18:15 *Continual Learning in Multilingual NMT via Language-Specific Embeddings*
Alexandre Berard

16:45–18:15 *DELA Corpus - A Document-Level Corpus Annotated with Context-Related Issues*
Sheila Castilho, João Lucas Cavalheiro Camargo, Miguel Menezes and Andy Way

16:45–18:15 *Multilingual Domain Adaptation for NMT: Decoupling Language and Domain Information with Adapters*
Asa Cooper Stickland, Alexandre Berard and Vassilina Nikoulina

16:45–18:15 *Translation Transformers Rediscover Inherent Data Domains*
Maksym Del, Elizaveta Korotkova and Mark Fishel

16:45–18:15 *Improving Machine Translation of Rare and Unseen Word Senses*
Viktor Hangya, Qianchu Liu, Dario Stojanovski, Alexander Fraser and Anna Korhonen

16:45–18:15 *Pushing the Right Buttons: Adversarial Evaluation of Quality Estimation*
Diptesh Kanojia, Marina Fomicheva, Tharindu Ranasinghe, Frédéric Blain, Constantin Orăsan and Lucia Specia

Thursday, November 11, 2021

9:00–10:15 Session 6: Shared Task Overview Papers I

9:00–9:12 *Findings of the WMT 2021 Shared Task on Efficient Translation*
Kenneth Heafield, Qianqian Zhu and Roman Grundkiewicz

9:12–9:24 *Findings of the WMT Shared Task on Machine Translation Using Terminologies*
Md Mahfuz Ibn Alam, Ivana Kvapilíková, Antonios Anastasopoulos, Laurent Besacier, Georgiana Dinu, Marcello Federico, Matthias Gallé, Kweonwoo Jung, Philipp Koehn and Vassilina Nikoulina

9:24–9:36 *Findings of the WMT 2021 Biomedical Translation Shared Task: Summaries of Animal Experiments as New Test Set*
Lana Yeganova, Dina Wiemann, Mariana Neves, Federica Vezzani, Amy Siu, Inigo Jauregi Unanue, Maite Oronoz, Nancy Mah, Aurélie Névéol, David Martinez, Rachel Bawden, Giorgio Maria Di Nunzio, Roland Roller, Philippe Thomas, Cristian Grozea, Olatz Perez-de-Viñaspre, Maika Vicente Navarro and Antonio Jimeno Yepes

9:36–9:48 *Findings of the WMT 2021 Shared Task on Quality Estimation*
Lucia Specia, Frédéric Blain, Marina Fomicheva, Chrysoula Zerva, Zhenhao Li, Vishrav Chaudhary and André F. T. Martins

9:48–10:00 *Findings of the WMT 2021 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT*
Jindřich Libovický and Alexander Fraser

10:00–10:15 *Results of the WMT21 Metrics Shared Task: Evaluating Metrics with Expert-based Human Evaluations on TED and News Domain*
Markus Freitag, Ricardo Rei, Nitika Mathur, Chi-kiu Lo, Craig Stewart, George Foster, Alon Lavie and Ondřej Bojar

10:15–10:30 ***Coffee Break***

10:30–12:00 Efficient Translation Task

10:30–12:00 *Efficient Machine Translation with Model Pruning and Quantization*
Maximiliana Behnke, Nikolay Bogoychev, Alham Fikri Aji, Kenneth Heafield, Graeme Nail, Qianqian Zhu, Svetlana Tchistiakova, Jelmer van der Linde, Pinzhen Chen, Sidharth Kashyap and Roman Grundkiewicz

10:30–12:00 *HW-TSC's Participation in the WMT 2021 Efficiency Shared Task*
Hengchao Shang, Ting Hu, Daimeng Wei, Zongyao Li, Jianfei Feng, ZhengZhe Yu, Jiaxin Guo, Shaojun Li, Lizhi Lei, ShiMin Tao, Hao Yang, Jun Yao and Ying Qin

10:30–12:00 *The NiuTrans System for the WMT 2021 Efficiency Task*
Chenglong Wang, Chi Hu, Yongyu Mu, Zhongxiang Yan, Siming Wu, Yimin Hu, Hang Cao, Bei Li, Ye Lin, Tong Xiao and Jingbo Zhu

10:30–12:00 *TenTrans High-Performance Inference Toolkit for WMT2021 Efficiency Task*
Kaixin WU, Bojie Hu and Qi Ju

10:30–12:00 Terminology Translation Task

10:30–12:00 *Lingua Custodia's Participation at the WMT 2021 Machine Translation Using Terminologies Shared Task*
Melissa Ailem, Jingshu Liu and Raheel Qader

10:30–12:00 *Kakao Enterprise's WMT21 Machine Translation Using Terminologies Task Submission*
Yunju Bak, Jimin Sun, Jay Kim, Sungwon Lyu and Changmin Lee

10:30–12:00 *The SPECTRANS System Description for the WMT21 Terminology Task*
Nicolas Ballier, Dahn Cho, Bilal Faye, Zong-You Ke, Hanna Martikainen, Mojca Pecman, Guillaume Wisniewski, Jean-Baptiste Yunès, Lichao Zhu and Maria Zimina-Poirot

10:30–12:00 *Dynamic Terminology Integration for COVID-19 and Other Emerging Domains*
Toms Bergmanis and Mārcis Pinnis

10:30–12:00 *CUNI Systems for WMT21: Terminology Translation Shared Task*
Josef Jon, Michal Novák, João Paulo Aires, Dusan Varis and Ondřej Bojar

Abstract

This paper presents the results of the news translation task, the multilingual low-resource translation for Indo-European languages, the triangular translation task, and the automatic post-editing task organised as part of the Conference on Machine Translation (WMT) 2021. In the news task, participants were asked to build machine translation systems for any of 10 language pairs, to be evaluated on test sets consisting mainly of news stories. The task was also opened up to additional test suites to probe specific aspects of translation. In the Similar Language Translation (SLT) task, participants were asked to develop systems to translate between pairs of similar languages from the Dravidian and Romance family as well as French to two similar low-resource Manding languages (Bambara and Maninka). In the Triangular MT translation task, participants were asked to build a Russian to Chinese translator, given parallel data in Russian-Chinese, Russian-English and English-Chinese. In the multilingual low-resource translation for Indo-European languages task, participants built multilingual systems to translate among Romance and North-Germanic languages. The task was designed to deal with the translation of documents in the cultural heritage domain for relatively low-resourced languages. In the automatic post-editing (APE) task, participants were asked to develop systems capable to correct the errors made by an unknown machine translation systems.

1 Introduction

The Sixth Conference on Machine Translation (WMT21)[1] was held online with EMNLP 2021 and hosted a number of shared tasks on various aspects of machine translation. This conference built on 15 previous editions of WMT as workshops and conferences (Koehn and Monz, 2006; Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Bojar et al., 2013, 2014, 2015, 2016, 2017, 2018a; Barrault et al., 2019, 2020).

This year we conducted several official tasks. In this paper we report on the news task, the multilingual low-resource translation for Indo-European languages task, the triangular translation task, and the automatic post-editing task. Additional shared tasks are described in separate papers in these proceedings:

[1] http://www.statmt.org/wmt21/

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1–88
November 10–11, 2021.

- biomedical translation (Yeganova et al., 2021)
- efficiency (Heafield et al., 2021)
- large-scale multilingual machine translation (Wenzek et al., 2021)
- machine translation using terminologies (Alam et al., 2021)
- metrics (Freitag et al., 2021b)
- quality estimation (Specia et al., 2021)
- unsupervised and very low-resource translation (Libovický and Fraser, 2021)

In the news translation task (Section 2), participants were asked to translate a shared test set, optionally restricting themselves to the provided training data ("constrained" condition). We included 20 translation directions this year, with translation between English and each of Chinese, Czech, German, Japanese and Russian, as well as French↔German being repeated from last year, and English to and from Hausa and Icelandic being new for this year, along with Bengali↔Hindi and Xhosa↔Zulu. The translation tasks covered a range of language families, and included both low-resource and high-resource pairs. System outputs for each task were evaluated both automatically and manually, but we only include the manual evaluation here.

The human evaluation (Section 3) involves asking human judges to score sentences output by anonymized systems. We obtained large numbers of assessments from researchers who contributed evaluations proportional to the number of tasks they entered. We collected additional assessments from a pool of linguists, as well as crowd-workers. This year, the official manual evaluation metric is again based on judgments of adequacy on a 100-point scale, a method (known as "direct assessment", DA) that we explored in the previous years with convincing results in terms of the trade-off between annotation effort and reliable distinctions between systems. In addition, other golden standards with this year's systems were collected. The human-in-the-loop GENIE leaderboard (Khashabi et al., 2021) conducted de→en evaluations independently in a Likert scale (Section 3.5). We refer the reader to Freitag et al. (2021b) for MQM scoring of en→de, en→ru, and zh→en.

The primary objectives of WMT are to evaluate the state of the art in machine translation, to disseminate common test sets and public training data with published performance numbers, and to refine evaluation and estimation methodologies for machine translation. As before, all of the data, translations, and collected human judgments are publicly available.[2] We hope these datasets serve as a valuable resource for research into data-driven machine translation, automatic evaluation, or prediction of translation quality. News translations are also available for interactive visualization and comparison of differences between systems at http://wmt.ufal.cz/ using MT-ComparEval (Sudarikov et al., 2016), and also on ExplainaBoard[3] (Liu et al., 2021b).

In order to gain further insight into the performance of individual MT systems, we again organized a call for dedicated "test suites". Test suites are custom additions to the inputs. Anyone can provide a test suite for any subset of news translation task languages and we ensure that the test suite is requested from all participating MT systems. The MT outputs are delivered back to test suite authors for evaluation, which can be manual, automatic or both, focusing on any possible aspect of the MT systems. This year, five test suites were acquired and translated by participating MT systems but only two were then analyzed in time for these proceedings:

- Freitag et al. (2021b), the metrics task paper, used TED talks as additional domain, scored them with MQM, and further used these outputs and scores to assess domain-dependence of MT evaluation metrics.

- Macketanz et al. (2021) reports on the fourth application of a fine-grained test suite for German↔English linguistic phenomena. The previous instances (Macketanz et al., 2018; Avramidis et al., 2019, 2020) use the same underlying collection of sentences and thus allow to observe the overall development of MT systems in clear categories. This year, the major jump was observed in the category of idioms, especially due to a few exceptional MT systems. Many phenomena are being solved almost perfectly, the difficult categories remain false friends, ambiguity and multi-word expressions.

The goal of the Similar Language Translation (SLT) task (Section 4) is to evaluate the perfor-

[2] http://statmt.org/wmt21/results.html
[3] http://explainaboard.nlpedia.ai/leaderboard/task-mt/index.php

mance of MT systems taking into account the similarity between pairs of closely-related languages from the same language family. Following the interest of the community in this topic (Costa-jussà et al., 2018; Popović et al., 2020) and the success of the past two editions of the SLT task task at WMT 2019 and WMT 2020, we organize a third iteration of the task at WMT 2021. SLT 2021 features a pair of similar Dravidian languages, namely Tamil - Telugu, and multiple pairs of Romance languages involving Catalan, Spanish, Portuguese, and Romanian in all possible combinations. A new track with French and two similar low-resource Manding languages: Bambara and Maninka was also included to encourage participants to take advantage of the similarity between Bambara and Maninka and explore data augmentation techniques, a typical scenario of low-resource languages. Finally, translations were evaluated in both directions using three automatic metrics: BLEU, RIBES, and TER.

The primary goals of the Triangular MT task (Section 5) are to promote translation between non-English languages, to optimally mix direct and indirect parallel resources and exploit noisy web data sources to build an MT system. Specifically, the task was Russian to Chinese machine translation, given parallel data comprising of direct (Russian-Chinese) and indirect (Russian-English and English-Chinese) sources. The submitted systems were evaluated on a (secret) mixed-genre test set, drawn from the web and curated manually for high-quality segment pairs.

The multilingual low-resource translation for Indo-European languages task (MLLR, Section 6) aims to investigate the best approaches to deal with multilingual translation. Usually, multilingual translation is done with the help of a high-resourced language, e.g. English. In MLLR, we evaluate translation quality for Icelandic–Norwegian Bokmål–Swedish (North-Germanic) and Catalan–Italian–Occitan–Romanian (Romance). Higher resourced languages (Danish, German, English, Spanish, French and Portuguese) are allowed for training but not evaluated. We focus on a specific domain: cultural heritage documents are extracted from Europeana and Wikipedia, a domain where named entities may also play a role in translation quality. The evaluation is done at language family level with a combination of automatic metrics (BLEU, TER, chrF, BertScore and COMET) and complemented by a manual evaluation on a subset of language pairs.

The automatic post-editing (APE) task (Section 7) focuses on another MT-related problem: the correction of machine-translated text generated by an unknown system. In continuity with last year, in this seventh iteration of the task at WMT we focused on two language pairs (English-German and English-Chinese), using data drawn from English Wikipedia articles and translated with neural MT systems. The evaluation was carried out both automatically – with TER and BLEU respectively used as primary and secondary metric - and manually – with the same direct assessment method used for the news translation task.

2 News Translation Task

This recurring WMT task assesses the quality of MT on text from the news domain. As in the previous year, we included Chinese, Czech, German, Japanese and Russian (to and from English) as well as French↔German. New language pairs for this year were Icelandic and Hausa (to and from English) as well as Bengali↔Hindi and Xhosa↔Zulu.

2.1 Test Data

As in previous years, the test sets consist of unseen translations prepared specially for the task. The test sets are publicly released to be used as translation benchmarks in the coming years. Here we describe the production and composition of the test sets.

The source texts for the test sets were all extracted from online news sites, with the exception of Bengali↔Hindi and Xhosa↔Zulu, which were part of the FLORES-101 benchmark (Goyal et al., 2021) and extracted from Wikipedia. The sources used for the online news are shown in Table 1, and all articles are from the second half of 2020. For the French↔German task, we specifically selected financial and economic news, whereas for the other news sources, we randomly selected articles from general online news, including politics, sports, international and local events.

For all language pairs, we aimed for a test set size of 1000 sentences, and to ensure that the test sets were "source-original", in that the source text is the original article and the target text is the translation. This is to avoid "translationese" effects on

the source language, which can have a detrimental effect on the accuracy of evaluation (Freitag et al., 2019; Laubli et al., 2020; Graham et al., 2020). The exceptions were Chinese→English, where we used a larger test set of 1948 sentences, and the FLORES-101 test sets which were around 500 sentences, and derived from English source documents. For language pairs that were new this year (i.e. Icelandic↔English and Hausa↔English) we prepared development sets using the same process as the test set, but concatenating both translation directions into the same set. For each translated article in the development set, the direction of translation is clearly identified.

For WMT20, we experimented with using test sources with line (segment) boundaries at paragraphs (not sentences) for some language pairs, but we found no evidence that translators used their new freedom to reorganise sentences, and the longer lines possibly made evaluation more difficult, so we reverted to a sentence-per-line format this year. For selected language sources (Czech, German and English, when translated into the recurring languages) we retained the paragraph boundaries from the original articles, but within the paragraphs, the sentences were in separate segments. It was up to the participating systems to make use of the paragraph breaks or not, but the systems were expected to preserve the segment boundaries.

The test sets for WMT21 were released using a new XML format, replacing the "pseudo xml" SGML format which had been used for many years. The advantages of the new format are: (i) it can be processed with standard XML tools, and there is no longer any doubt about how to treat special XML characters such as the ampersand ("&"); (ii) the source, all references and all submissions can be contained in one convenient XML file; (iii) the metadata better matches the needs of the task, and can be extended as necessary. We created simple tools for converting from text-based files to the new XML format.[4]

The translation of the test sets was performed by professional translation agencies, according to the brief supplied in Appendix B. Several language pairs got special attention. For Chinese↔English, Russian↔English and German↔English, we obtained a second reference in each direction from a different translation agency, labelled "B". For German↔English, the "B" reference was found to be a post-edited version of one of the participating online systems, so we had to discard it. Microsoft then sponsored a third independent translation, labelled "C", and the metrics task organizers with the support from Google later provided yet another German↔English reference, discussed only in Freitag et al. (2021b) as "D". For Czech↔English, the first reference (labelled "A") which served in reference-based manual evaluations, was provided by a translation agency in both directions. The second Czech↔English reference (labelled "B") which served as another system in the competition was provided by professional translators recruited from teachers and students of translation studies into Czech and three students and graduates of translation studies and one translator, English native speaker, into English.

2.2 Training Data

As in past years we provided a selection of parallel and monolingual corpora for model training, and development sets to tune system parameters. Participants were permitted to use any of the provided corpora to train systems for any of the language pairs. As well as providing updates on many of the previously released data sets, we included several new data sets, mainly to support the new language pairs.

Our training data includes the latest version of ParaCrawl (Bañón et al., 2020) for all language pairs where it is available. New for this year is a ParaCrawl corpus for Chinese↔English, which contains 14M sentences, as well as a small Hausa↔English ParaCrawl. The JParaCrawl corpus (for Japanese↔English) is constructed in a similar way to ParaCrawl, but by a different group (Morishita et al., 2020).

For Icelandic↔English we used the recently released ParIce (Barkarson and Steingrímsson, 2019) a source of parallel data, and the Icelandic Gigaword corpus for monolingual data (Steingrímsson et al., 2018).

For Hausa↔English, the data was mainly drawn from Opus (Tiedemann and Nygaard, 2004), which is mostly religious and IT localisation text. We added a small (< 6000) parallel sentence corpus extracted from the website of Ayatollah Khamenei,[5] now only accessible using the

Wayback Machine.[6]

For the two FLORES-101 language pairs (i.e. Bengali↔Hindi and Xhosa↔Zulu) all training data is from the CC-Aligned corpus (El-Kishky et al., 2020).

Other language pairs used the same data sets as last year, with updates wherever available.

The monolingual data we provided was similar to last year's, with a 2020 news crawl[7] added to all the news corpora. Note that news crawl now includes 59 languages, so is not limited to languages used in WMT. In addition, we provided versions of the news corpora for Czech, English and German, with both the document and paragraph structure retained. In other words, we did not apply sentence splitting to these corpora, and we retained the document boundaries and text ordering of the originals.

Some statistics about the training and test materials are given in Figures 1, 2, 3 and 4.

2.3 Submitted Systems

In 2021, we received a total of 173 submissions. The participating institutions are listed in Table 2 and detailed in the rest of this section. Each system did not necessarily appear in all translation tasks. We also included online MT systems (originating from 5 services), which we anonymized as ONLINE-A,B,G,W,Y. All submissions, sources and references are made available via github[8].

The collect submissions, we used the submission tool, OCELoT,[9] replacing the matrix that has been used up until 2019. Using OCELoT gives us more control over the submission and scoring process, for example we are able to limit the number of test submissions by each team, and we also display the submissions anonymously to avoid publishing any automatic scores.

For presentation of the results, systems are treated as either *constrained* or *unconstrained*. When the system submitters report that they were only trained on the provided data, we class them as constrained. The online systems are treated as unconstrained during the automatic and human evaluations, since we do not know how they were built.

In Appendix C, we provide brief details of the submitted systems, for those where the authors provided such details.

3 Human Evaluation

A human evaluation campaign is run each year to assess translation quality and to determine the official ranking of systems taking part in the news translation task. This section describes how data for the human evaluation is prepared, the process of collecting human assessments, and computation of the official results of the shared task.

3.1 Direct Assessment

We have employed Direct Assessment (DA, Graham et al., 2013, 2014, 2016) as the primary mechanism for evaluating systems since running a comparison of DA and relative ranking in 2016 (Bojar et al., 2016). DA has several important features including accurate quality control of crowdsourcing. With DA human evaluation, human assessors are asked to rate a given translation by how adequately it expresses the meaning of the corresponding reference translation or source language input on an analogue scale, which corresponds to an underlying absolute 0–100 rating scale.[10]

3.1.1 Source and Reference-based Evaluations

The original definition of DA provides human assessors with a reference translation. The benefit of this reference-based evaluation is that only speakers of the target language are needed, but the quality of the reference translation becomes critical and even if flawless, evaluating against a single reference translation could bias evaluators towards that reference.

In 2018, we trialled source-based (or "bilingual") evaluation for the first time, for English to Czech translation. In this configuration, the human assessor is shown the source input and system output only (with no reference translation shown). The assessor thus has to understand both the source and target languages very well but the quality of the reference is no longer vital. In fact, the human-generated reference can be included in the evaluation as an additional system to provide an estimate of human performance.

[8] https://github.com/wmt-conference/wmt21-news-systems

[9] https://github.com/AppraiseDev/OCELoT

[10] No sentence or document length restriction is applied during manual evaluation. Direct Assessment is also employed for evaluation of video captioning systems at TRECvid (Graham et al., 2018; Awad et al., 2019, 2021) and multilingual surface realisation (Mille et al., 2018, 2019).

Table 2: Participants in the shared translation task. The translations from the online systems were not submitted by their respective companies but were obtained by us, and are therefore anonymized in a fashion consistent with previous years of the workshop.

For both reference and source-based evaluation, we require human assessors to only evaluate translation *into* their native language. Following WMT19 and WMT20, we thus again use the source-based evaluation only for out-of-English language pairs. This is especially relevant since we have a large group of volunteer human assessors with native language fluency in non-English languages and high fluency in English, while we generally lack the reverse, i.e. native English speakers with high fluency in non-English languages.

We use different implementation and human annotators for into-English and out-of-English. We describe the approaches separately. Reference-based (monolingual) into-English human evaluation is described in Section 3.2, while source-based (bilingual) out-of-English and non-English human evaluation is described in Section 3.3. A third, simplified annotation was used for Bengali↔Hindi and Xhosa↔Zulu, Section 3.4.

3.1.2 Translationese

Prior to WMT19, all the test sets included a mix of sentence pairs that were originally in the source language, and then translated to the target language, and sentence pairs that were originally in the target language but translated to the source language. The inclusion of the latter "reverse-created" sentence pairs has been shown to introduce biases into the evaluations, particularly in terms of BLEU scores (Graham et al., 2020). Therefore we have avoided it for all language pairs, apart from Bengali↔Hindi and Xhosa↔Zulu, where the texts are all translated from English.

3.1.3 Document Context

As mentioned already in our discussion in WMT18 and as also established within the community (Läubli et al., 2018b; Toral et al., 2018a), evaluating sentences out of their document context can skew the results. The effect is particularly pronounced when comparing human and machine translation, where it is observed that evaluators tend to rate the human translation higher (relative to the machine translation) when the translations are viewed in context. Human translators always have access to the document context when translating to create the references.

In WMT19, we experimented with a DA style that considers document context in a simple way.

Chinese→English	24	44,268	1,844.5
Total to-English	104	137,636	1,323.4

Table 3: Amount of data collected in the WMT21 manual evaluation campaign for evaluation into-English; after removal of quality control items.

Dubbed "SR+DC" (segment rating with document context), this method presents one segment at a time but the segments are no longer shuffled (as in "SR−DC", segment rating without document context). Instead, they are provided in the order in which they appear in the document. The implementation still has the limitation that the assessors cannot go back to the previous segment.

An improved alternative to "SR+DC" is to offer the full document and allow the assessors to review their segment-level ratings. We call this setup "SR+FD" (segment ranking in a full document) and illustrate the user interface in Appraise in Figure 5.[11]

This year, for all language pairs for which document context was available, we include it when evaluating translations. Note that the ratings are nevertheless collected on the segment level, motivated by the power analysis described in Graham et al. (2019) and Graham et al. (2020). The particular details on how document context is made available to assessors depends on the translation direction, as described in more detail in Sections 3.2 to 3.4.

3.2 Human Evaluation of Translation into-English

In terms of the News translation task manual evaluation for into-English language pairs, a total of 589 turker accounts were involved.[12] 488,396 translation assessment scores were submitted in total by the crowd, of which 170,194 were provided by workers who passed quality control.[13]

System rankings are produced from a large set of human assessments of translations, each of which indicates the absolute quality of the out-

[11] Compare with Figures 3 and 4 in Bojar et al. (2019).

[12] Numbers do not include the 1,078 workers on Mechanical Turk who did not pass quality control.

[13] Numbers include quality control segments.

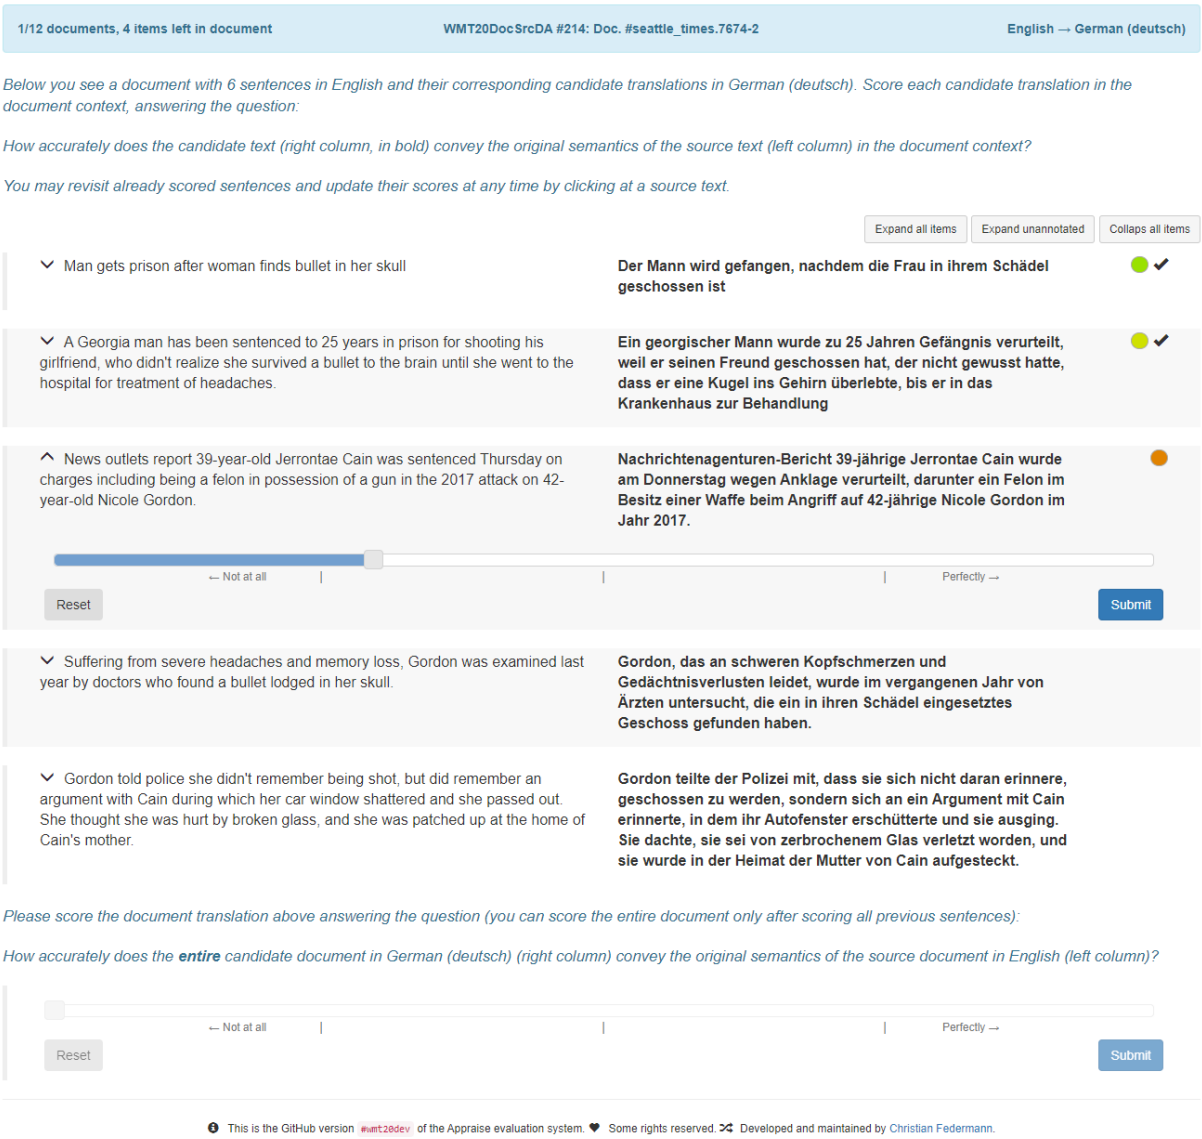

Figure 5: Screen shot of the document-level DA (SR+FD, segment rating within the full document) configuration in the Appraise interface for an example assessment from the human evaluation campaign. The annotator is presented with the entire translated document randomly selected from competing systems (anonymized) and is asked to rate the translation of individual segments and then entire document on sliding scales.

put of a system. Table 3 shows total numbers of human assessments collected in WMT21 for into-English language pairs contributing to final scores for systems.[14]

3.2.1 Crowd Quality Control

Collection of segment-level ratings with document context (SR+DC, Segment Rating + Document Context) involved constructing HITs so that each sentence belonging to a given document (produced by a single MT system) was displayed to and rated in turn by the human annotator.

We then injected the three kinds of quality control translation pairs described in Table 4: we repeat pairs expecting a similar judgment (Repeat Pairs), damage MT outputs expecting significantly worse scores (Bad Reference Pairs) and use references instead of MT outputs expecting high scores (Good Reference Pairs). For each of these three types, we include the MT output, along with its corresponding control item.

HITs were then constructed as follows, with as close as possible to 100 segments in a single HIT:

1. All documents produced by all systems are pooled;[15]

[14] Number of systems for WMT21 includes four "human" systems comprising human-generated reference translations used to provide human performance estimates.

[15] If a "human" system is included to provide a human per-

Repeat Pairs:	Original System output (10)	An exact repeat of it (10);
Bad Reference Pairs:	Original System output (10)	A degraded version of it (10);
Good Reference Pairs:	Original System output (10)	Its corresponding reference translation (10).

Table 4: Standard DA HIT structure quality control translation pairs hidden within 100-translation HITs, numbers of items are provided in parentheses.

2. Documents are then sampled at random (without replacement) and assigned to the current HIT until the current HIT contains close to (but less than) 70 segments

3. Once documents amounting to close to 70 segments have been assigned to the current HIT, we select a subset of these documents to be paired with quality control documents; this subset is selected by repeatedly checking if the addition of the number of the segments belonging to a given document (as quality control items) will keep the total number of segments in the HIT below 100; if this is the case, it is included; otherwise it is skipped until the addition of all documents has been checked. In doing this, the HIT is structured to bring the total number of segments as close as possible to 100 segments.

4. Once we have selected a core set of original system output documents and a subset of them to be paired with quality control versions for each HIT, quality control documents are automatically constructed by altering the sentences of a given document into a mixture of three kinds of quality control items used in the original DA segment-level quality control: bad reference translations, reference translations and exact repeats (see below for details of bad reference generation and Table 5 for numbers of words replaced in document segments);

5. Finally, the documents belonging to a HIT are shuffled.

Construction of Bad References As in previous years, bad reference pairs were created automatically by replacing a phrase within a given translation with a phrase of the same length, randomly selected from n-grams extracted from the full test set of reference translations belonging to that language pair. This means that the replacement phrase will itself comprise a mostly fluent sequence of words (making it difficult to tell that the sentence is low quality without reading the entire sentence) while at the same time making its presence highly likely to sufficiently change the meaning of the MT output so that it causes a noticeable degradation. The length of the phrase to be replaced is determined by the number of words in the original translation, as listed in Table 5.

formance estimate, it is also considered a system during quality control set-up.

Translation Length (N)	# Words Replaced in Translation
1	1
2–5	2
6–8	3
9–15	4
16–20	5
>20	$\lfloor$ N/4 $\rfloor$

Table 5: Number of words replaced when constructing quality control items.

Quality Filtering When an analogue scale (or 0–100 point scale, in practice) is employed, agreement cannot be measured using the conventional Kappa coefficient, ordinarily applied to human assessment when judgments are discrete categories or preferences. Instead, to measure consistency we filter crowd-sourced human assessors by how consistently they rate translations of known distinct quality using the bad reference pairs described previously. Quality filtering via bad reference pairs is especially important for the crowd-sourced portion of the manual evaluation. Due to the anonymous nature of crowd-sourcing, when collecting assessments of translations, it is likely to encounter workers who attempt to game the service, as well as submission of inconsistent evaluations and even robotic ones. We therefore employ DA's quality control mechanism to filter out low quality data, facilitated by the use of DA's analogue rating scale.

Assessments belonging to a given crowd-source worker who has not demonstrated that he/she can reliably score bad reference translations significantly lower than corresponding genuine system

	All	(A) Sig. Diff. Bad Ref.	(A) & No Sig. Diff. Exact Rep.
Czech→English	290	73 (25%)	68 (93%)
German→English	605	162 (27%)	150 (93%)
Hausa→English	423	109 (26%)	101 (93%)
Icelandic→English	273	75 (27%)	67 (89%)
Japanese→English	315	103 (33%)	91 (88%)
Russian→English	187	84 (45%)	77 (92%)
Chinese→English	617	195 (32%)	178 (91%)
Total	**1,694**	**589 (35%)**	**544 (92%)**

Table 6: Number of crowd-sourced workers taking part in the reference-based SR+DC campaign; (A) those whose scores for bad reference items were significantly lower than corresponding MT outputs; those of (A) whose scores also showed no significant difference for exact repeats of the same translation; note: many workers evaluated more than one language pair.

output translations are filtered out. A paired significance test is applied to test if degraded translations are consistently scored lower than their original counterparts and the p-value produced by this test is used as an estimate of human assessor reliability. Assessments of workers whose p-value does not fall below the conventional 0.05 threshold are omitted from the evaluation of systems, since they do not reliably score degraded translations lower than corresponding MT output translations.

Table 6 shows the number of workers participating in the into-English translation evaluation who met our filtering requirement in WMT21 by showing a significantly lower score for bad reference items compared to corresponding MT outputs, and the proportion of those who simultaneously showed no significant difference in scores they gave to pairs of identical translations. We removed data from the non-reliable workers in all language pairs.

3.2.2 Producing the Human Ranking

This year all rankings (for to-English translation) were arrived at via segment ratings presented one at a time in their original document order (SR+DC).

In order to iron out differences in scoring strategies of distinct human assessors, human assessment scores for translations were first standardized according to each individual human assessor's overall mean and standard deviation score.

Average standardized scores for individual segments belonging to a given system were then computed, before the final overall DA score for a given system is computed as the average of its segment scores (Ave z in Table 7). Results are also reported for average scores for systems, computed in the same way but without any score standardization applied (Ave % in Table 7).

Human performance estimates arrived at by evaluation of human-produced reference translations are denoted by "HUMAN" in all tables.

Clusters are identified by grouping systems together according to which systems significantly outperform all others in lower ranking clusters, according to Wilcoxon rank-sum test. Rank ranges are based on the same head-to-head statistical significance tests. For instance, if a system is statistically significantly worse than 2 other systems, and not statistically different from 4 other systems, its rank is reported as 3–6 (the top of the rank range is 2+1, the bottom 2+4).

All data collected during the human evaluation is available at `http://www.statmt.org/wmt21/results.html`. Appendix A shows the underlying head-to-head significance test official results for all pairs of systems and also reports BLEU, chrF, and COMET scores.

3.3 Bilingual Human Evaluation

Human evaluation for nine out-of-English and non-English translation directions used a source-based (sometimes called "bilingual") direct assessment of individual segments in the full document context (SR+FD), as established in WMT20 (Barrault et al., 2020).

In an attempt to break more ties among the participating systems, we also ran a second stage of annotation using segment-level contrastive source-based DA ignoring document context (labelled "contr:SR−DC") for top-10 systems (plus human references) for 3 out-of-English language pairs. Details on the second stage are in Section 3.3.5.

In the source-based DA campaign, we collected 303,627 assessments in total after excluding quality control items and users who did not pass the quality control. The contrastive source-based DA campaign provided 64,031 translation assessments. The total numbers of collected assessments per language pair are presented in Table 8. For data collection, we used the open-source Appraise Evaluation Framework (Federmann, 2012) for both assessment types.

Table 8: Amount of data collected in the WMT21 manual document- and segment-level evaluation campaigns for bilingual source-based evaluation out-of-English and non-English language pairs. The system counts include the human references (either 1 or 2 references, depending on language pair).

3.3.1 Sources of Human Annotators

We used three groups of annotators: participants in the News Shared Task, crowd-workers from the Toloka platform, and paid professional annotators sponsored by Microsoft.

We asked participants of the news task to contribute around 9 hours of annotation time (which we estimated at 12 HITs) per each primary system submitted, with each HIT including roughly 100 segment translations. Furthermore, we collected information about the classification of their annotators type. Unfortunately, only 65% of the requested annotations were finished by participating teams.

The second annotator group was provided by Toloka AI.[16] Toloka AI is a global data labeling company that helps its customers generate machine learning data at scale by harnessing the wisdom of the crowd from around the world. It relies on a geographically diverse crowd of several million registered users (Pavlichenko et al., 2021).[17] Toloka tests proficiency of their annotator crowd and excludes from future annotations anyone who does not pass quality control in the Appraise tool.

The last part of annotations is sponsored by Microsoft, who contributed with their crowd of qualified paid bilingual speakers experienced in the annotation process. Moreover, Microsoft tracks the performance of the annotators, and those who fail quality control are permanently removed from the pool of annotators. This increases the overall quality of the human assessment.

For bilingual human evaluation, Microsoft contributed with 42%, WMT News participants contributed with 37%, and Toloka platform with 21% of all valid annotations (after removal of annotators that do not pass quality control). The distribution of individual groups of annotators per each language is presented in Table 9.

3.3.2 Document-Level Assessment

This year's human evaluation for out-of-English and non-English language pairs features a document-level direct assessment configuration as presented last year (Barrault et al., 2020). We again use the segment level rating but provide the full document at once (SR+FD, segment rating within a full document), for a more reliable evaluation (Castilho et al., 2020; Laubli et al., 2020).

Figure 5 above shows a screenshot of the fully document-level interface. In the default scenario, an annotator scores individual segments one by one and, after scoring all of them, on the same screen, the annotator then judges the translation of the entire document displayed. Annotators can, however, revisit and update scores of previously assessed segments at any point of the annotation of the given document. It has been shown that presenting the entire document context on a screen may lead to higher quality segment- and document-level assessments (Grundkiewicz et al., 2021) improving the correlation between segment and document scores and increasing inter-annotator agreement for document scores. A similar setup has been used by Popel et al. (2020) even for more than two systems compared at once.

3.3.3 Quality Control

For the document-level evaluation of out-of-English translations, HITs were generated using the same method as described for the SR+DC evaluation of into-English translations in Section 3.2.1 with a minor modification: Since the annotations are made by researchers and professional translators who ensure a better quality of assessments than the crowd-sourced workers, only bad references are used as quality control items.

3.3.4 Including Human Translations

Source-based DA allows us to include human references in the evaluation as another system to provide an estimate of human performance. Human references were added to the pool of system outputs prior to sampling documents for tasks generation. Each reference is assessed individually if multiple references are available, which is the case for English→German, English→Czech, English→Russian, and English→Chinese.

3.3.5 Contrastive Direct Assessment

This year we extended the bilingual source-based human evaluation with contrastive evaluation using segment-level pairwise direct assessments (Novikova et al., 2018; Sakaguchi and Van Durme, 2018). It has been pointed out (Freitag et al., 2021a) that standard direct assessment may not be able to properly differentiate high-quality MT system outputs. The contrastive approach to DA can strengthen the discriminative power as annotators judge translations in relation to each other. When standard DA can likely provide better *absolute* quality assessment, the contrastive evaluation can provide better *relative* quality assessments between system pairs. This may help create a more reliable ranking of systems if used on top of the standard approach described in Section 3.3.

The contrastive evaluation is similar to the relative ranking used from WMT08 (Callison-Burch et al., 2008) to WMT16 (Bojar et al., 2016), where annotators were presented with up to five system outputs and corresponding source and reference sentence and asked to rank these systems between each other. The main differences in this year's contrastive evaluation to the relative rankings are that 1) the evaluation is source-based, i.e. without the reference, 2) the continuous scale is used instead of ranks, and 3) only two system outputs are judged at the same time instead of five.

To reduce the cognitive load on annotators, we decided to trial this contrastive approach evaluating individual sentences independent of their context. This is a very important difference compared to the the first stage (Section 3.3).

We ran the contrastive evaluation for English→Chinese, English→Czech and English→German, and we selected top-10 best performing systems based on DA z-score from the ranking created using standard direct assessment for those languages (Table 10), and two human references.

This contrastive evaluation was sponsored by Microsoft and performed by the bilingual paid annotator group as described in Section 3.3.1. Assessments were collected using the open-source Appraise Evaluation Framework (Federmann, 2012). A screenshot of the user interface used in this stage is shown in Figure 6. Each annotator is presented with two randomly selected translated segments from competing systems (anonymized) and asked to rate both of them on a continuous scale of 0-100. Upon request by the annotator, the differences between the two translations were highlighted at the word level to help avoid missing differences. This highlighting may however reduced the effectiveness of control items.

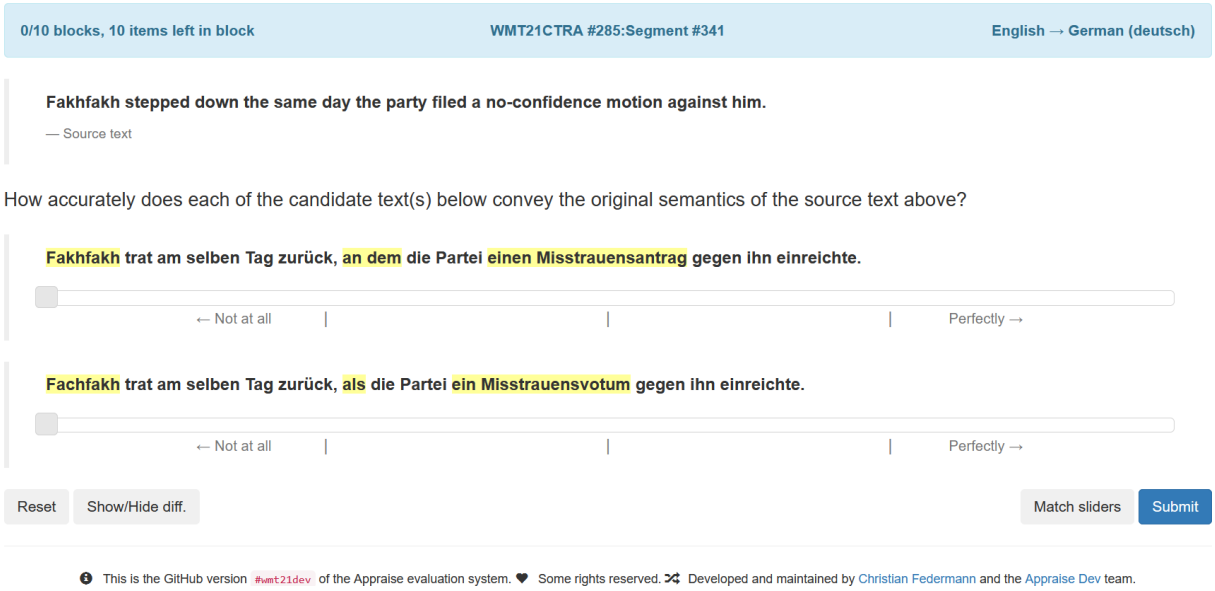

Figure 6: Screen shot of the contrastive DA configuration in the Appraise interface for an example assessment from the 2nd stage of human evaluation campaign. The annotator is presented with two translated segments randomly selected from competing system outputs (anonymized) and is asked to rate both of them on sliding scales.

3.3.6 Human Rankings

Table 10 shows official news task results for translation out-of-English, where lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$.

Source-based DA scores were collected based on the document-level annotation interface, so context was available during annotation. All systems are evaluated in isolation, based on the annotators' perception of translation quality given the source text and document context. Across all language pairs, human reference translations end up in the top-scoring cluster, indicative of a (relatively) high quality of these references. For language pairs with large numbers of submissions, we observe little to no clustering. Notably English→German has only two clusters, one of which contains all but one of the submitted systems, and English→Chinese ends up with a huge mono cluster containing all submissions. While there are differences in average scores and z scores these are not statistically significant enough for effective clustering. As a substitute, rank ranges give an indication of the respective system's translation quality.

Table 11 shows contrastive news task results for translation out-of-English, where lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$.

Contrastive, source-based DA scores (contr:SR−DC) were collected using a segment-level annotation interface, so context was *not* been available to annotators. Results for the source-based DA annotation phase (SR+FD) in Table 11 were computed on the subset of data for the ten systems and two references for which we have run the contrastive, source-based DA annotation phase.

We generally observe better clustering for the contr:SR−DC. This is especially noteworthy as the number of annotations collected per system is much higher for the first, SR+FD, DA phase (for two of the three language pairs on which contr:SR−DC was run). It seems that pairwise comparison of system outputs is beneficial for determining whether differences between systems are statistically significant.

In contrast to the first annotation phase, we find that human reference translations are scored worse, and significantly worse than the top cluster. We explain this by the fact that our contrastive setup was run on segment-level while the source-based DA annotators had access to the full document context. A simple explanation that should nevertheless be empirically validated is that the wording of the sentence created for and within the context of the document does not sound flawless and natural when evaluated in isolation (Läubli et al., 2018a; Toral et al., 2018b). Some machine translation systems do consider the surrounding sentences but their capacity of 'contextualizing' the candidate sentences is probably limited.

Observing the striking difference in system

Table 10: Official results of WMT21 News Translation Task for translation out-of-English (SR+FD). Systems ordered by DA score z-score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$; rank ranges are based on the same test (for details, see Section 3.2.2); grayed entry indicates resources that fall outside the constraints provided. DA scores are collected using a document-level annotation interface, so context is available to annotators.

ranking by SR+FD vs. contr:SR−DC, esp. the discrepancy in the ranking of human translations, we conclude that evaluating MT systems without document context is no longer reliable for mid- and high-quality MT systems. This is also supported by the surprising observation in Czech→English in Table 7 where humans seemed to be surpassed by *all* participating MT systems. (Considering statistical significance, the claim is arguably weaker: humans share the second cluster with the majority of the systems.) We acknowledge that it is possible that the Czech→English HUMAN-B references are of much worse quality than the English→Czech ones,[18] but we tend to put more trust in the reference quality than in the SR+DC method for two reasons: (1) The annotators did not see the whole document at once and cannot go back in their annotation, so their effective capability to consider context is limited. (2) It is possible that other effects of reference-based DA in the Czech→English start playing role when both the candidate and reference are human vs. when only the reference is human. One possibility would be a stronger confidence of assessors when scoring human translations, leading e.g. to more polarized scores. A detailed investigation into manual evaluation methods that word reliably for both human and machine translations is thus still needed.

3.4 Human Evaluation of Bengali↔Hindi and Xhosa↔Zulu Translation (Wikipedia Data)

Translation quality for Bengali↔Hindi and Xhosa↔Zulu was evaluated using Direct Assessment without considering document context (SR−DC) with a scoring scale of 1-100 by vetted human evaluators. The human evaluators were asked to provide a judgment that they felt most accurately reflected the perceived quality of each corresponding translation of the give source sentence. Definitions of translation quality within several scoring ranges were provided to assist evaluators in providing consistent annotations.

A participating system translation was displayed on the right next to its corresponding source sentence on the left. The sentence pairs were then randomized and passed to a human evaluator for a single direct assessment. The evaluation was performed on the sentence level and evaluators provided a direct assessment score for each sentence-translation pair. The user interface was simpler than the one shown in Figure 5: instead of a slider, the annotators had to enter the scores numerically.

Because evaluators were extremely difficult to recruit for these language pairs and the evaluation was thus low resource, no quality control items were injected and we focused on the vetting process of the evaluators prior to performing any assessment. The only sanity check was that evaluators enter an integer between 1 and 100 as the scores.

All segments from the FLORES Wikimedia test set were included for the evaluation. Each segment was annotated and assessed by one evaluator only once.

All four language directions were assessed by trusted evaluators who have been vetted by a localization vendor specializing in translation evaluation services, to have native fluency of the target language, fluent to native understanding of the source language, have lived in the target region for at least five years recently, and have had at least two to five years of professional translation experience. For Hindi→Bengali and Bengali→Hindi, two human evaluators were used with the translation data being split in half and randomly assigned to the respective evaluators. Two human evaluators assessed for Xhosa→Zulu data and one evaluator assessed for Zulu→Xhosa. The number of evaluators and judgments they made is provided in Table 12.

The final scores for Bengali↔Hindi and Xhosa↔Zulu are provided in Table 13.

3.5 GENIE DE-EN Evaluation

This year, human evaluations for German→English translation with the GENIE leaderboard were also carried out. GENIE is an ongoing effort that centralizes and facilitates human evaluations for natural language generation tasks (Khashabi et al., 2021). In

[18] The quality assurance for each of "A" and "B" references for English↔Czech was comparable; not that the same translators would be producing both directions. In fact, we expected the "B" translations to be *better*, because they were created by experienced students and teachers of translation studies, who are active translators themselves and who *specifically attempted to produce as good translations as possible*. As the to-Czech scores suggest, our annotators preferred the translation agency "A" translations significantly more. But even if the "A" translations were also better than "B" in from-Czech, we see it as very unlikely that the translatologist translations would be worse than all systems.

Hindi→Bengali	9	4,512	2
Xhosa→Zulu	6	2,952	2
Zulu→Xhosa	5	2,502	1
Total	29	14,437	7

Table 12: Amount of data collected in the WMT21 manual evaluation campaign for evaluation Hindi to/from Bengali and Zulu to/from Xhosa

addition to all German→English submissions, four original transformer baselines with varying sizes and depths were trained and evaluated: GENIE-large-6-6 (transformer large with a 6-layer encoder and a 6-layer decoder), GENIE-base-6-6, GENIE-base-3-3, and GENIE-base-1-1.[19] These models were trained solely on the given training data without ensembling, backtranslation, or any other data augmentation method.

Similar to the official into-English evaluations, evaluations are done monolingually where Human-A is used as the reference. Each HIT contains 5 segments that are randomly shuffled, and no document context is considered during evaluations. Turkers are asked to decide whether they agree or disagree that the prediction adequately expresses the meaning of the reference. Turkers are given the following additional instructions: *a prediction is adequate if in the absence of the reference, the prediction perfectly conveys the meaning intended by the reference*. The user interface for annotating one candidate segment in the HIT is illustrated in Figure 7.

For quality control, we first selected Amazon Mechanical Turkers who had completed at least 5000 HITs with a 99+% approval rate and had a locale of US, GB, AU, or CA. They were then asked to carefully read the instructions and finish 10 sample questions created from WMT 2019 submissions and references. They were allowed to participate only when they correctly annotate 9 instances at least. In addition to this quality control at the entry point, we kept monitoring to detect spamming behavior. In particular, we randomly replaced 5% of the model predictions with sentences identical to the corresponding reference (Perfect Ref., similar to *good reference* in Section 3.2.1), and 5% of the model predictions with the reference from a different question (Wrong Ref.). We then randomly selected 800 examples from the test set to annotate. During annotation, we monitored how annotators labeled the Perfect Ref. and Wrong Ref. questions. Annotators that failed to both assign a high score to the Perfect Ref. and a low score to the Wrong Ref. questions were removed from the annotator pool, and all of their annotations were discarded. This qualification resulted in removing 5% of the participants. Since spammers invest little effort into completing each HIT, they can complete many more than other annotators (we found they would have completed up to 50% of the HITs in our preliminary experiments). Therefore, removing the 5% of participants that spammed annotations substantially improved the quality of our assessment.

In summary, there are several major differences from the setup used in the official evaluations:

- Turkers assess the adequacy by a five-category Likert scale, which is later converted to scalar values: *strongly agree* (1.0), *agree* (0.75), *neutral* (0.5), *disagree* (0.25), and *strongly disagree* (0.0).
- All 5 segments are randomly chosen for each HIT, and the document context is disregarded.
- For evaluating each system, we randomly sample 800 segments from the test set. The randomly selected instances are shared across all systems.
- To maximize the number of segments annotated for a given budget, each segment is annotated only once (*unilabeling*). Under a fixed annotation budget, unilabeling results are shown to be relatively stable compared to *multilabeling* (i.e., evaluating one segment by multiple annotators. See Section 5.1 of Khashabi et al., 2021).
- The overall scores are calculated by averaging raw numbers over the 800 segments. No standardization is applied.
- Different quality controls are applied as discussed above.

Table 14 shows results from the GENIE evaluation for German to English translation. There are systems that are ranked highly, both in the official and GENIE evaluations, such as Online-A and VolcTrans-AT. Conversely, happypoet and Manifold are given low scores consistently. Further, the

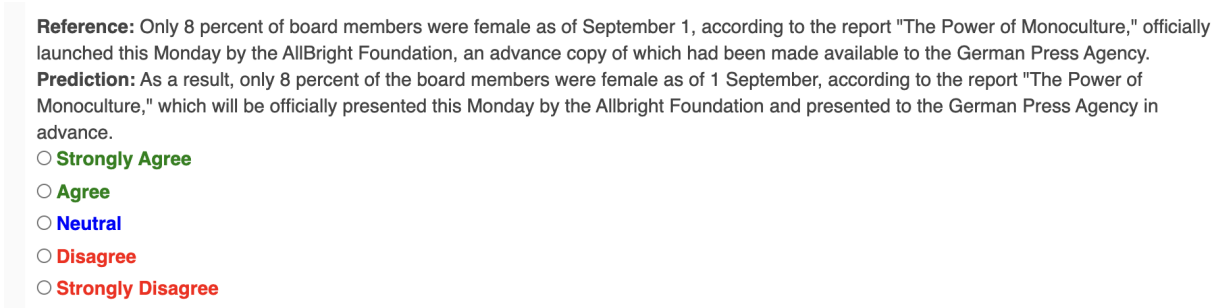

Figure 7: GENIE annotation interface for one segment.

transformer baselines are ranked in the expected order: large-6-6, base-6-6, base-3-3, followed by base-1-1. This confirms the validity of the evaluations. Nonetheless, we see some noticeable difference from the official ranking. In particular, HUMAN and the Watermelon systems are ranked high in contrast to the official evaluations. It is left to future work to analyze which parts of the crowdsourcing setup are contributing to the diverging system rankings; these analyses would help us improve our human evaluation method in the future.

4 Similar Language Translation

In this section we present the findings of the third SLT shared task organized at WMT 2021. The task follows the success of the two past SLT shared tasks organized at WMT 2019 and WMT 2020. SLT 2021 is motivated by the growing interest of the community in translating between similar languages, low-resource languages, dialects, and language varieties, and the challenges faced by state-of-the-art systems in these settings evidenced in recent studies (Hassani, 2017; Costa-jussà et al., 2018; Popović et al., 2020; Tapo et al., 2020).

The main goal of the task is to evaluate the performance of state-of-the-art MT systems on translating between closely-related language pairs of languages from the same language family. Past editions of the task (Barrault et al., 2019, 2020) featured language pairs such as Spanish - Portuguese, Czech - Polish, and Hindi - Nepali to name a few. This year's SLT features multiple pairs of similar languages from the Indo-Aryan and Romance family.

Finally, SLT 2021 also features a track including French and two similar low-resource Manding languages spoken in West Africa, namely Bambara and Maninka, where participants were pro-

vided with the opportunity to combine datasets of the two Manding languages taking advantage of their similarity. As in past editions of the task, translations at SLT 2021 are evaluated in all directions using three automatic evaluation metrics: BLEU, RIBES, and TER.

4.1 Data

Training We have made available a number of data sources for the SLT shared task. Some training datasets were used in the previous editions of the WMT News Translation shared task and were updated (News Commentary v16, Wiki Titles v3), while some corpora were newly introduced. We also used data collected from Opus (Tiedemann and Nygaard, 2004; Tiedemann, 2012)[20].

For the Spanish–Catalan language pair we used parallel corpora: Wiki Titles v3, ParaCrawl (Bañón et al., 2020), DOGC v2, and monolingual: Europarl v10 (Koehn, 2005), News Commentary v16, News Crawl, caWaC (Ljubešić and Toral, 2014) (see Table 15). Released corpora for the Spanish–Portuguese language pair included parallel datasets: Europarl v10 (Koehn, 2005), News Commentary v16, Wiki Titles v3, Tilde MODEL (Rozis and Skadiņš, 2017), JRC-Acquis (Steinberger et al., 2006), and monolingual corpora: Europarl v10 (Koehn, 2005), News Commentary v16, News Crawl (see Table 16). Moreover, corpora for the Romanian–Spanish language pair (see Table 17) and the Romanian–Portuguese language pair (see Table 18) contained parallel datasets: Europarl v8 (Koehn, 2005), Wiki Titles v3, Tilde MODEL (Rozis and Skadiņš, 2017), JRC-Acquis (Steinberger et al., 2006), and monolingual data: Europarl v10 (Koehn, 2005), News Commentary v16, News Crawl, Common Crawl.

The released parallel Tamil–Telugu dataset was collected from news (Siripragada et al., 2020), PMIndia (Haddow and Kirefu, 2020) and MKB (Man Ki Baat) datasets. All data were initially combined, tokenized using indic-nlp tokenizer (Kunchukuttan, 2020) and randomly shuffled. A subset of data extracted from the dataset are used for test and development set. The remaining data were considered as training set (cf. Table 21).

Finally, the parallel Bambara-French corpus is a part of the Bambara Reference Corpus [21].

Development and Test Data The development and test sets for Spanish–Catalan, Spanish–Portuguese, Romanian–Spanish and Romanian–Portuguese language pairs were created from a corpus provided by Pangeanic[22]. Catalan translations were provided by the Directorate-General for Language Policy at the Ministry of Culture, Government of Catalonia. Each dev and test dataset was cleaned, deduplicated and shuffled, resulting in 969 and 999 sentences in dev and test sets respectively.

4.2 Participants and Approaches

SEBAMAT SEBAMAT submitted their system for two language pairs, Spanish–Catalan and Spanish–Portuguese, in both directions. The SEBAMAT approach is based on the Marian NMT toolkit that leverages the Transformer architecture. The systems were trained using only the parallel corpora that were made available for the participants. For all the language pairs and directions, SEBAMAT submitted PRIMARY and CONTRASTIVE systems with different vocabulary sizes (40,000 and 85,000, respectively). Interestingly, in all the cases, the PRIMARY systems with a smaller vocabulary size performed better in terms of BLEU scores.

T4T The T4T team participated in the SLT 2021 Romance languages track, submitting their system for Spanish ↔ Catalan and Spanish ↔ Portuguese. While their systems are built using out-of-the-box OpenNMT toolkit, the team developed custom cleaning scripts and an adhoc tokenizer. SentencePiece library was used for pre-processing and reducing the vocabulary size to 16,000 symbols.

UBC-NLP The UBC-NLP team submitted their Spanish ↔ Portuguese, Catalan → Spanish and French ↔ Bambara systems to the SLT 2021 task. Their systems are built using Transformers from the HuggingFace library. The UBC-NLP team experimented with tokenized (PRIMARY) and untokenized (CONTRASTIVE) systems and compared them with models developed by fine-tuning pre-trained models as well as models trained from

scratch. The pre-trained models were developed using Marian NMT by Helsinki-NLP on HuggingFace.

A3-108 The A3-108 team submitted 3 systems (one PRIMARY and two CONTRASTIVEs) based on statistical machine translation for Tamil ↔ Telugu language pair. The team explores various tokenization schemes for their submissions. Their PRIMARY run achieved top rank in Telugu → Tamil and ranked 3^{rd} in Tamil → Telugu translation task.

oneNLP oneNLP team participation on Tamil ↔ Telugu system is based on transformer based NMT. The team explored different subword configurations, script conversion and single model training for both directions. Their primary submission achieved 2.05 BLEU for Tamil → Telugu and 5.03 for Telugu → Tamil.

CNLP-NITS The team submitted their run for Tamil ↔ Telugu similar language translation task. The CNLP-NITS system used pre-train word embeddings from monolingual data and applied in transformer based neural machine translation. The model achieved BLEU score 4.05 for both Tamil → Telugu and Telugu → Tamil.

NITK-UOH NITK-UoH's submission system is based on vanilla Transformer model initialized with MultiBPEmb – a collection of multilingual subword segmentation based pretrained embeddings. NITK-UoH performs top in Tamil → Tel-

ugu translation task.

4.3 Results

Similarly to the previous edition of the SLT shared task, participants could submit systems for the Spanish–Catalan and Spanish–Portuguese language pairs (in both directions). The best systems for Spanish-to-Portuguese (see Table 25) achieved over 40 BLEU and around 85 RIBES. While in the opposite direction (Portuguese-to-Spanish) the best performing system reached 47.71 of BLEU (see Table 24). As the Spanish–Catalan dev and test sets were aligned with Spanish–Portuguese ones, we noticed that the best results for the Spanish–Catalan language pair are in general much better than for Spanish–Portuguese. For Spanish-to-Catalan the best system attained over 79 BLEU and below 15 TER (see Table 27). However, its RIBES score (95.76) was lower than the runner-up system's (96.24). In the case of Catalan-to-Spanish, the best system scored over 82 BLEU and less than 11 TER (see Table 26). As there were no submissions for Romanian–Spanish and Romanian–Portuguese, we do not provide any evaluations for these language pairs.

4.4 Summary

This section presented the results and findings of the third edition of the SLT shared task at WMT. The third iteration of this competition featured data from multiple language pairs from three different language families: Dravidian, Manding, and Romance languages. We evaluated the systems translating in both directions of the language pair using three automatic metrics: BLEU, RIBES, and TER. Most teams this year participated in the Dravidian language pairs. Following a trend observed in the past editions of the task, we observed that the performance varies widely between language pairs and domains.

5 Triangular MT

This section presents an overview of the Triangular MT shared task. Given a low-resource language pair (X/Y), the bulk of previous MT work has pursued one of two strategies.

- Direct: Collect parallel X/Y data from the web, and train an X-to-Y translator , OR
- Pivot (Utiyama and Isahara, 2007; Wu and Wang, 2009): Collect parallel X/English and Y/English data (often much larger than X/Y data), train two translators (X-to-English + English-to-Y), and pipeline them to form an X-to-Y translator

However, there are many other possible strategies for combining such resources. These may involve, for example, ensemble methods, multi-source training methods, multi-target training methods, or novel data augmentation methods. For eg. (Zoph et al., 2016; Dholakia and Sarkar, 2014; Kim et al., 2019).

5.1 The Task

The goals of this shared task is to promote:

- translation between non-English languages,
- optimally mixing direct and indirect parallel resources, and
- exploiting noisy, parallel web corpora

The task is Russian-to-Chinese machine translation. We provided parallel corpora to the participating teams. We evaluate system translations on a (secret) mixed-genre test set, drawn from the web and curated for high quality segment pairs. After receiving test data, participants had one week to submit translations. After all submissions are received, we posted a populated leaderboard that will continue to receive post-evaluation submissions.[23] The evaluation metric for the shared task is 4-gram character Bleu. The script to be used for Bleu computation is Moses `multi-bleu-detok.perl`. Instructions to run the script were released as part of the shared task.[24] The participants indicated their intent to participate via registration on the Codalab website for the shared task[25] and obtained the instructions and links to various resources.

5.2 Training Data

We provided three parallel corpora:

- Chinese/Russian: crawled from the web and aligned at the segment level, and combined with different public resources.

- Chinese/English: combining several public resources.
- Russian/English: combining several public resources.

The details of the training resources provided are shown in Table 30. The provenance of the collected parallel data is as follows. We used a parallel data harvesting pipeline developed at DiDi (Zhang et al., 2020) to harvest Russian/Chinese parallel data on the Internet. We downloaded parallel datasets available from Opus (Tiedemann, 2009) for all the three language pairs - Russian/Chinese, Russian/English and English/Chinese. Since united nations data and subtitles data (Ru/En) are very large sources of parallel data, we report statistics on these two types of Opus parallel sources. In addition to Opus, we also curate parallel data from Wikimatrix (Schwenk et al., 2019) in all three language pairs and social media parallel data - Weibo and Twitter (Ling et al., 2013). We also release the provenance of each parallel segment, in case teams want to use this information to filter noisy data sources.

5.3 Creating the Test Dataset

We spent a considerable amount of time to curate high quality, parallel data online to be used as development and evaluation datasets. This was a completely manual process undertaken by a native speaker of Russian who consulted with a native Chinese speaker from our team to ensure good quality translations (that does not contain tell-tale signs of automatic translation). Our workflow entailed finding websites and large chunks of parallel text, not necessarily from the same pages. The sources selected were also hard to be harvested from a parallel data pipeline due to their difference in URL structure. The sources selected were from a diverse range of non-traditional sources, and have a balance of different types of documents. The topics would be famous works of literature, or tourism related news stories, and so on. We copied large chunks of text from such sources and manually aligned the paragraphs, followed by manual sentence alignment, each done manually to ensure top quality parallel segments. This was followed by a final filtering step to remove sentences and entire sources which had a significant overlap with training and development data. The details of the development and test datasets are shown in Tables 31 and 32.

5.4 Baselines and Final Results

We released a baseline system[26] as part of the shared task. This is based on the Google Tensor2tensor[27] toolkit to train a Transformer-based NMT system. We also provided the baseline bleu score on the development dataset ahead of the evaluation phase. We had 2 simple baselines - (1) Direct - Transformer model trained on the entire Russian/Chinese parallel dataset and decoded with $\alpha = 1.0$ and $beam\_size$=4. (2) Pivot model - 2 MT systems - Russian-to-English and English-to-Chinese - each trained with the corresponding parallel data. Both the Russian-to-English and the English-to-Chinese systems were decoded with $alpha$=1.0 and $beam\_size$=4. The baseline results on the development dataset as shown in Table 33.

We had a total of six teams submitting their system outputs on the test dataset. The evaluation metric was 4-gram character bleu score. The final evaluation results are shown in Table 34.

5.5 Overview of the Submitted Systems

Five out of the six participating systems submitted system description papers. In this section we briefly discuss the outline of these systems. For more details please refer to the proceedings.

- istic-team-2021 (Guo et al., 2021) The team's system is based on the Transformer architecture. They used several corpus pre-processing steps such as special symbol filtering and filtering based on segment length. In addition, they used context-based system combination - which is a multi-encoder to encode source sentence and contextual information from the machine translation results on the source sentence. They tried with both a direct and pipeline-based pivot system and report that the latter outperforms the former.

- HW_TSC (Li et al., 2021a) Huawei's submission used a multilingual model which is a single neural machine translation model to translate among multiple languages. Upon adding more parallel data, they report an increase in bleu score of upto 2 points using the multilingual model compared to the baseline model. In addition they used several data pre-processing techniques to denoise the training data and data augmentation techniques such as back-translation to improve overall system performance.

- Papago (Park et al., 2021) Naver's system reports that they get better performance by treating this as a bilingual machine translation task rather than as a multilingual translation task, based on their early experiments. They use the transformer model with extensive data pre-processing, filtering and data augmentation. To augment the direct bilingual data they synthetically generate bilingual sentence pairs using monlingual Chinese back-translated to Russian and the 2 sets of indirect parallel dataset provided.

- DUT-MT (Liu et al., 2021a) This team experimented with 2 different multilingual training models called mBART and mRASP, both of them based on underlying Transformer architecture. They report boosted performance especially on rare words when using mRASP. In addition, they also carry out data preprocessing and filtering to improve system performance.

- CFILT-IITB (Mhaskar and Bhattacharyya, 2021) CFLIT-IITB team's system used a pivot-based transfer learning technique. In this technique they have 2 encoder-decoder models, source-pivot (Russian-to-English) and pivot-target (English-to-Chinese), each of them trained on the respective training datasets. They use the encoder of the former and the decoder of the latter to initialize a third encoder-decoder for the actual task of Russian-to-Chinese translation. They fine tune this decoder using the given parallel data for Russian/Chinese. They report this system has a better performance compared to either a direct or pivot-based cascaded system. They do not experiment much with data pre-processing and filtering.

Table 32: Triangular MT: Test dataset details

5.6 Conclusion

The triangular machine translation shared task set out to explore various modeling possibilities when building a machine translation system for a non-English language pair. We received enthusiastic participation from the participants. Almost all of them performed data filtering and preprocessing to denoise the training datasets and that seemed to substantially help improve system performance. The transformer model and its variants were used in all the system submissions confirming Transformer's ubiquitous acceptance as the model of choice for building machine translation systems. Many teams explored model ensembling and model averaging in addition to model reranking strategies. Several teams explored back-translation as an effective data-augmentation strategy. There was a wide variety of modeling architectures experimented by the participants. Almost everyone used all the parallel datasets provided underlining the importance of using parallel data in all directions to build a better machine translation system. Overall we are happy that the shared task provided a platform to the participants to experiment with different modeling strategies. We hope practitioners will find these techniques useful when working on machine translation between non-English language pairs.

6 Multilingual Low-Resource Translation for Indo-European Languages Task

Massively multilingual machine translation has shown impressive results, including zero and few-shot translation of low-resource languages. However, these models are often evaluated from or into English, where the most data is available, and one assumes that the models would generalise to other language pairs and low-resource languages. This shared task focuses explicitly on checking this assumption and aims to explore multilingual archi-

tectures for languages in a same family and evaluate only low-resource pairs even if using the high-resourced pairs in the same language family is not forbidden. We work in the cultural heritage domain, where we can consider full documents, and in two Indo-European language families: North-Germanic and Romance. With these goals in mind (multilinguality, specific domain and document-level translation) we define two tasks, one per family:

Task 1. Europeana thesis abstracts and descriptions. North-Germanic languages: from/to Icelandic (is), Norwegian Bokmål (nb) and Swedish (sv). Danish (da), German (de) and English (en) data is allowed for training but translation quality is not evaluated.

Task 2. Wikipedia cultural heritage articles. Romance languages: from Catalan (ca) to Occitan (oc), Romanian (ro) and Italian (it). Spanish (es), French (fr) and Portuguese (pt) data (+ English) is allowed for training but translation quality is not evaluated.

6.1 Data and Resources

6.1.1 Training Corpora

One of the purposes of the shared task is to obtain state-of-the-art systems for the language pairs in the domain involved. In principle, this would imply an unconstrained data setting but, we also want to be able to compare systems and architectures among themselves. For this, we constrain the amount of parallel and monolingual corpora to be used but we allow pretrained open-source systems which might use more data than allowed for the languages considered. All the sources listed below apply to the following languages (except for pretrained models): Icelandic, Norwegian Bokmål, Swedish, Danish, German and English (Task 1); and Catalan, Italian, Occitan, Romanian, Spanish, French, Portuguese and English (Task 2).

- Corpora available at ELRC.[28] This data includes Paracrawl and Global voices.
- Europarl, JW300, WikiMatrix, MultiCCAligned, OPUS-100, Books, the Bible and TED talks.
- Common Crawl, Wikipedia and Wikidata dumps.
- Wordnets with open license, BabelNet.
- (Multiligual) pre-trained embeddings or other models that can be found freely available online (Hugging Face).
- Additional resources in Section 6.1.2 (multilingual lexicons).

6.1.2 Additional Resources

Given the importance of named entities in the cultural heritage domain, we provide participants with parallel/multilingual lexicons from Wikidata, Wikipedia titles and Wiktionary. The figures for each source are summarised in Table 35.

Table 36: Statistics on the validation and test sets of the multilingual low-resource translation task. Source (Src) are original documents and target (Tgt) are human translations.

Wikidata. We extract aligned lexicons from the wikidata-20210301-all.json dump and provide two versions. The complete ("all") version includes all the entries, including duplicates. The "cleaner" version excludes duplicates, most of the terms that are equal in all the languages, terminology related to Wikimedia and a naïve cleaning on terms including years, parenthesis, and others.

Wikipedia titles. We extract aligned titles for the languages in Task 2 from the May 2020 Wikipedia dumps using the Wikitailor Toolkit[29] (Barrón-Cedeño et al., 2015; España-Bonet et al., 2020). We also provide two versions: the complete version ("all") includes all the entries. The "cleaner" version results from a naïve cleaning on titles including years, dates, parenthesis, and others.

Wiktionary. Each Wiktionary entry contains a word, its translation into several languages and its part of speech. We extract bilingual entries from April 2021 dumps for adjectives, adverbs, nouns and verbs from the Icelandic, Swedish, English and German Wiktionaries (Task 1) and from the Catalan and English ones (Task 2). The part of speech is kept in the dictionaries. Since the xlm dump contains the information in a text element with different structure for different dictionaries, we provide the extraction scripts for reproducibility.[30]

6.1.3 Validation and Test Sets

The documents used for constructing the validation and test sets are obtained from the Europeana collection (Task 1) and Wikipedia (Task 2).

Europeana kindly provided us with thesis abstracts, descriptions of archaeological sites and bibliographic entries for Icelandic, Norwegian Bokmål and Swedish. These monolingual documents are available at the Europeana portal but no intra-family parallel data exists and even the monolingual extraction is not straightforward for two main reasons: (i) collections with pan-Scandinavian labels and descriptions are uncommon, and (ii) language attributes in general are uncommon. For documents tagged as Norwe-

[29] github.com/cristinae/WikiTailor

[30] github.com/LeHarter/Extracting-translations-from-wiktionary

gian there is no distinction between Bokmål and Nynorsk, so texts where classified according to simple heuristics based on lexicons.

The original Europeana crawl obtained 1,192 documents (150,080 tokens) for Icelandic, 2,000 documents (166,303 tokens) for Norwegian Bokmål and 2,046 bilingual documents in English and Swedish with 443,111 tokens for Swedish. From these sets, we eliminate very similar documents (specially for Icelandic) and split documents at sentence level manually; we selected documents to collect around 1,000 sentences per language. Documents are finally divided evenly to build a validation set and a test set (Table 36).

The Wikipedia sets were built from articles in the Catalan edition. We selected original articles in Catalan that have no comparable article in any other language and that cover the cultural heritage domain (food, locations, sport, literature, traditions, people and animals). We selected 83 articles which were sentence-split manually to gather 3,013 sentences and 69,231 tokens. Similarly to the North-Germanic family, documents are divided evenly to build a validation set and a test set (Table 36). In this case, we also marked some entities in the source test documents (dates and locations) for further analysis in the manual evaluation (see Section 6.4).

Validation and test sets were sent to professional translators. A first translation was done by a native professional translator and afterwards there was a quality evaluation check by a second native professional translator. For the North-Germanic languages, we translated the source texts in Icelandic, Norwegian Bokmål and Swedish into the other two languages. For the Romance languages, we translated the source texts in Catalan into Italian, Romanian and Occitan. Translators were asked to keep the same sentence division as in the source and no indications were given on the translation of named entities.

6.2 Baselines and Submitted Systems

Nine different teams downloaded the validation data set but only five of them participated: BSC, CUNI, EdinSaar, Tencent and UBCNLP. We allowed two submissions per group and task, a primary (P) and a contrastive (C) system. With these constraints, we received four submissions for Task 1 and seven submissions for Task 2. We also prepared two baseline systems for comparison purposes.

6.2.1 M2M-100 (baseline)

We use M2M-100 without any modification, a multilingual model trained on a data set with 7.5 billion sentences for 100 languages including all the languages in our task (Fan et al., 2020). The sequence-to-sequence system is trained with parallel data enriched with backtranslations. We use the model with 1.2 B parameters available at the Hugging Face site.[31]

6.2.2 mT5-devFinetuned (baseline)

mT5 is a sequence-to-sequence model pretrained on a masked language modeling span-corruption objective with 8.5 billion monolingual sentences from 101 languages (Xue et al., 2021). As baseline, we use the model with 580 M parameters from Hugging Face. We finetune mT5-base only with the multilingual validation sets for each task described in Section 6.1.3. For Task 1, that involves 5,500 sentences, where we use the parallel sentences L_1–$L_{2\text{dev}}$ in both directions $L_1 2 L_2$ and $L_2 2 L_1$ (that is, we use $\text{is2nb}_{\text{dev}}$ sentences as is2nb and nb2is, and $\text{nb2is}_{\text{dev}}$ sentences as nb2is and is2nb because $\text{is2nb}_{\text{dev}}$ and $\text{nb2is}_{\text{dev}}$ are different; the same for the other pairs). We prepend one of the extra_id tokens in mT5 vocabulary to the source sentences to indicate the language of the target sentences. The remaining 440 sentences are used for validation. We repeat the process for Task 2, but in this case the training is multilingual but not bidirectional, so sentences are only used in one direction with a total of 3,600 sentences (1,200 ca2it, 1,200 ca2ro and 1,200 ca2oc) for finetuning and 207 for validation.

6.2.3 BSC (Kharitonova et al., 2021) – Task 2

BSC submission is a multilingual semi-supervised machine translation model. It is based on a pretrained language model, XLM-RoBERTa, that is later finetuned with parallel data obtained mostly from OPUS (5.1 M sentences). XLM-RoBERTa is only used to initialize the encoder while the shallow decoder is randomly initialised.

6.2.4 CUNI (Jon et al., 2021) – Task 2

Multilingual supervised machine translation model (primary) enriched with backtranslated data (contrastive). The multilingual systems

Table 38: Official ranking according to the automatic metric average for the multilingual low-resource translation task of Wikipedia articles in the cultural heritage domain for Romance languages (Task 2).

use 41 M original parallel sentences including all language pairs in the task plus French and English. Besides leveraging multilingual training data, various subword granularities are explored and phonemic representation of texts are added via multi-task learning. For Catalan–Occitan, character-level rescoring on the translations n-best lists is applied and Apertium is used for backtranslations when included.

6.2.5 EdinSaar (Tchistiakova et al., 2021) – Task 1

Semi-supervised systems with multilingual pretraining, backtranslation, finetuning and checkpoint ensembling. The primary system is a semi-supervised machine translation model. mT5 is finetuned with 1.2 M parallel sentences in the languages of the task plus Danish, German and English. The contrastive system is a transformer base architecture trained with 422 M parallel sentence pairs in all 30 language directions (including Danish, German and English) and finetuned only with pairs with the languages of the task as target language.

6.2.6 TenTrans (Yang et al., 2021) – Task 2

TenTrans submissions are semi-supervised multilingual systems based on a transformer base architecture. The basic system is an 8-to-4 multilingual model with Catalan–Italian–Romanian–Occitan as the target side and the inclusion of the high resource languages Spanish, French, Portuguese and English on the source side. In-domain finetuning is done with data selected using a domain classifier trained with multilingual BERT. Knowledge transfer is achieved with knowledge distillation of the M2M 1.2B model previously finetuned on the languages of the task. The primary submission is an ensemble between the in-domain multilingual and the distilled M2M. The contrastive submission adds a multilingual base model enriched with backtranslations to the ensemble and pivot-based methods to augment the training corpus.

6.2.7 UBCNLP (Chen and Abdul-Mageed, 2021) – Task 1, Task 2

Supervised bilingual systems based on a transformer base architecture where the Helsinki-NLP pretrained models available at the Hugging Face site are finetuned to the languages of the shared task. The primary submission finetunes the

Table 39: Automatic evaluation per language pair in the North-Germanic family of the multilingual low-resource translation task (Task 1). Best scores boldfaced. Notice that the final ranking is done per family and not per language pair as shown in Table 37.

Catalan–Spanish Helsinki-NLP model with WikiMatrix data (1.1 M sentences for ca-it, 139 k for ca-oc and 490 k for ca-ro). The same data is used to finetune the Catalan–English Helsinki-NLP model in the contrastive submission.

6.3 Automatic Evaluation

Recently, automatic metrics based on contextual embeddings have been shown to correlate better than string matching ones with human judgments (Kocmi et al., 2021). COMET was shown to be the best performing metric for languages with Latin script and chrF the best performing string-based method. Still, BLEU is used as *de facto* metric in most papers. As we cannot perform human evaluation for the 9 language pairs involved in this shared task, for the official ranking we use a combination of several metrics including the ones just mentioned plus BertScore as representative of contextual embedding-based metrics and TER as representative of plain string methods.

We evaluate the submissions and the baseline systems for the two tasks using BLEU,[32] TER,[33] chrF,[34] (all with SacreBLEU) COMET,[35] and BertScore.[36] The final ranking is done according to the average ranking of the individual metrics per family, ties on individual metrics are considered.

We report the results for Task 1 in Table 37 and for Task 2 in Table 38. M2M-100 resulted in a very strong baseline for North-Germanic languages. EdinSaar systems are second and third, followed by UBCNLPs. The ranking is consistent

Table 40: Automatic evaluation per language pair in the Romance family of the multilingual low-resource translation task (Task 2). Best scores boldfaced. Notice that the final ranking is done per family and not per language pair as shown in Table 38.

across metrics. The quality of the second baseline, the finetuned version of mT5, is low as compared to the other systems because it has only been trained for machine translation with 5,500 parallel sentences for the 6 language pairs. EdinSaar-Primary is also a version of mT5 finetuned with 1.2 M parallel sentences and that improves translation quality significantly, but still, it lies below the multilingual baseline system trained with huge amounts of parallel data, M2M-100.

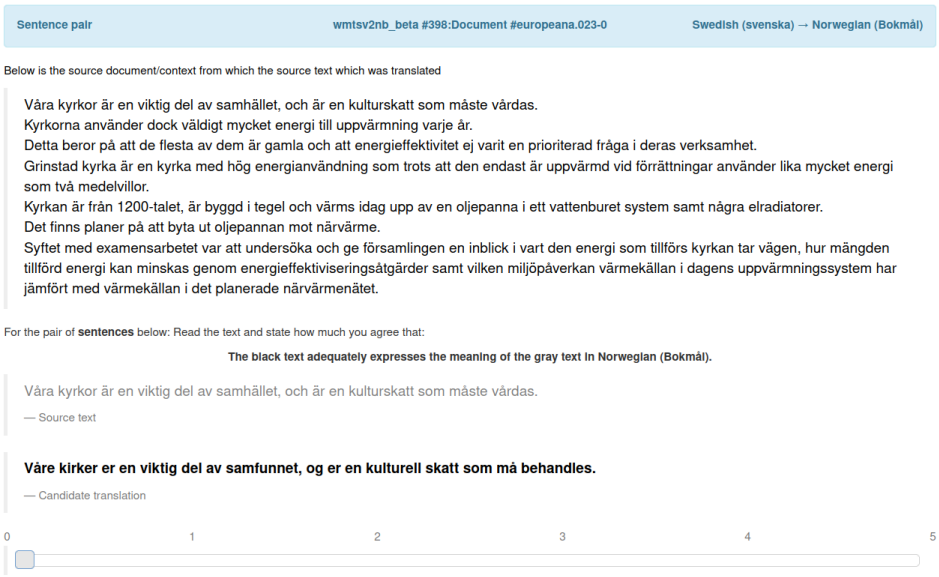
A more fine-grained analysis (Table 39) shows that translation into Icelandic is difficult for all the systems, and also translation from Icelandic into Swedish (Norwegian) is more difficult than translation from Norwegian (Swedish) into Swedish (Norwegian). Systems do not behave consistently across language pairs: mT5-devFinetuned (mT5-dFT in the table) achieves top performance when translating from Icelandic but performs poorly for the remaining pairs; UBCNLP-Contrastive (UBCNLP-C) is specially good for translating from Swedish.

For Task 2, the Romance family, the CUNI systems are significantly better than the rest, both at family and language pair levels (Tables 38 and 40). Only for ca2ro, M2M-100 is better according to some metrics; however, this system performs comparatively bad for ca2it. TenTrans and BSC perform very close one to each other. Globally, TenTrans performs better with BSC showing good performance for ca2oc. For this language pair, the reranking strategy via a character-based model by CUNI achieves very good results.

6.4 Human Evaluation

In order to complement and corroborate the automatic evaluation, we also perform human evaluation on a subset of the languages. However, since not all language pairs are covered, we cannot use the manual evaluation results for the official ranking of the systems.

The type of evaluation has been conditioned by the number and expertise of the raters we could attract. We hired a total of 14 raters: 5 Swedish annotators to rate nb2sv and is2sv documents; 3 bilingual Catalan–Occitan annotators to rate ca2oc documents and 6 bilingual Catalan–Italian annotators to rate ca2it documents. With these numbers in mind, we decided to do ratings on a Likert-like scale but following the philosophy of direct assess-



(a)

(b)

Figure 8: Modifications to the Appraise Evaluation Framework (Federmann, 2018) for the multilingual low-resource translation task. (a) We conduct reference document-level direct assessments on a discrete scale [1,5]. (b) For languages where we can conduct source document-level assessments, we we also evaluate term translation (dates and locations).

ments (DAs). We do source DA for Italian and Occitan, and reference DA for Swedish.

Following the conclusions in (Graham et al., 2020) and (Castilho et al., 2020), we perform sentence level evaluation with document context. Figure 8(a) shows that evaluators rate each sentence in context and when all the sentences in document are evaluated, the whole document is also scored. The evaluation is done using the Appraise Evaluation Framework (Federmann, 2018) with several modifications. Appraise implements document direct assessments as used in the WMT News Task evaluation campaign (Barrault et al., 2020). In our case, we have fewer annotators so we cannot expect > 15 ratings per sentence to get statistically significant results with a 100 points DA scale. To tackle this limitation, we constrain the DA scale to a 5 points Likert-like scale [1,5]. This resembles an adequacy+fluency evaluation where raters still answer the question "*The black text adequately expresses the meaning of the gray text.*", but they do not evaluate adequacy and fluency separately. After a small pilot experiment (see below), the guidelines to the evaluators were the following:

Rank a sentence with a 5 if it completely expresses the same meaning as the source/reference. Notice that we do not ask for a literal translation but for a sentence that preserves the meaning and it is grammatically correct. For a 3 score, the sentence should convey part of the meaning

of the original sentence but some relevant parts are missing or not well translated. For a 4, only non-relevant parts are not OK. For a 2, most of the sentence is wrong but still some bits, probably non-relevant, are well translated. Finally, rate the sentence with a 1 if none of the content is preserved.

Bilingual raters allow us to do a small term translation evaluation for Catalan to Italian and Occitan. Figure 8(b) shows that we boldface some terms in the source text and evaluators are asked to say if *(i) The phrase is not translated*, *(ii) The phrase is well translated* or *(iii) The phrase is mistranslated*.

6.4.1 Data Preparation

We select test documents or parts of them to cover 100 sentences per language. Table 36 shows that considering full documents would limit the evaluation to very few texts so we select a subset of contiguous sentences in documents to make the evaluation more heterogeneous. For Catalan to Italian and Occitan, we selected fragments in 9 documents with lengths between 5 and 15 sentences; for Icelandic to Swedish fragments in 7 documents with lengths between 8 and 20 sentences; and for Norwegian to Swedish fragments in 7 documents with lengths between 7 and 22 sentences.

We extract the same 100 sentences from the participants primary submissions and from the reference. For source DA evaluation (Catalan and Occitan), the reference is also rated and used to establish human performance. For reference DA (Swedish), the reference is just used for rating translations.

Finally, we mark 60 of the source sentences in Catalan with one term each. Selected terms[37] are mostly named entities (dates, locations or titles) and might be multi-word. Named entities that appear only a few times in training data are a challenge for neural systems, so the aim is to check the quality of these translations. Since professional translators did not receive any instructions on how to translate these terms, we can observe a mixture of untranslated and translated named entities, which makes it difficult to assess its quality in an automatic way.

[37]List of terms which translation is evaluated manually: Plaça del Mercadal, segle XV, segle XIX i XX, la Casa Pinyol, Festes de Maig, Rambla de Badalona, la Cremada, la Segona República, Josep Maria Cuyàs, Baró de Maldà, 11 de maig de 1940, Francesc de Paula Giró i Prat, Aristeus antennatus, Productes de l'Empordà, 400 metres, mitjan segle XX, Canyó de Palamós, Confraria de Pescadors de Palamós, finals del segle XIX, Xat de Benaiges, començaments del segle XX, "salvitxada", la calçotada, Alt Camp, Congrés de Cultura Catalana, Valls, Concurs de salsa de la "calçotada", Fogueres de Sant Antoni, Nadal, Sant Antoni, Química Orgànica, Universitat de Barcelona, Junta d'Energia Nuclear, Universitat de Chicago, Universitat de València, Física Teòrica, Mecànica Teòrica, Premi d'Investigació Ramón y Cajal, Manaies de Girona, any 1751, Dijous Sant, Setmana Santa, segles xviii i xix, 1851, mitjans de segle XIX, finals del XVIII, port del Masnou, dos quilòmetres i mig, Club Nàutic del Masnou, Creu Roja, festival Ple de Riure, Masnou, N-II, Premià de Mar, any 2019, platja d'Ocata, Michelin, Ferran Adrià, El Celler de Can Roca, Can Fabes

6.4.2 Pilot Experiment

We prepared a pilot experiment with two goals: (i) provide some training to the raters and (ii) check the feasibility of the task. For this, we prepared a manual with instructions to work with the modified Appraise interface and the guidelines for rating the translations. We populate the task with 20 translated sentences from one of the submissions. Sentences come from two test documents so that the annotators go through the full document annotation process twice.

After the pilot, we made the guidelines more concrete to accommodate the raters questions. These annotations are discarded for the final analysis described in the next section.

6.4.3 Results

The results of the evaluation task are the average DA scores per system. In order to take into account that some raters might be more strict than others, we rank the systems according to the z-score, where the DA score is mean-centered and normalised per rater.

Inter-annotator agreement as measured by Fleiss' κ (Fleiss, 1971) is moderate: 0.32±0.03 (nb2sv, fair agreement), 0.16±0.04 (is2sv, slight agreement), 0.28±0.03 (cat2it, fair agreement) and 0.16±0.02 (ca2oc, slight agreement). These values are in agreement with previous analyses (Castilho, 2020). Intra-annotator agreement ranges from 0.88±0.06 to 0.24±0.09 for the North-Germanic languages and from 0.56±0.09 to -0.04±0.07 for the Romance family. We discard raters with $\kappa \sim 0$ and report results with 4 raters for Swedish, 3 for Catalan–Occitan and 4 for Catalan–Italian. Tables 41 and Table 42 show the results for Task 1 and Task 2 respectively.

For Task 1, we obtain very different scores depending on the language pair. This is in line with the automatic evaluation: translations from Icelandic do not behave in the same way as Swedish and Norwegian which are closer languages. Baselines perform very well on this family, but not simultaneously. M2M-100 offers good translation quality for nb2sv while mT5-dFT is specially good for is2sv. For is2sv, systems are not statistically significantly different, for nb2sv mt5-dTF is significantly worse than the others and EdinSaar and UBCNLP show similar performance.

For Task 2, the reference (HUMAN) is ranked first in both language pairs, but the deviation is large and it is not significantly better than the CUNI system. For ca2it, HUMAN is not significantly better than the baseline system M2M-100 either. In some cases though, the distinction seemed to be easy. Raters pointed out several reasons: (i) mistranslations of very frequent words —*got* in Catalan (cup, glass) translated into Italian as *getto* (jet), *grigio* (gray) or *vetro* (glass, the material); (ii) bad translation in context of ambiguous words —*quarentena* in Catalan translates into Italian as *quarantina* (about fourty) or *quarantena* (quarantine); (ii) mistaken roots (this can be related to BPE subunits as explained below) —*calçots* (a local vegetable) translated as *calzatura* (footwear); or changing words —*un físic català* (a Catalan physicist) translated as *un fisico spagnolo* (a Spanish physicist).

	ca2it				ca2oc			
System	**well**	**mis**	**no**	Σ	**well**	**mis**	**no**	Σ
HUMAN	53	0	3	56	40	0	2	42
CUNI	39	3	5	47	30	7	1	38
M2M-100	33	2	6	41	26	9	0	35
TenTrans	37	0	9	46	32	4	1	37
BSC	27	7	5	39	33	4	0	37
UBCNLP	29	16	1	46	19	1	0	20
mT5-dFT	20	17	10	47	25	11	4	40

Table 43: Number of **well** translated, **mis**-translated and **no**t translated terms for the language pairs manually evaluated for Task 2. The last column per language shows the total number of terms considered from the maximum of 60 bold faced terms (see text).

Similar to the automatic evaluation, TenTrans and BSC are very close to each other according to the human ratings although the two architectures are completely different. The evaluation also confirms the bad performance of M2M-100 on ca2oc but its good performance on ca2it. In general, all the systems perform worse on ca2oc than ca2it according to the raw scores in Table 42, but the trend is reversed when analysing the z-scores. This result points to differences between the scale that annotators used in the two tasks even if they received the same instructions. Notice that almost all automatic metrics but COMET tend to score higher ca2oc than ca2it for most systems.

Term translation. The evaluation against the source for the Romance languages allows us to study the translation quality of selected terms. For ca2it we use the annotations from 5 raters but only 2 were considered for ca2oc as the remaining raters did not do the task properly. The agreement for this task is 0.34±0.05 (ca2it) and 0.19±0.05 (ca2oc). Table 43 shows the number of well translated, mis-translated and untranslated terms for both pairs.

For each term, we sum the votes from all the raters per class (well translated, mis-translated or untranslated) and consider the winning class the one with the majority of votes. In case there is a tie with 2 or more classes, the term is not considered in the analysis, this is why the last columns Σ in Table 43 differ from 60. The disagreement is high, and one of the causes is the ambiguity in the annotation of toponyms. For instance, the name of the city of "Valls" has been evaluated 17 times: 7 times as well translated and 10 times as not translated being always the translation

"Valls". The same happens with other toponyms and years. This ambiguity damages specially the majority voting for Occitan (low Σ) since we only consider 2 raters.

The systems with the largest number of mistranslations are those with less access to the task languages, that is, the baselines. mT5-devFinetuned and M2M-100 (specially for Occitan) do the most mistakes. A curious case is UBNLP which only produces 1 mistranslation for Occitan but 16 for Italian. Also BSC generates more errors for Italian (7) than for Occitan (4) even though translation quality into Italian is higher than into Occitan. Looking at some examples, we hypothesise that this can be related to the subunit segmentation strategy. For instance, the word "calçotada" is translated as *calzotada, calzolata* or as we have seen before *calzatura* in Italian, where no Italian word for this concept exists. For Occitan, it is always translated by *calçotada* (BPE units in Catalan and Occitan might be the same, but not for Italian), only two times it is mistranslated as *escòla*.

Besides these errors that might be due to the split in subunits, we also observe multi-word named entities where one of the words has been literally translated and the others have not. Also, in few occasions, a number (specially centuries) is translated by another one.

6.5 Discussion

This shared task faced three challenges: multilingual translation, document translation and in-domain (cultural heritage) translation. 60% of the submissions approached multilinguality with a single system while 40% used a combination of several bilingual systems. None of the participants focused on the document-level aspect of the task, and those who dealt with the specific domain did not use any of the in-domain multilingual lexicons but selected in-domain data from the available training corpus.

More details and comparisons among the submissions can be found in Figures 9 and 10. Figure 9 focuses on the resources. Participants did not use all the data available, probably because of its heterogeneous nature and the difference of language pairs available in the different corpora. WikiMatrix is the favourite corpus, with 80% of the submissions trained on it. 90% of the systems used some kind of pretrained model:

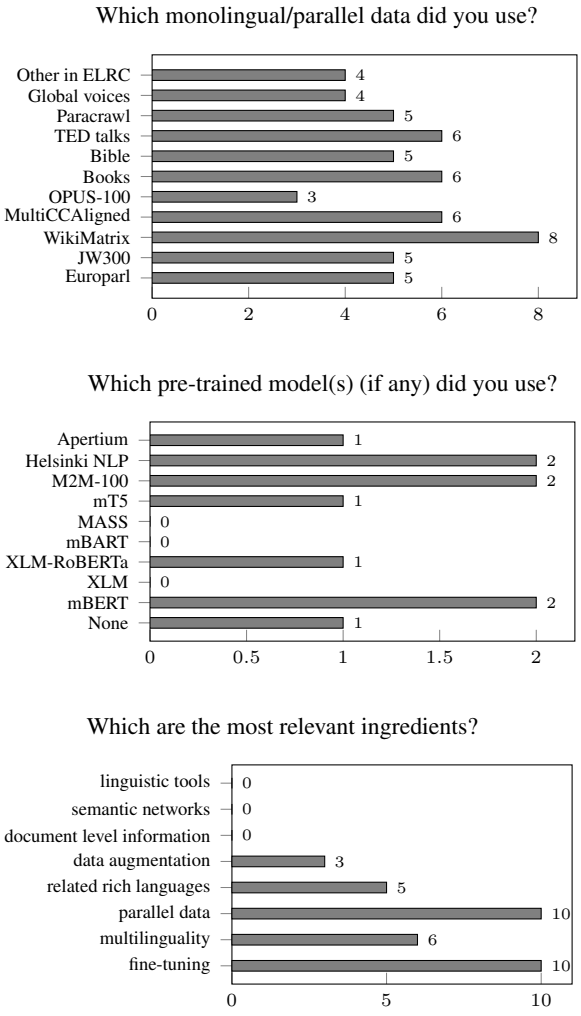

Figure 9: Resources used by the participants to train the systems submitted to the multilingual low-resource translation task (10 responses).

from language models such as mBERT (TenTrans, EdinSaar) or XLM-RoBERTa (BSC) to machine translation models such as M2M-100 (TenTrans) or Helsinki's NLP (UBCNLP). There is no clear favourite system here, and each team followed a different approach. In all cases, systems were finetuned with language specific data, either data made available for the task or backtranslations made by themselves. 50% of the submissions also used data from the related high resourced languages for training.

Figure 10 compares the architectures. As expected, neural systems dominate the number of submissions. In fact, all of them where 100% neural, without any hybridisation with any non-neural component. All participants used direct translation, either multilingual (60%) or bilingual (40%), but none of them submitted translations done

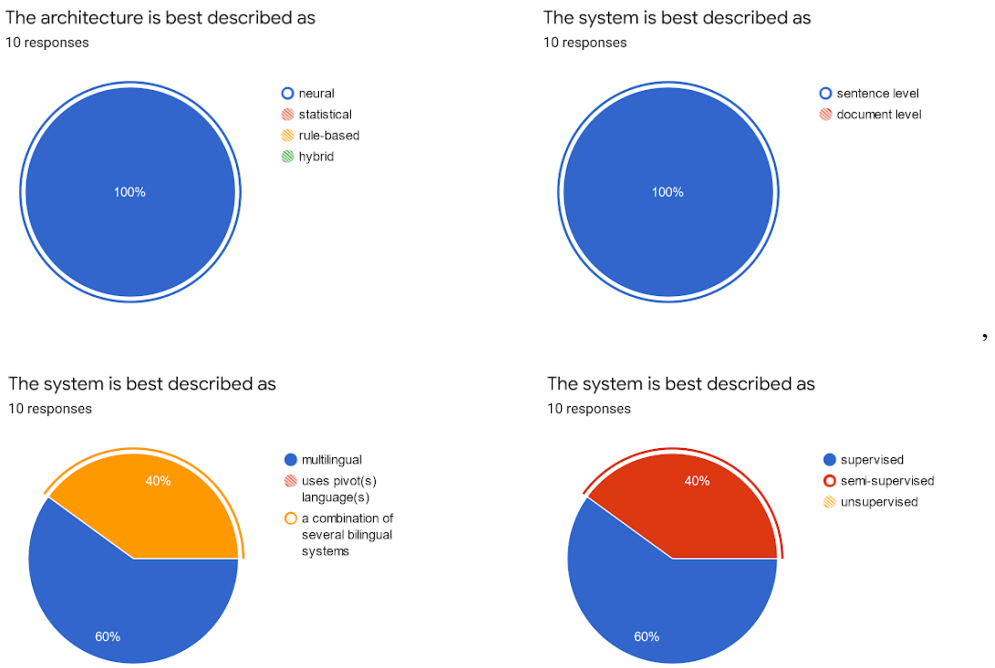

Figure 10: Main characteristics of the systems submitted to the multilingual low-resource translation task. Percentages are over the sample of 10 submissions.

through a pivot language. One team, CUNI, tried pivot through English for the Romance languages but translation quality was significantly better with direct systems. TenTrans used a pivot language for creating a synthetic corpus using backtranslation. Similarly to CUNI's, the approach worked well for ca2it and ca2ro but did not work at all for the lowest resourced language, Occitan, damaging the quality of the multilingual system as a whole. In both cases, multilingual systems trained with parallel data of the task languages plus additional corpora with the related rich languages as source gave the best performance.

Data augmentation via backtranslations and/or parallel data including high-resourced languages have been beneficial for all the systems. Two teams also got improvements by selecting data close to the domain of the validation set, but the in-domain adaptation was not decisive to win the shared task. TenTrans extracted in-domain sentences with a domain classifier trained on mBERT in Task 2 while EdinSaar used cross-entropy for the same purpose in Task 1.

In this shared task, we have evaluated systems per family, but differences among translation pairs are significant and determine the final ranking. The trends for the 2 families are similar. One of the languages has a relatively large amount of data (Swedish/Italian), the second language in terms of amount of data is the most distant one within the family (Icelandic/Romanian) and the lowest-resourced language is linguistically very similar to the richest language (Norwegian Bokmål/Occitan). Icelandic is the bottleneck for Task 1 and Romanian for Task 2 showing that in this case the distance between languages is more important than the amount of data.

It is interesting to see how the ranking depends on the language pair. The most extreme case is our baseline mT5-devFinetuned which performed the best when translating from Icelandic and the worst in the other cases (Task 1). Similarly but not so extreme, UBCNLP-Contrastive performed very well when translating from Swedish and significantly worse on the other cases. In Task 2, Romance languages, the two baselines specially M2M-100, are penalised by the bad performance on ca2oc showing that the amount of Occitan text might be too diluted in their multilingual training. M2M-100 is the best for ca2ro, and this is the only pair where the best system is not CUNI. For all the systems, ca2ro is the most difficult pair.

Finally, we want to emphasise the correlation between automatic and human evaluations among systems even though standard deviations are high and top performing systems are not significantly

different.

7 Automatic Post Editing

This section presents the results of the 7^{th} round of the WMT task on MT Automatic Post-Editing. The task consists in automatically correcting the output of a "black-box" machine translation system by learning from human-revised machine-translated output. In continuity with last year, the challenge consisted of fixing the errors present in English Wikipedia pages translated – into German and Chinese – by state-of-the-art, not domain-adapted neural MT (NMT) systems unknown to participants. Despite a number of data downloads in line with the previous rounds, this year we observed an unexpected drop in participation: two teams participated in the English-German task, submitting two runs each, while the English-Chinese task had no participants. Most likely, this setback can be ascribed to the difficulty to handle the released test data, which are characterized by NMT output of very high quality. This is reflected by much higher baseline results compared to last year (18.05 TER / 71.07 BLEU for en-de, 22.73 TER / 69.2 BLEU for en-zh), which only one run was able to improve according to both the automatic metrics used (-0.77 for the primary TER metric and +0.48 for the secondary BLEU metric). Nevertheless, the outcomes of human evaluation still reveal the ability of APE systems to improve MT output quality: significant gains over the baseline are indeed observed for all the participating systems.

7.1 The Task

MT Automatic Post-Editing (APE) is the task of automatically correcting errors in a machine-translated text. As pointed out by (Chatterjee et al., 2015), from the application point of view, the task is motivated by its possible uses to:

- Improve MT output by exploiting information unavailable to the decoder, or by performing deeper text analysis that is too expensive at the decoding stage;
- Cope with systematic errors of an MT system whose decoding process is not accessible;
- Provide professional translators with improved MT output quality to reduce (human) post-editing effort;
- Adapt the output of a general-purpose MT system to the lexicon/style requested in a specific application domain.

This 7^{th} round of the WMT APE shared task kept the same overall evaluation setting of the previous six rounds. Specifically, the participating systems had to automatically correct the output of an unknown "black box" (neural) MT system by learning from training data containing human revisions of translations produced by the same system. The selected language pairs (English-German and English-Chinese) and the data domain (Wikipedia articles) were the same of last year (Chatterjee et al., 2020), as well as the type of MT systems (generic NMT systems not adapted to the target domain).

7.2 Data, Metrics, Baseline

7.2.1 Data

In continuity with all previous rounds, participants were provided with **training** and **development** data consisting of (*source*, *target*, *human post-edit*) triplets (7,000 for the training and 1,000 for the development sets for both languages) where:

- The source (SRC) is a tokenized English sentence;
- The target (TGT) is a tokenized German/Chinese translation of the source, which was produced by a generic, black-box NMT system unknown to participants.[38]
- The human post-edit (PE) is a tokenized manually-revised version of the target, which was produced by professional translators.

For the English-German sub-task, two additional training resources were made available to participants. These are: *i)* the corpus of 4.5 million artificially-generated post-editing triplets described in (Junczys-Dowmunt and Grundkiewicz, 2016), and *ii)* the 14.5 million artificially-generated instances of the English-German section of the eSCAPE corpus (Negri et al., 2018).

[38]The NMT systems for both the languages are based on the standard Transformer architecture (Vaswani et al., 2017) and follow the implementation details described in (Ott et al., 2018). They were trained on publicly available MT datasets including Paracrawl (Bañón et al., 2020) and Europarl (Koehn, 2005), summing up to 23.7M parallel sentences for English-German and 22.6M for English-Chinese.

Test data consisted of newly-released (*source*, *target*) pairs (1,000 in total for each target language), similar in nature to the corresponding elements in the train/dev sets (i.e. same domain, same NMT architectures). The human post-edits of the target elements were left apart to measure APE systems' performance both with automatic metrics (TER, BLEU) and via manual assessments.

7.2.2 Metrics

Also this year, the participating systems were evaluated both by means of automatic metrics and manually (see Section 7.5). Automatic evaluation was carried out by computing the distance between the automatic post-edits produced by each system for the target elements of the test set, and the human corrections of the same test items. Case-sensitive TER (Snover et al., 2006) and BLEU (Papineni et al., 2002) were respectively used as primary and secondary evaluation metrics. The official systems' ranking is hence based on the average TER calculated on the test set by using the TERcom[39] software: lower average TER scores correspond to higher ranks. BLEU was computed using the multi-bleu.perl package[40] available in MOSES. Automatic evaluation results are presented in Section 7.5.1.

Manual evaluation was conducted via source-based direct human assessment (Graham et al., 2013). Complete details are provided in Section 7.5.3.

7.2.3 Baseline

Also this year, the official baseline results were the TER and BLEU scores calculated by comparing the raw MT output with human post-edits. This corresponds to the score achieved by a "*do-nothing*" APE system that leaves all the test targets unmodified. For each submitted run, the statistical significance of performance differences with respect to the baseline was calculated with the bootstrap test (Koehn, 2004).

7.3 Complexity indicators

To get an idea of the difficulty of the task, in previous rounds we have focused on three aspects of the released data, which provide us with information about the possibility of learning useful correction patterns during training and successfully applying them at test time. These are: *i)* repetition rate, *ii)* MT quality, and *iii)* TER distribution in the test set. For the sake of comparison across the seven rounds of the APE task (2015–2021), Table 44 reports, for each dataset, information about the first two aspects. The third one, instead, will be discussed by referring to Figure 11. Concerning this year's round, we only report information for the English-German sub-task, the only one for which we had participants; also the discussion henceforth will exclusively focus on this sub-task.

7.3.1 Repetition Rate

The repetition rate, measures the repetitiveness inside a text by looking at the rate of non-singleton n-gram types (n=1...4) and combining them using the geometric mean. Larger values indicate a higher text repetitiveness that may suggest a higher chance of learning from the training set correction patterns that are applicable also to the test set. However, over the years, the influence of repetition rate in the data on systems' performance was found to be marginal.[41] For the sake of completeness, we hence just observe that, being drawn from the same Wikipedia domain, this year's data feature very low repetitiveness values (i.e. 0.73, 0.78, and 0.76 respectively for the SRC, TGT and PE elements), which are comparable to those from last year (0.653, 0.823, and 0.656). In spite of this, while last year's gains over the baseline were the highest ever observed in the APE task history, this year's results are significantly lower. This suggests the higher importance of other complexity factors, on which repetition rate might have an additive effect that still has to be fully understood.

7.3.2 MT Quality

MT quality, that is the initial quality of the machine-translated (TGT) texts to be corrected, is indeed a much more reliable indicator of task difficulty. We measure it by computing, the TER (↓) and BLEU (↑) scores using the human post-edits as reference. As discussed in (Bojar et al., 2017; Chatterjee et al., 2018, 2019, 2020) higher quality of the original translations leaves to the APE systems a smaller room for improvement since they have, at the same time, less to learn during training and less to correct at test stage. On one

[39] http://www.cs.umd.edu/~snover/tercom/

[40] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

[41] The analyses carried out over the years produced mixed outcomes, with impressive final results obtained in spite of low repetition rates (Chatterjee et al., 2020) and vice-versa (Chatterjee et al., 2018, 2019).

Table 44: Basic information about the APE shared task data released since 2015: languages, domain, type of MT technology, repetition rate and initial translation quality (TER/BLEU of TGT). The last row (δ TER) indicates, for each evaluation round, the difference in TER between the baseline (i.e. the "*do-nothing*" system) and the top-ranked submission. For this year's round we report results for the only sub-task – English-German – for which we had participants.

side, training on good (or near-perfect) automatic translations can drastically reduce the number of learned correction patterns. On the other side, testing on similarly good translations can *i)* drastically reduce the number of corrections required and the applicability of the learned patterns, and *ii)* increase the chance to introduce errors, especially when post-editing near-perfect TGTs. The findings of all previous rounds of the task support this observation and, as discussed in Section 7.5, this year is no exception. For English-German, the quality of the initial translations (18.05 TER / 71.07 BLEU) is close the level of the "hardest" previous rounds (2017-2019), characterized by baseline scores in the 15.5-16.8 TER interval (and BLEU>70.0). Accordingly, this year's gains over the baseline amount to less than 1 TER/BLEU points. The strict correlation between the quality of the initial translations and the actual potential of APE is hence confirmed.

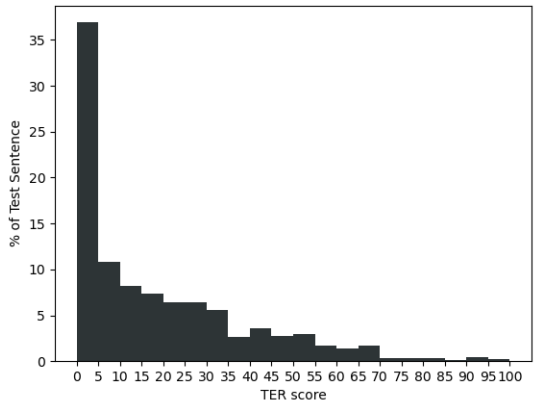

Figure 11: TER distribution in the **English-German** test set.

7.3.3 TER Distribution

A third reliable complexity indicator is the TER distribution (computed against human references) for the translations present in the test sets. Although TER distribution and MT quality can be seen as two sides of the same coin, it's worth remarking that, even at the same level of overall quality, more/less peaked distributions can result in very different testing conditions. Indeed, as shown by previous analyses, harder rounds of the tasks were typically characterized by TER distributions particularly skewed towards low values (i.e. a larger percentage of test items having a TER between 0 and 10). On one side, the higher the proportion of (near-)perfect test instances requiring few edits or no corrections at all, the higher the probability that APE systems will perform unnecessary corrections penalized by automatic evaluation metrics. On the other side, less skewed distributions can be expected to be easier to handle as they give to automatic systems a larger room for improvement (i.e. more test items requiring - at least minimal - revision). In the lack of more focused analyses on this aspect, we can hypothesize that, in ideal conditions from the APE standpoint, the peak of the distribution would be observed for "post-editable" translations containing enough errors that leave some margin for focused corrections, but not too many errors to be so unintelligible to require a whole re-translation from scratch.[42]

Also with respect to this complexity indicator, this year's test set looks particularly difficult to handle. As shown in Figure 11, more than 35%

[42]For instance, based on the empirical findings reported in (Turchi et al., 2013), TER=0.4 is the threshold that, for human post-editors, separates the "post-editable" translations from those that require complete rewriting from scratch.

ID	Participating team
PVIE	Amazon Prime Video, India (Sharma et al., 2021)
Netmarble	Netmarble AI Center, South Korea Korea (Oh et al., 2021)

Table 45: Participants in the WMT21 Automatic Post-Editing task.

of the test instances feature a TER between 0 and 5 and almost 50% of them have 0<TER<10. This distribution, which is very different from last year (where less than 7% of the test samples had 0<TER<5 and ∼55% of them had 15<TER<45), is similar to the one featured by the most challenging datasets from previous rounds.

All in all, the small gains over the baseline mentioned above also confirm the strict correlation between TER distribution and task difficulty. This goes hand in hand with the above considerations about MT quality and, together with the possible additive effect of very low repetition rate values in raising the difficulty bar, might have discouraged potential participants.

7.4 Submissions

As shown in Table 45, we received submissions from two teams, which is indeed a significant drop with respect to last year's round. Moreover, as anticipated, both teams participated only in the English-German sub-task by submitting 2 runs each.

Amazon Prime Video (*PVIE*). Amazon participated with a model leveraging a state-of-the-art MT system based on fairseq (Ott et al., 2019) and pre-trained on data from the WMT'19 News Translation task (Barrault et al., 2019). The basic model is first fine-tuned on the APE dataset, by creating (*source*, *target*) pairs where the *source* is a concatenation of the SRC and MT elements of the APE data and the *target* is the corresponding PE element. Then, to cope with the domain mismatch between the initial training data and the APE task ones, the model is fine-tuned on *i)* data drawn from WikiMatrix (Schwenk et al., 2019) (64k parallel sentences after cleaning), *ii)* additional APE samples (45k triplets) from previous rounds (2016-2018) of the shared task, and *iii)* this year's APE data. The primary submission is obtained by ensembling models built from different combinations of the available data.

Netmarble AI Center (*Netmarble*). Netmarble participated with a Transformer-based system (Vaswani et al., 2017) built using: *i)* the WMT21 News Translation data, *ii)* the additional artificial synthetic data provided to the APE task participants, and *iii)* data augmentation techniques that make use of an external MT component. These resources are processed through a curriculum training procedure aimed to step-wise learn from easier problems to more complex ones. Multi-task learning is also applied to alleviate data sparsity issues by sharing knowledge across related tasks (in this case part of speech recognition, named entity recognition, masked language modeling and keep/translate classification). All tasks are jointly trained and, to cope with imbalanced data from the selected tasks, task-specific losses – namely focal loss (Lin et al., 2017) and class-balanced loss (Cui et al., 2019) - are exploited in addition to standard cross-entropy. Moreover, dynamic weight average (Liu et al., 2019), which adapts the task weighting over time by considering the rate of change of the loss for each task, is applied to optimize the contribution of each task in the multi-task framework.

7.5 Results

7.5.1 Automatic evaluation

Participants' results are shown in Table 46. The submitted runs are ranked based on the average TER (case-sensitive) computed using human post-edits of the MT segments as reference, which is the APE task primary evaluation metric. We also report the BLEU score, computed using the same references, which represents our secondary evaluation metric.

As it can be seen from the table, the two rankings slightly differ: while the top submission (17.28 TER, 71.55 BLEU) is the same, the BLEU-based ranking presents few swaps, with the *do nothing* baseline reaching the 2nd position. One obvious observation is that these fluctuations are due to the fact that all systems substantially perform on par: except for one case (i.e. the 0.77 TER reduction achieved by the top submission), all the results' differences with respect to the baseline are indeed not statistically significant.

Quite surprisingly, we also observe that the best

		TER	BLEU
en-de	Netmarble_CURRICULUM-ENSEMBLE_CONTRASTIVE	**17.28**	71.55
	PVIE_single_CONTRASTIVE	17.74	70.54
	PVIE_ensemble_PRIMARY	17.85	70.5
	Netmarble_CURRICULUM-MTL_PRIMARY	17.97	70.53
	Baseline	18.05	71.07

Table 46: Results for the WMT21 APE English-German – average TER (↓), BLEU score (↑) Statistically significant improvements over the baseline are marked in **bold**.

submission for both participants is the contrastive one. This highlights the difficulty to select the best configuration during system development, and indirectly confirms the difficulty to handle APE data characterized by very high MT quality, TER distribution skewed towards perfect/near-perfect translations and very low repetition rate values.

7.5.2 Systems' behaviour

Modified, improved and deteriorated sentences. In light of the hard conditions posed by what seems to be the hardest APE dataset ever released, we now turn an eye toward the changes made by each system to the test instances. To this aim, Table 47 shows, for each submitted run, the number of modified, improved and deteriorated sentences, as well as the overall system's precision (i.e. the proportion of improved sentences out of the total number of modified instances for which improvement/deterioration is observed). It's worth noting that, as in the previous rounds, the number of sentences modified by each system is higher than the sum of the improved and the deteriorated ones. This difference is represented by modified sentences for which the corrections do not yield any TER variations. This grey area, for which quality improvement/degradation can not be automatically assessed, contributes to motivate the human evaluation discussed in Section 7.5.3.

As it can be seen from the table, systems' behaviour reflects the difficulty to handle this year's test set. The quite low percentage of modified sentences (50.2 on average, 46.2 for the top submission) is in line with our previous observations about TER distribution (see Section 7.3.1). With ∼50% of the test instances having 0<TER<10, all systems seem to have properly managed the small room for intervention by not exceeding the number of expected corrections. Accordingly, different from last year,[43] systems' final scores are inversely proportional to their aggressiveness.

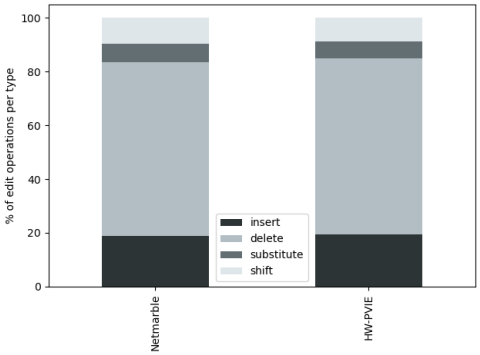

Figure 12: Distribution of edit operations (insertions, deletions, substitutions and shifts) performed by the two primary submissions to the English-German task.

Precision-wise, however, we are far from last year's values: despite lower aggressiveness, system's precision is 51.12 on average (in 2020 it was 58.0) with the best run peaking at 53.96 (vs 69.0 in 2020). This is due to significant variations in the percentage of improved (43.5 on average, 45.67 for the top submission) and deteriorated sentences (41.6 on average, 38.96 for the winning system), which are very different from last year where, on a simpler test set, the average values were respectively 58.2 and 23.6.

Edit operations. Similar to previous rounds, we analysed systems' behaviour also in terms of the distribution of edit operations (insertions, deletions, substitutions and shifts) done by each system. This fine-grained analysis of how systems corrected the test set instances is obtained by computing the TER between the original MT output and the output of each primary submission taken as reference. Similar to last year, and in line with the close TER/BLEU results obtained by the two systems, differences in their behaviour are barely visible. Both of them are characterised

[43] On the much simpler 2020 test set, featuring only ∼15.0% of instances with 0≤TER≤10, the modified sentences were 69.2% on average, with the more aggressive behaviour of the top systems peaking to more than 90.5%.

Systems	Modified	Improved	Deteriorated	Prec.
Netmarble_CURRICULUM-ENSEMBLE_CONTRASTIVE	462 (46.2%)	211 (45.67%)	180 (38.96%)	53.96
PVIE_single_CONTRASTIVE	504 (50.4%)	212 (42.06%)	212 (42.06%)	50.0
PVIE_ensemble_PRIMARY	508 (50.8%)	215 (42.32%)	218 (42.91%)	49.65
Netmarble_CURRICULUM-MTL_PRIMARY	533 (53.3%)	235 (44.09%)	227 (42.59%)	50.87
Average	50.2	43.5	41.6	51.12

Table 47: Number (raw and proportion) of test sentences modified, improved and deteriorated by each run submitted to the APE 2021 **English-German** sub-task. The "Prec." column shows systems' precision as the ratio between the number of improved sentences and the number of modified instances for which improvement/deterioration is observed (i.e. Improved + Deteriorated).

	Avg	Avg z
Netmarble_CURRICULUM-MTL_PRIMARY	79.82	0.144
Netmarble_CURRICULUM-ENSEMBLE_CONTRASTIVE	78.52	0.095
PVIE_ensemble_PRIMARY	76.85	0.02
PVIE_single_CONTRASTIVE	76.67	0.011
test.mt	69.68	-0.27

Table 48: Results for the WMT21 APE **English-German – human evaluation**. Systems ordered by DA score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$.

by a large number of deletions (65.0% on average), followed by insertions (19.2%), shifts (9.2%) and substitutions (6.5%). Although this year's test set turned out to be very different in terms of difficulty, this distribution is practically identical to last year. More thorough future investigations would be needed to find clear explanations for these observations. For the time being, to get further insights about systems' performance, we now complement our analysis by discussing the outcomes of human evaluation of the submitted runs.

7.5.3 Human evaluation

In order to complement the automatic evaluation of APE submissions, manual evaluation of the 4 submissions for English-German was conducted. In this section, we present the evaluation procedure, as well as the results obtained.

7.6 Evaluation procedure

We evaluated the overall quality of the MT and PE output using source-based direct assessment (Graham et al., 2013; Cettolo et al., 2017; Bojar et al., 2018b). We used the same instructions that are used in the News Translation track of WMT2021. Instead of using crowd-workers, we hired 2 professional translators for English-German that are native German speakers as suggested by Freitag et al. (2021a).

Human evaluation results for English-German are summarized in Table 48. Similar to last year's task (Chatterjee et al., 2020), all 4 submissions significantly improved the original MT output. Furthermore, the APE system of *Netmarble_CURRICULUM-MTL_PRIMARY* significantly outperforms all other submission and can be declared as the single winner of this years' APE task. Interestingly, the human evaluation results show no correlation with the automatic scores from Table 46 which confirms the findings from Freitag et al. (2019) that automatic evaluation is hard for post-edited systems.

7.7 Summary

We presented the results from the 7^{th} shared task on Automatic Post-Editing at WMT. This round of the challenge featured the same overall setting of last year. Specifically, the language directions were the same (English-German and English-Chinese), as well as the domain of the data (Wikipedia articles) and the neural MT systems used to produce the translations to be automatically post-edited. Also the evaluation process was carried out in continuity with the past, both with automatic metrics (TER and BLEU, respectively the primary and secondary metrics) and by means of human evaluation (via source-based direct assessment, similar to the News Translation track but involving professional translators). According to several complexity indicators (repetition rate, original MT quality and TER distribution), this year's data can be safely considered as the most difficult one ever released. On one side, this might have discouraged potential participants, which were only two for the English-German sub-task. On the other side, it contributes to explain the lower results compared to last year.

Indeed, only one submitted run was able to achieve statistically significant improvements over the *do-nothing* baseline in terms of our primary automatic metric. Nevertheless, all submissions were consistently ranked higher by human evaluators, indicating the effectiveness of APE technology even under such extremely challenging conditions.

8 Conclusion

The news translation task in 2021 covered 20 translation pairs, 14 of which had English on the source or target side and 6 were without English. Direct assessment (DA) was the main golden truth again, although the style varied across language pairs. Into-English translation was evaluated against human reference translation, preserving the order of sentences in a document but not presenting the whole document at once (SR+DC). Out-of-English and some of non-English pairs offered the full document context to the annotators and allowed them to revisit the scores assigned to individual segments (SR+FD), evaluating against the source. Four non-English pairs used a simpler evaluation without any document context (SR−DC). For English→Czech, English→German and Chinese→English, a contrastive DA scoring was also tested, presenting individual sentences in pairs of candidate translations (contr:SR-DC), aimed at a more discerning pairwise comparisons. And finally, an alternative scoring style called GENIE was additionally applied to German→English.

Document context was found to be extremely important for evaluation of high-quality MT systems. The ranking of participating systems differs considerably between SR+FD and contr:SR-DC. In particular, human reference is scored well if full document context is available throughout the annotation but tends to be surpassed by top systems when sentences are evaluated in isolation. Surprising effects were also observed when using these evaluation methods on different human translations.

The triangular machine translation task encouraged participants to use all the parallel data provided (involving direct and indirect sources) to build a better machine translation system for the particular language pair and direction (Russian-to-Chinese). The participants explored several modeling choices and data augmentation strategies that would help practitioners when building machine translation systems involving non-English language pairs.

The multilingual low-resource translation task dealt with two Indo-European language families: North Germanic and Romance. The best performing systems used multilingual supervised machine translation models enriched with backtranslated data and additional sentences from higher-resourced languages in the same family. Pivot translation via these high-resourced counter-parts and in-domain data selection was not beneficial for the final performance.

The results of the task on automatic post-editing were highly influenced by the difficulty of this year's data, which can also explain a drop in participation (two teams, only in the English-German sub-task). In light of the very high quality of the translation to be automatically corrected, the very skewed TER distribution towards near-perfect translations and the very low repetition rate in the data, it comes as no surprise that only one run was able to outperform the strong *do-nothing* baseline with statistically significant improvements. Nevertheless, human evaluation results reveal significant gains by all runs, attesting the difficulty to apply automatic evaluation procedures to APE and, on a positive note, the effectiveness of the proposed methods.

Acknowledgments

The organizers of the automatic post-editing task would like to thank Apple and Google Research for their support and sponsorship in organizing this round of the APE challenge. The organizers of the triangular machine translation task would like to thank DiDi Chuxing for providing data and research time to support this shared task.

The multilingual low-resource translation for Indo-European languages task has been funded by the European Language Resource Coordination ELRC (SMART 2019/1083) and LT-BRIDGE (H2020, 952194), and supported by the Directorate-General for Language Policy, Ministry of Culture. Government of Catalonia. We are thankful to Europeana for providing source texts in Icelandic, Norwegian and Swedish and to Antonio Toral for fruitful discussions on human evaluation.

For the news task, we are very grateful to the sponsors of our test sets. Translation of the tests sets received funding from the Eu-

ropean Union's Horizon 2020 Research and Innovation Programme under Grant Agreement Nos. 825460 and 825303 (Elitr and Bergamot, for Czech↔English) and No. 825299 (GoURMET, for Hausa↔English). The translation of the German↔English and Chinese↔English test sets was funded by Microsoft, the Russian↔English test sets were funded by Yandex, the Japanese↔English test sets by University of Tokyo and NTT and the French↔German test sets by LinguaCustodia. The Icelandic↔English task was sponsored by the Language Technology Programme for Icelandic 2019–2023. The programme, which is managed and coordinated by Almannarómur, is funded by the Icelandic Ministry of Education, Science and Culture. The Bengali↔Hindi and Xhosa↔Zulu test sets were sponsored by Facebook. The human evaluation was co-funded by Microsoft, Toloka AI, and Facebook. The effort that goes into the manual evaluation campaign each year is impressive, and we are grateful to all participating individuals and teams for their work. We are also grateful to the many workers who contributed to the human evaluation via Mechanical Turk.

The organizers of the Similar Languages Task would like to thank Pangeanic for the Spanish, Catalan, Portuguese, and Romanian data and the Directorate-General for Language Policy at the Ministry of Culture, Government of Catalonia for the Catalan translations. They further thank the AI Journal - Funding Opportunities for Promoting AI Research for supporting the French - Maninka data collection. The French - Bambara dataset is partially funded by a grant awarded by the Lacuna Fund within the scope of the program "Datasets for Languages in Sub-Saharan Africa". We also thank Andrij Rovenchak for the support on data collection. Marta R. Costa-jussà would like to acknowledge the support of the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (grant agreement No. 947657).

Ondřej Bojar would like to acknowledge the grant no. 19-26934X (NEUREM3) of the Czech Science Foundation for his time as well as co-funding manual annotation.

Support was provided by Science Foundation Ireland in the ADAPT Centre for Digital Content Technology (www.adaptcentre.ie) at Trinity College Dublin funded under the SFI Research Centres Programme (Grant 13/RC/2106) co-funded under the European Regional Development Fund.

A Differences in Human Scores

Tables 49–59 show differences in average standardized human scores for all pairs of competing systems for each language pair. The numbers in each of the tables' cells indicate the difference in average standardized human scores for the system in that column and the system in that row.

Because there were so many systems and data conditions the significance of each pairwise comparison needs to be quantified. We applied Wilcoxon rank-sum test to measure the likelihood that such differences could occur simply by chance. In the following tables $\star$ indicates statistical significance at $p < 0.05$, † indicates statistical significance at $p < 0.01$, and ‡ indicates statistical significance at $p < 0.001$, according to Wilcoxon rank-sum test.

Each table contains final rows showing the average score achieved by that system and the rank range according according to Wilcoxon rank-sum test ($p < 0.05$). Gray lines separate clusters based on non-overlapping rank ranges.

Tables 49-68 provide automatic metric scores (COMET, BLEU, chrF) for all competing systems.

B Translator Brief: Sentence-Split News Test Sets

Translator Brief

In this project we wish to translate online news articles for use in evaluation of Machine Translation (MT). The translations produced by you will be compared against the translations produced by a variety of different MT systems. They will be released to the research community to provide a benchmark, or "gold-standard" measure for translation quality. The translation therefore needs to be a high-quality rendering of the source text into the target language, as if it was news written directly in the target language. However there are some constraints imposed by the intended usage:

- All translations should be **"from scratch", without post-editing from MT**. Using post-editing would bias the evaluation, so we need to avoid it. We can detect post-editing so will reject translations that are post-edited.
- Translation should **preserve the sentence boundaries.** The source texts are provided with exactly one sentence per line, and the translations should be the same, one sentence per line.
- Translators should **avoid inserting parenthetical explanations** into the translated text and obviously **avoid losing any pieces of information** from the source text.

We will check a sample of the translations for quality, and we will check the entire set for evidence of post-editing.

The source files will be delivered as text files (sometimes known as "notepad" files), with one sentence per line. We need the translations to be returned in the same format. If you prefer to receive the text in a different format, then please let us know as we may be able to accommodate it.

C News Task System Submission Summaries

This appendix lists self-reported details on MT systems participating in the News Translation Task.

C.1 AFRL (Erdmann et al., 2021)

No brief description provided.

C.2 ALLEGRO.EU (Koszowski et al., 2021)

Allegro news translation system is based on the transformer-big architecture, it makes use of corpora filtering and backtranslation both applied to parallel and monolingual data alike.

ALLEGRO.EU	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: Unigram (as in https://github.com/google/sentencepiece) Vocabulary Size: 32000 Toolkit Used: OpenNMT-py Batch size: 8192 tokens Features of your model structure: Dropout, Tied source and target word embeddings Document-level training: No document-level: Our system processes each segment independently. Number of GPUs Used Concurrently: 1x A100 Wallclock training time: 13h Number of contrastive configurations used: 4 Other comments: fp16 was used
ALLEGRO.EU	en-is	True Parallel Training Data Size in Sentence Pairs: 3935903 parallel.en-is True Parallel Training Data Size in Words: 60185218 parallel.en 55419088 parallel.is Synthetic Parallel Training Data Size in Sentence Pairs: 2953528 synt.en-is Synthetic Parallel Training Data Size in Words: 47082741 synt.en 44441374 synt.is Monolingual Training Data in Sentences: 4044137 mono.en-is Monolingual Training Data in Words: 81559107 mono.en 72315845 mono.is Processing Tools Used: Language detection (e.g. for data cleanup) Features of your model development: Data filtering, Data selection, Iterative back-translation, Oversampling Number of Systems Ensembled/Averaged: 1

C.3 AMU (Nowakowski and Dwojak, 2021)

AMU submission for the low-resource English-Hausa language pair involved data filtering and cleaning, transfer learning from the pretrained unrelated high-resource language pair (German-English) and iterative backtranslation. The initial iteration of backtranslation was performed with a PB-SMT model, while the subsequent iterations were performed with NMT Transformer models.

C.4 BJTU-NMT (no associated paper)

No brief description provided.

C.5 BORDERLINE (Wang et al., 2021)

No brief description provided.

C.6 BUPT-RUSH **(no associated paper)**

No brief description provided.

C.7 CAPITALMARVEL **(no associated paper)**

No brief description provided.

C.8 CFILT

We train our DE-DSB system using transfer learning from DE-HSB model. Our DE-HSB model is using monolingual data of HSB and DE and train an unsupervised system first using MASS objective, then finetune it with iterative back-translation and then finetune it for translation using parallel data of DE-HSB. This system is then trained using monolingual data of DE and DSB with iterative back-translation. We use shared encoder and decoder with 6 layers in both encoder and decoder.

CFILT	common	Multilingual MT System: No.
CFILT	de-dsb	Basic System Classification: Masked sequence to sequence pretraining (Song et al 2019)+ Transfer learning Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt), Moses Tokenizer Vocabulary Size: 33678 True Parallel Training Data Size in Sentence Pairs: de-hsb 147521 de-dsb 0 Processing Tools Used: Tokenizer Other Processing Tools Used: fastBPE Toolkit Used: Moses, fastBPE, MASS Features of your model development: Iterative back-translation, Unsupervised (i.e. not involving parallel data), Language model pretraining with MASS objective Pre-trained parts of models: Masked Sequence to Sequence Pre-training (MASS) Document-level training: No document-level: Our system processes each segment independently. Other Features of Your Training: Transfer learning
CFILT	de-hsb	Basic System Classification: MASS pretraining (song et al) Token Unit Type Used: Unigram (as in https://github.com/google/sentencepiece), Moses Tokenizer Toolkit Used: Moses, fastBPE, MASS Pre-trained parts of models: Masked Sequence to Sequence Pre-training (MASS) Document-level training: No document-level: Our system processes each segment independently.
CFILT	dsb-de	Basic System Classification: MASS pretraining, Transfer learning Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt), Moses Tokenizer
CFILT	hsb-de	Basic System Classification: MASS pretraining (song et al 2019), Transfer learning Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt) Pre-trained parts of models: Masked Sequence to Sequence Pre-training (MASS)

C.9 CUNI **(Gebauer et al., 2021)**

CUNI-DOCTRANSFORMER CUNI-DocTransformer is similar to the sentence-level version called CUBBITT (Popel et al., 2020), but trained on sequences with multiple sentences of up to 3000 characters. This year, a better sentence detection and number/unit conversion post-processing have been applied.

CUNI-TRANSFORMER2018 CUNI-Transformer2018, also called CUBBITT, is exactly the same system as in WMT2018. It is the Transformer model trained according to Popel and Bojar (2018) plus a Block Back-translation (Popel et al., 2020).

CUNI	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: SubwordTextEncoder of Tensor2Tensor (as in https://github.com/tensorflow/tensor2tensor) Vocabulary Size: 32k Monolingual Training Data in Sentences: see synthetic Monolingual Training Data in Words: see synthetic Processing Tools Used: Tokenizer Toolkit Used: Tensor2Tensor Features of your model development: Data filtering, Data selection, Block-backtranslation as in Martin Popel, Marketa Tomkova, Jakub Tomek et al. (2020), Iterative back-translation, Oversampling, Averaging Features of your model structure: Dropout, Tied source and target word embeddings, Weight tying (other than word embeddings) Number of Systems Ensembled/Averaged: 8 checkpoints Wallclock training time: 8 days (without iterated backtranslation)
CUNI-DocTransformer	cs-en, en-cs	True Parallel Training Data Size in Sentence Pairs: 61000000 True Parallel Training Data Size in Words: en=617000000, cs=702000000 Synthetic Parallel Training Data Size in Sentence Pairs: en=76000000, cs=51000000 Synthetic Parallel Training Data Size in Words: en=1296000000, cs=833000000 Batch size: 1800*10 subwords Document-level training: Overlapping windows: A window is moved over segments, receiving multiple translations of each of them, with some voting or combination afterwards. Number of GPUs Used Concurrently: 10 GTX 1080 Ti Number of contrastive configurations used: 4
CUNI-Transformer2018	cs-en, en-cs	True Parallel Training Data Size in Sentence Pairs: 58000000 True Parallel Training Data Size in Words: en=642000000, cs=563000000 Synthetic Parallel Training Data Size in Sentence Pairs: en=47000000, cs=65000000 Synthetic Parallel Training Data Size in Words: en=935000000, cs=927000000 Batch size: 2900*8 subwords Document-level training: No document-level: Our system processes each segment independently. Number of GPUs Used Concurrently: 8 GTX 1080 Ti Number of contrastive configurations used: Now only one. In 2018, I trained hundreds of models on smaller data or less GPUs, as described in Training Tips for the Transformer Model (Popel and Bojar, 2018).

C.10 DIDI-NLP **(no associated paper)**

No brief description provided.

C.11 EPHEMERALER

We use Transformer big model and ensembling.

EPHEMERALER	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...)
EPHEMERALER	en-ja	Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt)
EPHEMERALER	en-zh	—

C.12 eTranslation **(Oravecz et al., 2021)**

eTranslations's En-De system is an ensemble of 4 big transformers, trained from all available parallel data (cleaned up and filtered with heuristic rules and with a language model built from the German NewsCrawl data) and with additional tagged, back-translated data generated from the monolingual news corpora. The original parallel data is upsampled to a 1:1 ratio. Each transformer model is then tuned on a 10M top subset of original parallel data scored and ranked by the monolingual news language model and then fine-tuned further on previous year's test sets. The models use a 36k SentencePiece vocabulary. The SentencePiece module as built in the Marian toolkit is used for end-to-end text processing, without the standard pre- and postprocessing steps of truecasing, or (de)tokenization.

The Fr-De system is an ensemble of 4 big transformers. Three of them are trained on original parallel (OP) data and back-translated (BT) data in a 1:1 ratio. The 4th big transformer was additionally fine-

tuned for 7 epochs on 2M of the OP data scored by a domain language model. BT data and data for the domain language model were selected using topic modelling techniques to tune the model towards the domain defined in the task.

The En-Cs system is an ensemble of two big transformer models from last year's submission, trained on the WMT 2020 data, both original parallel and back-translated. Training on the 2021 data had not finished until the submission deadline and intermediate models scored worse than the 2020 models.

ETRANSLATION	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) C.13 FACEBOOK-AI (Tran et al., 2021)

Facebook AI participated in the unconstrained track for all 14 English-centric directions. To explore the limit of scaling multilingual translation, we trained two multilingual systems: Any-to-English, and English-to-Any, and submitted them to all directions. In addition to well-known techniques such as large scale backtranslation, in-domain finetuning, ensembling, and noisy channel re-ranking, we also experimented with scaling dense transformer (up to 4.7B parameters), and sparse mixture of experts (up to 52B parameters)

FACEBOOK-AI	common	Multilingual MT System: Yes, the system was trained and used jointly for all the language pairs. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt)

C.18 HW-TSC (Wei et al., 2021)

We participate in 7 language pairs including Zh/En, De/En, Ja/En, Ha/En, Is/En, Hi/Bn, and Xh/Zu and in both directions under the constrained condition. We use the standard Transformer-Big model as the baseline and obtain the best performance via two variants with larger parameter sizes. We perform detailed pre-processing and filtering on the provided large-scale bilingual and monolingual datasets. Several commonly used strategies are used to train our models such as Back Translation, Ensemble Knowledge Distillation, etc. We also conduct experiments regarding similar language augmentation, which lead to positive results, although not used in our submission. Our submission obtains competitive results in the final evaluation.

No brief description provided.

C.20 IICT-YVERDON

IICT-Yverdon presents the systems submitted by our team from the Institute of ICT (HEIG-VD / HES-SO) to the Unsupervised MT and Very Low Resource Supervised MT task. We first study a baseline system using a Transformer architecture, using the Upper Sorbian (HSB) / German data from the 2020 edition of the task. We quantify the improvements brought by additional techniques such as back-translation of large German corpora and parent-language initialization using Czech-German data, and show that each of these is beneficial, and helps to reach scores that are comparable to more sophisticated systems from the 2020 task. We then present the application of this system to the 2021 task for low-resource supervised HSB-DE translation, in both directions. Finally, we present a contrastive system for HSB-DE in both directions, and for unsupervised German to Lower Sorbian (DSB) translation, which uses multi-task training with various training schedules to improve over the baseline. More specifically, we present a baseline system using a Transformer architecture, which uses back-translation of large German corpora and parent-language initialization using Czech-German data. We submit translations from this system for low-resource supervised HSB-DE, in both directions. We also present a contrastive system that makes use as well of back-translation and Czech-German initialization, and also multi-task training, in which we first train Czech-German systems by giving them different denoising tasks, together with translation, in increasing order of complexity. Afterwards, we first present the child systems with denoising tasks, and later introduce translation. Finally, we train different models with some changes in their training setups that we use for ensembling, in order to maximize diversity among the models.

C.21 IIE-MT **(no associated paper)**

No brief description provided.

C.22 ILLINI **(Le et al., 2021)**

Illini team presents an end-to-end NMT pipeline for the Japanese ↔ English news translation task using Transformer models and techniques such as politeness and formality tagging, back-translation, model ensembling, and n-best reranking to improve our translation systems.

No brief description provided.

C.24 LAN-BRIDGE-MT **(no associated paper)**

No brief description provided.

C.25 LISN **(Xu et al., 2021)**

LISN's systems for DE↔FR use Transformer-big model with the "priming" based on a prior retrieval step, which looks for similar sentences (in source and target) to prime a similar translation. These techniques aim to perform some unsupervised domain transfer, which is one of the challenge of this task. Our system only uses the data provided for the task (bilingual and backtranslated monolingual data) and are thus constrained submissions. They are built using the fairseq toolkit.

LISN	de-fr, fr-de	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt), Moses Tokenizer Processing Tools Used: Tokenizer, Language detection (e.g. for data cleanup) Toolkit Used: fairseq(-py) Batch size: 4096

C.27 MANIFOLD (no associated paper)
No brief description provided.

C.28 MIDEIND (Jónsson et al., 2021)
We fine-tuned a sentence-level mBART25 model on the en-is/is-en translation task using a filtered version of the ParIce parallel corpus and a back-translated corpus of roughly 30 million sentence pairs per translation direction. The back-translated corpus was generated via iterative back-translation using a Transformer-base model and a final iteration using the mBART25 translation model. Miðeind is an Icelandic startup company focusing on NLP and AI applications for the Icelandic language.

C.29 MISS (Li et al., 2021b)
No brief description provided.

C.30 MOVELIKEAJAGUAR (no associated paper)
No brief description provided.

C.31 MS-EGDC (Hendy et al., 2021)
We develop NMT for low resource language pairs Bengali to/from Hindi, English to/from Hausa and Xhosa to/from Zulu. We use constrained resources provided by the organizers. The main idea is to train a multi-lingual model with a multi-task objective using both parallel and monolingual data. This model is then used to forward and backward translate monolingual and parallel data (the latter is known as knowledge distillation). The resulting synthetic data is then used to train bilingual MT models for each language pair. The best multi-lingual and multi-task models are then combined with the best bilingual model for each pair using a novel transformer-based method.

C.39 TRANSSION

This paper describes the submission systems of TRANSSION for WMT21 . We participated in 6 translation directions including Hindi ↔ Bengali, Zulu ↔ Xhosa and English ↔ Hausa in both directions. Our systems are based on Google's Transformer model architecture, into which we integrated the most recent features from the academic research. We also employed most techniques that have been proven effective during the past WMT years, such as Multi-Lingual Training, Back Translation, In-domain Finetuning, Transfer Learning, ensemble and Reranking.

TRANSSION	common	Multilingual MT System: No. Token Unit Type Used: Custom Tokenizer, BPE (as in https://github.com/rsennrich/subword-nmt) Vocabulary Size: 50000 Processing Tools Used: Tokenizer, Shallow Dependency Parser (UD), Shallow Consituency Parser, Word Aligner (e.g. fast_align or GIZA++), Language detection (e.g. for data cleanup) Batch size: 6144 Document-level training: No document-level: Our system processes each segment independently. Number of Systems Ensembled/Averaged: 5 Number of GPUs Used Concurrently: 1
TRANSSION	bn-hi	Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...), Hybrid Monolingual Training Data in Sentences: 44,035,924 Monolingual Training Data in Words: 329,604,211,372,512,000 Toolkit Used: Custom in Tensorflow, Custom in Keras (whatever is below it) Features of your model development: Data filtering, Data selection, Back-translation with sampling, Iterative back-translation, Forward translation for synthetic data, Extra languages used beyond those listed above (e.g. some form of pivoting or multi-lingual training), Ensembling, Averaging, Right-to-left reranking, Target-to-source reranking, Fine-tuning for domain adaptation Features of your model structure: Dropout, Tied source and target word embeddings, Residual adapters Pre-trained parts of models: Pre-trained word embeddings Wallclock training time: 12hours Number of contrastive configurations used: 15
TRANSSION	xh-zu, zu-xh, bn-hi, hi-bn, ha-en, en-ha	Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Toolkit Used: Custom in Tensorflow Features of your model development: Data filtering, Data selection, Back-translation with sampling, Iterative back-translation, Forward translation for synthetic data, Oversampling, Extra languages used beyond those listed above (e.g. some form of pivoting or multi-lingual training), Ensembling, Averaging, Right-to-left reranking, Target-to-source reranking, Fine-tuning for domain adaptation Features of your model structure: Dropout, Tied source and target word embeddings Wallclock training time: 12 hours

C.40 TWB

We developed a bidirectional transformer-based system for Hausa-English news translation task. In our paper we give an overview of the data available including the 15,000 hand-crafted parallel dataset which was created internally. Our best systems achieved 17.1 and 12.3 BLEU on EN-HA and HA-EN directions on the task test sets, respectively.

TWB	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt) Vocabulary Size: 50,000 True Parallel Training Data Size in Sentence Pairs: 806345 True Parallel Training Data Size in Words: 10697192(en), 11405851(ha) Toolkit Used: OpenNMT-py Batch size: 4096 tokens Features of your model development: Data filtering, Data selection, Back-translation with sampling, Ensembling, Averaging, Fine-tuning for domain adaptation Features of your model structure: Dropout Document-level training: No document-level: Our system processes each segment independently. Number of Systems Ensembled/Averaged: Averaged up to 8 models Number of GPUs Used Concurrently: 2 Number of contrastive configurations used: 1
TWB	en-ha	Synthetic Parallel Training Data Size in Sentence Pairs: 567231 Synthetic Parallel Training Data Size in Words: 25495541(ha), 23815542(en) Monolingual Training Data in Sentences: Only the 567231 sentence dataset that were machine translated to make synthetic data Monolingual Training Data in Words: 25495541 Wallclock training time: 24 hours
TWB	ha-en	Synthetic Parallel Training Data Size in Sentence Pairs: 1,000,000 Synthetic Parallel Training Data Size in Words: 11442297(en), 13188160(ha) Monolingual Training Data in Sentences: Only the 1,000,000 sentence dataset that were machine translated to make synthetic data Monolingual Training Data in Words: 11442297 Wallclock training time: 36 to 48 hours

C.41 UEDIN (Chen et al., 2021; Pal et al., 2021)

UEdin's bn-hi and hi-bn systems use models trained on constrained parallel data to back-translate all of the provided monolingual data. New transformer models are then pre-trained on back-translated data, and fine-tuned on parallel data. A second stage of fine-tuning is done on training data that is in-domain, which is extracted in a number of ways, including n-gram matching, TF-IDF similarity, and language model scoring with the validation set. Finally, multiple models fine-tuned in different ways are ensembled to generate the final translations.

UEdin's approach to de↔en started with rule-based and dual conditional cross-entropy filtering of the provided corpora. All models were trained on a mix of parallel and back-translated data, and further trained on parallel sentences only. Specifically for en→de, we trained the model on additional title-cased sentences. The models were then fine-tuned on previous WMT test sets. We ensembled 5 models for en→de and 6 for de→en. During inference, each test instance was split at sentence-level, translated, and then concatenated.

UEDIN	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) C.44 WATERMELON

We only truly participated de-en direction using constraint settings. For other directions, we submit results from online translators (mainly from DeepL) just in order to see the performance.

WATERMELON	de-en	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) Token Unit Type Used: BPE (as in https://github.com/rsennrich/subword-nmt) Vocabulary Size: 32000 True Parallel Training Data Size in Sentence Pairs: 45M Synthetic Parallel Training Data Size in Sentence Pairs: 65M Processing Tools Used: Tokenizer, Word Aligner (e.g. fast_align or GIZA++), Language detection (e.g. for data cleanup) Other Processing Tools Used: Truecaser Toolkit Used: fairseq(-py) Features of your model development: Data filtering, Data selection, Knowledge distillation, Back-translation with greedy decoding, Back-translation with sampling, Iterative back-translation, Forward translation for synthetic data, Ensembling, Averaging, Right-to-left reranking, Target-to-source reranking, Fine-tuning for domain adaptation Features of your model structure: Dropout, Tied source and target word embeddings Number of Systems Ensembled/Averaged: 15

C.45 WECHAT-AI (Zeng et al., 2021)

We have participated in the WMT 2021 shared news translation task on English-to-Chinese, English-to-Japanese, Japanese-to-English and English-to-German. Our systems are based on the Transformer (Vaswani et al., 2017) with some effective variants, such as mixed-aan model, dual-attention model, weighted-aan model, talking-heads attention model, etc. In our experiments, we employ data selection, several synthetic data generation approaches, advanced finetuning approaches and self-bleu based model ensemble. Our constrained systems achieve 36.9, 46.9, 27.8 and 31.3 case-sensitive BLEU scores on English-to-Chinese, English-to-Japanese, Japanese-to-English and English-to-German, respectively. The BLEU scores of English-to-Chinese, English-to-Japanese and Japanese-to-English are the highest among all submissions, and that of English-to-German ranks the second. Additionally, one of our submissions on English-to-Chinese also achieves the highest chrF score 0.344.

WECHAT-AI	common	Multilingual MT System: No. Basic System Classification: Seq2seq Transformer Style [Vaswani+2017] (self-attention, ...) {namangoyal,somyaj,dkiela,tthrush,fguzman}@fb.com

Abstract

We present the results of the first task on Large-Scale Multilingual Machine Translation. The task consists on the many-to-many evaluation of a single model across a variety of source and target languages. This year, the task consisted on three different settings: (*i*) SMALL-TASK1 (Central/South-Eastern European Languages), (*ii*) the SMALL-TASK2 (South East Asian Languages), and (*iii*) FULL-TASK (all 101 x 100 language pairs). All the tasks used the FLORES-101 datasetas the evaluation benchmark. To ensure the longevity of the dataset, the test sets were not publicly released and the models were evaluated in a controlled environment on Dynabench.There were a total of 10 participating teams for the tasks, with a total of 151 intermediate model submissions and 13 final models. This year's result show a significant improvement over the known baselines with +17.8 BLEU for SMALL-TASK2, +10.6 for FULL-TASK and +3.6 for SMALL-TASK1.

1 Introduction

Despite recent advances in translation quality for a handful of languages and domains, MT systems still perform poorly on *low-resource languages*. Yet, most of the world's population speak low-resource languages and would benefit from improvements in translation quality on their native languages. As a result, the field has been shifting focus towards the evaluation of MT in low-resource situations (Thu et al., 2016; Guzmán et al., 2019; Barrault et al., 2020; ∀ et al., 2020; Ebrahimi et al., 2021; Kuwanto et al., 2021). However, these efforts have had poor coverage of low-resource languages which limits our understanding on generalization.More importantly, there has been little focus on the evaluation of true many-to-many multilingual models, which hampers the progress of the field despite all the recent excitement on this research direction (Fan et al., 2020).

The recent release of the FLORES-101 (Goyal et al., 2021) benchmark made possible to evaluate massively multilingual systems in a consistent way. The benchmark consists of 3001 sentences sampled from English Wikipedia and professionally translated in 101 languages. This poses a unique opportunity to understand translation across many languages with varied typology, resources, etc.

In this first multilingual large-scale shared task, we use the FLORES-101 benchmark to evaluate the progress on massively multilingual translation, where the evaluation is performed in a non-English-centric way. We propose 3 different tasks: two small tasks involving translation between 6 languages each (30 pairs), and a large task involving the translation across 101 languages (10K pairs). In the remainder of this paper, we describe the task setup, the participants, and the official results for the task. We also analyze the results to understand better the languages for which progress has been attained, and those where a gap in quality is still observed. Finally, we propose future directions for other tasks in the future.

2 Shared tasks

In this section, we briefly describe each of the tasks, the data, the baselines and metric used for evaluation.

2.1 Languages

The languages and statistics for the languages in the small tasks can be observed in Table 1, while the statistics for the complete set of languages in the full task can be obtained in Goyal et al. (2021).

SMALL-TASK1 - This task consisted of English and Central and South-Eastern European Languages: Croatian, Estonian, Hungarian, Macedonian, Serbian. These languages were chosen by their low availability of resources, geographical

proximity, language family diversity (Balto-Slavic, Uralic and Germanic), and different scripts.

SMALL-TASK2 This task consisted of English and South-Eastern Asian languages: Javanese, Indonesian, Malay, Filipino (Tagalog) and Tamil. These were chosen by their low-resource nature, geographical proximity and relatedness to a high-resource language (Indonesian).

FULL-TASK This task consisted of all 101 languages in the FLORES-101 benchmark, including English.

2.2 The evaluation data

The original sentences in FLORES-101 were sourced in English, from a broad group of topics that could be of general interest regardless of the native language of the reader. The sentences were sampled equally from *Wikinews*, *Wikijunior* and *WikiVoyage* by selecting an article randomly from each domain, and then selecting 3 to 5 contiguous sentences (not considering segments with very short or malformed sentences).

All source sentences were sent to a Language Service Provider (LSP) for translation into 101 languages. After that, the data was sent to different translators within the LSP for editing and quality assessment which then moved on to an automated quality control setup to ensure that the translation quality score was at least 90 on a scale of 0-100.

2.3 The baselines

Fan et al. (2021) worked on creating a Many-to-Many translation model, but it did not have the full coverage of languages in FLORES-101. Hence, we used the extended model trained in Goyal et al. (2021) which was supplemented with OPUS data and extended to 124 total languages. We trained two different sizes of models with 615M and 175M parameters.

2.4 Evaluation Metric

Automatically evaluating translation quality using BLEU is suboptimal as it relies on n-gram overlap which is heavily dependent on the particular tokenization used. The challenge of making BLEU comparable by using equivalent tokenization schemes has been partially addressed by `sacrebleu` (Post, 2018). Ideally, the automatic evaluation process should be robust, simple and can be applied to any language without the need to specify any particular tokenizer, as this will make it easier for researchers to compare against each other.

Towards this goal, we trained a SentencePiece (SPM) tokenizer (Kudo and Richardson, 2018) with 256K tokens using the CC100 monolingual data[1] (Conneau et al., 2020; Wenzek et al., 2020) from all the FLORES-101 languages. SPM is a system that learns subword units based on untokenized training data, providing a *universal* tokenizer that can operate on any language. One challenge is that the amount of monolingual data available for different languages is not the same — an effect that is extreme when considering low-resource languages. Languages with small quantities of data may not have the same level of coverage in subword units, or an insufficient quantity of sentences to represent a diverse enough set of content. To address

[1] http://data.statmt.org/cc-100/

this, we train our SPM model with temperature upsampling similar to Conneau et al. (2020), so that low-resource languages are represented. Finally, to compute BLEU, we apply SPM tokenization to the system output and the reference, and then calculate BLEU in the space of sentence-pieces. Due to the difference in tokenization, spBLEU scores are not strictly comparable across different target languages. However, to compare different models, here we use averages across the same set of target languages assuming that difference in tokenizations do not favor any specific model. In Goyal et al. (2021) this metric is described as spBLEU, but in this paper we use BLEU and spBLEU interchangeably.

3 Participants

In this section, we list each of the task participants and briefly describe each of their submissions. For reproducibility, we link to each of the model submitted, available in the Dynabench platform.

eBay (Liao et al., 2021) This submissions compares different kind of back-translation settings to improve the baseline model. They compare different generation algorithms: top-5 beam search; regular decoding without beam search; regular decoding with sampling from top-10 words. Contrary to Edunov et al. (2018), they find that top-10 decoding works best. They also consider how much English data should be used for the back translation (since it's more abundant than for the other languages). The models are trained from scratch using iterative back translation. **Models:** model 440 (SMALL-TASK1), model 441 (SMALL-TASK2), model 425 (FULL-TASK)

Huawei-TSC (Yu et al., 2021) The Huawei-TSC's team use a deep transformer encoder-decoder architecture (Sun et al., 2019), and focus their efforts on a combination of heuristics for data preprocessing, synthetic data generation, fine-tuning language-specific layers, and ensemble knowledge distillation. Compared to their baseline transformer on devtest, they get +2.8 BLEU from the synthetic data generation, +0.5 BLEU from layer fine tuning, and +0.8 BLEU from the ensemble knowledge distillation. **Models:** model 439 (SMALL-TASK2)

LMU (Lai et al., 2021) The LMU team's submission was based on a multilingual model, which were improved based on two techniques: (*i*) Tagged back-translation originating from bilingual models (+1.6 above back-translation coming from a multilingual)[2]; (*ii*) data selection w.r.t to the dev/devtest corpora following (Axelrod et al., 2011). **Models:** model 444 (SMALL-TASK1)

Maastricht University (Liu and Niehues, 2021) This submission trained a single multilingual Machine translation system by training on all 30 directions of track 2 languages. They mainly adapted the released pretrained M2M-100 model. They also did some data filtering to create a cleaner version of training corpus. Also they created synthetic pairs by taking parallel source to pivot language translation dataset and automatically translating pivot language sentences into target language, which gives 0.5 BLEU score improvement. They also tried similarity regularizer and language specific adapter weight which give 0.2 BLEU score gains overall. **Models:** model 445 (SMALL-TASK2)

Microsoft (Yang et al., 2021) The Microsoft team participated in all three tasks. The submission is based on the newly-released pretrained model DeltaLM (Ma et al., 2021a). The final submission to the shared task uses a mixture of direct and pivoted translation to improve the performance of individual directions, depending on whether the direct or pivoted models perform best. The mixture results in an improvement of +3.63 BLEU for the FULL-TASK, over their baseline architecture (24/12), but smaller improvements for the SMALL-TASK2. In addition, the models use progressive learning, which starts with a smaller architecture, noisier training data, and later changes to improve performance. The model also uses a combination of parallel, back-translated and noisy-parallel data (obtained for langs. X and Y from back-translating into X and Y) **Models:** model 483 (FULL-TASK) model 448 (SMALL-TASK1) model 457 (SMALL-TASK2)

MMTAfrica (Emezue and Dossou, 2021) This submission creates a non-English-centric multilingual translation system focusing on six African languages (Igbo, Kinyarwanda, Fon, Swahili, Xhosa, Yoruba) and English and French. The system starts from mT5 (Xue et al., 2021) and finetunes it on parallel data with additional monolingual data used

[2] Authors hypothesized that the difference in performance could be due to the implicit *self-training* coming from a multilingual model, as opposed to the diversity introduced by a bilingual model.

for online backtranslation (Sennrich et al., 2016). To cover Fon and Kinyarwanda, which are not included in FLORES-101, a small new test set was created. Compared to the small baseline models provided in Goyal et al. (2021), significant improvements were obtained.

Samsung RPH - Konvergen AI (Sutawika and Cruz, 2021) The submission of the Samsung Research Philippines/Kovergen AI's team focuses on the languages in SMALL-TASK2, in particular on data preprocessing. For large-scale multilingual models, the importance of preprocessing has risen as researchers focus on using web crawls or noisily aligned data to train translation models. In this submission, various different preprocessing techniques are applied while holding the model and architecture fixed. The authors have gains of more than 1 BLEU point from improving preprocessing. **Models:** model 443 (SMALL-TASK2)

TenTrans (Xie et al., 2021) The submission explores several techniques to improve performance. It focuses on two systems: TenTrans and FLORES101, although the second one is favored in later experimentation. The authors achieve large improvements in performance by using a the pretrained M2M124 FLORES101 model. Main benefit comes from in-domain knowledge adaptation and fine-tuning. The authors use a domain classifier based on BERT. Then they use gradual fine-tuning to gradually removing the least-likely in-domain sentence pairs at the later stages of training. They also explore other techniques, including model averaging that help to improve the performance of their system. **Models:** model 460 (SMALL-TASK2)

TelU-KU (Budiwati et al., 2021) The team from TelU-KU participated in SMALL-TASK2. Their approach explores an interesting alternative of improving NMT performance via hyper-parameter optimization (most promising for low resource languages). Although simple, this approach effectively provides improvements by +1.08 BLEU on top of the small baseline and opens up a promising direction for hyper-parameter optimization. **Models:** model 465 (SMALL-TASK2)

UMD (Bandyopadhyay et al., 2021) This system build upon the baseline M2M-124 model (Fan et al., 2020). It includes two improvements: (*i*) fine-tuning over MultiCCAligned; (*ii*) it uses ReLUs, which improve +0.8 BLEU over GELUs. In addition, the final system is the result of an extensive hyper-parameter optimization. Interestingly, the authors find that using the bible for finetuning improves performance over the baseline model despite its small size (only about 0.5 BLEU behind MultiCCAligned). **Models:** model 304 (SMALL-TASK2)

4 Evaluation Environment

All models were evaluated within the Dynaboard evaluation-as-a-service framework (Ma et al., 2021b) that is a part of the Dynabench platform (Kiela et al., 2021). This was done to ensure that the FLORES test set remains hidden while we evaluate many-to-many translation. Moreover, the testing conditions were constrained to a p2.xlarge AWS instance, which has one NVIDIA K80 GPU.

All model submissions had to be wrapped in a torchserve[3] handler and were required to follow a fixed input/output specification using Dynalab[4]. Submitting a system to the task required writing some wrapper code, and often testing different configurations (e.g. batch size), to ensure that the model was able to run under the constraints.

Given the additional work needed to run the evaluation, participants were encouraged to test the platform and to submit models early on. To avoid fine-tuning on the devtest set, we established a submission cap of one model per day.

In total, we had 81 distinct model submissions for the small task2 (South-East Asian Languages), 57 distinct submissions to the small task1 (Central / South-East European Languages), and 13 model submissions to the full task. During the evaluation period, participants were requested to mark a model as their final submission. In the end, we had 10 final submissions to the small task2, 4 to the small task 1 and 3 to the full task.

In Figure 1 we observe the total number of submissions per day. We can see that the total number of submissions per day remained low (less than 5) until August, where the number of submissions reached 16 per day.

5 Results

Present the analysis of the results for each of the tasks. Furthermore, we analyze the progress made for each task, that is, how much improvement has

[3]https://pytorch.org/serve

[4]https://github.com/facebookresearch/dynalab

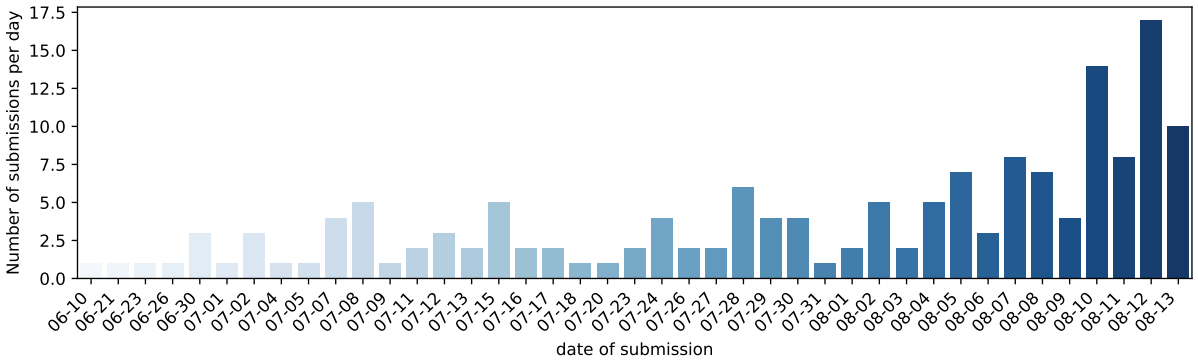

Figure 1: Submissions to the shared task through Dynabench per day. As expected, we see a rise in the number of submissions towards the end of the evaluation period.

there been between the baselines and the best models. Lastly, we analyze the difference between the models for the full task and each of the smaller tasks.

5.1 Main Results

In Table 2 we observe the final results for each of the shared tasks. From the results we observe that the DeltaLM model from the Microsoft team performs best by a large margin on the SMALL-TASK1 (+2.6 BLEU) and FULL-TASK (+9.1 BLEU), but the margin is smaller for the SMALL-TASK2 (0.6 BLEU). Below, analyze each task's results independently.

	BLEU
SMALL-TASK1 ***(CSE European langs)***	
Microsoft	37.59

Microsoft	16.63
eBay	7.55
baseline M2M-175	6.05

Table 2: Official results for the three shared tasks in the large-scale multilingual machine translation task

SMALL-TASK1 In the Central/South-East European languages we observed that the model pre-trained with DeltaLM performed best, followed by eBay's model by a margin of 2.6 BLEU. In this task we observe that the progress between the M2M-615 baseline and the next best system of 3.6 BLEU.

SMALL-TASK2 In the South-East Asian languages task, there were many more submissions than in the other tasks. We see a smaller gap between the first and second models. These two models are very different, one using a large pre-trained language model, while the other one trains from scratch and uses iterative back translation. There is also a second cluster formed by the submission of the next three models, with a gap less than 0.5 BLEU among them. In this cluster, two models are based on the pre-trained M2M model while the third one is trained from scratch. Six out of eight participants perform better than the M2M-615 baseline, while all participants perform better than the M2M-175 baseline. The gap between the best system and the M2M-615 baseline is of 17.8 BLEU.

FULL-TASK In the full task we had fewer submissions, possibly due to the difficulty and resources to train an evaluate such models. Here the gap between the best and second-best models is significant, around 9 BLEU. However, note that the gap between the best systems and the baseline is much smaller (∼10.6 BLEU), denoting how much harder is translating more languages with similarly sized models.

5.2 Analysis of the progress on quality

One interesting aspect that we can analyze is how much progress has there been since the release of M2M-100 (Fan et al., 2020), and its subsequent adaptation for FLORES101, M2M-124. Here, we break down the improvements by language pairs to understand better the changes in performance.

Note that looking at spm-BLEU numbers across target languages can be deceiving. This is due to the different spm vocabularies that are used for each target language. However, for the sake of simplicity in the following analyses we assume that: (*i*) relative improvements (deltas) are comparable across language pairs, (*ii*) averages of relative improvements from two different source languages (say English and Hausa) into the remaining 101 languages are roughly comparable, even though the average for Hausa on the source doesn't contain on the target Hausa and contains English, and the average for English on the source doesn't contain English on the target but contains Hausa.

5.2.1 Progress on SMALL-TASK1

SMALL-TASK1 is constrained and encompasses Central and South-East European Languages. In Table 3 we see that the top performing pairs (most progress) are into and out of English, while the worst performing ones include Croatian and Macedonian. The gap between the best and the worst performing pairs is of 13 BLEU, yet on average, translation across language pairs improved 11.3 BLEU.

Source	Target	ΔBLEU
Best 5		
English	Serbian	19.08
Serbian	English	15.58
Macedonian	English	14.81
Estonian	English	14.17
Hungarian	English	13.37
Worst 5		
Hungarian	Croatian	9.05
Macedonian	Croatian	8.09
Croatian	Macedonian	6.96
Serbian	Macedonian	6.49
Serbian	Croatian	6.13
Average:		11.32

Table 3: Progress in quality for the best and worst language pairs in SMALL-TASK1

In Table 4 we present the average progress for languages in the source or target, and we observe the following: there was more progress in translating from English than any other language. However, the gap between the best and worst is less than 5 BLEU. When looking at the performance when translating into each of the task languages, we see a very similar tendency: English tops the list, Croatian is at the bottom, and the gap between best performing and worst performing languages is less than 5 BLEU.

Source	ΔBLEU	Target	ΔBLEU
English	14.20	English	13.97
Macedonian	11.65	Serbian	13.58
Estonian	11.43	Hungarian	10.96
Hungarian	11.22	Estonian	10.91
Serbian	9.84	Macedonian	9.47
Croatian	9.58	Croatian	9.02

Table 4: Average progress for each of the languages in SMALL-TASK1

5.3 Progress on SMALL-TASK2

For SMALL-TASK2, there was a significant progress on languages like Tamil (tam) and Tagalog (tgl). In Table 5 we see a progress of 30+ BLEU for translation between Tamil <> English. This is encouraging, as the baseline model had issues translating from/into Tamil. It is also encouraging to see that even for the translation between Malay <> Indonesian (which was strong to begin with), we see more than 10+ BLEU improvement. On average, we see an improvement of 21.8 across all directions. It's important to note the fact that all submissions for this task were constrained, so these improvements come from better modeling and training techniques.

Another aspect to note comes from Table 6, where we see that the language with most progress is Tamil, followed by English and Tagalog. On the other hand, in this case we see more disparity on the progress between the languages with most and least progress. For instance, it is harder to translate into Javanese, which only improves 14.7 BLEU on average.

5.3.1 Progres on FULL-TASK

In Table 7 we present the deltas between the best scores in the competition for each language pair, and the baseline. We observe that there are significant improvements for certain languages, particularly: Welsh (cym), Irish (gle), Maltese (mlt) and their pairings with English. These are languages for which the original M2M model was doing poorly,

Source	Target	ΔBLEU
Best 5		
English	Tamil	32.63
English	Tagalog	31.04
Tagalog	English	30.16
Tamil	English	30.00
Indonesian	Tamil	28.45
Worst 5		
Tagalog	Javanese	14.67
Malay	Javanese	12.40
Indonesian	Malay	11.59
Indonesian	Javanese	11.05
Malay	Indonesian	10.45
Average:		21.75

Table 5: Progress in quality for the best and worst language pairs in SMALL-TASK2

Source	ΔBLEU	Target	ΔBLEU
Tamil	24.35	Tamil	27.29
English	24.30	Tagalog	25.29
Tagalog	23.19	English	24.68
Javanese	20.68	Malay	19.72
Indonesian	19.13	Indonesian	18.81
Malay	18.88	Malay	14.74

Table 6: Average progress for each of the languages in SMALL-TASK2

yet the DeltaLM model is doing much better [5]. In fact, as seen in Fig. 2, these language pairs are an exception, and most language pairs fall around the 11 BLEU improvement range. The average improvement across language pairs is 10.6 BLEU. However, there are several language pairs for which there was no progress at all. In Fig. 2, close to 10% (∼1K pairs) have less than 5 BLEU improvement.

[5]Since this is an unconstrained submission, it is hard to know what data went into the models. However, we hypothesize that the improvement is likely due to the amount of training data available for DeltaLM. As pointed out in Yang et al. (2021) their model contains about 300K sentences for Maltese (mt), 1.5M sentences for Irish (ga), and 3M sentences for Welsh (cy)

Source	Target	ΔBLEU
Best 5		
English	Welsh	46.41
Irish	English	43.55
English	Irish	43.10
Maltese	Welsh	42.88
Irish	Maltese	41.83
Average:		10.60

Table 7: Progress in quality for the best and worst language pairs in FULL-TASK. Note that we exclude the worst performing pairs, which made no progress at all.

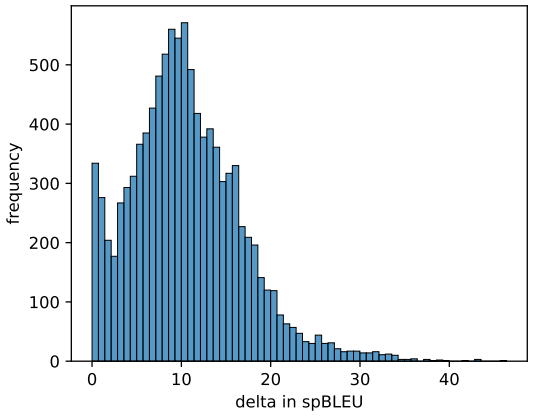

Figure 2: Distribution of improvements in BLEU for different language pairs in the full task

To facilitate the analysis of the progress across languages, in Fig. 3 we present the improvements by language groupings. We see big improvements coming from Other Indo-European (influenced by Irish, Welsh), Dravidian (influenced by Tamil, Telugu), Austronesian (influenced by Tagalog). However we note that there is very little progress for African Languages as represented by the Bantu and Nilotic subgroups. Another interesting finding is that progress trends to be lower when translating into harder languages.

In summary, there is large progress for a few languages, but sadly, there is little progress made for very low-resource languages, particularly those unrelated to other major languages.

5.4 Moderately Multilingual vs. Massively Multilingual

A natural question that arises is: what is the gap that remains between what we're calling moderately multilingual models (MoM), i.e models handle just a few languages and a couple dozen pairs; vs. the massively multilingual models (M2M) that handle hundreds of languages and tens of thousand pairs?

To analyze this aspect, we compare the best models for the full task, and each of the small tasks.

5.4.1 SMALL-TASK1 vs. FULL-TASK

In Figure 4 we present the scores of the best system for task1 (MoM) vs. the best system for the full task (M2M). Here we observe that there is a consistent gap of about 4.7 BLEU between the MoM and the M2M models when averaging across source languages. We can observe on the distribution of deltas of performance that drops in performance are similarly distributed across languages. This

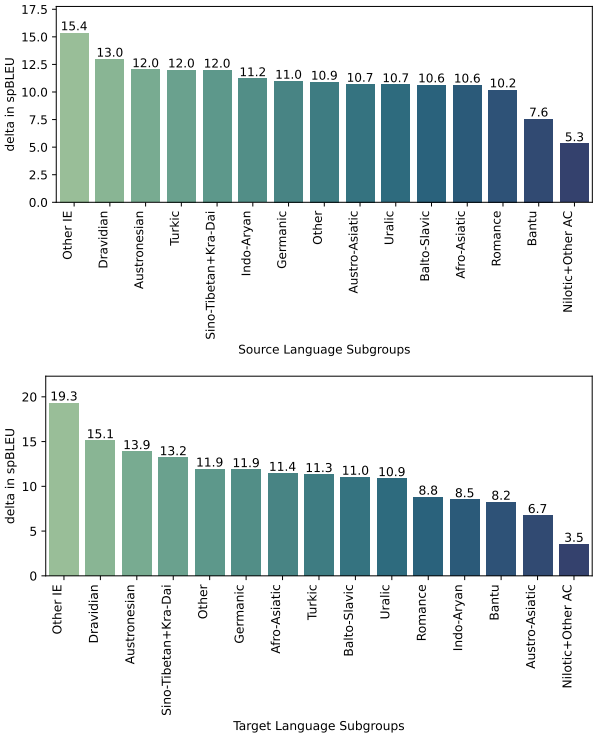

Figure 3: Average BLEU improvements per languages in the source and target language families

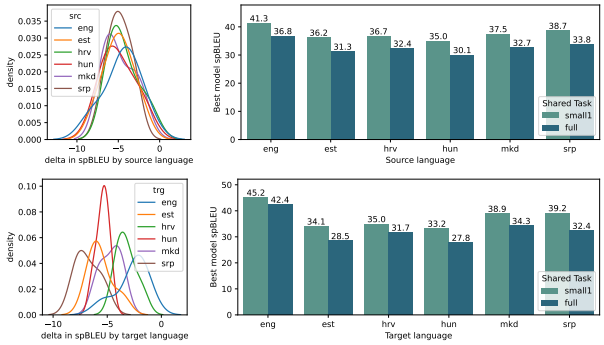

Figure 4: Comparison of average performances of the best systems in the FULL-TASK and SMALL-TASK1 by source and target languages

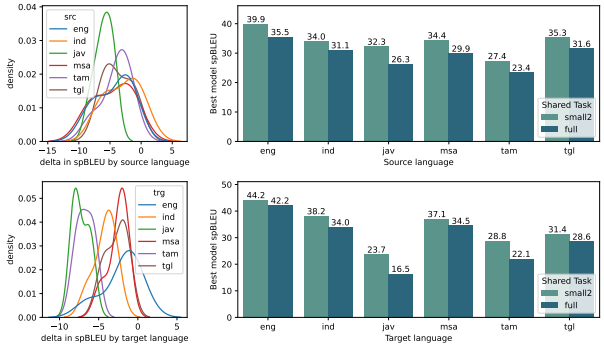

Figure 5: Comparison of average performances of the best systems in the FULL-TASK and SMALL-TASK2 by source and target languages

suggests that the *curse of multilinguality* (Conneau et al., 2020), i.e. the loss in performance by adding more languages into to a model with fixed capacity, affects equally the encoding of different languages to a rate of about 0.05 BLEU per language added to the model. This is encouraging, as it suggests that encoding is robust to the addition of new languages.

On the other hand, when we look at the target side the picture is quite different. Particularly, we observe more variation in performance, ranging from -2.7 BLEU for English to -6.8 BLEU for Serbian. We hypothesize that these differences could be due to a combination of factors: (*i*) amount of supervision (which would explain why English performance doesn't drop as much), (*ii*) additional supervision from similar languages, (*iii*) morphological richness (which would explain why Hungarian and Estonian are more affected), and (*iv*) script usage (which would explain why Serbian is more affected than Croatian). However, proving these hypotheses is beyond the scope of this paper.

5.4.2 SMALL-TASK2 vs. FULL-TASK

In Figure 5 we present the scores of the best system for task2 (MoM) vs. the best system for the full task (M2M). Here we see again that the model with more parameters per language is still ahead by about 4.26 BLEU. We also observe more variability in the distribution of drops in performance, notably, Javanese, the lowest resource language, being the most different to the others.

On the target side, we observe that English is ahead of the curve, showing the least regression. On the other hand Javanese and Tamil further reinforce our observations that additional supervision and morphology play an important role in decoding performance.

5.5 African Languages

While not officially a track on this year's competition, Emezue and Dossou (2021) focused on the task of multilingual machine translation for African languages that are in FLORES-101. They introduced MMTAfrica, the first many-to-many multilingual translation system for six African languages: Fon (fon), Igbo (ibo), Kinyarwanda (kin), Swahili/Kiswahili (swa), Xhosa (xho), and Yoruba (yor) and two non-African languages: English (eng) and French (fra). For multilingual translation concerning African languages, a novel backtranslation

and reconstruction objective, BT&REC, was introduced which is inspired by the random online back translation and T5 modelling framework respectively, to effectively leverage monolingual data. Additionally, MMTAfrica improves over the FLORES 101 benchmarks (BLEU gains ranging from +0.58 in Swahili to French to +19.46 in French to Xhosa).

6 Conclusion and Future Work

In this paper we presented the first iteration of the large-scale multilingual translation task. This task attracted several teams from across the globe and many models submissions. We kept the test set blind and used a platform to evaluate model submissions under a controlled environment. In this task, we observed significant progress in translation quality across tasks, but particularly in the *small* tasks. We observed that pre-trained language models and large amounts of back-translation (either at one go, or in iterative fashion) were important tools used by many participants.

We observed that models that have to translate fewer languages trend to do better on average, and that lower resources and morphology complicate translation, particularly for decoding. We also observed that languages in certain groups, like the African languages in the Bantu and Nilotic families, experience little to no improvement.

In the future, we want to organize shared tasks with languages for which little or no progress was achieved this time around. Additionally, we want to open up the FLORES evaluation setup to other organizers interested groups of languages within the FLORES-101 set.

Acknowledgements

We would like to thank Geeta Chouhan and Hamid Shojanazeri for their support setting up the GPU inference and batch decoding with torchserve. We would like to thank Carlos Escapa for his support in getting compute credits for this competition, and Microsoft Azure, Google Cloud and Amazon AWS for donating credits for participants.

GTCOM Neural Machine Translation Systems for WMT21

Chao Bei, Hao Zong, Qinming Liu and Conghu Yuan
Global Tone Communication Technology Co., Ltd.
{beichao, zonghao, liuqingmin and yuanconghu}@gtcom.com.cn

Abstract

This paper describes the Global Tone Communication Co., Ltd.'s submission of the WMT21 shared news translation task. We participate in six directions: English to/from Hausa, Hindi to/from Bengali and Zulu to/from Xhosa. Our submitted systems are unconstrained and focus on multilingual translation model, back-translation and forward-translation. We also apply rules and language model to filter monolingual, parallel sentences and synthetic sentences.

1 Introduction

We applied fairseq(Ott et al., 2019) as our develop tool and use transformer(Vaswani et al., 2017) as the main architecture. The primary ranking index for submitted systems is BLEU (Papineni et al., 2002), therefore we apply BLEU as the evaluation matrix for our translation system.

For data preprocessing, punctuation normalization, tokenization and BPE(byte pair encoding) (Sennrich et al., 2015) are applied for all language. Further, we apply truecase model for English, Hausa, Zulu and Xhosa according to the character of each language. Regarding to the tokenization, we use polyglot [1] as the tokenizer for Hausa, Hindi, Bengali, Zulu and Xhosa. Besides, knowledge based rules and language model are also involved to clean parallel data, monolingual data and synthetic data.

Due to the quantity limitation of parallel corpus in low-resource language pair, we use forward-translation with monolingual data to generate more synthetic data instead of knowledge distillation (Kim and Rush, 2016). Here forward-translation refers to translate the source language sentences to the target language, and then clean this synthetic data with the above described method. In order to enrich the low-resource language corpus, we add English to X corpus to construct a multilingual translation model. This multilingual model is expected to obtain the inner deep information among all languages and give us a better translation.

This paper is arranged as follows. We firstly describe the task and show the data information, then introduce our multilingual translation model. After that, we describe the techniques on low-resource condition and show the conducted experiments in detail of all directions, including data preprocessing, model architecture, back-translation, forward-translation and multilingual translation model. At last, we analyze the results of experiments and draw the conclusion.

2 Task Description

The task focuses on bilingual text translation in news domain and the provided data is show in Table 1, including parallel data and monolingual data. For the directions between Hindi and Bengali, the parallel data is mainly from CC-Aligned, as well as the directions between Zulu and Xhosa. For the directions between English and Hausa, the parallel data is mainly from English-Hausa Opus corpus, Khamenei corpus, ParaCrawl v8. The monolingual data we used includes: News Crawl in English, Hindi and Bengali; extended Common Crawl in Hausa, Xhosa and Zulu; Common Crawl in Hausa. All language directions we participated are new tasks in this year, therefore we only use the provided newsdev2021 as our development set for the directions of English to/from Hausa, flores-dev for the directions of Hindi to/from Bengali and Zulu to/from Xhosa.

3 Multilingual Translation Model

In low-resource condition, data augmentation and pretrained model are the most effective approaches to improve translation quality. According Google's Multilingual Neural Machine Translation System(Johnson et al., 2017), we use other language

Table 1: Task Description

pairs parallel data along with the provided bilingual data to training a multilingual translation model, the low-resource language pair is expected to get the benefits from other language pair's parallel data, especially in similar language. For the multilingual model preprocessing, we add a language tag at beginning of each source sentence, and use joint BPE for all languages in one multilingual translation model.

4 Experiment

4.1 Model architecture

- **Baseline** Table 2 shows the baseline model architecture.

- **Big transformer** We use fairseq to train our model with transformer big architecture. The model configuration and training parameters is almost same as GTCOM2020(Bei et al., 2020).

4.2 Training Step

This section introduces all the experiments we set step by step and Figure1 shows the full improvement status.

- **Date Filtering** The methods of data filtering are mainly the same as GTCOM2020, including knowledge based rules, language model and repeat cleaning.

configuration	value
architecture	transformer
word embedding	512
Encoder depth	5
Decoder depth	5
transformer heads	2
size of FFN	2048
attention dropout	0.2
dropout	0.4
relu dropout	0.2

Table 2: The FLoRes model architecture.

- **Baseline** We use FLoRes (Guzmán et al., 2019) architecture to construct our baseline in low-resource condition.

- **Multilingual translation model.** Due to the language distinction, We construct two multilingual translation models with the corpus organized as: 1. English-Bengali parallel data, English-Hindi parallel data and Bengali-Hindi parallel data; 2. English-Hausa parallel data, English-Xhosa parallel data, English-Zulu parallel data and Xhosa-Zulu parallel data. Each multilingual translation model has a shared vocabulary.

- **Back-translation** We use multilingual translation model to translate the target language sentence to source language, and clean synthetic data with language model. Here, we translate all language pairs we have added into this multilingual translation model. Then we combine the cleaned back-translation data and provided parallel sentences to train a new multilingual translation model.

- **Forward-translation** Source language sentences are translated to target language, and then cleaned by language model. Again we add this forward translation data with cleaned back-translation data and provided parallel sentences to train another multilingual translation model.

- **Joint training** Repeat generating back-translation data and forward-translation data by currently trained best multilingual model until there is no improvement.

- **Transformer big** Using bilingual parallel data and synthetic data generated by cur-

rently best multilingual model to train a bilingual model with transformer big architecture and repeat back-translation step and forward-translation step, until there is no improvement.

- **Ensemble Decoding** We use GMSE Algorithm (Deng et al., 2018) to select models to obtain the best performance.

5 Result and analysis

Table 3, Table 4 and Table 5 show the BLEU score we evaluated on development set for Hind to/from Bengali, English to/from Hausa and Xhosa to Zulu

model	xh2zu	zu2xh
baseline	10.58	10.60
multilingual translation model	11.66	10.73
+ back-translation	12.48	10.76
+ forward-translation	12.70	10.86
+ joint training	12.74	10.92
big transformer	12.77	10.95
+ Ensemble Decoding	12.95	11.02

Table 5: The BLEU score between Xhosa and Zulu after truecase.

respectively. Back-translation is still the most effective method with improvement ranging from 0.03 to 6.07 BLEU score in low-resource condition. And multilingual translation model gets the improvement ranging from 0.02 to 1.16 BLEU score. Forward translation enrich the information in low-resource condition, with improvement of 0.1 to 0.65 BLEU score. Further, ensemble decoding increase the performance with 0.07 to 2.67 BLEU score.

6 Summary

This work mainly focus data augmentation and pay less attention on modeling. Because optimizing translation by data augmentation is the most elegant way for a commercial system. It can avoid many unexpected translation result generated by a newly proposed model which may give our customers worse translating experience.

This paper describes GTCOM's neural machine translation systems for the WMT21 shared news translation task. For all translation directions, we build systems mainly base on multilingual translation model and enrich information by back-

translation and forward-translation. The effect of increasing information is also dependent on data filtering.

Abstract

This paper presents the University of Edinburgh's constrained submissions of English-German and English-Hausa systems to the WMT 2021 shared task on news translation. We build En-De systems in three stages: corpus filtering, back-translation, and fine-tuning. For En-Ha we use an iterative back-translation approach on top of pre-trained En-De models and investigate vocabulary embedding mapping.

1 Introduction

We describe the University of Edinburgh's participation in English↔German (En↔De) and English↔Hausa (En↔Ha) at the WMT 2021 news translation task. We apply distinct sets of techniques to the two language pairs separately, as the two pairs are very different in terms of language proximity and the availability of resources. We follow the constrained condition where we only use the provided data available to all participants.

For En↔De we first employ rule-based and dual conditional cross-entropy filtering to clean the datasets. Then we add to training back-translations generated in a few ways: tagged, greedy, beam search and sampling. We fine-tune our models on past years' test sets, and finally tune a few configurations: length normalization, test sentence splitting, and German post-processing.

For En↔Ha we adopt iterative back-translation, where at each iteration we initialize the model parameters from an En-De model in the corresponding direction (En→De for En→Ha and De→En for Ha→En). These En-De models are trained in the same way as those submitted to the En-De task, except that their vocabulary includes subwords from the Hausa language. Besides, we experiment with vocabulary mapping at the embedding level.

Some configurations are kept consistent across language pairs and systems. Sentences are tokenized using SentencePiece (Kudo and Richardson, 2018) with a 32K shared vocabulary, except that we added a few extra tokens for tagged back-translation. All models are trained following Marian's Transformer-Big task preset (Vaswani et al., 2017; Junczys-Dowmunt et al., 2018) unless otherwise specified: 6 encoder and decoder layers, 16 heads, 1024 hidden embedding size, tied embeddings (Press and Wolf, 2017), etc.[1]

Section 2 and Section 3 describe the detailed model building process for En↔De and En↔Ha respectively. While awaiting human evaluation results, we summarize our automatic metric scores on the WMT 2021 test sets computed by the task organizers in Table 1.

Direction	BLEU	ChrF
En→De	29.90	0.59
De→En	51.78	0.66
En→Ha	14.81	0.45
Ha→En	14.89	0.42

Table 1: Automatic metric scores on WMT21 test computed by the task organizers.

2 English↔German

2.1 Data and cleaning

English-German is considered to be a high-resource language pair, with over 90 million parallel and hundreds of millions monolingual sentences provided in the shared task. Following our last year's submission (Germann, 2020), we divide the data into three categories, and we use all the parallel data, as well as monolingual news from 2018 to 2020:

- High-quality parallel: News Commentary, Europarl and Rapid.

[1] https://github.com/marian-nmt/marian/blob/master/src/common/aliases.cpp

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 104–109
November 10–11, 2021.

- Crawled parallel: ParaCrawl, WikiMatrix, CommonCrawl, and WikiTitles.
- Monolingual news: News Crawl

The majority of parallel data are mined and aligned sentences from the web (Bañón et al., 2020; Schwenk et al., 2021), so our first step is corpus filtering to remove noisy sentences which could harm neural machine translation (Khayrallah and Koehn, 2018). We run rule-based filtering using FastText language identification (Joulin et al., 2016), and various handcrafted features such as sentence length, character ratio and length ratio. Similar rules are applied on the monolingual data, omitting the features designed for parallel data. More details can be found in our cleaning script which is made public.[2]

We then train seed Transformer-Base models on the filtered high-quality data, as well as the crawled data separately, to (self-)score translation cross-entropy of the crawled parallel sentences. This enables us to rank and filter out sentences by their dual conditional cross-entropy (Junczys-Dowmunt, 2018). The method prefers the sentences in a pair to have low and similar translation cross-entropy given each other. After empirical trials, we find it is always better to score using models trained on the high-quality data, and we choose to keep the best 75% of the crawled data. The filtering efforts are reported in Table 2. Next, we train Transformer-Big models on the combination of filtered high-quality and crawled data. These models serve as baselines and are used for back-translation later.

Amount of crawled	Scoring model	De→En	En→De
top 25%	high-qual	41.47	-
	crawled	39.35	-
top 50%	high-qual	41.64	**43.68**
	crawled	41.51	-
top 75%	high-qual	**42.15**	**43.40**
	crawled	41.90	-
all	-	**42.02**	42.70

Table 2: BLEU of filtering experiments on WMT19 test used as dev.

2.2 Back-translation

Since its introduction, back-translation (Sennrich et al., 2016) has been widely used to boost NMT. We use ensembles of our best seed and baseline models trained on the filtered data, to generate back-translations from the monolingual news data from 2018 to 2020, hoping that the domains are similar to that of the test. For En→De we mix back-translations generated using greedy search, beam search, and sampling; for De→En, we adopt tagged back-translation (Caswell et al., 2019).

After merging the original and back-translated data, for each direction we train 4 standard Transformer-Big models, as well as a model with 8 encoder layers and 4 decoder layers. Specifically for De→En, we have an extra pre-layer normalized variant.

As we observed last year, validation BLEU does not improve after we add back-translated data to training. As a result, after the models converge, we continue training them on filtered parallel data only. The models' validation BLEU scores[3] on WMT19 test are displayed in Table 3.

Configuration	De→En	En→De
Baseline	42.2	43.4
+ BT	41.8	43.0
+ cont. training	**42.5**	**43.6**

Table 3: Average BLEU scores of BT experiments on WMT19 test used as dev.

2.3 Fine-tuning and submission

We grid search on length normalization during decoding, and find 1.2 to be ideal for En→De and 0.8 for De→En. Particularly for En→De, we have two more steps to make German text read more natural: 1) continued training on 25% title-cased parallel data to improve headline translation and 2) post-processing on German quotes to make them consistent.

Previous submissions show that fine-tuning on past years' test data helps model performance (Schamper et al., 2018; Koehn et al., 2018). In the early years of WMT news translation tasks, the test sentence pairs can originate in either source or target language, and are translated and merged into one set. However, the current evaluation is on translating sentences originally in the source language only. Therefore, we experiment with fine-tuning on the combined sets, as well as on sentence pairs originated from the source language. We fine-tune

[2] https://github.com/browsermt/students/tree/master/train-student/clean

[3] sacreBLEU (Post, 2018) with signature BLEU+case.mixed+numrefs.1+smooth.exp+tok.13a+version.1.5.1

all our models on WMT 2008-2019 test sets and validate on WMT 2020 test set.

While the training data contain mainly one sentence per line, the test set can have multiple sentences in the same segment. As a result, we split each test instance into single sentences, translate, and rejoin them. We experiment with fine-tuning and sentence splitting on the 8-encoder-4-decoder variant for both languages. Table 4 indicates that the model achieves the best BLEU (and a significant improvement over BT baseline) if we fine-tune it on previous test sentences originating in the source language only, and split long sentences in both validation and test sets.

FT on	Dev split	Test split	De→En	En→De
BT baseline			30.8	31.9
none		✓	41.7	35.2
all			34.7	-
all		✓	41.1	-
all	✓		31.2	-
all	✓	✓	41.9	36.7
orig.	✓	✓	**42.5**	**36.9**

Table 4: BLEU of fine-tuning and sentence-splitting experiments on WMT20 test

For each translation direction, we apply the best configuration to each model and ensemble them by averaging their predictions post-softmax. Overall, we have a 5-model ensemble for En→De, and a 6-model ensemble De→En.

3 English↔Hausa

3.1 Data

The main sources of English-Hausa parallel data are OPUS (Tiedemann, 2012) and ParaCrawl. We also include data from WikiTitles[4] and the Khamenei[5] corpora, which are however much smaller. In total, we gather 759,061 parallel sentences. For back-translation, we use 9.5 million monolingual Hausa sentences from Common Crawl, Extended Common Crawl, and News Crawl provided by the task organizers. We randomly select 50 million English monolingual sentences from the News Crawl collections from 2018, 2019, and 2020.

[4] http://data.statmt.org/wikititles/v3/

[5] http://data.statmt.org/wmt21/translation-task/ha-en/khamenei.v1.ha-en.tsv

For training, we use a mix of back-translated monolingual data and parallel data. Since the dataset sizes differ substantially, we over-sample the parallel data to achieve a balanced mix: 10× for English→Hausa, and 50× for Hausa→English. Similar to our En-De models, we used tagged back-translation to distinguish synthetic and authentic sentences in the data.

3.2 Iterative back-translation and fine-tuning

In our experiments, we combine a transfer learning approach (Zoph et al., 2016; Kocmi and Bojar, 2018) with 3 iterations of back-translation (Hoang et al., 2018; Edunov et al., 2018). In each iteration, we initialize the En→Ha model with a pre-trained En→De Transformer-Big model (and vice versa for the other direction). Then, we fine-tune the model on the English-Hausa data created by the model from the previous back-translation iteration (the initial model for the first iteration is fine-tuned on parallel data only).

We notice that the model generates a large number of empty translations. We suppress this issue by taking the second-best candidate translation from the n-best list if the first one is empty. Another problem is heavy overfitting in the models. In many translations, the sentences begin with the prefix "Never miss an important update!", followed by the actual translation. Unfortunately, we only noticed this issue after the submission.

3.3 Vocabulary embedding mapping

An additional approach we investigate is mapping the Hausa vocabulary to the German embeddings of the En→De model, when initializing the En→Ha model. We train the models with a 32K SentencePiece vocabulary obtained from datasets in all three languages. Using the frequency-based metric introduced by (Wang et al., 2020) we assign each SentencePiece token to an English, German, Hausa or joint vocabulary. This results in 9192 German tokens, 6485 Hausa tokens and a joint vocabulary of approximately 11k. Having established a separate Hausa and German vocabulary it is then possible to map between the embeddings of the two.

In order to map the vocabularies, we independently train BWEs (bilingual word embeddings) using an implementation of Bivec (Luong et al., 2015) combined with FastText (Bojanowski et al., 2017). This implementation uses a joint learning objective as described by Liu et al. (2020) utilising alignments combined with sub-word information.

In lieu of a parallel De-Ha dataset an En→De NMT model is used to translate the English side of the En-Ha dataset. We constrain SentencePiece encoding using the previously extracted vocabularies for example the Huasa data is encoded using only the Hausa tokens and the joint tokens. Once both sides are encoded FastAlign is used to extract automatic alignments and the BWEs are trained.

We first map the Hausa tokens to their nearest neighbour using the Cross-Domain Similarity Local Scaling (Lample et al., 2018) distance metric in the order of Hausa tokens' frequency, and only permit a German token to be mapped to exactly one Hausa token. For tokens that do not have a one-to-one mapping, we adapt Gu et al. (2018)'s approach, whereby the embedding of a Hausa token is initialized to the weighted sum of all German embeddings. The weights are given by a probability distribution derived from the distance of the Hausa token to each German token in the bilingual embedding space. It is worth noting that we only map between the tokens in the Hausa and German vocabularies not any of the joint tokens. Finally, we initialize the embedding table using the new embeddings and remove all tokens identified as German. After initialization, we fine-tune the model using the parallel and back-translated data as described previously.

Our experiments show that although initializing the embedding table using a mapping-based approach results in faster model convergence, it does not improve the final BLEU score compared to just fine-tuning from the En-De models. This was observed for both the parallel data and the combined parallel and back-translated data. The outputs of the mapping approach to the baseline for the Ha-En system are qualitatively very similar and indicates that while the embedding mapping increases convergence there is no knowledge transfer from the German embeddings.

4 Conclusion

We describe our English-German and English-Hausa submissions to the news translation task at WMT 2021. For the En↔De task, fine-tuning and splitting test instances significantly boosts BLEU while back-translation alone does not help. In the En↔Ha task, we experiment with interesting low resource NMT techniques, but unfortunately, our submission contains translations from overfitted models.

Tune In: The AFRL WMT21 News-Translation Systems

Grant Erdmann, Jeremy Gwinnup, Timothy Anderson
Air Force Research Laboratory
{grant.erdmann, jeremy.gwinnup.1, timothy.anderson.20}@us.af.mil

Abstract

This paper describes the Air Force Research Laboratory (AFRL) machine translation systems and the improvements that were developed during the WMT21 evaluation campaign. This year, we explore various methods of adapting our baseline models from WMT20 and again measure improvements in performance on the Russian–English language pair.

1 Introduction

As part of the 2021 Conference on Machine Translation (wmt, 2021) news-translation shared task, the AFRL human language technology team participated in the Russian–English portion of the competition. We experiment with OpenNMT-tf [1] (Klein et al., 2018) and Marian [2] (Junczys-Dowmunt et al., 2018) transformer (Vaswani et al., 2017) models trained as part of our WMT20 (Gwinnup and Anderson, 2020) efforts and apply varying continued-training and fine-tuning approaches (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016), including a new method to select a fine-tuning set from a separate, larger corpus not used in training.

We submit an OpenNMT-based transformer system fine-tuned on newstest test sets from 2014-2017 as our primary entry, and a Marian-based transformer system fine-tuned on newstest test sets from 2014-2018 as a contrast.

2 Data and Preprocessing

Since most of our efforts focus on fine-tuning existing models this year, we reuse the training corpus from our WMT20 systems which includes the following parallel corpora: Commoncrawl (Smith et al., 2013), Yandex[3], UN v1.0 (Ziemski et al., 2016), Paracrawl[4](Esplà et al., 2019), Wikimatrix (Schwenk et al., 2019), and backtranslated data from our WMT17 system (Gwinnup et al., 2017) as well as Edinburgh's WMT17 system (Sennrich et al., 2017) yielding a raw corpus of over 76.3 million lines.

The new Russian–English version 8 Paracrawl corpus is reserved for tuning set selection as described in Section 2.3.

2.1 Data Preparation

We re-use the fastText (Joulin et al., 2016b,a) based language ID filtered corpus with an ID threshold of 0.8 as described in Gwinnup and Anderson (2020), shown in Table 1, allowing us to make concrete progress comparisons to last year's systems.

2.2 Data Augmentation with Speech Recognition-like output

In order to build a larger pool of training data, we have created Automatic Speech Recognition (ASR) - like training data for the Russian–English translation task. Whereas written text can include upper and lowercase characters, punctuation, special symbols, and numbers written using digits, transcripts produced by ASR systems are typically uncased with no punctuation, no special symbols, and numbers written as spoken (e.g., 4.1% rendered as "four point one percent"). In previous experiments on an English-German spoken language translation task (Ore et al., 2020), we found that we could get an improvement in BLEU score by formatting the MT training data such that the source language text matched the output format of our ASR system, while leaving the target language text unmodified. We applied a similar procedure to the Russian side of the Russian-English training corpus using the text2norm.pl script from ru2sphinx.[5] This copy of the ASR-like training text was then appended to

the original training data, effectively doubling the size of the corpus.

2.3 Selecting Tuning Sets from Representative Data

We performed experiments involving automatic selection of fine-tuning corpora. Given a monolingual application corpus, we wish to test the possibility of selecting an appropriate fine-tuning set to improve a general-purpose neural MT system's performance on that application corpus. We anticipate such techniques to be of increasing importance, especially for high-value application corpora, as computational costs of subcorpus selection and fine-tuning continue to decrease.

2.3.1 Method

We performed subselection as in Erdmann and Gwinnup (2019), which can flexibly incorporate a text quality metric and multiple parallel text corpora. In short, this algorithm tries to simultaneously optimize the quality of the subset's text and its coverage of the vocabulary present in given application corpora.

Of special note is our use of clustering to select data. We hierarchically applied the MAPPER algorithm (Singh et al., 2007) to cluster sentence vectors of a monolingual corpus. The clusters deemed useful were then used to assign fuzzy clustering to the application corpus and the corpus from which we subselect. This clustering information was included as one of the text corpora.

2.3.2 Application

The application corpus we used was the Russian side of newstest2019 and newstest2020, totalling 6777 lines. The pool of possible parallel text for subselection we took to be the given 12.6M-line subset of Russian–English version 8 ParaCrawl corpus with LASER score at least 1.1. For subselection algorithms, we first preprocessed the Russian text, applying a 90k-element joint BPE. We used the algorithm in Erdmann and Gwinnup (2019) to subselect a corpus, using 3-grams in the vocabulary coverage. As a text quality metric in this algorithm we used either the provided Bicleaner scores (Sánchez-Cartagena et al., 2018; Ramírez-Sánchez et al., 2020) or the word-averaged scores provided by OpenNMT's scoring functionality, using the untuned OpenNMT model we developed for this year's task. In order to provide meaningful comparisons with our baseline fine-tuning set of newstest2014-2018, we matched its size by always subselecting a fine-tuning set with fifteen thousand lines. Fine-tuning was performed using a single-model Marian-based untuned MT system as a baseline.

Sentence vector clustering was learned using a 570M-line monolingual Russian corpus built from the concatenation of monolingual CommonCrawl (Smith et al., 2013) data provided by WMT organizers as part of our WMT18 efforts towards pretraining word embeddings. The word vectors were trained using word2vec (Mikolov et al., 2013) on this corpus, after applying a 90k-element joint BPE. These embeddings have a dimensionality of 512 to match our Marian transformer-base system configuration as described in Gwinnup et al. (2018). A randomly-chosen 100k-line subset of the corpus was used to find the clustering.

Several methods of converting word vectors to sentence vectors were considered, and we empirically chose a "softened sum" of the word vectors

w_i as the sentence vector s:

$$s = \frac{\sum w_i}{\log(1 + \text{number of words in sentence})}.$$

Clusters were considered to be useful if they covered between 1% and 5% of this corpus. In this case there were 19 such clusters, having between 1000 and 5000 representatives each. These clusters were found to have qualitative meaning to a Russian linguist: clusters with relatively high representation in our application corpus tended to be news-like, and clusters with relatively high representation in ParaCrawl tended to be noisier.

We computed membership of a given sentence vector in a fuzzy clustering sense, with weight of cluster i defined as

$$z_i = (\min \text{distance}/\text{distance}_i)^4$$

where we use Euclidean distance, and the minimum is taken over all 19 clusters. Although the exact form is empirical, note that the weight has a maximum of unity at the closest cluster and that a cluster will get lower weight if it is farther from the sentence vector. This fuzzy clustering was computed once using k-means (distance is to cluster mean) and once using single-linkage (distance is to nearest member) clustering. These two membership clusters were then averaged. Coverage of the clusters was encouraged by including the clustering as another text corpus in our standard algorithm (Erdmann and Gwinnup, 2019) — each sentence vector was converted into a 100-word "sentence," where each cluster's "word" appeared a number of times relative to the magnitude of its weight in the line's clustering[6]. Naturally, coverage of these clustering words was computed using only unigrams.

2.3.3 Results

Table 2 shows the results of our fine-tuning experiments. The "clustering" and "metric" columns designate whether clustering was incorporated and whether Bicleaner ("Bic") or NMT scoring ("NMT") was used as the text quality metric. We see consistent gains over the untuned set, even on newstest2021, which was not used in the selection. The three subselection methods produced similar results on the three test sets. Fine-tuning with our selected sets did not produce consistent improvement over our baseline fine-tuning using newstest2014-2018. Compared to this baseline fine-tuning, the new sets improved performance on newstest2019 (roughly $+0.7$ BLEU), but they lowered performance on newstest2020 (roughly -0.7 BLEU) and the unseen newstest2021 (roughly -1.1 BLEU). Our generated fine-tuning sets did not show a consistent benefit for this task, so they were not used in our submission systems. Without further information, we cannot attribute the quality of the results to the method, the quality of data in ParaCrawl, or other causes.

Our method generates a pseudo in-domain set for an unknown application domain, using only source-side data of the application corpus. This generated set can be used for fine-tuning, training, or other purposes in natural language processing. We believe that such techniques warrant further investigation, especially for an application corpus where the domain is unknown or human-curated parallel data are unavailable.

3 Machine Translation Systems

3.1 OpenNMT-tf

The OpenNMT-tf system trained for this task used the configuration for a big deep transformer network.

We used the following network hyperparameters:

- 1024 embedding size
- 4096 hidden units
- 12 layer encoder
- 12 layer decoder
- 16 transformer heads
- dropout 0.3
- attention dropout 0.1
- feed forward network dropout 0.1
- embeddings for source, target and output layers were not tied
- Layer normalization
- Label smoothing 0.1
- Learning rate warm-up 8000 steps

The corpus used for the initial model consisted of commoncrawl, paracrawl v1, and newscommentary-v13 from wmt19 and was processed

[6]For example, using a 10-word sentence for brevity, this process would convert the fuzzy cluster membership vector $[0.2, 0.0, 0.8, 1.0]$ into the sentence "0 2 2 2 2 3 3 3 3 3".

tuning set	clustering	metric	newstest2019	newstest2020	newstest2021
untuned			35.9	34.5	46.5
newstest2014-2018			37.5	35.7	49.3
selected	no	NMT	38.0	35.0	48.4
selected	no	Bic	38.3	35.0	48.2
selected	yes	Bic	38.2	34.9	47.9

Table 2: Tuning sets and resultant BLEU scores.

with SentencePiece(Kudo and Richardson, 2018) using a model with a vocabulary size of 40K trained on this ru-en corpus of 16,805,109 bi-text. This was one of our WMT20 submitted systems (Systems 3 and 4 in Table 3). Additionally the corpus was processed as described in Section 2.2 to resemble ASR output and the resulting data was combined with the above for a final count of 33,610,218 bi-text. The network was trained for 10 epochs of this training data using a batch size of 3124 and an effective batch size of 49984 using the lazy Adam (Kingma and Ba, 2015) optimizer with beta1=0.9, beta2=0.998 and learning rate 2.0. This was a system that had been originally trained for speech translation application but showed improvements in text translation as well. The final submitted system continued training an additional 2 epochs using the unfiltered data described in Table 1. This was done to try to take advantage of the larger data set and not having the computational resources or time to train a new system with with the larger data set in time for submission deadline. The output was an average of the last 8 checkpoints of training. Checkpoints were saved every 5000 steps. The system was then tuned with three epochs of newstest data from years 2014-2017 (Systems 5 and 6 in Table 3).

3.2 Marian

Our Marian systems utilize the transformer architecture in the transformer-base configuration. We use the WMT14 newstest2014 test set for validation during training and the following network hyperparameters:

- 512 embedding size
- 2048 hidden units
- 6 layer encoder
- 6 layer decoder
- 8 transformer heads
- Tied embeddings for source, target and output layers
- Layer normalization
- Label smoothing
- Learning rate warm-up and cool-down

We experimented with tuning these systems with the concatenation of WMT newstest sets from 2014-2018 yielding a tuning corpus of 14,820 parallel sentences. For each of the five separate transformer models trained for the Marian transformer-base ensemble systems in Gwinnup and Anderson (2020), continued training was performed for 10 epochs on the concatenated tests sets. An ensemble of the five resulting tuned models is then used to decode newstest sets from 2019-2021. Resulting scores reported by SacreBLEU are shown as Row 2 in Table 3, while the baseline, untuned ensemble is shown as Row 1. We note gains between +2.0 and +3.5 BLEU as measured by SacreBLEU over the baseline ensemble system depending on test set.

4 Experimental Results

Results reported here and in Table 3 for Marian systems were scored with SacreBLEU (Post, 2018) while results for OpenNMT systems were score with mult-bleu-detok.perl from the Moses toolkit (Koehn et al., 2007). Internal comparisons between the two scoring methods have been in agreement. All scores are on detokenized cased output.

The primary submission system was the OpenNMT-tf configuration described in section 3.1 and shown in Table 3 as onmt+asr-tune. It resulted in official scores of 53.31 BLEU-all, 38.83 BLEU-A, 39.56 BLEU-B, 0.64 chrf-all, 0.63 chrf-A, and 0.64 for chrf-B on the 2021 test-set.

Post evaluation a model with the OpenNMT-tf configuration described in section 3.1 was trained on all the unfiltered data (approx. 76M million bi-text). The results are shown in Table 3 as onmt-large. The baseline onmt-large system was approx-

imately +1 BLEU better that the baseline onmt-asr system while the onmt-asr system which continued training with two epochs of the large data set and tuned with newstest2014-2017 (onmt-+asr-tune) was +2.5 BLEU better than the baseline onmt-large system which was trained with 10 epochs and comparable to the onmt-large system tuned with newstest2014-2017. Experiments were conducted on both onmt+asr and onmt-large with tuning sets comprised of different combinations of the supplied news test sets from 2014 to 2019. Tune7 is news test sets from 2014-2017 (11,820 bi-text), tune8 is news test sets from 2014-2018 (14,820 bi-text), and tune9 is news test sets from 2014-2019 (16,820 bi-text). Systems were tuned for three epochs using these tuning sets. Generally performance dropped off or decreased slightly with more than 3 epochs of tuning. To be consistent across systems and tuning sets we are only reporting results for 3 epochs. As can be seen in Table 3 all three tuning sets provided significant improvements over the baseline systems, generally in the range of +3.5 BLEU on test 2021. For onmt+asr there was little difference in tuning with tune7 or tune8 whereas tune9 was approximately +0.4 BLEU better than those two. For onmt-large tune7 did not provide as much benefit as tune8 and tune9 which were basically the same, less than 0.1 BLEU difference between the two.

5 Conclusion

While our two submission systems employ a standard method of fine-tuning to adapt models towards a test set, we find that our methods to sample a similarly-sized tuning corpus from a larger body of text while only using information about the source side of that data yields a reasonable improvement in translation quality. Such a technique could be useful in adapting translation models to specific domains where only the source language of a text source is available.

Using actual in-domain data, such as the provided news development sets, for fine-tuning provide a substantial gain in translation quality. Such data is not always available and thus other selection techniques as described in Section 2.3 come into play. Future work will investigate combining the two approaches to see if additional gains can be obtained.

The authors would like to thank Emily Conway and Braeden Bowen for their assistance in human evaluation of MT output.

Abstract

This paper describes the submission to the WMT 2021 news translation shared task by the UPC Machine Translation group. The goal of the task is to translate German to French (De-Fr) and French to German (Fr-De). Our submission focuses on fine-tuning a pre-trained model to take advantage of monolingual data. We fine-tune mBART50 using the filtered data, and additionally, we train a Transformer model on the same data from scratch. In the experiments, we show that fine-tuning mBART50 results in 31.69 BLEU for De-Fr and 23.63 BLEU for Fr-De, which increases 2.71 and 1.90 BLEU accordingly, as compared to the model we train from scratch. Our final submission is an ensemble of these two models, further increasing 0.3 BLEU for Fr-De.

1 Introduction

Monolingual data is usually more abundant than parallel data as it does not need any human processing. Neural Machine Translation (NMT) has focused traditionally on parallel data between languages and monolingual data as back-translation (Sennrich et al., 2016). This method consists of translating a monolingual corpus with an NMT system and training the model using the synthetic data. Alternatively, in recent years, pre-trained models have been proposed using monolingual data as a pre-training step with self-supervised learning, before performing task-specific fine-tuning. An example of this approach is BERT (Devlin et al., 2019), which is a Transformer model (Vaswani et al., 2017), pre-trained on masked language modeling and next sentences prediction on a large unlabeled corpus. While BERT is used primarily for classification tasks, BART (Lewis et al., 2020) has been proposed for sequence-to-sequence tasks. BART is a Transformer encoder-decoder, pre-trained as a Denoising Autoencoder (DAE) on monolingual unlabeled text. Since BART is pre-trained on monolingual data, an additional encoder should be introduced during fine-tuning to obtain a bilingual NMT system. mBART overcomes this restriction by being pre-trained on multilingual denoising. mBART (Liu et al., 2020; Tang et al., 2020) is liable to fine-tuning on several translation directions in order to obtain a multilingual NMT system.

Our participation to the news translation task at WMT focuses on translating between German (De) and French (Fr) in both directions, De-Fr and Fr-De. To accomplish this, we employ a pre-trained mBART model, and more specifically mBART50 (Tang et al., 2020), which is pre-trained with 50 languages. We fine-tune the mBART50 on both translation directions to obtain a single multilingual model for the task. To measure the importance of the pre-training step, we additionally train a Transformer with the same architecture and hyperparameters but randomly initialized. Our experiments show that the fine-tuned mBART50 can achieve better translation quality in both directions, with improvements of 2.71 for De-Fr and 1.9 for Fr-De. Apart from fine-tuning a pre-trained model, our approach also includes extensive filtering of a large bilingual corpus to ensure high-quality training data. Finally, we have considered ensembling the fine-tuned mBART50 and the trained-from-scratch Transformer for our submission. This ensembling has resulted in BLEU scores of 31.69 and 23.93 for De-Fr and Fr-De accordingly.

The rest of this paper is organized as follows: In Section 2 we describe the background techniques this work builds upon, multilingual NMT and mBART. In Section 3 we present the datasets we used for training and the techniques applied for filtering them. In Section 4 we provide the system description along with the implementation details and Section 5 involves the results of our experiments. Finally, in Section 6 we discuss the conclusions of this work and present possible directions for further research.

2 Background

2.1 Neural Machine Translation

Neural Machine Translation (NMT) uses sequence-to-sequence models, with an encoder-decoder architecture, built upon deep neural networks (Sutskever et al., 2014; Bahdanau et al., 2014; Gehring et al., 2017; Vaswani et al., 2017). In a sequence-to-sequence model, the source sentence is mapped to its contextualized representation and fed to the decoder to generate the translation output in an auto-regressive way. Traditionally, recurrent neural networks (Hochreiter and Schmidhuber, 1997) have been used for the encoder and decoder, with an attention mechanism (Bahdanau et al., 2014) that enables each target token to concentrate on certain tokens in the source sentence. Recently, the Transformer (Vaswani et al., 2017) led to large improvements on sequence-to-sequence tasks and NMT, relying exclusively on attention mechanisms. The systems trained in this work, are also based on Transformer models.

2.2 Multilingual NMT

Multilingual NMT aims to provide a single model that can translate several language directions (Firat et al., 2016; Johnson et al., 2017). These can be one-to-many, many-to-one, or many-to-many, with the "one" being usually English due to the broadly available corpora. Previous studies have explored different design approaches, focusing on sharing parts of the model between the different languages, with shared encoder-decoder attention between languages (Firat et al., 2016), a shared encoder (Sen et al., 2019), a task-specific attention (Blackwood et al., 2018), shared parameters (Zhu et al., 2020) and full model sharing (Johnson et al., 2017). Recently, the paradigm of full model sharing has been extended to accommodate for many more languages and directions by training huge models for massively multilingual NMT (Arivazhagan et al., 2019; Fan et al., 2020). Our submission is also based on multilingual models that are fully shared between the two language directions German-French and French-German.

2.3 mBART

BART (Lewis et al., 2020) is a Transformer encoder-decoder, which is pre-trained with self-supervised learning on reconstructing the text corrupted by a noise function. Its multilingual version, mBART (Liu et al., 2020), uses the same self-supervised approach, but reconstructs corrupted text from multiple monolingual corpora. The nature of this pre-training makes mBART a good initialization for a multilingual NMT system. mBART can be fine-tuned on multiple bitext corpora providing gains in all directions of 25 languages, except for the very highest resource ones (Liu et al., 2020). Our system is initialized with mBART50 (Tang et al., 2020) (an extension of mBART from 25 to 50 languages). This initialization is followed by multilingual fine-tuning on both directions of a large German-French bitext.

3 Data

In this section we introduce the datasets used for training our systems and we go through the data filtering process that was applied in each one of them.

3.1 Datasets

In order to train Transformer models for Machine Translation, commonly, a large parallel corpus is needed. For the purpose of this research, we focus on creating a French-German parallel corpus from several publicly available datasets. More specifically, these are the Europarl (Koehn, 2005), Paracrawl (Bañón et al., 2020), Common Crawl[1], News Commentary (Tiedemann, 2012), Wiki Titles[2], Tilde Rapid and EESC (Rozis and Skadiņš, 2017), WikiMatrix[3] and TED Talks (Cettolo et al., 2012). If the dataset contains more languages, we only keep examples that have non-empty sentences for French-German. We use the development and test data of the news test datasets of 2019 and 2020, as provided by WMT. The size of each dataset can be found in the first column of Table 1.

3.2 Data Filtering

We employ two stages of data filtering to ensure that our system is trained on high-quality data. In the first stage, we process each example, either from the French or German side, separately by altering its content. This process includes the following steps in the listed order:

1. Removal of non-utf8 characters
2. De-escaping html characters

[1] http://data.statmt.org/wmt19/translation-task/fr-de/bitexts

[2] http://data.statmt.org/wikititles/v3/

[3] https://github.com/facebookresearch/LASER/tree/master/tasks/WikiMatrix

3. Normalization of different types of punctuation

4. Normalization of spacing

5. Removal of redundant apostrophes

The normalization of spacing and punctuation is applied using the SacreMoses[4] package. During the second stage of filtering, we completely remove whole examples, when either the French or the German sentence contain noise or inconsistent information.

1. **Basic Filtering.** We remove examples where either side is empty, or the two sides contain the same lower-cased text.

2. **Language Filtering.** Here we intend to identify sentences that are written in languages other than French and German. We remove examples where the language of either sentence does not match the expected one. To predict the language of a sentence, we use a pre-trained language detection model from FastText (Joulin et al., 2016).

3. **Length Filtering.** Here we aim to identify sentences or examples with unnatural length characteristics that potentially result from noise. We remove examples where either side is found to have a large number of words (greater than 200), an extreme character-to-word ratio (lower than 1.5 or greater than 12), at least one word with a high number of characters (greater than 25), or the example has an extreme source-to-target word ratio (lower than 0.4 or greater than 2.5). For setting the boundaries of what is an acceptable length or ratio, we follow (Shi et al., 2020).

4. **Alignment Filtering.** At this point, we want to identify noisy pairs by computing their alignment scores. We use the fast-align library (Dyer et al., 2013) and remove examples where the alignment score is 2.5 times above the average alignment score of the corpus. The alignment score of an example is calculated as the normalized log-probability of the German-French alignment, and the alignment score of the corpus is the sum of the alignment scores of its examples. Specifically for the WikiMatrix pairs, which are not human-generated and possibly contain more noise, we follow a more aggressive approach and remove a pair if its alignment score is 15 absolute points above the average.

4 System Description

In this section we are going to describe the two main steps of our submission, fine-tuning of a pre-trained with the provided data and ensemble of pre-trained and not pre-trained models.

4.1 Multilingual fine-tuning

Traditionally, models are trained from random initialization. We initialize our model with mBART50 (Tang et al., 2020) pre-trained weights. These weights act as a more informed initialization that already contains useful features for language representation. Given the support of the public model to the French and German languages, no modifications of the embedding model were needed. Following mBART50 strategy, we fine-tune all the layers of the multilingual model on all the filtered French-German and German-French data. To condition the language generation (Johnson et al., 2017), a source language token was added as the first token of the source sentence, and a target language token was added as the first decoder token to the decoder.

Implementation Both randomly initialized baseline and mBART50 models were trained using *fairseq*'s (Ott et al., 2019)[5] mBART large imple-

[5] https://github.com/pytorch/fairseq

mentation for multilingual fine-tuning. The architecture consists of 12 layers with 1024 embedding size, 4096 feed-forward size, and 16 attention heads, both for encoder and decoder, with a total number of parameters of 610, 878, 464. Models were trained for approximately 400k updates or seven epochs using validation loss as an early stopping criterion, with a learning rate of $1 * 10^{-4}$ and $3 * 10^{-5}$ for the baseline and fine-tuned model, respectively. Both models are trained using the original vocabulary of 250k tokens, at subword level using the *sentencepiece*[6] model available with the mBART50 model. Both models were trained on two Nvidia GTX 3090 with eight batches of gradient accumulation. At generation time, beam size was set to eight.

4.2 Model ensemble

Model ensembling is a popular technique to leverage the features learned by several models. This is especially important in our case as the pre-trained model has been trained on data not constrained to the domain. As the pre-training step is performed on data that does not belong to the task domain, it could generate structures or patterns that are not commonly used, even when keeping the sentence's intended meaning. In order to balance the provided data, we ensemble the best checkpoint from the baseline and the fine-tuned mBART. Thus, next token prediction during inference is done according to the combined probability from both models.

Implementation Ensembling was performed using the standard *fairseq* generation script. The two models ensembled were the same checkpoints at 400k updates reported for the individual systems. Beam size was set to eight as in the previous experiments.

5 Experiments and Results

Multilingual fine-tuning. Our first hypothesis is that the use of pre-trained models could improve translation performance. Therefore, we compare our system with a baseline system with the same vocabulary and parameter configuration with random initialization to measure the impact of the translation step. Tables 2 and 3 show the translation results for German-French and French-German translation directions, respectively. Results show that fine-tuning of pre-trained models improves translation quality in both directions by 2.3 BLEU points on average, showing that a more informed model initialization significantly impacts the final model performance. It is worth noticing that we expected the fine-tuning approach to converge faster than the randomly initialized baseline, but they both show similar behaviors and required approximately 400k training updates. Figure 1 show that the fine-tuned model's validation loss is lower over the entire training but both converge to the best value at the seventh epoch.

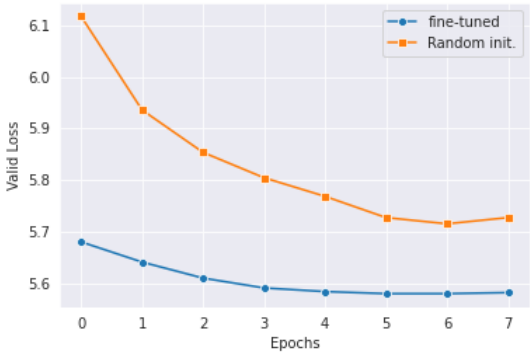

Figure 1: Validation loss during training for the fine-tuned mBART (fine-tuned) and randomly initialized (Random init.) models.

	BLEU	**ΔBLEU**
Baseline	28.98	-
mBART50	**31.69**	2.71
+Ensemble	**31.69**	0.00

Table 2: Results measured in BLEU for the German to French translation direction

Model Ensemble. Our second hypothesis is that the pre-training step on the out-of-domain data may affect the model's phrasing at inference time, and ensembling with the baseline trained only on the provided constrained data could improve its performance. Results show that, although a minor improvement of 0.3 BLEU points has been reported for the French to German translation direction, it is not consistent on German to French, where no performance difference has been observed. These results may indicate that the pre-training step has a limited impact on the final domain performance and that the fine-tuning step on the provided constraint data is the most crucial factor in the final model's domain adaptation.

mBART50	23.63	1.90
+Ensemble	**23.93**	0.30

Table 3: Results measured in BLEU for the French to German translation direction

6 Conclusions

This work describes the TALP-UPC system for the WMT 2021 shared news translation task for French-German and German-French. Experimental results show that pre-trained models help improve translation performance in this kind of scenario, even for high-resource language pairs with millions of parallel sentences available, with 2.71 points for German-French translation direction and 1.90 points for French-German. Results also show that ensembling of pre-trained and randomly initialized models can lead to minor performance improvements (up to 0.3 BLEU) but not consistently on both tested languages.

In future work, better results may be obtained by combining fine-tuned pre-trained models with traditional back translation. Both techniques would benefit from the additional monolingual in two different aspects of the NMT model, initialization and additional training on the monolingual data provided.

Abstract

We describe our two NMT systems submitted to the WMT2021 shared task in English-Czech news translation: CUNI-DocTransformer (document-level CUBBITT) and CUNI-Marian-Baselines. We improve the former with a better sentence-segmentation pre-processing and a post-processing for fixing errors in numbers and units. We use the latter for experiments with various backtranslation techniques.

1 Introduction

In this paper, we describe our two NMT systems submitted to the WMT 2021 English-Czech news translation shared task: "CUNI-DocTransformer" (Charles University document-level Transformer) and "CUNI-Marian-Baselines". In addition, we submitted also "CUNI-Transformer2018", which is exactly the same system (sentence-level) as submitted in 2018 (Popel, 2018).

CUNI-DocTransformer uses the same model as submitted last year (Popel, 2020), but with improved sentence segmentation (Section 3.1) and number-unit postprocessing (Section 3.2). This system was submitted for both English→Czech and Czech→English.

CUNI-Marian-Baselines is an attempt at reimplementation of the original CUNI-Transformer2018 in Marian (Junczys-Dowmunt et al., 2018), where we experiment with various setups of tagged backtranslation (Section 4). This system was trained only for English→Czech.

According to automatic evaluation provided by the WMT organizers (Table 1), CUNI-DocTransformer is the third best English→Czech system.

Table 1: Evaluation of English→Czech WMT21 systems. The systems are ordered by BLEU with reference A, ordering by the other metrics is provided in parentheses. Names of systems described in this paper are in bold.

2 Common settings

Both our systems use the Transformer (Vaswani et al., 2017) architecture, checkpoint averaging (using the last 8 checkpoints) and a 32k joint English-Czech subword vocabulary. Both systems are trained on CzEng 2.0 (Kocmi et al., 2020) with 61M authentic parallel and 127M synthetic (back-translated) sentences (see Table 2), but the English→Czech CUNI-DocTransformer does not use directly the EN-mono section,[1] while CUNI-Marian-Baselines uses all three sections including EN-mono (i.e. using forward-translation).

Both systems use Block-backtranslation (Popel et al., 2020), although CUNI-Marian-Baselines uses too small block size, so it does not have the expected positive effect as described in Section 4.

3 DocTransformer improvements

3.1 Sentence segmentation

CUNI-DocTransformer was trained on multi-sentence sequences of up to 3000 characters and

[1]The synthetic data in CzEng 2.0 were prepared using iterated backtranslation, so the EN-mono data were used for training a Czech→English system, which produced the English translation of the CS-mono data in CzEng 2.0. Thus, indirectly also the EN-mono data were used for training the English→Czech CUNI-DocTransformer.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 123–129
November 10–11, 2021.

data set	sentence pairs (M)	words (M) EN	CS
authentic	61	617	702
EN-mono (NewsCrawl 2016–2018)	76	1296	1474
CS-mono (NewsCrawl 2013–2018)	51	700	833
total	188	2613	3009

Table 2: Training data sizes (in millions). All the data are taken from CzEng 2.0.

750 subwords. However, the WMT submission format requires a segment-level alignment and also the CUNI-DocTransformer decoding employs overlapping sequences where sentence alignment is needed (for details see Popel (2020)). Thus, the sentences within a sequence are separated with a special token on both source and target side (both during training and at inference time), which allows a simple extraction of the sentence alignment.[2]

Some segments in the WMT input format contain multiple sentences. When treating such segments as a single sentence, the resulting translations often missed sentence-initial capital letters because there were almost no such examples in the training data, where multiple sentences would not be separated by the special token.

We thus decided to first split the input segments into sentences using UDPipe (Straka et al., 2016). Unfortunately, UDPipe tends to over-segment.[3] Such over-segmentation may lead to serious errors in the translation, even when using the document-level model. We thus restrict the sentences boundaries detected by UDPipe only to boundaries after sentence-final punctuation, using a simple rule-based segmenter from Udapi (Popel et al., 2017). This improved BLEU on our dev set slightly.

3.2 Number-unit post-processing

We noticed three types of translation errors related to numbers and units.

1. Attempt at converting numbers and units. For example, the Czech sentence *Je vysoký pouhých 190 cm* (meaning *He's only 190 cm tall*) was translated as *He's only six feet tall*. Note that six feet is 183 cm, so the translation was not exact.

2. Converting units without numbers. For example, *27 Kč* was translated as *$27*, while the correct translation should be *27 crowns* or *27 CZK*.

3. Not converting separators. English uses commas (or thin spaces) as thousand separators and dots as decimal separators, but Czech uses the opposite convention (with space being a more common thousand separator than dot). So e.g. Czech *179,500 kg* means 179 and a half kg (with precision up to 1 gram) and the correct translation to English should be *179.500 kg*, but CUNI-DocTransformer (and many other systems) keeps the phrase untranslated, resulting in a thousand times higher value.

The first type is quite rare – 0.7% of numerical expressions with units in cs-en and 0.6 in en-cs, according to Table 3, while some of these cases may be correct translation (correctly converted number and unit). The second type is more frequent – 11.1% and 6.5%, respectively. The third type is also frequent – in 100,000 Czech sentences from CzEng 2.0 cs-mono, there were 2594 numbers with a separator and out of these 275 (10.6%) were not correctly converted in the English CUBBITT translations; similarly in 100,000 English sentences in en-mono, there were 4376 numbers with a separator and out of these 263 (6.0%) were not converted in the Czech CUBBITT translations. We have noticed all three types of errors not only in CUBBITT, but we have not inspected these other MT systems in detail yet.

We implemented a rule-based tool which tries to fix such errors in post-processing.[4] It detects imperial/SI units of length, weight, speed, area and volume; units of temperature (Fahrenheit/Celsius) and currencies (USD, CZK, EUR), but it can be easily extended. By default, it keeps the units and numbers the same (except for the thousand/decimal separators), but it can be configured to convert the units and numbers. We had to deal with several edge cases, such as various ways how to write numbers and units or handling multiple numbers in a sentence with a possibly changed word order (using a word aligner).

[2] If the number of special tokens on the source side does not match the number of special tokens on the target side at inference time, we back off to translating each sentence in a given sequence independently.

[3] UDPipe is trained on Universal Dependencies (Zeman et al., 2018), where titles and headlines with no final punctuation are treated as sentences, which need to be detected by the sentence segmentation.

[4] https://github.com/vsvandelik/cubbitt-fixer

	kept		cs-en		en-cs	
	number	**unit**	#	**%**	#	**%**
A	yes	yes	2 689	86.5	3 548	85.7
B	yes	no	346	**11.1**	268	**6.5**
C	no	yes	21	**0.7**	24	**0.6**
D	no	no	21	0.7	13	0.3
E	detection failure		31	1.0	287	6.9
	total		3 108	100.0	4 140	100.0

Table 3: Automatic analysis of numerical expressions with units in a sample of 100 000 sentences from the synthetic parts of CzEng 2.0. Numerical expressions that were detected only in the source sentences, but not in the (MT) translation, are marked as *detection failure*. Cases B and C where only the unit or only the number were converted can be safely considered as errors – so the percentages are marked in bold.

Using our tool, we analyzed a sample of the synthetic training data in CzEng 2.0 and found out that at least 11.8% of Czech and 7.1% of English expressions with numbers and units are translated wrong, see Table 3.

After submitting CUNI-DocTransformer, we analyzed the WMT2021 news test sets and found out that there were only 4 sentences affected by our post-processing. All 4 cases were of the same type – "korun" was translated as "$", which was corrected to "crowns",

4 Experiments in Marian

The goals of the experiments described in this section were:

- Reimplement the Block-backtranslation training (Popel et al., 2020) in Marian (Junczys-Dowmunt et al., 2018). Block-backtranslation was first implemented in the Tensor2Tensor framework in the CUBBITT system, also known as CUNI-Transformer2018 (Popel, 2018).
- Explore the effect of Block-backtranslation (vs. standard shuffled backtranslation (Sennrich et al.)), checkpoint averaging and Tagged backtranslation (Caswell et al., 2019).
- Try a novel type of Tagged backtranslation with tags on the target side.
- Explore interactions of the above-mentioned methods.

4.1 Marian settings

We followed the standard Transformer Big hyperparameters, with 6 encoder and 6 decoder layers (unlike CUNI-DocTransformer, which has 12 encoder layers). Other differences from CUNI-DocTransformer are: Marian was trained on sentences (no document level) of up to 150 subwords (`--max-length 150`). It was trained on a single GPU (instead of 8), but using 8 batches per updated (`--optimizer-delay 8`), thus resulting in a similar effective batch size. Due to time reasons we trained all our Marian models just for a single epoch on the whole CzEng 2.0 training data, containing all three parts: authentic parallel data, synthetic CS-mono and synthetic EN-mono, i.e. using both backtranslation and forward translation (Ueffing et al., 2007; Kim and Rush, 2016). The English→Czech CUNI-DocTransformer was not trained on the EN-mono part, but it was trained "until convergence", for 700k updates (which is not easily converted to epochs because the authentic data was upsampled for the Block backtranslation), i.e. several times more updates that the Marian model. Finally, we accidentally used too small blocks in the Block backtranslation, as described in the following section.

4.2 Replicating CUBBITT

In our first experiment, we tried to replicate the CUNI-Transformer2018, which also uses the Transformer Big hyperparameters (with 6 encoder and 6 decoder layers) and sentence-level training. Our Marian results were about 1.5 BLEU worse on various WMT dev sets on average, which is better than we expected when training for a single epoch only. According to our preliminary experiments, including forward-translation data (EN-mono in our case) makes the initial training faster (i.e. better BLEU after the first epoch), although it does not improve the final BLEU when training until convergence. Forward translation data are great for fast uptraining and model distillation – the newly trained model is being trained to behave similarly as the original model used to produce the synthetic translations. The synthetic translations are consistent (if no noising is used) – the same sentence is translated always the same way.

While the final BLEU results are good enough, the learning BLEU curves on Figure 1 do not show the camel-shape progress typical for Block Backtranslation Popel et al. (2020). We also did not

observe the synergy effect of Block backtranslation and checkpoint averaging. The explanation is simple: when dividing the data for Block backtranslation, we accidentally used 10 blocks of authentic data and 20 blocks of synthetic data. Thus there was less than one checkpoint per each block on average, which goes against the main idea of Block backtranslation, where each block of authentic or synthetic data should be big enough to fit at least 8 checkpoints (considering checkpoint averaging with 8 checkpoints). We think this is the reason why we do not see any significant differences between *block* and *shuffled* in Tables 4 and 5 and also between these two tables (as an effect of checkpoint averaging).

4.3 Tagged backtranslation

For our experimenting, we decided to try labeling the data based on its authenticity — The labels would have two parts, one specifying whether the source side was an authentic sentence, or created using back translation or forward translation (Ueffing et al., 2007; Kim and Rush, 2016), and the other part specifying the same for the target side. We tried having no labels at all, labeling only one side or the other, or labeling both sides. However, in all these scenarios, every label that existed specified the authenticity of both the source and the target side. This is very similar to tagged backtranslation (Caswell et al., 2019) but we tried using our labels on the target side as well and we explored possible synergy between block ordering or checkpoint averaging by trying the different versions.

Since all of czeng20-train, czeng20-enmono, czeng20-csmono were used, the labels were `auth+auth`, `auth+synth` and `synth+auth`. In each dataset, where the label was present, it was situated at the beginning of each sentence, space-separated from the sentence itself.

In addition to the main experimenting with the four variants of source and target side labeling, we created versions with data ordered in blocks (of authentic vs backtranslated data). This resulted in eight versions being trained — all combinations of: source side labeling yes/no, targets side labeling yes/no, block order / completely shuffled data.

When the training data was ordered into blocks, there were about 10 blocks of each of the data kinds (czeng20-train, czeng20-csmono, czeng20-enmono) meaning 30 blocks in total. With our checkpoint frequency this meant that one block was slightly smaller than the data seen between two neighboring checkpoints, which are very small blocks. The completely shuffled datasets were created from the block ones by shuffling them using a random permutation. The order of data points was the same among all block-ordered datasets and same among all completely shuffled datasets.

For time reasons, we only managed to train each model on a single epoch (using marian's `--after-epochs 1`). From the training, we obtained eight variants, which we then did checkpoint averaging on, creating additional eight variants. We then evaluated these 16 variants on the wmt17 newstest dataset, and chose two representing models for each — one was the model at the end of the training, the other was the model that achieved the best BLEU score on wmt17. We evaluated these 32 models on concatenation of wmt15, wmt16 and wmt18 and chose those seven models that reached the best BLEU on this testset.

4.4 Results

We observed some differences in performance among the trained versions. The images below show the development of BLEU score (measured on a test set, not the training data) as the training progressed. We can see that there are differences among the versions but it is hard to find a pattern in them. They also do not seem to be consistent among the test sets — wmt15, wmt16, wmt17, wmt18. When wmt15, wmt16 and wmt17 are concatenated, the differences seem to largely disappear (see the tables below) and we still do not see any clear pattern in the results.

We also fail to see clear differences in performance between block ordering vs. completely shuffled corpora, and checkpoint averaging vs. no averaging. There is also no synergy between those two in our results, which is very likely caused by our setup of extremely small blocks. The blocks used in CUBBITT were large enough to contain all eight averaged checkpoints of certain models, while our blocks didn't even fully contain one checkpoint.

5 Conclusions

In this paper, we presented two sets of experiments: automatic correction of numeric expressions with units in rule-based post-processing and various settings of Tagged backtranslation.

The correction of numeric expressions with units focuses on errors which are relatively rare and do

Source labeling	Target labeling	Ordering	best-BLEU	final-BLEU
yes	yes	block	27.3	27.4
yes	yes	shuffled	27.3	27.2
yes	no	block	27.2	27.4
yes	no	shuffled	27.2	27.3
no	yes	block	27.2	27.2
no	yes	shuffled	27.4	27.4
no	no	block	27.3	27.3
no	no	shuffled	27.5	27.5

Table 4: Both BLEU scores shown were measured no the concatenation of wmt15, wmt16 and wmt18. best-BLEU is the score of the model that achieved the best BLEU on wmt17, while final-BLEU is the BLEU of the model at the end of the training. All of the models in this table are without checkpoint averaging.

Source labeling	Target labeling	Ordering	best-BLEU	final-BLEU
yes	yes	block	27.4	27.4
yes	yes	shuffled	27.2	27.2
yes	no	block	27.5	27.5
yes	no	shuffled	27.2	27.2
no	yes	block	27.3	27.3
no	yes	shuffled	27.4	27.4
no	no	block	27.3	27.3
no	no	shuffled	27.5	27.5

Table 5: This table contains the BLEU scores of models with checkpoint averaging. The columns are the same and have the same meaning as in the previous table.

Source labeling	Target labeling	Ordering	checkpoint averaging	point	wmt21 BLEU
yes	**no**	**blocks**	**yes**	**last**	**20.1**
yes	no	blocks	no	last	20.0
yes	no	blocks	yes	best	19.9
no	no	shuffled	no	last	19.9
no	no	shuffled	no	best	19.6
no	no	shuffled	yes	last	19.6
no	yes	shuffled	no	last	19.6

Table 6: These are the BLEU scores of the submited models on the wmt21 test set.

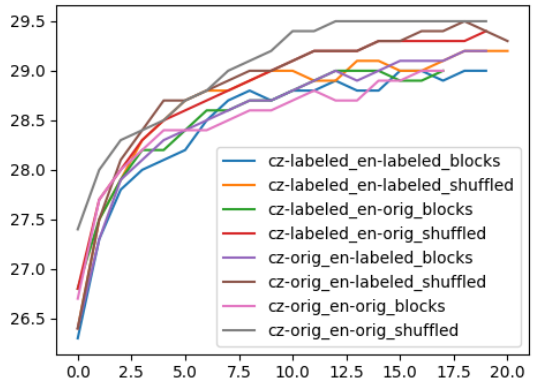

Figure 1: wmt16 BLEU training curves of averaged models

not affect automatic metrics such as BLEU much, but can result in serious misunderstanding of the meaning of the translation. Unfortunately, these errors won't be properly reflected even in the official WMT (context-sensitive, but sentence-level) manual evaluation, where each sentence's score is weighted the same, even if some errors are crucial for the meaning of the whole document.

The experiments with Tagged backtranslation using a Marian reimplementation of CUBBITT did not show any substantial differences in the results nor any consistent pattern. However, we hope that future work continuing the research on various types of training data (authentic vs. synthetic; forward vs backward; different domains) and their synergies may bring new results and better understanding of the backtranslation training etc.

Abstract

This paper describes our submission to the constrained track of WMT21 shared news translation task. We focus on the three relatively low resource language pairs Bengali ↔ Hindi, English ↔ Hausa and Xhosa ↔ Zulu. To overcome the limitation of relatively low parallel data we train a multilingual model using a multitask objective employing both parallel and monolingual data. In addition, we augment the data using back translation. We also train a bilingual model incorporating back translation and knowledge distillation then combine the two models using sequence-to-sequence mapping. We see around 70% relative gain in BLEU point for $En \leftrightarrow Ha$ and around 25% relative improvements for $Bn \leftrightarrow Hi$ and $Xh \leftrightarrow Zu$ compared to bilingual baselines.

1 Introduction

Neural machine translation (NMT) witnessed a lot of success in the past few years especially for high resource languages (Vaswani et al., 2017). Improving the quality of low resource languages is still challenging. Some of the popular techniques are adding high resource helper languages as in multilingual neural machine translation (MNMT) (Dong et al., 2015; Firat et al., 2016; Ha et al., 2016; Johnson et al., 2017; Arivazhagan et al., 2019), using monolingual data including pre-training (Liu et al., 2020), multi-task learning (Wang et al., 2020), back translation (Sennrich et al., 2016) or any combination of these methods (Barrault et al., 2020) and system combination of multiple systems (Liu et al., 2018).

This paper describes the Microsoft Egypt Development Center (EgDC) submission to the WMT21 shared news translation task for three low resource language pairs (six directions), Bengali ↔ Hindi ($Bn \leftrightarrow Hi$), English ↔ Hausa ($En \leftrightarrow Ha$) and Xhosa ↔ Zulu ($Xh \leftrightarrow Zu$). We focus on the constrained track because it is easier to compare different systems and it is always possible to improve performance by adding more data. The main features of our approach are as follows:

- Using a recently proposed multitask and multilingual learning framework to benefit from monolingual data in both the source and target languages (Wang et al., 2020).
- Using knowledge distillation (Freitag et al., 2017) to create bilingual baselines from the original multilingual model and combining it with the multilingual model.

The paper is organized as follows. Section 2 gives an overview of the data used in the constrained scenario, followed by section 3 that gives a detailed description of our approach. Section 4 presents our experimental evaluation. Finally, our findings are summarized in Section 5.

2 Data

Following the constrained track, we use bitext data provided in WMT21 for the following pairs: Bengali ↔ Hindi, English ↔ Hausa, Xhosa ↔ Zulu and English ↔ German. Statistics of the parallel data used for the three pairs in addition to the German helper are shown in Table 1. We also use monolingual data for all previously mentioned languages provided in WMT21 for techniques such as multi-task training and back-translation. Statistics of the monolingual data used for the 6 languages in addition to the German helper are shown in Table 2. For very low resource languages, Hausa, Xhosa and Zulu, we use all the available monolingual data, e.g. NewsCrawl + CommonCrawl + Extended CommonCrawl for Hausa, and Extended CommonCrawl for both Xhosa and Zulu. For relatively high resource languages, Bengali, Hindi, English and German, we only use a subset of the provided data mostly from NewsCrawl due to its high-quality. In addition to the NewsCrawl monolingual subset, we add a sampled subset from CommonCrawl to

Language pair	# of sentences
Bengali ↔ Hindi	3.36M
English ↔ Hausa	750K
Xhosa ↔ Zulu	94K
English ↔ German	84.8M

Table 1: Bitext data used for bilingual and multilingual systems. For each language pair, we use all available sources released in WMT21

Language	# of sentences	
	Raw	Cleaned
Bengali	53.8M	53.3M
English	75M	73.5M
German	111.2M	109.9M
Hausa	10.8M	6.2M
Hindi	60.2M	59.8M
Xhosa	1.6M	950K
Zulu	2M	1.4M

Table 2: Monolingual data used for multi-task training and back-translation

avoid biasing into the news domain especially for Bengali ↔ Hindi and Xhosa ↔ Zulu whose target evaluation domain come from Wikipedia content.

2.1 Data Filtering

For Bengali, English, Hindi and German, we apply fastText [1] language identification on the monolingual data to remove sentences which are not predicted as the expected language. We do the same for Hausa, Xhosa and Zulu using Polyglot [2] because fastText does not cover these three languages. The resulting size of the monolingual data of each language is shown in Table 2.

3 System Architecture

The final MT system in each direction is an ensemble of two NMT models comprising a bilingual model (one for each of the six primary directions) and a multilingual model trained to provide translations for 8 directions (the six primary directions plus English ↔ German). The multilingual system uses a recently proposed multitask framework for training (Wang et al., 2020). We describe the individual systems in Subsection 3.1. This is followed by presenting our system combination techniques in Subsection 3.2. Finally we present the architecture of the submitted system highlighting our design decisions in Subsection 3.3.

3.1 Individual Systems

This subsection describes the individual systems and their training leading to the proposed system combination strategy in the following subsection. We first build bilingual models for the six primary directions using the data shown in Table 1 except the English ↔ German. These serve as baselines to compare to the developed systems. The models use a transformer base architecture comprising 6 encoder and 6 decoder layers and a 24K joint vocabulary built for Bengali ↔ Hindi, a 8K joint vocabulary built for English ↔ Hausa and a 4K joint vocabulary built for Xhosa ↔ Zulu using sentencepiece (Kudo and Richardson, 2018) to learn these subword units to tokenize the sentences. In addition to the baseline bilingual models, we use knowledge distilled (KD) data and back-translated (BT) data generated from a multilingual model to build another set of bilingual models for each of the six primary directions. This multilingual model is described below. The purpose of these models is to participate in the ensemble along with the multilingual models. The latter bilingual models follow the same transformer base architecture and joint vocabulary used in the baseline bilingual models.

The multilingual model combines the 8 translation directions shown in Table 1. These are the six primary directions plus English ↔ German as a helper. The latter is mainly used to improve generation on the English centric directions. The model uses a 64K joint vocabulary constructed using sentencepiece (Kudo and Richardson, 2018) from a subset of the monolingual data of each language as described in Section 2. The transformer model has 12 encoder and 6 decoder layers. In addition, a multitask objective is used during training to make use of monolingual data. The objective comprises the usual parallel data likelihood referred to as MT, a masked language model (MLM) at the encoder and a denoising auto-encoder (DAE) (similar to mBART (Liu et al., 2020)) at the decoder side. The latter two objectives help leverage monolingual data for both the encoder and the decoder sides. The three objectives are combined using different proportions according to a schedule during the training. Please refer to (Wang et al., 2020) for details.

[1] https://fasttext.cc/docs/en/language-identification.html
[2] https://github.com/aboSamoor/polyglot

To summarize we build the following models:

- Bilingual models trained using parallel data in Table 1 for the 6 primary directions. These are mainly used as baselines.
- Multilingual models trained using a multitask objective using parallel and monolingual data and comprising 8 directions.
- Bilingual models trained using KD and BT data generated using our best multilingual model. These are combined with the best multilingual model as described in 3.2.

3.2 System Combination

System combination or ensembling is known to improve the performance over individual systems. There are many ways to create an ensemble (Liu et al., 2018; Dabre et al., 2019). For example, individual models obtained from different checkpoints during the same training or by training models sharing the same vocab and architecture using different data or simply different random seeds can be combined using model averaging techniques. Here, we opt to combine different models since it generally leads to better performance because different models tend to be more complementary. To this end, we propose a simple and effective method to combine completely different architectures. The proposed method could be also used in conjunction with checkpoint and model averaging for further gains, but we haven't tried this in our experiments due to time limitations.

The basic idea of our combination is very simple. Assume we have the translation pair $x \rightarrow y$ where y is the reference translation. The output of model 1 is the pair $x \rightarrow y1$ and the output of model 2 is the pair $x \rightarrow y2$. This can be generalized to multiple systems but we limited our combination to only two models. We train a new model that takes the set of hypotheses (possibly augmented by the source sentence) from the two models to generate the target sentence. Thus this model combines the outputs of two models in the ensemble to produce a translation closer to the original target sentence i.e. $< HYP > y1 < HYP > y2 \rightarrow y$.We also experimented with adding the source to the input i.e. $< SRC > x < HYP > y1 < HYP > y2 \rightarrow y$ which led to around 0.3 BLEU improvement for $Ha \rightarrow En$, but we haven't tried on other pairs due to time limitation. All combination models use 6 layers encoder and decoder and a 64K vocabulary similar to the multilingual system. These combination models use the full bitext and dev data provided in WMT21 as shown in Table 1. The system combination is outlined in Figure 1. This ensembling technique can be thought of as providing both system combination and post-editing capabilities.

3.3 Overall System

Our overall system is depicted in Figure 2. The first module shows the data input where language identification (LID) is used to filter the monolingual data. As mentioned in Section 2.1 we use fastText and polyglot for LID depending on the language. We first build bilingual baselines which are not shown in the figure. Then as shown in the second module, we build 4 multilingual systems using different task objectives as follows: $MT, MT + MLM, MT + DAE$ and $MT + MLM + DAE$ trained on the 8 directions shown in Table 1 following the temperature-based strategy in (Arivazhagan et al., 2019) to balance the training data in different resource languages using T = 5. We pick the best system and use it to back translate the selected monolingual data. For most pairs, as detailed in Section 4, we find that $MT + DAE$ and $MT + MLM + DAE$ are quite close. Therefore, we use the $MT + DAE$ to do back translation for all submitted 6 pairs. We use beam search with beam size = 5 when generating the synthetic back-translated data. Once we get the back-translated data (called BT_1) we add it to our parallel and monolingual data and build a new multilingual model called $MT + DAE + BT_1$. We tag the back-translated data with <BT> tag at beginning of each source sentence so the model can differentiate between the genuine parallel and back-translated data quality. The resulting model is used to regenerate the back-translated data (called BT_2) and to knowledge distill the bitext (called KD). The latter two data sets are augmented and used to build a bilingual system (called $MT + KD + BT_2$). We upsample the KD data set and the upsampling ratio is selected based on parameter sweeping and validating the resulting improvement on the validation set. Finally, the latter bilingual model is combined with our final multilingual model using the method in Section 3.2 to create our submission.

4 Experimental Results

In this section, we describe the results of our intermediate and final systems. We report Sacre-

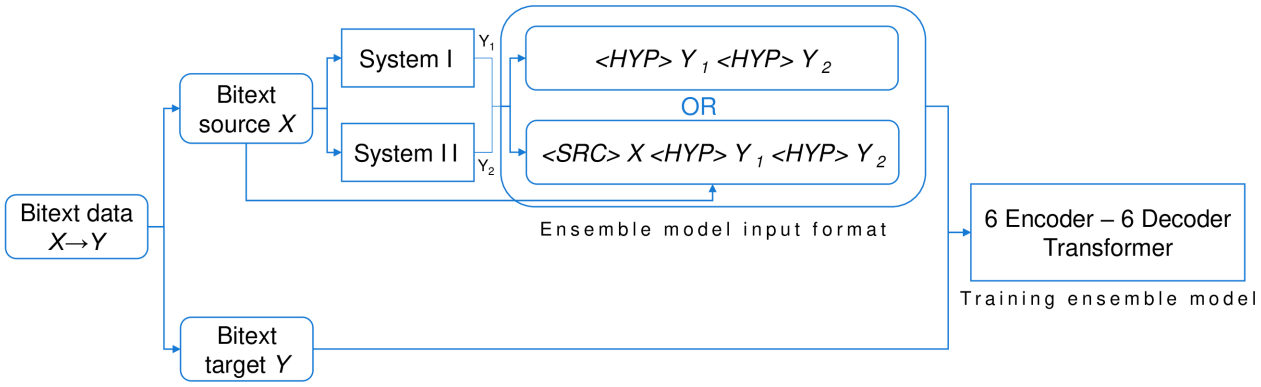

Figure 1: The system combination component used for our experiments.

BLEU (Post, 2018) on the validation set released in WMT21, and both SacreBLEU and COMET (Rei et al., 2020) using the available implementation [3] on the official test set released in WMT21. The results for the six submitted language pairs are in Tables 3-5. The first row in each table shows the bilingual baseline which performs relatively poor due to the limited amount of parallel data for each pair. This is followed by the four multilingual systems with different objectives. It is clear that adding a monolingual objective brings nice improvements for all language pairs. The $MT + DAE$ and $MT + MLM + DAE$ perform closely for all language pairs indicating that target monolingual data is most important. The next two rows show the results of adding back-translated data to the multilingual model and a bilingual baseline using back-translated and knowledge distilled data generated from the best multilingual model. As expected adding back translation brings significant improvement to all language pairs. Also using the multilingual model to create data for a bilingual model shows excellent results that outperform the multilingual model. Finally, the ensemble, as expected, performs better than the individual models. The significant difference between reported improvements in $Ha \leftrightarrow En$ and other directions shows the effectiveness of adding $De \leftrightarrow En$ parallel and monolingual data that helps English centric directions more than other directions. We evaluated the final submitted systems on the official test set released in WMT21 as shown in Table 6.

5 Summary

This paper describes our submission to the constrained track of WMT21. We focus on the three relatively low resource language pairs $Bn \leftrightarrow Hi$, $En \leftrightarrow Ha$ and $Xh \leftrightarrow Zu$. To overcome the limitation of relatively low parallel data we train a multilingual model using a multitask objective recently proposed in (Wang et al., 2020). In addition,

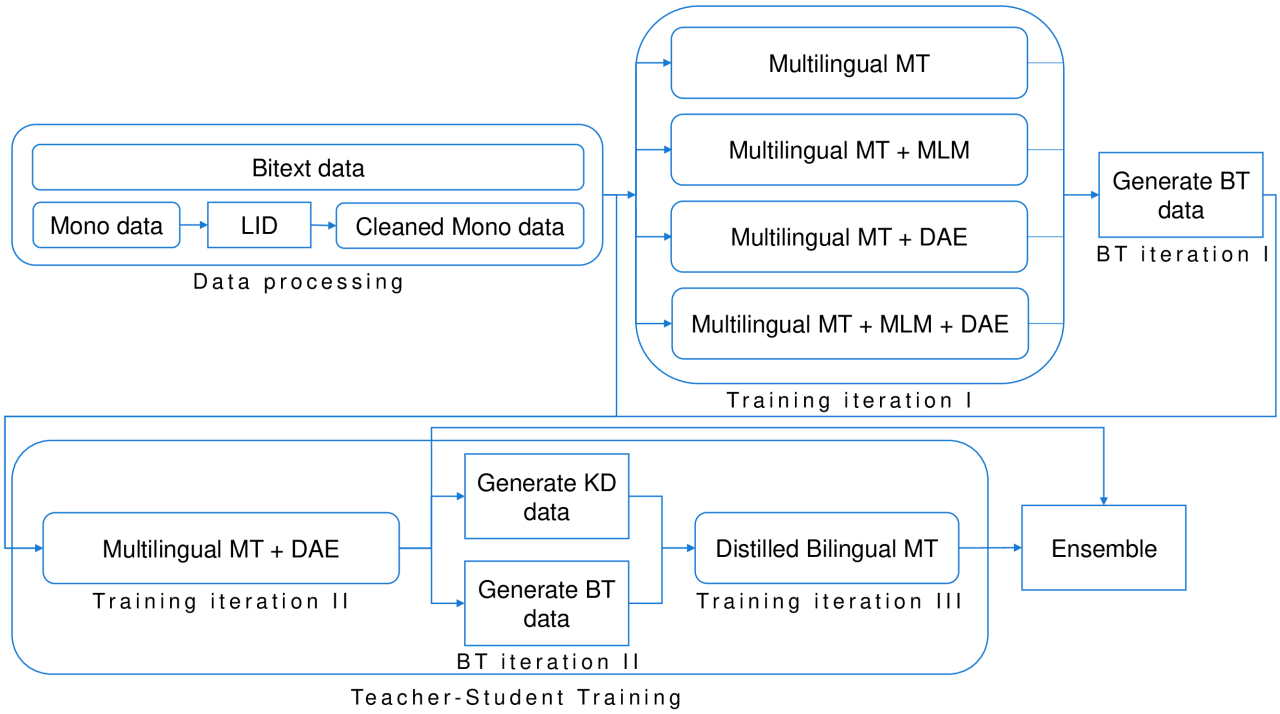

Figure 2: The overall system flow used for our experiments

System	Xh-Zu	Zu-Xh
bilingual baseline	8.00	7.60
multi. MT	7.53	7.47
+ MLM	7.23	7.02
+ DAE	8.53	8.24
+ MLM + DAE	8.20	7.80

Translation direction	BLEU	COMET
$Ha \rightarrow En$	17.13	0.149
$En \rightarrow Ha$	16.13	0.086
$Bn \rightarrow Hi$	21.08	0.532
$Hi \rightarrow Bn$	10.93	0.411
$Xh \rightarrow Zu$	9.94	0.180
$Zu \rightarrow Xh$	9.25	0.299

Table 6: Results of the submitted systems. We report SacreBLEU and COMET scores on the official test set provided in WMT21. For COMET, we use the recommended model "wmt20-comet-da".

we augment the data using back translation. We also use the resulting multilingual model to create a bilingual model incorporating back translation and knowledge distillation. Finally, we combine the two models, using a flexible sequence-to-sequence approach, to yield our submitted systems. We see large gains up to 8-10 BLEU points for $En \leftrightarrow Ha$ and nice improvements of up to 2-3 BLEU points for $Bn \leftrightarrow Hi$ and $Xh \leftrightarrow Zu$.

{haukur, vesteinn, petur, haukurpj, vt}@mideind.is

Abstract

We present Miðeind's submission for the English→Icelandic and Icelandic→English subsets of the 2021 WMT news translation task. Transformer-base models are trained for translation on parallel data to generate back-translations iteratively. A pretrained mBART-25 model is then adapted for translation using parallel data as well as the last backtranslation iteration. This adapted pretrained model is then used to re-generate backtranslations, and the training of the adapted model is continued.

1 Introduction

Our work on machine translation for Icelandic has been going on for a couple of years as a part of the government sponsored Icelandic Language Technology Programme (Nikulásdóttir et al., 2020). By building on state-of-the-art solutions we have developed an open and effective translation system between Icelandic and English.

To achieve this, we collect parallel Icelandic and English texts which are filtered for good quality alignments. We also collect monolingual text for backtranslations. We follow tried and tested methods in neural machine translation using iterative backtranslation (Edunov et al., 2018) and adapt the multilingual denoising autoencoder model mBART-25 (Liu et al., 2020) for translation.

2 Datasets

We used several parallel and monolingual datasets, both publicly available and created in-house.

2.1 Parallel data

The parallel data used are ParIce (Steingrímsson et al., 2020) and the JW300 corpus (Agić and Vulić, 2019). In addition we used a parallel student theses and dissertation abstracts corpus, IPAC, generated in-house and sourced from the Skemman repository[1] as described in (Símonarson and Snæbjarnarson, 2021). A breakdown of the data is shown in Table 1.

Corpus	#Sentences
The Bible	33k
EEA regulatory texts	1,700k
EMA	404k
ESO	12.6k
OpenSubtitles	1,300k
Tatoeba	10k
Jehova's Witnesses (JW300)	527k
Other*	93k
IPAC	64k

Table 1: Parallel corpora used. #Sentences are the number of sentence pairs. *Other** denotes software localizations, Project Gutenberg literature and the Icelandic sagas.

Following (Pinnis, 2018) we apply simple heuristic filters to the parallel data, mainly for capturing OCR and PDF errors, and correcting or removing character encoding errors after deduplication. Filters include but are not limited to: empty sequence removal, length cut-offs, character whitelists, mismatch in case and symbols between languages, edit-distances between source and target, normalizing of punctuation, and ad-hoc regular expressions for Icelandic specific OCR/PDF errors. For a more in-depth description see (Jónsson et al., 2020).

Other potential parallel datasets are ParaCrawl (Bañón et al., 2020) and CCMatrix (Schwenk et al., 2021). Manual review of a couple of hundred randomly chosen lines from ParaCrawl revealed that the data quality is quite low for Icelandic, many lines are machine translated or badly aligned. We therefore did not include ParaCrawl. CCMatrix did not exist when the project started and we have not

[1] https://skemman.is

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 136–139

taken the time to review and integrate it although a quick inspection indicates that the quality is higher than in ParaCrawl.

2.2 Data used for backtranslation

We collected and translated monolingual data for backtranslations, made available in (Símonarson et al., 2020), mostly building on the work in (Edunov et al., 2018). The English sentences (44.7m) are retrieved from the Wikipedia, Newscrawl and Europarl corpora. The Icelandic sentences (31.3m) are sourced from the Icelandic Gigaword Corpus (Steingrímsson et al., 2018).

Lang.	Name	#Sentences
IS	Court rulings	1.8M
IS	Supreme court rulings	2M
IS	Laws	814k
IS	Web of Science	268k
IS	Wikipedia	405k
IS	Parliamentary proc.	6.2M
IS	Misc	350k
IS	Newspaper (Mbl)	13.6M
IS	Newspaper (Visir)	4.9M
IS	Radio transcripts	1M
EN	Newscrawl	33.4M
EN	Wikipedia	9.3M
EN	Europarl	2.0M

Table 2: Monolingual data used for backtranslation.

3 Training of small transformer models

Our earlier models were trained using the transformer-base configuration described in (Vaswani et al., 2017) as implemented in Google's Tensor2Tensor (TensorFlow-based) (Vaswani et al., 2018) library. For later models we switched to Facebook's Fairseq (Ott et al., 2019) library. An improved translation task was implemented in Fairseq to include BPE dropout; it is available in the `greynirseq`[2] library.

The transformer-base models were trained iteratively and used to generate new backtranslations. We stopped when each language direction had been trained on backtranslations that were produced by a model that had itself seen backtranslations at training time. We compared tagged and untagged backtranslations, sampling versus beam search and different mixing ratios (upsampling rate) between parallel and backtranslated data. Using tagged backtranslations as opposed to no tag showed an improvement from 16.5 to 17.5 BLEU[3] after the first iteration over the IPAC development set, while using no backtranslations gave 15.0, so we proceeded to use tagged translations.

Model	BLEU
Transformer-base	16.5
Transformer-base + bt	17.5
Transformer-base + iterative-bt	18.5
mBART (first run)	23.1
mBART (continued)	23.6

Table 3: BLEU scores over IPAC for the EN-IS direction.

We use the IPAC test set to measure BLEU since it was available, has a large range of topics (although maybe not a large range of style) and is very unlikely to be accidentally included in the training data. The IPAC data is out of distribution with the rest of the training data but we do not consider that to be a problem since our goal is a general purpose model. The WMT dev set did not exist at the time.

We used a joint BPE vocabulary of size 16k and shared input-output embedding matrices. We pretokenized the input using `tokenizer` [4] for the Icelandic side and spaCy (Honnibal et al., 2020) for the English side. A beam width of 4 was used for beam search during backtranslation. Each training iteration took approximately one week on a single GTX 1080 graphics card. We were pleasantly surprised with how far we got with only this modest hardware.

3.1 Translation mixing ratio selection and beam noise

We assessed the impact of the ratio of synthetic backtranslation data to authentic parallel data on translation performance. Best results were obtained with a 1:2 ratio of authentic to synthetic data, using IPAC (held out from training) for evaluation.

For noising the backtranslation beam outputs, we follow (Edunov et al., 2018) and used within-k permutation of whole words (with k=3), whole-word masking, and word dropout. Using sampling and noised beam outputs yielded comparable results.

4 Adapting mBART-25 for translation

The mBART-25 (Liu et al., 2020) (610M parameters) language model is far larger than the Transformer-base model (110M parameters). It was pretrained on 25 languages, including English and Swedish, but not Icelandic. We adapt it for translation from Icelandic to English and vice versa, using the same human-derived parallel translation data as for the transformer-base model along with the synthetic backtranslated corpus in a ratio of 1:2. We do not use any pre-tokenization and inherit the BPE sententencepiece vocabulary from mBART-25 (of size 250k) with the addition of an Icelandic language marker that was randomly initialized. We use the same hyperparameters as in (Liu et al., 2020) and the implementation from Fairseq (Ott et al., 2019). The models are trained until their performance on the development sets plateaus.

The initial learning rate was set to 3e-4. Sixteen 32GB nVidia V100 GPUs connected with Infiniband were used for training. The effective batch size was around 10k sequences and the training took around 4 days of wall clock time per model.

Subsequently, these trained models were used to generate improved backtranslations. We then continued training the first iteration of our models with the new backtranslated data for another 30,000 steps for the Icelandic-English direction, and 36,000 steps for the English-Icelandic direction. The same training configurations were maintained as for the earlier runs.

Dir.	Steps	'21 test	'21 dev	EEA
En-Is	40k	22.7	25.9	54.5
En-Is	40k + 36k	24.3	27.8	57.6
Is-En	36k	32.9	30.4	61.0
Is-En	36k + 30k	33.5	31.8	63.2

Table 4: BLEU scores for the mBART-25 adapted translation models over the newstest2021 and EEA evaluation sets.

The benefit of continuing training of the mBART-derived models ranges from 0.6 to 3.1 BLEU as shown in Table 4. BLEU performance is shown for both the newstest2021 development set as well as our cleaned-up dataset with sentence pairs from the EEA regulation corpus. Note that we do not fine-tune prior to evaluation nor do we perform checkpoint averaging.

5 Conclusion

We have shown how a small team with modest resources can adapt state-of-the-art methods to a medium resource language and achieve competitive results on machine translation between English and Icelandic.

The trained models are available for translation at `https://velthyding.is` and will be made available at the open `CLARIN-IS`[5] repository. While a formal human comparison of the current models to the popular Google Translate service has not been performed, hundreds of monthly active users choose our solutions for translation between Icelandic and English.

6 Future work

We note the relatively small training time of the mBART adaptation and the lack of Icelandic data in the pretraining task for mBART as primary factors that can be addressed for improving results. Additionally online (or semi-online) self-training instead of train-then-translate would also improve results, especially with selective loss truncation as described in (Zhou et al., 2021). The data selected for backtranslation should also be expanded for greater diversity of both genre and vocabulary. Finally, extending the translation context beyond the current sentence level is likely to improve results.

Acknowledgements

We would like to thank Prof. Dr.-Ing. Morris Riedel and his team for providing access to the supercomputer at Forschungszentrum Jülich where the mBART-25 translation models were trained.

This project was supported by the Language Technology Programme for Icelandic 2019–2023. The programme, which is managed and coordinated by Almannarómur, is funded by the Icelandic Ministry of Education, Science and Culture.

Abstract

This paper describes Allegro.eu submission for the WMT21 news translation shared task. We focus on exploring data filtering and data augmenting methods. We submitted two single-directional models, one for English→Icelandic direction and other for Icelandic→English direction. Our news translation system is based on the transformer-big architecture, it makes use of corpora filtering, back-translation and forward translation applied to parallel and monolingual data alike.

1 Introduction

We participated in the WMT21 news translation shared task for English↔Icelandic language pair. It is a medium-resource regime with under 10M parallel sentences. In our experiments we focused on two approaches for improving translation system: data filtering methods inspired by work of (Jónsson et al., 2020) and data augmentation methods like back-translation or self-training (Edunov et al., 2018; Sennrich et al., 2016; He et al., 2019). We tried to use bi-directional translation models but single-directional proved to be better. We also tried to make use of pretraining on monolingual corpora, but it also was unsuccessful. Krubiński et al. (2020) showed in their ablation study that pretraining is the most successful for low-resource regimes under 1M parallel sentences.

2 Data

2.1 Data Preprocessing

We removed malformed utf-8 encodings, normalized text with NFKC Unicode normalization form, unescaped HTML, removed control characters and converted different whitespaces to a basic space character.

2.2 Data Filtering

We took part in a constrained track for the English↔Icelandic language pair for the news translation task. We used similar heuristic for filtering monolingual and parallel data. A proper sentence pair should fulfil these criteria:
For each sentence separately:

- length in chars $\in (10, 500)$
- length in words $\in (2, 100)$
- average word length in chars < 12
- max word length in chars < 28
- digit ratio < 0.15
- outside alphabet ratio < 0.015
- language detection probability > 0.9

Criteria calculated on a sentence pair:

- no digit sequence mismatch
- Levenshtein distance > 5
- Poisson based length logprob $>$ -10

For language identification we used the CLD2 library. We arrived at these threshold values by analyzing outliers of clean corpora: newsdev2021 development dataset and Jónsson's cleaned ParIce corpus (Jónsson et al., 2020). Our filtering procedure is inspired by Jónsson's and extracts 72% of the same sentences they extracted from the raw ParIce corpus (Barkarson and Steingrímsson, 2019). Each heuristic removes up to 5% of lines from those clean corpora, when all thresholds would be applied they would remove around 9% from the cleaned ParIce corpus. For all available raw parallel corpora this procedure would remove 35% of sentences. Table 1 shows sizes of raw and filtered corpora available in the constrained track.

2.3 Poisson based length filtering

This section describes an improved method of filtering sentences based on their lengths. A simple ratio of sentence lengths is a common method, but it is often too strict for short sentences and too loose

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 140–143
November 10–11, 2021.

Parallel corpora	raw	filtered	left
ParIce.1_1	3.56M	1.98M	0.56
ParaCrawl.7_1	2.39M	1.95M	0.81
WikiMatrix.1	313k	177k	0.57
wikititles.3	50k	2k	0.04
Total	6.31M	4.1M	0.65

Table 1: Sizes of parallel corpora.

for longer ones. We are using a simple assumption, that the distribution of lengths of expected translation is given by the Poisson distribution with a mean equal to a length of the source sentence. This type of length filtering is used by bicleaner framework (Sánchez-Cartagena et al., 2018). We use a correction factor $scl = 1.04$, which is a ratio of chars in the English side to the Icelandic side for the whole parallel corpus. We multiply source length by it or by its reciprocal before calculating probabilities, depending on the context. Figure 1 compares this method with a ratio-based heuristic where the allowable ratio range is $(0.5, 2)$. For this language pair the correction factor is close to 1.0, but for other language pairs it can deviate more, which can lead to bias when using a simple ratio-based heuristic.

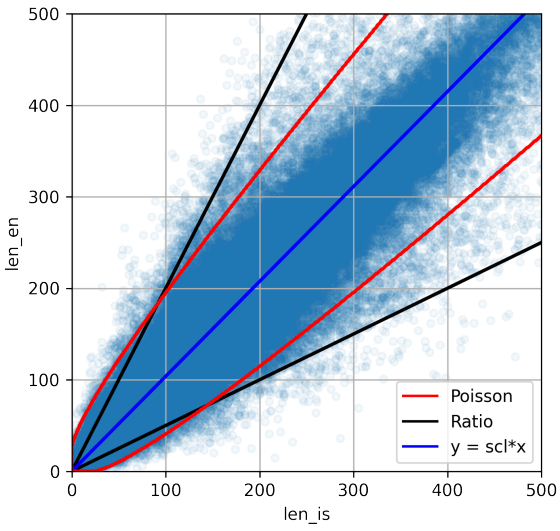

Figure 1: Distribution of lengths of parallel corpora. As depicted, Poisson-based heuristic allows more variation for shorter sentences and lower variation in length for longer ones.

2.4 Translation postprocessing

Our system has a tendency to generate the same quotation as in source text. Therefore, before submitting our translations for evaluation, we applied simple regular expressions to fix quoting. We made sure that only (" ") for English submission was used and for Icelandic we made sure that („ “) was used.

3 System overview

All of our models are based on the Transformer big architecture, as described in Vaswani et al. (2017). For training we used OpenNMT-py framework (Klein et al., 2017) together with sentencepiece tokenizer (Kudo and Richardson, 2018) unigram model of size 32k with full character coverage. We trained models on A100 GPU for 210k steps with a batch of 8192 tokens which amounts to around 12h per model. We used half-precision and tied embeddings. For optimization we used Adam (Kingma and Ba, 2014), with a linear warmup for learning rate for 15k steps up to 0.0005 and inverse square root decay afterwards. Additionally, all of our models were randomly initialized.

4 Results

Results are presented in Table 3. We trained a tokenizer on a cleaned ParIce corpus. A baseline model we trained on all available parallel corpora and achieved 18.1 BLEU in English→Icelandic direction and 24.0 BLEU in Icelandic→English direction.

4.1 Data filtering impact

We ran 4 variants with the same parameters as described at the beginning of section 3, but only for 100k steps. We compared the translation quality of models trained with filtered training corpus and the impact of cleaning data used in training tokenizer. We used the aforementioned cleaned ParIce corpus (Jónsson et al., 2020) to train the tokenizer. Table 2 presents the results of this comparison.

4.2 Back-translation of monolingual corpora

We took 10M monolingual sentences for each language and filtered them as described in section 2.2. For English we took only News Crawl from 2020, for Icelandic we used News Crawl 2020 and also Icelandic Gigaword to obtain full 10M sentences. We translated the English source to Icelandic, then translated it back to English. Then we compared those second translations to source by GLEU score

	clean tokenizer	raw tokenizer
clean corpus	16.6/22.6	14.0/19.4
raw corpus	16.2/22.2	14.2/18.9

Table 2: Comparison of impact of filtering data. Values reported are BLEU scores for en→is/is→en direction for newsdev2021. We can easily see that training tokenizer on clean data has a big impact. Also we can notice that removing 35% of parallel corpora can improve the quality of the model given the same amount of compute.

(Wu et al., 2016) and filtered the best 40% of pairs of original source and first translation based on that. GLEU score is a variation on the BLEU score. It is claimed to be a more accurate measure of single sentence translation quality. We repeated this procedure for 10M Icelandic monolingual sentences. It is interesting to note that 4.4% and 2.0% of second translations were the same as the original source, for English and Icelandic respectively. We then created English biased corpus which consisted of:

- 4M of clean parallel corpus
- 4M of English based back-translation where we used original source as target
- 4M of Icelandic base forward translation where we used our first translations as target

Then we used this corpus to train a new model, it achieved 26.8 BLEU in Icelandic→English direction.

4.3 Back-translation of parallel corpora

We used this newly acquired model to translate the Icelandic side of clean parallel corpus to English and likewise filtered by GLEU score for the English side of the corpus, finally we extracted 75% of most similar pairs. It is interesting to note that 11% of translations were the same as the English side of the parallel corpus. We then created a corpus for training English→Icelandic model, this time with typical setup for back-translation where original sentences were used as a target:

- 4M of clean parallel corpus
- 4M backtranslated monolingual corpus
- 3M backtranslated parallel corpus

Then we used this corpus to train a new model. It achieved 23.6 BLEU in English→Icelandic direction and that was our final model for this direction.

	newsdev2021	
Model	**En→Is**	**Is→En**
baseline	18.1	24.0
BT and FT mono	-	26.8
BT mono and parallel	23.6	-
BT mono and parallel	-	27.2
final models	23.6	27.4
	newstest2021	
final submission	22.7	33.3

Table 3: Comparison of forward-translation (FT) and back-translation (BT) model trained on monolingual and parallel corpora

Then, analogously, we used this model to translate the other side of the clean parallel corpora and filter by GLEU score. It is interesting to note that also 11% of translations was the same as the Icelandic side of the parallel corpus. We then created a corpus and trained Icelandic→English model which achieves 27.2 BLEU on the development set. For this direction our final system was an ensemble of this new model and previous best.

4.4 Denoising

As it has been recently demonstrated by Raffel et al. (2020), transfer learning can be successfully applied to sequence-to-sequences models. Therefore, we tried doing unsupervised de-noising pre-training based on provided monolingual data. We experimented with three different denoising schemes:

- Token-based masked language modeling (Devlin et al., 2019)
- Whole Word Masking objective inspired by BERT models released in May 2019
- BART-like denoising with text infilling and sentence permutation (Lewis et al., 2020)

We tried it in two regimes. One where we pretrain model and then finetune it on translation downstream task. The other where we train both denoising and translation objectives simultaneously. However, we didn't observe any benefits from doing this. The reason for this is unknown.

5 Conclusion

This paper describes Allegro.eu submission for the WMT21 news translation shared task. We took part in constrained track for the English↔Icelandic language pair only. Participation in this task allowed

us to deepen the understanding of filtering methods common in NMT. The experiments demonstrated the importance of data filtering in medium-resource regime machine translation. In this regime, less data but of higher quality can lead to superior results.

Abstract

This system paper describes an end-to-end NMT pipeline for the Japanese ↔ English news translation task as submitted to WMT 2021, where we explore the efficacy of techniques such as tokenizing with language-independent and language-dependent tokenizers, normalizing by orthographic conversion, creating a politeness-and-formality-aware model by implementing a tagger, back-translation, model ensembling, and n-best reranking. We use parallel corpora provided by WMT 2021 organizers for training, and development and test data from WMT 2020 for evaluation of different experiment models. The preprocessed corpora are trained with a Transformer neural network model. We found that combining various techniques described herein, such as language-independent BPE tokenization, incorporating politeness and formality tags, model ensembling, n-best reranking, and back-translation produced the best translation models relative to other experiment systems.

1 Introduction

Despite recent advances in machine translation made possible by neural networks with attention mechanism (Bahdanau et al., 2014; Luong et al., 2015), the Japanese-English pair remains a challenging language pair for machine translation systems to handle. Challenges posed by this language pair are multifaceted, starting from seemingly trivial differences in orthographic representations to deep structural divergence in syntax. This paper describes an end-to-end neural machine translation system and related experiments dedicated to the News Translation Shared Task where the target language pair is Japanese ↔ English, as part of a submission to the Sixth Conference on Machine Translation - WMT 2021. In our experiments, we explored the efficacy of techniques such as tokenizing with language-independent and language-dependent tokenizers, normalizing by orthographic conversion, creating a politeness-and-formality-aware model by implementing a tagger, back-translation, model ensembling, and n-best reranking. We found that normalizing the text by orthographic conversion did not improve over the baseline but controlling for politeness and formality levels of the text increased BLEU by 1.2 points for the En→Ja direction, and other techniques such as back-translation, model ensembling, n-best reranking also produced improvements.

The paper gives a detailed review of prior work, with a particular focus on WMT 2020 submissions, and then proceeds to describe our data, model architecture, experiments, results, and discussion of their implications.

2 Prior Work

In this section, techniques and development in neural machine translation will be reviewed with a focus on the techniques and implementation most recently used for the Japanese-English language pair. General techniques deployed across papers submitted to WMT 2020 are bitext data filtering, back-translation, fine tuning with in-domain data, knowledge distillation, rule-based reranking, transfer learning, co-reference processing, hyperparameter search, segmenting by subword units, BPE dropout, model ensembling, pre-training with monolingual data, experimenting with different word segmentation methods, context word embedding, domain adaptation, using related languages in joint training, domain tagging, reranking using backward and forward scores, and dual conditional cross-entropy filtering

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 144–153
November 10–11, 2021.

(Barrault et al., 2020). In subsequent subsections, representative methods and techniques will be described and the impacts of these methods presented, in so far as they are applicable to the Japanese-English pair.

2.1 Data Preprocessing

Data filtering, cleaning, and normalizing are essential steps in an NMT pipeline, due to the noisy nature of text corpora. A cursory glance at some of the given parallel corpora shows that our data could benefit from additional filtering and cleaning. For instance, the Paracrawl corpus contains a fair amount of duplicates or near duplicates and about 6 percent of the WikiMatrix corpus contains texts outside the source and target language.

Previous submissions to WMT 2020 utilized a mix of language-independent and language-dependent data preprocessing methods to prepare the corpora for training. Researchers also noted a few issues in the parallel corpora requiring special attention; for example, Kiyono et al. (2020) remarked that their translation output contains additional transliteration in brackets after names already transliterated into *katakana*, because these patterns are very common in the KFTT training corpus. They advised that this issue be handled during preprocessing, because postprocessing clean-up, while possible, tended to hurt brevity (Kiyono et al., 2020). Following this suggestion, we incorporated a preprocessing step (described in section 3) to handle these patterns.

2.2 Tokenization

Tokenization is an indispensable step in many natural language processing (NLP) applications. Byte-Pair-Encoding (BPE) by Sennrich et al. (2016c) is a popular compression algorithm that takes care of splitting words into subword units based on how frequent these units are. The main idea of BPE is to recover smaller subwords that are recurring in fuzzy 'word' boundaries in order to compress the vocabulary and decomposes rare words into known subwords. BPE is an effective solution to the issue of rare words, open vocabulary, and agglutinating morphology in some languages. The algorithm works by splitting all words into individual characters, adding them to a vocabulary, and then iteratively merging the most frequency subword pairs and adding them to the vocabulary.

Kudo and Richardson (2018) implemented BPE in SentencePiece, an unsupervised toolkit for word segmentation. A language-agnostic tokenizing and detokenizing algorithm that implements subword unit BPE (Sennrich et al., 2016c) and unigram language model (Kudo, 2018) to tokenize the data, SentencePiece also provides a convenient interface to quickly tokenize and detokenize the data, because its implementation of BPE treats the sentences as sequences of Unicode characters, does not rely on language-dependent logic, and allows training from raw texts. The developers of SentencePiece experimented their toolkit with and without pre-tokenization for an English-Japanese translation task, and found that the performance of training on raw texts is comparable to training with pre-tokenization.

Previous submissions to WMT 2020 are divided when it comes to which method was preferred for tokenization. Three submissions (Kiyono et al., 2020; Oravecz et al., 2020; Marie et al., 2020) used SentencePiece and three submissions (Kim et al., 2020; Shi et al., 2020; Zhang et al., 2020) used language-specific tokenizers to preprocess Japanese (MeCab) and English (Moses) corpora. MeCab is a popular lattice-based tokenizer for Japanese. It builds a graph-like data structure to hold possible tokens in the text and then uses the Viterbi algorithm to find the best path through the graph. Moses is a well-known statistical machine translation toolkit; its perl scripts are often used to preprocess English corpora for NMT training (Koehn et al., 2007). We experimented with both SentencePiece and language-dependent tokenizers prior to submission. The details will be outlined in section 5.1 of this report.

2.3 Model Architecture

Most of the papers submitted to WMT 2020 used the Transformer Big settings described in Vaswani et al. (2017) for their NMT model architecture (Marie et al., 2020; Kiyono et al., 2020; Shi et al., 2020; Oravecz et al., 2020; Zhang et al., 2020).

Prior to the publication of *Attention is All You Need*, prominent approaches to sequence-

to-sequence modeling include recurrent neural networks, long short-term memory (Hochreiter and Schmidhuber, 1997), and gated recurrent neural networks. All of these approaches suffer from computational bottleneck due to their sequential nature, which prevents parallelization within training examples. The Transformer did away with convolution and recurrence and focused on attention mechanisms, allowing for modeling of long-distance dependencies in parallel. Subsequently, it has been proven to be very successful at handling long distance dependency in natural language, as it allows the model to focus attention on particular source tokens via computation of an attention score. The attention score can be determined by way of different methods, such as a (scaled) dot product (implemented in Vaswani et al. (2017)), bilinear functions, or multi-layer perceptrons. The Transformer achieved state-of-the-art results in English ↔ French and English ↔ German translation tasks while cutting down on training time thanks to parallelization.

2.4 Back-Translation

Back-translation is a commonly used method in NMT to augment bitext training data by creating an additional synthetic parallel corpus from monolingual corpora (Sennrich et al., 2016b). To create back-translated data, a model that translates from target to source is required. First, a monolingual corpus of the target language is used to obtain translations in the source language. Subsequently, this monolingual corpus and the translated synthetic data are appended to the original training data to train the source to target model. It is ideal to have a lower ratio of synthetic data to parallel corpus in training the desired model. As the amount of bitext corpora available for the Japanese-English pair is well under 20 million sentence pairs, Japanese-English can be considered to be a medium-resource language pair and additional back-translated data could help improve translations. It should also be noted that there are limited domain-specific corpora for the language pair, and adding additional synthetic data back-translated from NewsCrawl and NewsCommentary may help augment the models.

2.5 Model Reranking

Zhang et al. (2020) implemented model reranking following Ng et al. (2019). N-best reranking scores and chooses a translation hypothesis from a list of n-best hypotheses. This method is based on a noisy channel model and Bayesian theorem of conditional probability in log scale, where the weight parameters are learned from fine tuning a validation set. For decoding, they used beam search to generate an n-best candidate list and chose the candidate hypothesis that maximizes the objective conditional probability as the best hypothesis.

Besides the noisy channel approach, reranking can be done using various criteria, such as distortion score, word penality, phrase penality, and so on. Shi et al. (2020) generated n-best candidates by model ensembling of forward translation models, backward translation models, and language models of the target language and then apply K-batched MIRA (Cherry and Foster, 2012) or noisy channel (Yee et al., 2019) to score them. Kiyono et al. (2020) generated n-best candidates from Source-to-Target L2R, R2L models, Target-to-Source L2R, R2L models, Unidictionary Language models, and Masked Language models to compute the scores for reranking.

We reranked translation hypotheses using perplexity as a criteria.

3 Data

Our system was trained, developed, and tested fully on data provided by the WMT 2021 organizers, making it a constrained submission. Details of the raw parallel corpora prior to substantial filtering[1] used in our baseline and experiment models can be viewed in Table 1.

We used the WMT 2020 development and test sets to compare various experiment models against the baseline: 1998 sentences in the development set in both directions, 1000 test sentences for the En→Ja direction, and 993 sentences for the Ja→En direction.

From the raw datasets, we applied data filtering to remove noisy data based on two main criteria, alignment confidence and language

[1]The original raw WikiMatrix corpus contains 3.8M sentences. We obtained 3.6M after eliminating sentence pairs that do not have the correct language codes in the corpus. That is the only filtering applied to the bitext corpora in Table 1

Corpus	Sentences (M)
JParacrawl 2.0	10.12
News Commentary v16	0.0019
Wiki Titles v3	0.757
WikiMatrix	3.6448
Subtitle Corpus	2.8013
KFTT	0.4438
Ted Talks	0.4462
Total	**18.215**

Table 1: Size of parallel corpora before filtering

Hyperparameters	T-Base	T-Big
Encoder layers	6	6
Decoder layers	6	6
Hidden layers	8	16
RRN	512	1024
d_{ff}	2048	4096
Dropout	0.1	0.3
Optimization	Adam	Adam
Decay	noam	noam
Learning rate	0.2	0.2
Warmup steps	8,000	8,000
Train steps	20,000	300,000

Table 2: Model Hyperparameters

identification. An alignment score is available for both JParacrawl and WikiMatrix corpora; we chose 0.6 and 1.0 as the threshold for alignment confidence in JParacrawl and WikiMatrix respectively. We used fasttext (Joulin et al., 2017) and its pre-trained language identification model to identify the language of our text sentence-by-sentence, and then we filtered sentence pairs where the language identification confidence score is less than 0.8. We also applied on-the-fly filtering of sentences longer than 100 tokens during training.

According to Kiyono et al. (2020), the KFTT corpus contained instances of having Japanese names followed by its English equivalent in parentheses, which caused their model to append English names after the Japanese name in the translation output, for example キャシディ・ステイ (Cassidy Stay). To avoid this, we filtered out English translations of names in Japanese source text, specifically WikiMatrix and KFTT, so that any English names in parentheses following its Japanese equivalent were removed. For English, we normalized punctuation and remove non-printing characters using the Moses scripts (Koehn et al., 2007). The amount of parallel training data after filtering was 12.7 M for training our submission models.

4 Model Architecture

We trained the parallel corpora using the Transformer base and Transformer big settings as described in Vaswani et al. (2017), presented in Table 2. Pre-submission experiments were trained under the Transformer Base setting while all submission models were trained under the Transformer Big setting. We used the same optimization settings in the Transformer big model as in the Transformer base model. We utilized the OpenNMT toolkit (Klein et al., 2017) with a Pytorch backend to train our models. Most submission models took about 7 days to train on one single NVIDIA GeForce GTX 1080 GPU under the Transformer Big setting.

5 Experiments

5.1 SentencePiece and Language-Dependent Tokenizers

We compared two methods of tokenization for our system. The first is a tokenization method based on BPE and SentencePiece, as described in 2.2. We used SentencePiece (Kudo and Richardson, 2018) to train SentencePiece models for Japanese and English with 32,000 as the vocabulary size. SentencePiece is used to create a tokenizer that depends on subword units, similar to Byte Pair Encoding (BPE). This method of tokenization is especially effective for languages such as Japanese which does not use whitespace to separate words, has agglutinating morphology, and contains many compound words. Using SentencePiece helps extract subwords within compound words and create a more robust tokenizer. The tokenizer model was used with OpenNMT, which performed tokenization on-the-fly. SentencePiece was used again to detokenize by removing the meta symbols from the output translation.

The second tokenization method that we experimented with is language-dependent. We tokenized English using Moses, following the steps described in Hieber et al. (2018), namely normalizing punctuation in the

raw data with normalize-punctuation.perl, removing non-printing characters with remove-non-printing-char.perl, and tokenizing by tokenizer.perl.

For Japanese, we tokenized the data with *fugashi* (McCann, 2020), a Python wrapper of the MeCab morphological analyzer described in 2.2. After tokenization, we applied BPE (Sennrich et al., 2016c) on both Japanese and English with 25,000 merge operations to constrain the vocabulary size.

For this comparison, we used a mid-sized corpus to save time and resources instead of the full 18M corpus. The number of sentences after filtering and preprocessing is 6.4M sentences. We trained the models using the Transformer Base settings, as described in Table 1.

5.2 Normalizing by Orthographic Conversion

The Japanese writing system uses a combination of three distinctive orthographic scripts: *kanji*, *hiragana*, and *katakana*. *Kanji* are Chinese characters, used to write content words such as nouns, verb stems, adjectives, and so on. *Hiragana* was derived from *kanji*. It is a phonetic syllabary, typically used to write conjugational endings, particles, and grammatical words. *Katakana*, also a phonetic syllabary much like *hiragana*, is typically reserved to write foreign words, loan words, or strengthen the emotive content of the texts. In modern times, the Latin alphabet also has increased visibility due to the popularity of English, and the Japanese language can be transliterated using this alphabet as well. This way of writing Japanese is called *romaji*.

We were interested in examining if converting the raw training texts to other orthographic scripts such as *hiragana* and *romaji* affects the translation quality of the output. Because *hiragana* and *katakana* have a one-to-one correspondence, it sufficed to experiment with either one of them. Converting the raw text to *hiragana* has a normalizing effect as what it does is reducing the logographic/ideographic *kanji* characters to their pronunciation, the moraic units written in the *hiragana* syllabraries. In that sense, it helps reduce variability in the data and perhaps is beneficial. However, normalizing also strips the text off many contextual cues that would be helpful in translation. The dispersion of *hiragana* in between the content words written in *kanji* is arguably systematic enough for our model to learn that one is used to represent grammatical particles and the other is used to represent objects, names, actions, and so on. Similarly, converting the raw text to *romaji* has a normalizing effect at the quasi-phonemic level. In a related manner, Du and Way (2017) looked at how a model trained on *pinyin* performed on a Chinese → English translation task. They found that using *pinyin* can help alleviate the problem of rare words, although it can introduce ambiguities.

To investigate the question of what impact normalizing the Japanese source text in *hiragana* and *romaji* does, we experimented training three Ja→En models where the source text is written in three orthographic scripts, the regular mixed style (baseline), the normalized moraic level *hiragana*, and the normalized quasi-phonemic level *romaji*. Each training corpus contained 4M sentence pairs, after being filtered by setting the language identification score threshold at 0.85 and sampled. The data were preprocessed with SentencePiece and trained under the Transformer Base setting, as described in Table 1.

5.3 Politeness and Formality Tagger

Previous work showed that controlling politeness levels has a positive impact on machine translation systems. Feely et al. (2019) implemented a formality-aware tagging method for En→Ja NMT. The authors classified formality levels into three categories (informal, polite, and formal) and found that using a heuristics-based tagger improved the system's performance. Similar to Feely et al. (2019), Sennrich et al. (2016a) and Yamagishi et al. (2016) improved on the stylistics of the output (politeness and honorific forms, respectively), by applying a side-constraint approach where target and source suffixes were added during training to add more meta-textual information to the corpora. We tested the effectiveness of this technique on an En→Ja translation system.

The news genre is frequently written in fairly formal Japanese. Makino (2008) described politeness and formality in Japanese as orthogonal concepts. It's possible to use polite

but informal language in daily polite conversations as well as formal language devoid of polite conjugations such as in news articles, academic papers, and so on. While the given parallel corpora are generally of the latter type, the subtitles corpus contains mostly colloquial language and the Ted talks corpus contains polite endings not intended to be used in news articles.

Due to the presence of mixed writing styles in the training data, we developed a politeness and formality tagger that works in conjunction with the Kytea tokenizer (Neubig, 2011) to address this issue, because we observed that our initial translation outputs often contained polite forms not commonly used in the news genre. Makino (2008) notes that verbs and i-adjectives have distinct forms for plain and polite but do not have distinct forms to indicate the formality levels because the same forms are used in both non-formal and formal writings. Furthermore, the copula *da* conjugation is critical to indicate formality. The tagging schema developed in Feely et al. (2019) combines the formal, plain form *dearu* into the polite category, and the formal category is what is typically referred to as *keigo* (honorifics). Our tagging schema is tailored towards the news corpus where *dearu* features often as a marker of formal writing while polite endings and *keigo* do not typically surface (see Appendix A for the detailed schema). Our tagger extracts the verb endings from the annotated sentences returned by Kytea and appends a <polite> or <formal> tag to the beginning of the source (English) side. Plain forms are left untagged as they are the default forms in the news genre.

Applying this tagger on a 12.7M training corpus results in 34.76% tagged as polite and 3.81% tagged as formal. We tokenized the data using SentencePiece transforms, implemented in the OpenNMT toolkit. We also filtered out sentence pairs longer than 100 tokens. We trained the models using the Transformer Big settings, as described in Table 1.

5.4 Back-Translation

For back-translation, we preprocessed a subset of 4M sentences from the monolingual Newscrawl corpus in the same manner described in 3. The filtered corpus was 3,344,628 lines each. We then used the previously trained Ja→En and En→Ja model to translate the monolingual data to create synthetic data, setting a beam size of 1 during decoding. We obtained 2.4M and 2.6M sentences of Japanese and English synthetic data from back-translation, respectively. This was combined with the existing parallel data to create a corpus of approximately 15M sentences.

5.5 Model Ensembling and N-Best Reranking

For n-best reranking, we used a script by Xu Song, `bert-as-a-language-model`[2], which calculates the probability of tokens and perplexity of sentences given a corpus. Using OpenNMT's option to produce n-best translations from an emsemble of several high-performing checkpoints, we created 10 best translations, and used `bert-as-a-language-model` to pick the hypothesis with the best perplexity score. This method ensures the selected hypothesis has maximized fluency compared to other candidates.

6 Results and Discussion [3]

6.1 SentencePiece and Language-Dependent Tokenizers

We obtained the BLEU scores in Table 3 for our models. The comparison is not entirely fair because the amount of data trained for the Moses and *fugashi* tokenizer to translate in the Ja→En direction is 7.3M instead of 6.4M like other models. Additionally, the number of BPE merge operations learned for the language-dependent tokenizer case should have been set to the same as that of SentencePiece for a more equitable comparison.

Using SentencePiece appears to yield better BLEU result in this experiment; however, we also did not keep the other factors constant across the different models under comparison.

[2]https://github.com/xu-song/bert-as-language-model

[3]Please note that the baseline models for experiments vary, as some experiments related to data preprocessing such as tokenization method and normalizing by orthographic conversion were conducted very early on in our project. These models were also trained under the Transformer Base setting, unlike later models trained under the Transformer Big setting. It follows that the baseline results vary from experiment to experiment, except for the tagger and back-translation experiments, where the same En→Ja baseline was used.

Tokenizer Models Ja→En	BLEU
SentencePiece	14.0
Moses and *fugashi*	9.9
Tokenizer Models En→Ja	**BLEU**
SentencePiece	16.0
Moses and *fugashi*	9.9

Table 3: Tokenizer Comparison

Orthographic Scripts Ja→En	BLEU
Mixed scripts (baseline)	14.2
Hiragana	12.6
Romaji	12.8

Table 4: Orthographic Script Comparison

Models En→Ja	BLEU	chrF
Baseline	18.6 ±0.8	28.4 ±0.7
With tagger	19.8 ±0.8	29.5 ±0.7

Table 5: Politeness-and-Formality-Aware Model vs. Baseline

Models En→Ja	BLEU	chrF
Baseline	18.6 ±0.8	28.4 ±0.7
With BT data	18.8 ±0.8	28.8 ±0.7
Models Ja→En	**BLEU**	**chrF**
Baseline	17.0 ±0.8	44.7 ±0.8
With BT data	18.7 ±0.8	46.6 ±0.8

Table 6: Back-Translation vs. Baseline

Nonetheless, this experiment's result led us to adopt SentencePiece as our preferred method for segmentation in other experiments.

6.2 Normalizing by Orthographic Conversion

We obtained the BLEU scores in Table 4 for our models. It can be seen from the results that training with normalized data by orthographic conversion does not improve the models over the baseline. The models trained on normalized data also have similar performances.

The result of this experiment suggests that normalizing by orthographic conversion might have removed too many contextual cues for the model to perform well. Possible work for future experiments include investigating whether normalizing *katakana* in mixed-script text into *hiragana* could have a positive impact, because doing so would remove variability but would not introduce ambiguity to the extent it might have done when the content words in *kanji* were also normalized. Another direction for future research involves looking at training NMT models using sub-character units such as radicals or strokes, as was done in Zhang and Komachi (2018).

6.3 Politeness and Formality Tagger

BLEU and chrF scores with a 95% confidence interval from a baseline model and a tagger model as seen in Table 5 shows that using a formality and politeness aware model improves the model's performance.

The result of this experiment is very encouraging to us as the score increase is notable. It also suggests that the proposed classification of predicate endings works well for the news training data available. The training data used for this experiment contains 12.7M sentence pairs. Developing a politeness and formality aware model applicable to a wider selection of genres in Japanese remains future work, where careful consideration of different writing styles and additional classification of stylistic markers are needed.

6.4 Back-Translation

Using back-translated data improved the results (reported with a 95% confidence interval), although the gain in the En→Ja direction was modest, as shown in table 6. The results reinforce previous findings that back-translation generally improves translation quality, and for languages with low resources, it can be especially useful. Although the Ja-En pair is not considered low-resourced, the parallel data for news-specific corpus was very scarce, so using the monolingual newscrawl and newscorpus was beneficial to the model learning.

6.5 Model Ensembling and N-Best Reranking

During the decoding phase, we ensembled the highest performing checkpoints and obtained 10 best translations from those checkpoints. The best hypothesis was determined by the best perplexity score of the language model.

Models En→Ja	BLEU
Baseline	32.9
N-best reranking	34.0
Models Ja→En	**BLEU**
Baseline	17.6
N-best reranking	18.6

Table 7: N-best reranking vs. Baseline

We found that for both directions, this method resulted in improved translations, as demonstrated in table 7. This evaluation result was done on the WMT 2021 test set and was obtained during the submission period using the submitted models.

7 Conclusion

We produced several models to tackle the task of translating Japanese to English and English to Japanese. Namely, we have used BPE, employed a politeness and formality tagger, and during decoding, utilized model ensembling and n-best reranking. Normalizing by orthographic conversion did not produce improvement compared to the baseline, but the other techniques have all proven to be effective and thus have been employed in our final submissions. We also found that for both En→Ja and Ja→En, adding back-translated data improved the results. This may be explained by the fact that there is very little parallel data in the news domain, and adding synthetic data from alternative in-domain sources helped tune the model. While improvement in the BLEU score is modest for En→Ja, we expect the results to improve further if we increase the amount of back-translated data. We also showed that employing a tagger to introduce more contextual cues related to politeness and formality to our translation system is an effective technique. Differences in formality and politeness levels present are issues often encountered when using training data in languages with rich honorifics. Thus the technique employed in this paper could be extended to other languages such as Korean.

Abstract

In this paper, we describe our MiSS system that participated in the WMT21 news translation task. We mainly participated in the evaluation of the three translation directions of English-Chinese and Japanese-English translation tasks. In the systems submitted, we primarily considered wider networks, deeper networks, relative positional encoding, and dynamic convolutional networks in terms of model structure, while in terms of training, we investigated contrastive learning-reinforced domain adaptation, self-supervised training, and optimization objective switching training methods. According to the final evaluation results, a deeper, wider, and stronger network can improve translation performance in general, yet our data domain adaption method can improve performance even more. In addition, we found that switching to the use of our proposed objective during the finetune phase using relatively small domain-related data can effectively improve the stability of the model's convergence and achieve better optimal performance.

1 Introduction

News translation (Bojar et al., 2017, 2018; Barrault et al., 2019, 2020) is one of the most prominent and appealing tasks in machine translation evaluation (Wu et al., 2020b; Li et al., 2020c). Our MiSS system took part in the WMT21 news translation task, including English → Chinese (En → Zh), Chinese → English (Zh → En), and Japanese → English (Ja → En) translation directions. We developed translation systems for this year's submission to investigate machine translation techniques from two perspectives: model structure and model training. All of the data used by the submitted systems is constrained. Due to a lack of training resources, the English->Japanese translation direction is only investigated from the model structure perspective.

From the perspective of model structure, we choose the Transformer (Vaswani et al., 2017; Li et al., 2021c) model based on self-attention, which is extensively utilized in neural machine translation systems, as our basis (Zhang et al., 2020b; Li et al., 2020d). On this strong foundation, we opt to simply deepen the model by increasing the number of encoder layers or widen the model by increasing the hidden size of the model to obtain a deeper or wider model. When deepening or widening the model, we found that there is no need for additional sophisticated structure design (e.g., layer drop (Fan et al., 2020) / sublayer drop (Li et al., 2021a)) or training strategy when there is adequate training data available. In addition to Transformer architecture, Wu et al. (2019) propose a dynamic convolution structure that can perform competitively or better to the self-attention structure. Follow the practice in WMT20 (Wu et al., 2020a), we also applied the dynamic convolution architecture as another basis.

According to our preliminary results on the development set, domain has a significant impact on performance, despite the fact that we are working with the resource-rich En-Zh and En-Ja language pairs. This year's submissions are mostly concerned with utilizing training approaches to mitigate the impact of domain differences. Specifically, we first use data in all hybrid domains to train the initial NMT model, and then, based on sentence embedding model enhanced by contrastive learning, the parallel/monolingual corpus is filtered monolingually or cross-lingually, and the filtered domain-related parallel corpus is used for further finetuning, and the domain-related monolingual corpus is used for in-domain back-translation enhancement. In addition, we also adopted a self-supervised training method to train the model on the given source text of the test set and its domain-related monolingual text obtained by filtering. In self-supervised

training, we combine our *Data-dependent Gaussian Prior Objective* (D2GPo) objective (Li et al., 2020b) to alleviate the collapse due to non-golden targets. In the finetune stage with the domain-related parallel corpus, we adopted the training strategy of switching the optimization objective from the MLE to our proposed *Dual Skew Divergence* (DSD) (Li et al., 2019). The results demonstrated that switching to the DSD objective resulted in improved convergence.

From the evaluation results, we observe substantial improvements over the strong baseline with 4.3 (En → Zh), 4.8 (Zh → En), 3.2 (Ja → En) BLEU scores on the development sets, respectively. The gains can be attributed to larger model capacity and better training strategies. And the results suggest that the cost of domain adaptation to improve performance is less than the cost of increasing model capacity.

2 Model Perspective

With the development of deep learning in NLP (He et al., 2018; Cai et al., 2018; He et al., 2019; Li et al., 2021d), model ensembling can usually produce better results than single models, and the bigger the difference between the models used for ensembling, within a certain limit, the higher the improvement will be. As a result, we chose four distinct typical architectures as the basis for single NMT models and trained them on the same data. The detailed parameters of each model architecture are shown in Table 1.

Deep Transformer Some related works (Zhang et al., 2019; Wang et al., 2019; Li et al., 2020a, 2021a) have revealed that deep networks have great advantages in NMT performance compared to shallow networks recently. Based on the Transformer NMT model architecture, we found that in the presence of sufficient training data, merely increasing the number of stacked layers of the encoder can fulfill the goal of deep Transformer without the use of additional initialization, dropout, or layer skipping techniques.

Wide Transformer Recent researches (Sun et al., 2019; Wu et al., 2020a; Zhang et al., 2020a; Wu et al., 2020b; Meng et al., 2020) have demonstrated that, in addition to deepening the NMT model, widening the model can also effectively improve translation performance, with increasing the feed-forward network (FFN) size in the Transformer model bringing less training and inference cost than increasing the overall hidden size of the model. We took a same practice in our work by increasing the FFN size and established a Wide Transformer baseline.

	Deep Transformer	**Wide Transformer**	**Deep DynamicConv**
Enc. Layers	40	20	20
Dec. Layers	6	6	6
Attn. Heads	16	16	16
Hidden Size	1,024	1,024	1,024
FFN Size	4,096	8,192	4,096

Table 1: Hyper-parameters of different model architectures. Note that Wide Transformer with relative position encoding was also used as baseline models.

Deep DynamicConv Dynamic convolution (DynamicConv) (Wu et al., 2019) was proposed as a replacement for Transformer architecture and has piqued much interest (Wu et al., 2020a) due to its good speed advantage and comparable performance. To enhance the performance of single model, we also deepen the DynamicConv model by increasing the number of encoder layers, denoted as Deep DynamicConv. The original DynamicConv model consists of 7 encoder layers and 6 decoder layers. We deepen the DynamicConv model's encoder layers to Deep DynamicConv. Because the kernel size of each convolution layer in the DynamicConv model differs, we set the kernel sizes of the 16 encoder layers in Deep DynamicConv to `[3, 7, 15, 31, 31, 31, 31, 31, 31, 31, 31, 31, 31, 31, 31, 31]` and leave the other settings unchanged from the original model.

Relative Position Encoding Because self-attention in the convention Transformer model is position-independent, the encoded features must be enhanced with explicit positional information for natural language processing. Absolute position encoding is usually employed in the Transformer NMT model. Shaw et al. (2018) proposed to add relative position encoding (RPE) for improving self-attentional features and shown additional performance gains. We also applied relative position encoding to the Wide Transformer model and created another strong baseline.

We use the identical vocabulary and data to train these four baseline models separately, and then average the best 5 checkpoints in each model's training phase to generate the final model output

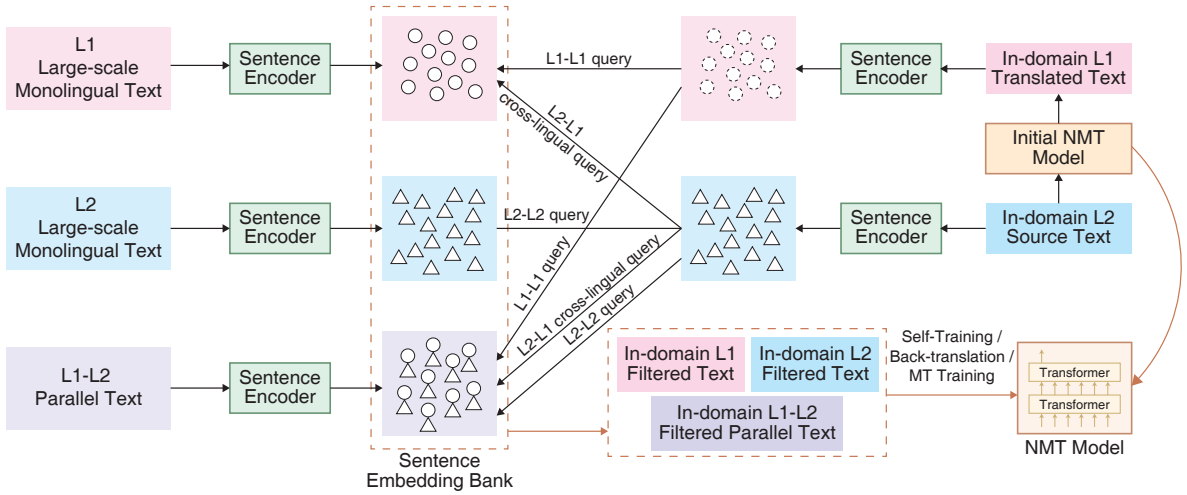

Figure 1: Illustration for contrastive learning-reinforced domain adaptation

in the corresponding stage. According to Wu et al. (2020a)'s experience, the best 5 checkpoints are determined based on the BLEU metric on the development set rather than the perplexity (PPL) metric. Furthermore, we applied the D2GPo objective (Li et al., 2020b) in the training process to obtain more stable convergence and decrease the impacts of overfitting resulting from the training set's noise.

3 Training Perspective

Contrastive Learning-reinforced Domain Adaptation Data domain issues have been found to have a significant impact on machine translation performance (Saunders, 2021). The official training data is of hybrid domain, despite the fact that the evaluation task is news translation. And, while news translation corpora can be deemed to be in the news domain, there are significant variances in news styles within the same domain. As a result, one of the keys to performance enhancement will be how to utilize the data training model that is closer to the evaluation data domain and style.

Using languages L_1 and L_2 as an example, the data that may be used comprises the parallel corpus $D^P_{L_1-L_2}$, as well as their respective large-scale monolingual corpus $D^M_{L_1}$ and $D^M_{L_2}$. Parallel corpora are typically utilized for direct training of NMT models, whereas monolingual corpora are used for back-translation (Edunov et al., 2018) and self-supervised training (Jiao et al., 2021). The domain filtering method can be utilized in these three training procedures to create corpus whose domain is more similar to the development and test sets.

Instead of relying on the co-occurrence probability of the surface tokens in the sentence, we based the domain filtering on the hypothesis that the more similar the sentence representations generated by the Transformer encoder are, the more likely they are to be dispersed in the same domain. Because the current Transformer encoder's representation is based on the bidirectional and full attention of all tokens, the combination and order of tokens have a significant impact on the final representation, the sentence representation is adequate for capturing domain information. As a result, we use the sentence embedding distance to measure the domain similarity.

We leveraged a universal paraphrastic sentence encoder (Wieting et al., 2016; Ethayarajh, 2018; Li and Zhao, 2020) to embed each given sentence to a dense representation. On a large scale monolingual corpus, we train our own monolingual and multilingual sentence encoder, a Transformer that has been pre-trained using masked language modeling (Devlin et al., 2019; Zhang et al., 2020c; Li et al., 2021b), with the XLM toolkit (Conneau et al., 2020) and fine-tuned to maximize cosine similarity between similar sentences. Contrastive learning seeks to acquire effective representation by pulling semantically close neighbors and pushing non-neighbors apart (Hadsell et al., 2006). Since this criterion precisely meets the requirements of sentence representation learning, we use contrastive learning to finetune the pre-trained sentence encoder. Figure 1 illustrates our contrastive learning-reinforced domain adaptation method.

According to the domain adaptation requirements in actual machine translation, the trained sentence encoder needs respond to four scenar-

ios: *Original Input Monolingual Filter*, *Translated Input Monolingual Filter*, *Original Input Cross-lingual Filter*, *Translated Input Cross-lingual Filter*. Because the fourth scenario can be covered by the first, we only employ the first three scenarios in our experiment.

For all scenarios, we first follow Gao et al. (2021)'s approach to perform unsupervised training in which the input sentence itself is used as a positive instance due to there will be some differences between the sentence representations of the two pass input with the presence of the model dropout, and other sentences in the in-batch are used as negative instances.

The unsupervised contrastive learning-trained monolingual sentence encoder can be used directly as an evaluator of the similarity of sentences in the same language and to mine similar sentences from the sentence bank. However, for the non-gold translated sentences filtering, we apply the baseline NMT models to translate parallel corpus and to back-translated monolingual corpus to generate pseudo-paraphrase corpus. And then triplet loss is used to fine-tune the unsupervised sentence encoder:

$$\mathcal{L}(x, y) = max(0, \alpha - cos(x, y)) + cos(x, y_n),$$

where positive pairs (x, y) are paraphrases from translation or back-translation, y_n are in-batch negative instances.

Likewise, we still need cross-language filtering, therefore we use parallel corpus instead of synthetic pseudo-restatement corpus and triplet loss for additional finetuning on the multilingual sentence encoder.

As shown in Figure 1, taking the L_2 in-domain source sentences in development set as an example, we first use the initial NMT model to translate these sentences to L_1 translated text. The different trained sentence encoder is then used to encode these sentences and the large-scale monolingual or parallel corpus based on different scenarios respectively. Then, using the faiss toolkit[1], a query procedure is performed to locate related in-domain monolingual or parallel corpora with similarity calculation and ranking.

Back-translation and Self-supervised Training Using the in-domain monolingual and parallel corpus, we may train the initial model using back-translation and self-supervised training approaches. For back-translation, we leverage the original multiple NMT models to translate these monolinguals into various pseudo-parallel corpora, and then combine them with the in-domain parallel corpus to finetune the NMT model. For self-supervised training, we use a variety of models to perform ensemble translation on the in-domain monolingual text as the translation target and combine the in-domain translation corpus to fine-tune the model. In the specific implementation, we perform back-translation and self-supervised training consecutively such that the self-supervised training stage can exploit the stronger NMT model trained during the back-translation stage.

Optimization Objective Switching Training It is easier to fall into a local optimum in the process of back-translation and self-supervised training because there are relatively fewer in-domain data and input or output in part of the data utilized is not gold. According to our experience in (Li et al., 2019), switching the training objective to the adversarial learning objective after MLE training converges might help jump out of the local optimal state and get better performance. Follow this practice, in the back-translation and self-supervised training stages, we first employ MLE target training to converge on a development set and then switch to Li et al. (2019)'s DSD loss for further training:

$$\begin{aligned}\mathcal{L}_{DSD} = -\frac{1}{n}\sum_{i=1}^{n}[&\beta(t)\mathbf{y_i}\log((1-\alpha)\hat{\mathbf{y}}_\mathbf{i} + \alpha\mathbf{y_i}) \\ &-(1-\beta(t))\hat{\mathbf{y}}_\mathbf{i}\log(\hat{\mathbf{y}}_\mathbf{i}) \\ &+(1-\beta(t))\hat{\mathbf{y}}_\mathbf{i}\log((1-\alpha)\mathbf{y_i} + \alpha\hat{\mathbf{y}}_\mathbf{i})],\end{aligned}$$

where $\mathbf{y_i}$ is the i-th token in the target sequence $\mathbf{y}$, $\hat{\mathbf{y}}_\mathbf{i}$ is the i-th predicted token, α is a hyper-parameter in α-skew divergence (Lee, 1999), and $\beta(t)$ is the controllable weight from the PID controller.

4 Data Setup

English↔Chinese In the English↔Chinese translation, we used all official parallel corpus, including ParaCrawl v7.1, News Commentary v16, Wiki Titles v3, UN Parallel Corpus V1.0, CCMT Corpus and WikiMatrix. For English, we use the tokenization tool provided by *Moses*[2], and

Table 2: BLEU evaluation results on the WMT 2021 development and test sets. The BLEU in the development set is a word-level MultiBLEU score, but the BLEU in the test set is from the official evaluation. Due to a lack of resources, En→Ja only completed the baseline training and ensemble submission.

for Chinese, we use *pkuseg* (Luo et al., 2019) as the word segmentor. We adopt a joint byte pair encoding (BPE) (Sennrich et al., 2016) with 44K operations for subword vocabulary in English and Chinese. Punctuation normalization is not employed to preprocess the training data in order to prevent complex post-processing of punctuation restoration. For English post-processing, we use the script in *Moses* to de-tokenize the translation, whereas for Chinese, we employ sacremoses[3] for de-segmentation.

English↔Japanese In the English↔Japanese translation, data for training were combined from ParaCrawl v7.1, News Commentary v16, Wiki Titles v3, WikiMatrix, The Kyoto Free Translation Task Corpus, and TED Talks. Similarly, the Japanese sentences are segmented using the Mecab[4] segmentor, while the English sentences are processed using the Moses tokenizer. The size of the English and Japanese joint BPE is also set to 44K. In post-processing, Moses script and sacremoses are also employed for detokenization.

We merged the whole news-crawl corpus for monolingual data. However, in Chinese and Japanese, news-crawl corpus alone is insufficient to train the sentence encoder, so we sampled some data from the common-crawl corpus and eventually produced the data in English, Chinese, and Japanese 100M sentences each. For pre-processing, we exclude sentences that are more than 175 words long, and the word ratio between the source and the target greater than 1:2 or 2:1.

5 Model Training

All of our NMT models are built using the Fairseq toolkit. Except for the switching training phase, all models are optimized with Adam optimizer, and SGD optimizer is utilized for optimization training when switching to DSD loss. During the baseline model training process, the learning rate is scheduled using the inverse sqrt scheduler with 4000 warm-up steps, maximum learning rate 5e-4, and betas (0.9, 0.98). Each model is trained on 8 NVIDIA V100 GPUs, with batch size limited to 8192 tokens per GPU. FP16 is emploted to save GPU memory and speed up calculations. To increase the virtual batch size, we set the gradient update steps to 8 during the training phase. The label smoothing and dropout values are both set to 0.1. In the finetuning stage, we utilize a smaller batch size, 4,096 tokens per GPU, and train the model at a fixed learning rate of 1e-4. Sentence encoder models are developed with the XLM toolkit, and the architecture is based on the BERT-base. The hidden size, heads, hidden layers, and FFN size are 768/12/12/3072 respectively. During training, a early stop mechanism is applied in which the training will stop when the PPL on the development set does not decrease after 25 epochs.

6 Results and Analysis

Table 2 shows the results on the development sets as well as the official evaluation results on the WMT21 test sets. First, when comparing Deep Transformer, Wide Transformer, and Transformer-big, we observed that increasing the number of model layers or widening the model to increase the number of model parameters can result in large performance benefits. Second, Deep DynamicConv has shown comparable results to Deep Transformer in multiple data sets, demonstrating that DynamicConv is a viable replacement option for Transformer. Third, the Deep Transformer w/ RPE model outperforms Deep Transformer model in most circumstances, demonstrating that machine translation benefits from additional relative position encoding information. Fourth, in-domain back-translation (ID-BT) and in-domain self-supervised training (ID-ST) improve the model's performance substantially more than the increased model parameters, indicating that the data domain is a primary factor limiting translation performance. Furthermore, these enhancements demonstrate that our domain adaption approach of contrast learning-reinforced is a effective approach. Finally, we performed ensemble on the four finetuned baselines and received even higher results, demonstrating that the models of the four architectures differ from each other.

7 Conclusion

In this paper, we introduce our MISS translation system, which participated in the WMT21 news translation task. We developed a new contrast learning-reinforced domain adaptation strategy in this work, and the experimental findings suggest that this method may significantly increase translation performance. Furthermore, we conducted experiments on a range of model architectures. Our domain adaption strategy improved these strong baseline models significantly, illustrating the method's generality and indicating that the performance deficiency is not due to a specific model structure.

Abstract

This paper describes the Fujitsu DMATH systems used for WMT 2021 News Translation and Biomedical Translation tasks. We focused on low-resource pairs, using a simple system. We conducted experiments on English-Hausa, Xhosa-Zulu and English-Basque, and submitted the results for Xhosa→Zulu in the News Translation Task, and English→Basque in the Biomedical Translation Task, abstract and terminology translation subtasks. Our system combines BPE dropout, sub-subword features and back-translation with a Transformer (base) model, achieving good results on the evaluation sets.

1 Introduction

WMT has been exploring the state of the art in MT for many years, and, particularly in recent editions, the participants have shown impressive results. However, often times, these results require very heavy or complex systems, trained on dozens of GPUs. Participants compete for a margin that places them above the rest, combining multiple methods from the latest research.

In recent years, different variants of the Transformer (Vaswani et al., 2017) architecture have been popular for NMT, so can be seen when inspecting the submissions to previous editions of WMT. In our systems, we use the Transformer `base` configuration, the smaller one. Our implementation is based on Sockeye 2 (Hieber et al., 2020; Domhan et al., 2020).

We combine several techniques or strategies for low-resource pairs. These techniques are described in Section 2.

We conducted a few experiments on language pairs Xhosa-Zulu and English-Hausa, from the News Translation task, and on English-Basque, from the Biomedical Translation task. The results of our experiments are shown in Section 3.

2 Techniques

This section describes the strategies used for our NMT models. The first two, *bpe dropout* and *sub-subword features*, were used in all the subtasks, while the last one was only used for the biomedical translation subtasks.

2.1 BPE dropout

BPE dropout (Provilkov et al., 2020) was introduced as an alternative to Kudo (2018). Provilkov et al. found that the main drawback to the subword regularization method is its complexity, since it requires training a unigram language model and uses uses EM and Viterbi algorithms to sample segmentations.

BPE dropout works on BPE vocabulary models (Sennrich et al., 2016b), that is, the vocabularies are built in the same way as vanilla BPE. While the unigram language model subword regularization method uses a statistical model and dynamic programming to be able to sample different segmentations from the same sequence, BPE dropout uses random noise to discard certain merges, randomly generating a different sequence of subwords each time. This is so because BPE does not store the frequencies of each subword, only the order of the merges. Merges are discarded with a probability p, which is usually 0.1. Provilkov et al. concluded through several experiments that BPE dropout achieves better results.

Our systems use BPE dropout during training, with a dropout proability p of 0.1.

2.2 Sub-subword features

The main idea of the Sub-subword feature method (Martinez et al., 2021) is to build the embedding matrices from the n-gram features of the subwords in the vocabulary. The features used to produce the embeddings are selected by an algrithm before training, and the neural network that produces the embeddings is trained with the rest of the model.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 162–166
November 10–11, 2021.

	Sentences	Words in source	Words in target	Word ratio
Xh-Zu	94,323	1,356,127	1,325,168	1.02
En-Ha	752,287	11,044,101	11,713,109	1.06
En-Eu	2,627,745	23,225,786	17,472,145	1.33

Table 1: Statistics of the datasets used for BT experiments. The rows of the table are ordered from smallest to largest, the source language being that of the pair. The ratios are the number of words of the largest language compared to the other.

The method has a regularizing effect, particularly effective under low-resource settings. The sub-subword feature method can be used with BPE and BPE dropout, to achieve better results.

2.3 Back-Translation

Back-translation (BT) (Sennrich et al., 2016a) can be used with monolingual data of the target language, to improve low-resource language pair performance. BT is a type of distant supervision, in which a model of the opposite direction to the one that one wants to build is used to synthesize more parallel data. The method requires training an opposite model, and the synthesized data is noisy. Still BT has been used extensively with good results reported (Poncelas et al., 2018; Edunov et al., 2018).

The effectiveness of the BT method depends largely on the quality of the monolingual corpora used. Monolingual corpora compiled automatically using web crawlers in combination with automatic language detection are prone to be noisy. Particularly for low-resource languages for which language detection has lower accuracy.

For example, we noted that the Hausa Extended Common Crawl corpus published for WMT21 contained a large number of Japanese song lyrics written in Latin alphabet.

Our systems used 2 million backtranslated sentences to improve performance.

2.4 Multilingual model

Johnson et al. (2017) introduced multilingual models to NMT. Multilingual models are capable of translating more than one pair. For this, they used a simple approach that consists of using a special symbol inserted in the source sentence, indicating the target language. The architecture of the model can be the same as that of non-multilingual models. In their experiments, they showed that, although the performance of pairs with more resources worsens when sharing a model with other pairs, the performance of pairs with fewer resources improves. Multilingual models allow translation between pairs with zero resources. This is known as zero-shot translation.

Much research has been done on Multilingual Neural Machine Translation (MNMT). Dabre et al. (2020) published a comprehensive survey that summarizes different ideas and techniques for MNMT.

For the English-Basque Biomedical task, we tried using multilingual models too. In particular, for the terminology translation subtask, we included the English-Spanish terminology from MeSpEN (Villegas et al., 2018). The terminology was included as training data, using the method described in this section. A more sophisticated vocabulary integration method could have given better results (Post and Vilar, 2018; Bergmanis and Pinnis, 2021).

3 Experiments

We conducted experiments on Xhosa → Zulu, Zulu → Xhosa, English → Hausa, Hausa → English and English → Basque. Notice that the WMT21 Biomedical Translation Task for English-Basque was only in the English → Basque direction, and not Basque → English.

Table 1 shows the statistics for three language pairs. The rows are ordered from smallest to largest. The Xhosa-Zulu and English-Hausa data were published in the WMT21 news translation task. Both are classified as low-resource in the task description, but Xhosa and Zulu are two closely-related languages, and English and Hausa, two distant languages. The English-Basque data were published for the biomedical task of WMT21. The English-Basque dataset cannot be considered low-resource, with 2.6M parallel sentences, but it represents two distant languages. The Basque language has a complex morphology that makes its generation difficult.

Word ratios can hint about the similarity or dissimilarity of the languages. Xhosa and Zulu are related languages, and that is why they show a ra-

	Xh→Zu	Zu→Xh	En→Ha	Ha→En	En→Eu
Baseline	6.5 (.416)	6.3 (.421)	12.0 (.412)	13.0 (.403)	16.5 (.456)
+SSWF	9.3 (.470)	8.5 (.468)	12.5 (.420)	14.5 (.429)	**17.3** (.471)
+BT	9.2 (.471)	8.6 (.467)	17.5 (.480)	**16.7** (.460)	16.4 (.462)
+BT+SSWF	**9.7** (.478)	**8.8** (.470)	**18.0** (.482)	15.5 (.461)	16.4 (.463)

Table 2: BT results for various language pairs. (+/-) BT indicates the use or non-use of BT data. The results follow the format "BLEU (CHRF2)". Best BLEU results are shown in bold and the best CHRF2 are underlined.

tio close to one. English and Hausa are distant languages, but their morphological characteristics result in sequences of similar length.

Table 3 shows the hyperparameters used to train the models. The Transformer hyperparameters are those of the *base* model. We use a relatively large vocabulary size of 32k subwords. Although Sennrich and Zhang (2019) showed that smaller vocabularies give better results on low-resource datasets, larger vocabularies work well when using sub-subword features (Martinez et al., 2021).

We used 4,000 warmup steps schedule as described in Vaswani et al. (2017) with an initial learning rate of 2.0 and evaluated the development cost every 2,000 updates. The model was reloaded from the best checkpoint when the development cost did not improve, and training stopped after 3 consecutive stallings.

Hyperparameter	Value
Vocabulary size	32,000 subwords
BPE dropout p	0.1
Batch size	4,096 (×2 GPUs)
Warmup steps	4,000
Learning rate	2.0
Encoder layers	6
Decoder layers	6
Attention heads	8
Transformer size	512
Hidden layer size	2,048
Dropout	0.1
Label smoothing ϵ	0.1
FTE layers †	3
FTE size †	3,072

Table 3: Hyperparameters used in our models. † FTE (feature-to-embedding) network size for sub-subword feature (+SSWF) models.

For the *News Translation Task* participants need agree to contribute to the manual evaluation about eight hours of work, per system submission. In consideration of this workload, we decided to submit only the Xhosa → Zulu system to the News Translation Task.

Table 2 shows the results for the languages in Table 1. The BT data were translated using the sub-subword feature (+SSWF) model. The BT data contain 2 million pairs of sentences. The English-Basque model shown in this table does not use the multilingual approach described in Subsection 2.4.

The results show that the sub-subword features (+SSWF) improve the results of the corresponding −SSWF models under low-resource settings. In the case of Hausa → English, the +SSWF system did not achieve better BLEU scores than the corresponding −SSWF system, but achieved better CHRF2.

Despite its noisy nature, we decided to use the *Extended Common Crawl* Hausa corpus. The results show that the data, although noisy, was effective in improving the performance.

The English → Basque biomedical abstract translation did not improve when using back-translation data. It is possible that the cause for this was the domain mismatch of the monolingual data, that was not exclusively from scientific papers' abstracts.

All models were trained on two *NVIDIA Tesla P100* GPUs. The Xhosa-Zulu models are trained in about 2.5 hours, and the English-Hausa models are trained in about 10 hours.

Table 4 shows the result of combining the English-Basque training data with the MeSpEN English-Spanish terminology (Villegas et al., 2018). The MeSpEN terminology dictionary that we used contained 125,519 term pairs after cleaning.

Model	BLEU	chrF2
En→Eu	16.47	.456
En→Eu +SSWF	17.34	**.471**
En→ {Eu,Es} +SSWF	**17.44**	.470

Table 4: NMT result of combining the English-Basque training data with the MeSpEN English-Spanish terminology.

The scores displayed were obtained by evaluating the trained models on a test set sampled from the provided data for abstract translation. The data used to build the development and test sets were removed from the training data. The results show the BLEU and CHRF2 scores for abstract translation, but we did not prepare any evaluation set for terminology translation, as we wanted to include WMT20 terminology in the training data.

The same models were used for abstract translation and terminology translation. Manual examination of the produced transations hinted better performance for the the model trained with English-Spanish terminology.

In consideration of the results, we decided to submit two systems to the abstract translation and terminology translation subtasks. One of the systems incorporated the MeSpEN terminology, and the other one did not. Both systems did not use backtranslated data.

4 Conclusions

We built and submitted three lightweight systems that used sub-subword features to build the embeddings. We evaluated the approach with different configurations and the results showed the adequacy of the approach.

The relatively small models could possibly use larger hyperparameters and other techniques to achieve better results, but we think the current results can show the strenght of the techniques that were applied.

Adam Mickiewicz University's English-Hausa Submissions to the WMT 2021 News Translation Task

Artur Nowakowski and **Tomasz Dwojak**
Faculty of Mathematics and Computer Science, Adam Mickiewicz University, Poznań, Poland
{artur.nowakowski,t.dwojak}@amu.edu.pl

Abstract

This paper presents the Adam Mickiewicz University's (AMU) submissions to the WMT 2021 News Translation Task. The submissions focus on the English↔Hausa translation directions, which is a low-resource translation scenario between distant languages. Our approach involves thorough data cleaning, transfer learning using a high-resource language pair, iterative training, and utilization of monolingual data via back-translation. We experiment with NMT and PB-SMT approaches alike, using the base Transformer architecture for all of the NMT models while utilizing PB-SMT systems as comparable baseline solutions.

1 Introduction

We describe the Adam Mickiewicz University's submissions to the WMT 2021 News Translation Task. We focused on translation between Hausa and English – a low-resource translation scenario between distant languages. Our methods combine data cleaning with OpusFilter (Aulamo et al., 2020) and fastText (Joulin et al., 2016), transfer learning (Aji et al., 2020; Zoph et al., 2016), iterative training, and back-translation (Sennrich et al., 2016a).

All NMT models were trained with FAIRSEQ (Ott et al., 2019), while the first iteration of the back-translation was generated with Moses (Koehn et al., 2007).

The results presented in the paper are based on the first released development set ("Dev-1"), which consists of 1000 sentences, the final development set ("Dev-full"), which adds additional 1000 sentences to the first development set, and the released test set without additional test suites ("Test"). The test set consists of 1000 sentences in English→Hausa direction and 997 sentences in Hausa→English direction.

The final submissions significantly outperform the vanilla NMT baselines in terms of BLEU (Papineni et al., 2002) metric results, as implemented in SACREBLEU (Post, 2018) with default settings.

All systems were trained in a constrained scenario i.e., using the data provided by the organizers of WMT 2021 only.

2 Data preparation

The quality of the training data has a great impact on the final performance of the NMT models (Rikters, 2018). The data preparation consisted of data cleaning and filtering performed by using OpusFilter (Aulamo et al., 2020) pipelines. We specified separate pipelines for monolingual and parallel data. Data cleaning phase consisted of normalizing punctuation, removing non-printable characters, and decoding HTML entities by using Moses (Koehn et al., 2007) pre-processing scripts.

We applied subword segmentation on filtered data by using SentencePiece (Kudo and Richardson, 2018) tool with byte-pair-encoding (BPE) (Sennrich et al., 2016b) algorithm. The corpora we used for model training, along with the number of sentences before filtering, are specified in Table 1. Number of sentences after filtering is presented in Table 2.

Monolingual data filtering For the monolingual data filtering, we defined an OpusFilter pipeline that consists of the following filters:

- deduplication filter,
- sentence length filter,
- word length filter,
- Latin character score filter,
- language identification filter.

The sentence length filter requires that the sentence contain a minimum of 3 and a maximum

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 167–171
November 10–11, 2021.

Data type	Sentences	Corpora
Parallel en-ha	751,560	Khamenei, Opus, ParaCrawl
Monolingual en	41,428,626	News crawl (only 2020)
Monolingual ha	2,311,959	News crawl, CommonCrawl
Parallel de-en	8,600,361	Tilde Rapid, CommonCrawl, Europarl, News commentary, ParaCrawl

Table 1: Corpora statistics before filtering.

of 100 words. A maximum of 40 characters is required for the word length. The required Latin character score for a sentence is set to 100%. Language identification filter is based on a fastText (Joulin et al., 2016) language identifier. The open-source fastText language identification models do not identify Hausa, so we used the JW300 corpus from the English-Hausa Opus collection to train our custom language identifier. A sentence must pass all filters to be included in the training data.

Data type	Sentences
Monolingual en	39,812,834
Monolingual ha	1,227,921
Parallel ha-en	494,246

Table 2: Monolingual corpora statistics after filtering.

Parallel data filtering The filters used in the parallel data filtering pipeline are nearly identical to those used in the monolingual data filtering pipeline. Filters are applied to both the source and target sentences in this scenario. We also included a length ratio filter with a threshold of 2, indicating that a sentence on the source side can be up to twice as long as a sentence on the target side and vice versa.

A similar pipeline was applied to the German-English data that was used for transfer learning. We downsampled 3M sentence pairs from ParaCrawl due to the imbalance in the German-English data.

3 Approach

Our models combine transfer learning from a high-resource language pair (German-English), iterative training, and back-translation. We used FAIRSEQ (Ott et al., 2019) toolkit in our experiments with NMT models, while we used Moses (Koehn et al., 2007) toolkit for our experiments with PB-SMT models.

All of our NMT models follow the base Transformer architecture (Vaswani et al., 2017), using ReLU as the activation function and Adam (Kingma and Ba, 2015) as the optimizer with the following parameters: $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1\text{e}{-8}$. We set the inverse square root learning rate scheduling with a peak value of $1\text{e}{-3}$. We used learning rate warmup stage for 4000 updates with initial learning rate of $1\text{e}{-7}$. Dropout probability was set to 0.2, while the attention dropout probability was set to 0.1. We also used label smoothing with a value of 0.1. In the case of baseline English-Hausa models, the joint vocabulary was based on both English and Hausa data. In all cases, the vocabulary size was set to 32,000.

The PB-SMT models were trained with default settings with Moses (Koehn et al., 2007) toolkit. In addition, we trained a 5-gram Operation Sequence Model (Durrani et al., 2013). All language models are 5-gram models and were binarized with KenLM (Heafield et al., 2013). The models were trained on tokenized, word-level, lowercased sentences. Re-casing was applied to the model outputs. After training the base models, we also applied MERT (Minimum Error Rate Training) (Och, 2003; Bertoldi et al., 2009) tuning on the development set.

3.1 Baseline systems

We decided to train baseline models of two types: vanilla Transformer (base) and PB-SMT. The experiments conducted on the first release of the development set showed that PB-SMT performs significantly better than NMT: we achieved +1.8 BLEU score on Hausa→English and +0.7 on English→Hausa. Based on these results, we decided to use PB-SMT models to generate data for the first iteration of iterative training.

When the test set was published, we computed the scores for the baselines. To our surprise, the scores obtained by NMT are much higher than PB-SMT, especially in the Hausa→English direction.

System	HA → EN		EN → HA	
	Dev-1	Test	Dev-1	Test
NMT baseline	12.21	11.44	10.28	11.05
PB-SMT baseline	14.00	6.59	11.02	9.36

Table 3: Baseline results according to the automatic evaluation with BLEU metric.

3.2 Transfer learning

According to recent studies, transfer learning (TL) enhances translation quality in low-resource scenarios (Zoph et al., 2016; Aji et al., 2020). We chose the German→English translation direction as a base. In general, we followed (Nguyen and Chiang, 2017) and trained a shared Hausa-German-English vocabulary (BPE). Then, we trained a German→English model using parallel data from the WMT 2021 Translation Task, which was filtered similarly to Hausa-English data. Finally, we used the Hausa-English data to fine-tune the pre-trained German→English model. We obtained a BLEU score of 13.31 on the "Dev-1" development set (+1.1 BLEU compared to the NMT baseline), which was lower than the PB-SMT baseline.

3.3 Iterative back-translation

Monolingual data has been widely employed in MT to enrich parallel corpora with synthetic data to improve the quality of MT systems, particularly in low-resource scenarios (Bojar and Tamchyna, 2011; Bertoldi and Federico, 2009). We applied the back-translation technique (Edunov et al., 2018) iteratively (Hoang et al., 2018) to translate Hausa and English monolingual data into the other language, using intermediate models to generate incrementally better translations.

1. First, we used the best baseline model (PB-SMT based on Moses) in English→Hausa direction to translate 5M English sentences into Hausa.

2. We used this additional data to train the Hausa→English model by applying transfer learning from the German→English model. We upsampled the original parallel data 10 times to match the size of the back-translated data. We used the resulting NMT model to translate all Hausa monolingual data into English via sampling.

3. We combined the obtained back-translated data with the original parallel corpora to train the English→Hausa model in a manner similar to step 2, with the exception that we did not upsample the parallel data in this scenario due to the fact that back-translated data was generated through sampling.

4. This technique was applied iteratively, resulting in the systems shown in Table 4. In all Hausa→English systems except the last, we utilized 5M English monolingual sentences in the model training; in the last system, we used 25M sentences. We used all accessible Hausa monolingual data in all English→Hausa systems.

System	HA → EN	EN → HA
1	16.22	-
2	-	13.04
3	20.05	-
4	-	14.38
5	22.85	-
6	-	14.77

Table 4: Iterative back-translation results of the NMT systems on the "Dev-1" development set according to the automatic evaluation with BLEU metric.

4 Final results

Table 5 presents the final results for both the English→Hausa and Hausa→English translation directions for both the development and test sets. These results were produced by the final models from the iterative back-translation step described in section 3.3.

Direction	Dev-1	Dev-full	Test
EN → HA	14.77	21.21	16.15
HA → EN	22.85	25.23	14.13

Table 5: Final results according to the automatic evaluation with BLEU metric.

We notice a severe decrease in BLEU metric results on the test set as compared to the development set, particularly in the Hausa→English direction. This could suggest a domain shift between the two sets. Because our models are heavily based on the back-translated data, some vocabulary, especially proper names, may be missing from the training data.

5 Post-submission work

Due to a lack of computing power and time, our experiments and submissions were based on single model training. After the submission deadline, we retrained the final models three times with different seeds. Table 6 presents the results for the ensemble of four models in both directions. We obtained slight improvements on both test sets, but the differences are insignificant. On the other hand, the ensemble performed worse on the development set, especially on the first version.

Direction	Dev-1	Dev-full	Test

Abstract

The paper describes the 3 NMT models submitted by the eTranslation team to the WMT 2021 news translation shared task. We developed systems in language pairs that are actively used in the European Commission's eTranslation service. In the WMT news task, recent years have seen a steady increase in the need for computational resources to train deep and complex architectures to produce competitive systems. We took a different approach and explored alternative strategies focusing on data selection and filtering to improve the performance of baseline systems. In the domain constrained task for the French–German language pair our approach resulted in the best system by a significant margin in BLEU. For the other two systems (English–German and English-Czech[1]) we tried to build competitive models using standard best practices.

1 Introduction

The eTranslation team is behind the translation services of the European Commission's eTranslation project[2]. This is a building block of the Connecting Europe Facility (CEF), with the aim of supporting European and national public administrations' information exchange across language barriers in the EU. The project is described in more details in (Oravecz et al., 2019).

The team's participation in the WMT shared tasks has provided valuable insights to improve the quality of our production systems and allowed us to explore languages and domains beyond the formal language of EU institutions, leading to a continuous extension of the eTranslation service and helping in the search for the right balance between the use of resources in production environments and the best possible performance of models.

This year the team participated in the news translation shared task with 3 different language pairs: English → German, English → Czech and French → German. The selection was motivated by the fact that these language pairs can all be considered as high or medium resource, which is the main scenario in the eTranslation service, while the constrained domain in Fr→De offered a good opportunity to focus on and experiment with data selection and filtering techniques, which is a more viable alternative in our environment than the resource demanding (brute-force) increase in model complexity.

2 Data Preparation

Here we briefly describe the base data sets, the general selection and filtering methods we applied to prepare these initial data sets used to train the first models. Further data selection and augmentation methods to improve the quality of baseline models are described in Section 3.2. For all models we only used the provided parallel and monolingual data, so our 3 submissions fall into the constrained category.

2.1 Base Data Selection and Filtering

As a first baseline approach, we tried to make use of all provided original parallel (OP) data to build the first models for reference or back-translation. Since these data sets were fairly similar to those from last year we followed the same practice and trained baseline models from all OP data. There was, however, a significant increase in the ParaCrawl data, which for En→De for example, doubled its size. As it turned out, the increase in size did not necessarily mean a better translation model trained from the full data set so we explored different subsets based on scoring by both source and target language models (see Section 4.1 for the details of these experiments).

The domain distribution of the data sets was not

[1]Due to returning problems of resource availability, the En→Cs experiments did not finish until the submission deadline so we could finally only submit last year's system.

Table 1: Number of segments in the filtered parallel data used for baseline models.

uniform across language pairs, which had some influence on some of the workflows but the basic procedure of data cleaning was similar in all cases. As a general clean-up, we performed the following steps on the parallel data:

- language identification with FastText[3] (Joulin et al., 2016),
- segment deduplication with masked numerals, i.e. we deleted duplicate segments regardless of differences in numerals,
- deletion of segments where source/target token ratio exceeds 1:3 (or 3:1),
- deletion of segments longer than 100-150 tokens (depending on language pair),
- exclusion of segments where the ratio between the number of characters and the number of words was below 1.5 or above 40,
- exclusion of segments without a minimum number of alphabetic characters (2–5 depending on the data set).

These filtering steps led to an average reduction of about 15-20% of the training data with the number of segments as shown in Table 1.

2.1.1 Monolingual data

To build language models or create synthetic parallel text from monolingual data, we generally selected recent target language News Crawl data sets filtered according to the above steps (where applicable) with some minor adjustments. For En→De, we used the 2016–2020 German News Crawl data but as in the previous years excluded the 2018 set due to the high number of garbage segments with scrambled tokens, we set a threshold on the maximum length of a token (40) and the minimum ratio of letters to digits in a segment (4), and reduced the maximum segment length to 80 tokens, resulting in a 167M segment monolingual German data set. A similar procedure applied to the 2016–2020 English NewsCrawl corpus resulted in a monolingual English data set of 133M segments.

To create domain specific back-translation data for Fr→De we used the same data as for En→De, but due to the document based filtering method (see Section 3.2.2) the versions with document boundaries were used.

2.1.2 Development and test data

Development and test data sets were selected from the development suites provided. For En→De, we used the 2019 test set as validation set in the trainings and the 2020 test set as the test set to evaluate the trained models[4]. These data sets already contained only source original segments. We also extracted a source original subset from the full En→De development set, which was used in fine tuning of the final En→De models (see Section 3.2.3).

For Fr→De, the development set was shuffled and split into 3000 segment pairs for validation set and the rest (1813 segment pairs) for a general test set. To get an indication of the effect of data selection as described in Section 3.2.2, it was necessary to create a domain specific custom test set as well. The Fr→De 2008–14 development sets were filtered using a pattern based approach based on a

[3] https://fasttext.cc/docs/en/language-identification.html

[4] The reverse direction was used for the back-translation engines.

small list of 50 manually selected domain specific keywords[5], as well as scored and ranked by a target language model built from selected monolingual data (see Section 3.2.2). These two candidate lists were then manually revised and filtered to result in a 2k domain specific test set. These segments were removed from the training data.

2.2 Pre- and Postprocessing

Similarly to previous years (Oravecz et al., 2019, 2020) we opted for the simplest possible workflow leaving out the standard pre- and postprocessing steps of truecasing, or (de)tokenization, and simply used SentencePiece (Kudo, 2018), which allows raw text input/output within the Marian toolkit (Junczys-Dowmunt et al., 2018)[6] in the experiments. In some language pairs some simple normalization steps were applied in post-processing, which are described in the language pair specific result sections.

3 Trainings

In competitive systems big transformer architectures have become the norm in recent years (Barrault et al., 2020). We can in general see a significant increase in the need for computational resources to train deeper and more complex architectures up to 40–50 encoder layers (Wu et al., 2020b; Zhang et al., 2020; Wu et al., 2020a). Our resource environment does not allow us to fully follow this trend, limiting the complexity of the models as well as the scope of the experiments. Similarly to previous years, in all experiments we used Marian, as the core tool of our standard NMT framework in the eTranslation service. All trainings were run as multi-GPU trainings on 2 or 4 NVIDIA V100 GPUs with 16GB RAM, while for one training we were able to use a server with 8 32GB V100 GPUs.[7] Base transformers were typically trained for 20-30 epochs, whereas big transfomers were generally trained for 4–9 epochs for very high resource setups (>400M segments) and 20–25 epochs for medium resource.

[5]For example: Abwicklung, Betrug, Finanzbeitrag, Kapital etc.

[6]We did not change the default settings for Marian's built-in SentencePiece: unigram model, built-in normalization and no subword regularization.

[7]Access to high capacity resources at an affordable price has been especially challenging for us this year. In a race where computational power plays a crucial role (particularly in high resource settings) this might lead to an inherent disadvantage, which can be difficult to handle.

3.1 NMT Models

We only used base transformer models (Vaswani et al., 2017) for the first baseline models and for models used for back-translation to gain time and efficiency in back-translating large amounts of target monolingual data. For more competitive systems we switched to big transformer architectures, which resulted in significant improvements but at the same time the rise in computing costs and training time was also substantial. Due to the limitations of available resources we could build only one set of a 2–4 member ensemble from big transformers as our submission systems for En→De and Fr→De; again a high cost for a relatively smaller scale improvement. Our training settings have not changed from last year's setup: for most of the hyperparameters we used the default settings for the base transformer architecture in Marian[8] with dynamic batching and tying all embeddings. To save time and resources, we stopped the trainings if sentence-wise normalized cross-entropy on the validation set did not improve in 5 consecutive validation steps. In the big transformer experiments, also following recommended settings for Marian, we doubled the filter size and the number of heads, decreased the learning rate from 0.0003 to 0.0002 and halved the update value for `--lr-warmup` and `--lr-decay-inv-sqrt`.

Following common ranges of subword vocabulary sizes, we set a 36k joint SentencePiece vocabulary in En→De and En→Cs, and 30k in Fr→De.

3.2 Improving Baseline Models

In this section we briefly describe the methods we experimented with to improve the baseline models, such as selecting and filtering domain specific monolingual corpora to build additional synthetic data sets with back-translation (Sennrich et al., 2016), using development data (where available) or language model scored subsets of original parallel data to continue the training of already converged models and building ensembles of deep models originally trained from different seeds. Evaluation scores are reported in Section 4.

3.2.1 Filtering ParaCrawl

Training the En→De baseline model from the original parallel (OP) data (Table 1) we noticed that the model performed only as well (32.8 BLEU

[8]See eg. `https://github.com/marian-nmt/marian-examples/tree/master/transformer`.

on the 2020 test set) as our comparable model from last year despite having about twice as much ParaCrawl data while the other datasets remained basically very similar. This suggested that the v7.1 ParaCrawl (PC) data might have been noisier or contained more out of (news) domain data than expected. This was confirmed by training an alternative baseline excluding the whole ParaCrawl data set, which in the end resulted in a better score (33.3). To find a more beneficial subset of the PC data we first experimented with the stock Bicleaner filtering (Ramírez-Sánchez et al., 2020), setting higher thresholds of 0.65 and 0.75, which filtered the PC data to 51M and 26M segments, respectively. Adding either of these subsets to the other OP data sets did not lead to a significant increase (33.4 in both setups), however, we used the 51M segment subset instead of the full PC data in some further filtering experiments (see Section 3.2.3).

As a second filtering method we trained transformer language models (LM) with Marian from the filtered monolingual English and German data sets, scored both sides of the ParaCrawl data and ranked the segments (by simply averaging the scores). We experimented with models trained by adding the top 10, 20 and 30M highest scoring PC segments to the other OP data and found the 20M segment subset to produce the best baseline score (35.2), therefore we selected this data set (non ParaCrawl OP data plus the 20M segment LM scored ParaCrawl subset) as the initial parallel data for more complex models as well as for back-translation.[9]

3.2.2 Synthetic Data

Back-translation (BT) is the most used data augmentation technique in neural machine translation, but one which can introduce a wide range of scenarios in the search for finding the most optimal setup in the amount of synthetic data, the ratio of bitext to back-translation data or in the methods to generate the synthetic source (Edunov et al., 2018; Hoang et al., 2018). Tagged back-translation (Caswell et al., 2019) has been proposed as a simple and efficient alternative to noising techniques, arguing that it is the indication of the data being synthetic that is relevant for the model. This has been confirmed in our experiments in previous years, therefore we tried to use this technique in our workflows.

In the En→De system, we trained the reverse engine as a base transformer from the best baseline data setup mentioned above. After the convergence of this model we continued the training with a 30M segment subset of the OP data created by language model scoring (with the same models as for ParaCrawl). This gave an additional small increase in BLEU (0.4). With this model we back-translated an aggressively sentence segmented version of the filtered German monolingual data (see Section 2.1), which increased the size of the training set from the initial 167M segments to 219M. Our first intention was to build strong sentence based models and postprocess their output with dedicated sentence-to-document methods (which we describe in Section 3.2.5), so we tried to build one sentence per segment back-translated data sets by splitting up segments containing several sentences.

To train the submission ready systems we upsampled the best baseline OP data set to a 1:1 ratio with the BT data (Ng et al., 2019; Junczys-Dowmunt, 2019). This setup was a one shot configuration, we had no time and resources to experiment with other OP-BT combinations.

The task in the Fr→De language pair was domain specific, which offered us the opportunity to follow suit with the more recent shift from model centric approaches to data centric ones and focus on methods for finding the optimal subsets of the provided data which help improve performance in the selected domain. Therefore we tried to tune our models towards the domain by making use of guided topic modeling[10]. We created financial seed word lists by manually selecting 40 and 175 domain specific tokens from the top of a raw frequency list from a few million German News Crawl segments, and then we clustered the documents in the 2016, 2017, 2019 and 2020 German News Crawl data set into different topics guided by the selected seed word list.[11] By selecting the documents clustered into the seed word list induced topic we finally collected ca. 12M German News Crawl segments derived from two topic modelling runs based on one or the other list. These segments overlapped to a great extent. We back-translated both selections then cleaned up the back-translated data the way

[9] Clearly, there are other data selection combinations possible, for example, by taking only the 0.65 threshold Bicleaner subset as the base data for the LM based filtering, however, we did not have the time and resources to explore more scenarios for this language pair.

[10] https://github.com/vi3k6i5/guidedlda

[11] The text was tokenized and we used a German stopword list but no lemmatization in creating the document-term matrices.

we cleaned up the OP data but removed additionally pairs of segments that contained more than 15 numeric characters or more than 15 non-decimal commas. We also used the two sets to train two domain specific language models to score and rank the original parallel data set.

After that we took the union of the filtered BTs and deduplicated it. This gave us ca. 15M BT segment pairs which was at almost 1:1 ratio with the OP data. We explored training with subsets of the BT data but this did not give any improvement so we decided to use it all. We also experimented with tagged and untagged BT data, of which somewhat unexpectedly the latter gave the better result. The reason might be that the BT data was more in-domain, while most of the OP data was out of (news) domain and the explicit OP vs. BT distinction might have presented a harmful signal to the model here.

3.2.3 Continued Trainings and Fine Tuning on Dev Sets

As last year, in the En→De system we followed a two-stage continued training process to improve performance as domain adaptation (Luong and Manning, 2015). We scored the non ParaCrawl OP plus the 0.65 threshold ParaCrawl subset (see Section 3.2.1) with the language models used for filtering the ParaCrawl data set (Section 3.2.1). Then we used the top 10, 20 and 30M subset to continue the training of the OP+BT converged models until the BLEU score on the test set increased (Junczys-Dowmunt, 2019); typically 2 epochs with an increase of 0.5 points. The second stage utilized the 2008–2019 development sets (34k segments) as fine tuning data in the experiments and for the final submission it was extended with the 2020 test set. We trained with reduced batch size and learning rate for 4 epochs on this set and then for additional 3 epochs we switched to a source original subset (16k) to reach the highest BLEU score. In the end this process gave only a minor improvement of 0.3 BLEU points.

For Fr→De, we experimented with fine-tuning the best converged models (see Section 4.2) by using different sets of in-domain data. We scored the OP data for domain, using the two different LMs as mentioned above. Then, we selected the top 1M segments of each scored set of OP data and intersected them. This gave us ca. 0.85M segment pairs. However, this approach was not successful. In the other setup, we selected the top 2M segments of each scored set of OP data and intersected them, which gave us ca. 1.75M segments. We fine-tuned with reduced batch size until the BLEU score increased, which gave us an increase of 0.8 points on the domain specific test set.

3.2.4 Ensembles

The En→De final submission consisted of a modest 4 model big transformer ensemble, trained with the same best configuration and workflow but with different seeds. This approach usually gives a small but steady improvement (about 0.5 BLEU points here) but for substantially high resource settings it also comes with large computational costs. It is not uncommon to use ensembling already for back-translation (Wu et al., 2020b) but for lack of time and resources we had to limit this technique to the submission setups.

The Fr→De ensemble was composed of 4 big transformer models – three of them trained on original parallel data and back-translated data in ratio 1:1. The 4th big transformer was one of the 3 big transformers, additionally fine-tuned for 7 epochs on the 1.75M OP data scored with the domain LMs. For lack of time it was only one experimental setup out of many other possible ones but proved to be better than our previous systems.

3.2.5 Methods Tested but not Selected for Submission Models

In the En→De system, this year we experimented with a two-stage translation process of using a strong sentence-level system at the first step and post-process its output with a dedicated sentence-to-document level model. Following the method proposed by Voita et al. (2019), we created a 100M segment synthetic dataset by round-trip translating the (filtered) 2019 and 2020 German News Crawl with document boundaries with the baseline sentence level (forward and reverse) systems, and then generating 1, 2, 3 and 4 sentence long "source German"–"target German" pairs from the round-trip translated segments and the sentences in the original News crawl documents. We trained a base transformer from this data set and used it as a second stage repair on the output of the best En→De sentence level system. Unfortunately, we observed a significant drop in BLEU (almost 5 points) and although this is somewhat consistent with what for example Ma et al. (2021) reports on automatic evaluation for this method, we did not want to take the risk of submitting a system with such a quality drop

on the automatic metric to manual evaluation.

4 Results

We submitted a constrained system for each of the 3 language pairs. For En→Cs, we ran out of time and had to reuse our last year submission. For the other language pairs, we provide the evaluation scores for models at important stages in the development, which reflect how the models got better as we tried various methods for improvement. All results are reported in detokenized BLEU.[12]

4.1 English→German

		Test sets	
System	Data	2020	2021
M1: Baseline	12M	33.3	–
M2: M1+PC	32M	35.2	–
M3: M2+BT^{bigT}	450M	36.7	–
M4: M3 tuned	450M+36k	37.5	–
M5: M4 ensemble	450M+36k	**38.0**	**29.6**

Table 2: Results for En→De models. The 2021 result is from the Ocelot submission.

In Table 2 we present the main stages of the development of the En→De systems. Model 1 was the initial baseline model and used only the original parallel data excluding ParaCrawl altogether. In Model 2 we added the language model filtered and scored top 20M subset from ParaCrawl (PC). For Model 3, we switched to the big transformer architecture and used the large aggressively segmented back-translation (BT) dataset with 1:1 upsampled original parallel data (OP). The next model (M4) was tuned for 3 additional epochs with the top 10M LM scored OP data and then with the development set, leading to a small but steady increase. Finally the system we submitted was an ensemble of four M4 models. Our primary system being a sentence-level model, we performed sentence segmentation as a preprocessing step and then simply remerged the sentence level hypotheses on the target side where needed. Finally, as in previous years, a post-processing step normalizing German punctuation and some space fixing around the % sign was run on the final output.

[12]sacreBLEU signatures: `BLEU+case.mixed+lang.en-de+numrefs.1+smooth.exp+tok.13a+version.1.4.13`

4.2 French→German

Table 3 summarizes the results of the Fr→De experiments. The first baseline model (M1) was trained only on the original parallel data with news data upscaled 5 times (NewsCrawl, NewsCommentary), while in model 2 and 3 (M2, M3) we added the domain specific back-translated data set (as described in Section 3.2.2). Switching from base transformers (M1 to M3) to the big transformer architecture in model 4 (M4) led to a decent improvement. This setup was used for the models in the M5 three model ensemble. In the primary submission (M6) this was extended with a 4th big transformer. In M6, the 4 models were trained on the original parallel (OP) data and back-translated data (in ratio 1:1), and one of the models was additionally fine-tuned for 7 epochs on the 1.75M domain LM scored original parallel data subset (see Section 3.2.3).

4.3 English→Czech

Due to problems with computational resources, the En→Cs trainings had not finished until the submission deadline. Our primary submission presented in Table 4 is therefore a clone of the 2020 system (trained on OP plus BT data).

5 Conclusion

We presented the submissions of the eTranslation team to the WMT 2021 news translation shared task on 3 language pairs: English-German, French-German and English-Czech. Unlike in previous years, we had to face a few unexpected challenges with respect to resource availability, which inevitably affected some experiments we planned to carry out. We tried to put more emphasis on data selection, filtering and domain specific evaluation with custom test sets in the task where it seemed to be most rewarding and automatic evaluation results justified this approach.

Abstract

We describe the University of Edinburgh's Bengali↔Hindi constrained systems submitted to the WMT21 News Translation task. We submitted ensembles of Transformer models built with large-scale back-translation and fine-tuned on subsets of training data retrieved based on similarity to the target domain. For both translation directions, our submissions are among the best-performing constrained systems according to human evaluation.

1 Introduction

We present the University of Edinburgh's participation in the WMT21 news translation shared task on the Bengali→Hindi (Bn→Hi) and Hindi→Bengali (Hi→Bn) language pairs. We followed the constrained condition, i.e. only using the data provided by the organizers. The training data for these language pairs consisted of noisy crawled data, and was mostly out-of-domain with respect to the validation and test domain. Therefore, most of our efforts concentrated on fine-tuning models to adapt to the target domain. We also explore multiple back-translation methods, and ensembles of models trained and fine-tuned with different methods.

Building our systems consisted of the following steps, each of which is described in more detail in the remaining sections of this paper:

- Cleaning the noisy parallel data (Section 3).
- Training ensembles of Transformer models on the cleaned provided data for back-translation; and using the back-translated data along with the clean parallel data to train new models (Section 4).
- Fine-tuning the models on subsets of training data retrieved that are similar to the target domain, based on different similarity measures (Section 5).
- Ensembling various models and decoding with optimal parameters (Section 6).

We also report some methods that we tried to use but did not work in Section 8.

2 Model Configuration

Our models follow the Transformer-Big architecture (Vaswani et al., 2017): 6 layers of encoders and decoders, 16 heads, an embedding size of 1024, a unit size of 4096, etc. We found that smaller Transformer architectures performed worse.

All models are trained with the same vocabulary of 32k SentencePiece subwords (Kudo and Richardson, 2018) to allow ensembling. We use a shared vocabulary between source and target, as well as tied embeddings (Press and Wolf, 2017). We tried other vocabulary sizes too: 5k, 10k, and 20k, though all of them had similar performance. We also included several special tokens in the vocabulary, of which we finally used only one for tagged back-translation (Caswell et al., 2019).

We train models with 32GB dynamic batch size and an optimizer delay (Bogoychev et al., 2018) of 3 with the Adam optimizer (Kingma and Ba, 2015) under a learning rate of 0.0003, until we see no improvement within 10 consecutive validation steps. All models were trained with the Marian NMT toolkit (Junczys-Dowmunt et al., 2018)[1]

3 Datasets and Cleaning

3.1 Corpora

All our models are trained in the constrained scenario – even more specifically, we only use data provided for the news translation task for these specific language pairs. This consists of 3.3M parallel sentences from the CCAligned corpus (El-Kishky et al., 2020), along with monolingual data in both languages. The details of the corpora used along with their sizes are shown in Table 1.

Bn CommonCrawl	49.6
Hi NewsCrawl	46.1
Hi CommonCrawl	202

Table 1: Bn and Hi corpora used in our submissions.

3.2 Cleaning

Since the CCAligned corpus is built from web crawls and is known to be very noisy (Caswell et al., 2021), we focused on cleaning the parallel data before training translation models. Our main approaches are rule-based and heuristic cleaning methods, along with language identification and language model filters. Our final systems used the following cleaning methods for the parallel corpus:

De-duplication Duplicate sentence pairs – around 17.3% of the corpus – were removed.

Splitting multi-language sentences We observed large chunks of the corpus where the sentences on the Bengali side also had their English translations attached in the same line. Some rough punctuation and script-based heuristics were used to remove the English segments from these lines. The roughness of these heuristics also affected a large number of other lines, mostly noisy ones containing non-lexical information, but we observed no degradation of quality due to this inaccuracy. We also found some such sentences on the Hindi side, but they were less frequent and removal showed no improvement in quality, so we did not split Hindi sentences in this way for our final models.

Language ID filtering We used publicly available FastText language identification models (Joulin et al., 2016, 2017)[2] to filter out lines in wrong languages. We get the top 3 predictions for each line, throw out lines where the right language does not appear in the top 3 for one or both sides, sort by the language prediction probabilities, and based on manual inspection, arrive at minimum threshold probabilities of 0.6 for Bengali lines and 0.4 for Hindi lines, above which lines are retained.

[2] https://fasttext.cc/docs/en/language-identification.html

Language model filtering We used KenLM (Heafield, 2011) to train separate trigram language models for Bengali and Hindi, on all provided Extended CommonCrawl monolingual data, and used these to score the parallel data. We retain sentences with $\log_{10}$ probabilities greater than -4.

4 Training with Synthetic Data

In each language direction, we trained 4 models with different seeds. We then ensembled these 4 models to back-translate (Sennrich et al., 2016) all the provided monolingual data. We used this translated data in many different ways as described in the remainder of this section.

Tagged back-translation Following Caswell et al. (2019), we prefixed a special <__BT__> token to all back-translated news monolingual data, combined the data with the clean parallel data, and trained new models.

Two-step training We first trained models on all the back-translated data only, then once that converged, continued training on the clean parallel data. Since the amount of monolingual data far exceeds the amount of parallel data, this training regime gave us better results than mixing parallel and back-translated data at the same time. The latter method would also involve finding the right amount of back-translated data to sample/select, since using it all would overwhelm the parallel training data.

Forward translation We also trained models on parallel data along with all the back-translations and all forward translations, i.e. instead of strictly keeping target monolingual data on the target side and synthetic back-translated data on the source side, we used both directions of translated data.

5 Fine-tuning to the Target Domain

5.1 Fine-tuning on retrieved sentences

Unlike many of the other language pairs in the news translation task, the Bengali-Hindi pair does not include any known in-domain training corpora. The training data is aligned from documents obtained through untargeted web crawling (El-Kishky et al., 2020), and thus contains out-of-domain and noisy text. On the other hand, the target domain, reflected in the validation and test sets, consists of Wikipedia content[3].

[3] Despite it being part of the 'news translation' task

To adapt our models to the target domain, we retrieved sentences from the training corpora which are similar to the **source** side of validation and test sets based on different similarity measures, and then fine-tuned the models on these subsets of data. The remainder of this section describes the different methods to retrieve the relevant subsets of data. The number of sentence pairs retrieved by each of these methods which are then used for fine-tuning is shown in Table 2.

Retrieval	Source	Lines (K)	
		Bn	Hi
1 bigram overlap	dev	448	891
2 bigram overlap	dev	243	597
3 bigram overlap	dev	158	445
1 bigram overlap	dev, test	487	932
2 bigram overlap	dev, test	273	639
3 bigram overlap	dev, test	183	479
LM threshold -2.5	dev	50	175
LM threshold -2.0	dev, test	12	13
TF-IDF	dev, test	5.6	27.9
TF-IDF cluster	dev, test	20	20

Table 2: Number of training sentence pairs retrieved for fine-tuning by different methods.

Based on vocabulary overlap The simplest method is to retrieve any sentence pairs whose source texts have 1, 2, or 3 non-punctuation bigrams which occur on the source side of the validation and test sets. Due to the large mismatch between training corpus and target domain, this method retrieves a surprisingly small proportion of the training corpus, as shown in Table 2.

Based on language model scoring We trained n-gram language models on the validation and test set or validation set data only, scored the parallel data with these language models, then kept sentences scoring above a certain threshold. Even though the small size of the validation data means that the language model is probably not very good, we still see some improvements by fine-tuning on data retrieved this way.

Based on TF-IDF similarity We first adapted the document aligner[4] from ParaCrawl (Bañón et al., 2020) to work at sentence level. This tool uses the translation of a source text (Uszkoreit et al., 2010) to match potential target text using cosine similarity of TF-IDF-weighted word frequency vectors. In this case, we match the source side of our validation and test sets with the parallel text to find potential "matches". This method retrieves too few matches with only the validation set, but we got a few thousand sentence pairs (Table 2) from a combination of validation and test sets.

Following Chen et al. (2020b), we also developed a variant where we first cluster each source sentence with another X sentences in the validation and test sets based on n-gram TF-IDF vector cosine similarity, then treat the cluster as a single query and compare it against each source sentence in the parallel training data. We always picked the top 20K resulting pairs. Through manual inspection, we found that the resulting corpus is very reasonable when we cluster the whole validation and test sets as one query, making the fine-tuning essentially a test domain adaptation process.

5.2 Fine-tuning on the validation set

Since the validation data is the only domain-specific data we had, similar to Chen et al. (2020a), we fine-tuned all our final models on a portion of the validation set (we used 95% of the data instead of 75%) until it stopped improving on the rest of the validation set. This was done as a final additional step after the other kinds of fine-tuning described previously.

6 Ensembles and Decoding Parameters

6.1 Ensembles

As shown in Table 3, our primary submissions consist of ensembles of multiple models trained and fine-tuned in different ways. Due to the component models not being very high-quality, we observed that this type of ensemble produces more robust translations than simple ensembles of models trained identically with different seeds.

6.2 Optimal decoding hyperparameters

Using an initial ensemble of 4 models, we swept a wide range of values of beam size and length normalization hyperparameters to decode the validation set. We find that optimizing these can result in an improvement of up to 0.5 BLEU on the validation set. We obtained the best scores with a beam size of 16, and a length normalization parameter of 1.3 for Bn→Hi and 0.7 for Hi→Bn, and used these values to decode the test set.

(8)+(9)+(10)+(11)	21.75	0.4895	–	
(6)+(7)+(8)+(9)+(10)+(11)+(16)+(17)	–		12.55	0.4536

Table 4: Test set BLEU and ChrF scores for our primary submissions. Model numbers refer to models from Table 3, but note that all models were fine-tuned on the validation set before ensembling.

6.3 Sentence splitting

In the source texts of the test set, we observed many instances of more than one sentence in one line. Since our models are trained on single sentences, we chose to run a sentence splitter on the test source, translate, and rejoin the translated sentences. For this purpose, we used the Moses sentence splitter (Koehn et al., 2007)[5] for Bengali text, and the IndicNLP sentence splitter (Kunchukuttan, 2020) for Hindi.

6.4 Numeral transliteration

Due to the fact that numerals in the Latin script are often used in Bengali and Hindi text, which is reflected by the web crawled training data, our models tend to generate a mix of Latin and Bengali/Hindi numerals, sometimes even in the same sentence. To ensure consistency, we transliterated all Bengali or Hindi numerals in our test outputs to their Latin script counterparts (it is equally feasible to convert Latin numerals to the target language). While this may not help in terms of automatic metrics (we lose 0.3-0.5 BLEU after this step), we believe human evaluators would prefer consistency in this regard.

7 Results

Table 3 shows BLEU[6] and ChrF[7] scored using sacreBLEU (Post, 2018) on the validation sets. We see that fine-tuning on the retrieved subsets of data consistently results in quality gains. We tried many different ensembles and, upon visual inspection, found that models fine-tuned on data retrieved on the basis of similarity to validation and test sets were not necessarily better than those from validation sets only.

□ constrained ▨ unconstrained

Table 5: Human evaluation results. Our submissions are in bold. Systems within a cluster are considered tied.

Table 4 reports the automatic scores of our final submitted systems on the test sets. As shown in Table 5, according to human evaluation conducted by the task organizers, our systems rank at the top (tied) among all the constrained submissions for both translation directions.

8 Unsuccessful Attempts

In this section, we document some methods that we tried to use, but which did not work at all or did not result in better systems.

Dual conditional cross-entropy filtering Our initial cleaning effort was to use dual conditional cross-entropy (Junczys-Dowmunt, 2018) to self-filter the parallel data, which yielded no useful results. We also randomly split the data into two halves, trained translation models on each half, to score and filter the other half of the data – this method did not work either. We conclude that these methods are not suitable in this scenario where we do not have any clean data, however small, to train the initial cleaning model.

Copied monolingual data We attempted to synthesize training data by copying (Currey et al., 2017) and transliterating[8] monolingual data in the target language to source. In this way, we obtained pseudo parallel data that could potentially improve the decoder side of a translation model without harming the encoder much.

Transfer learning We also explored utilizing dataset from another language in the form of model pre-training. Following Aji et al. (2020), we initialize our Bengali↔Hindi model weights, excluding the embeddings, from our English↔German submission to WMT21 (Chen et al., 2021).

These methods above did not increase BLEU, except that transliterated monolingual data brought a tiny improvement. Model pre-training achieved the convergence faster, but did not achieve better final BLEU. Consequently, we did not carry out any further experiments with these methods.

Abstract

This paper describes the Volctrans' submission to the WMT21 news translation shared task for German→English translation. We build a parallel (*i.e.*, non-autoregressive) translation system using the Glancing Transformer (Qian et al., 2020), which enables fast and accurate parallel decoding in contrast to the currently prevailing autoregressive models. To the best of our knowledge, this is the first parallel translation system that can be scaled to such a practical scenario like WMT competition. More importantly, our parallel translation system achieves the best BLEU score (35.0) on German→English translation task, outperforming all strong autoregressive counterparts.

1 Introduction

In recent years' WMT competitions, most teams develop their translation systems based on autoregressive models, such as Transformer (Vaswani et al., 2017). Although autoregressive models (AT) achieve strong results, it is also worth exploring other alternative machine translation paradigm. Therefore, we build our systems with non-autoregressive translation (NAT) models (Gu et al., 2018). Unlike the left-to-right decoding in the autoregressive models, the NAT models employ the more efficient parallel decoding. Specifically, our system employs single-pass parallel decoding, which generates all the tokens in parallel at one time, thus can accelerate decoding speed.

In this paper, we would like to present the best practice we explored in this year's competition for our parallel translation system, aiming at achieving top results while preserving decoding efficiency.

System Overview. To achieve this, we improve the parallel translation system in several aspects, including better model architectures, various data exploitation methods, mutli-stage training strategy, and inference with effective reranking techniques. For model architectures (§2), we build the parallel translation system based on the Glancing Transformer (GLAT, Qian et al., 2020). Besides, our system employs dynamic linear combination of layers (DLCL, Wang et al., 2019) for training deep models. For data exploitation (§3), we first filter data with multiple strategies. After filtering, we use the Transformer (Vaswani et al., 2017) to synthesize various distilled data. For training (§4), the NAT models employ multi-stage training to better exploit the distilled data. At inference phase (§5), the system generates the final results by reranking candidate hypothesis from multiple parallel generation models.

With the proposed techniques, our parallel translation system surpasses autoregressive models, and achieves the highest BLEU score (35.0) in the German→English translation task. Such results show that parallel translation system not only has great decoding efficiency, but also could achieve better performance compared to the autoregresssive counterparts.

2 Backbone Model Architecture

As depicted in Figure 1, our submitted system employs GLAT (Qian et al., 2020) as our backbone model architecture, and includes an auxiliary decoder in GLAT for achieving better translation performance. GLAT is a method for training non-autoregressive models rather than a model architecture, which adaptively samples target tokens in training. Although the target token sampling in GLAT helps training, it also introduces a gap between training and inference. To close the gap, we introduce the auxiliary decoder that shares the same encoder with the GLAT decoder, which is only used for training in a multi-tasking fashion.

[*]Equal contributions.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 187–196
November 10–11, 2021.

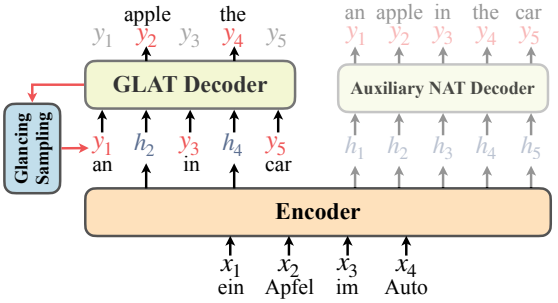

Figure 1: Illustration of our backbone model architecture: Glancing Transformer with an auxiliary decoder.

Besides, we train models with three architecture settings to increase model diversity.

2.1 Glancing Transformer

GLAT has three components: the encoder, the decoder, and the length predictor. The architecture of GLAT is built upon the Transformer (Vaswani et al., 2017). The encoder is the same as that of Transformer, and the decoder is different from the Transformer decoder in the attention mask. Transformer employs attention mask in self-attention layer to prevent decoder representations attending to subsequent positions. Since GLAT generates sentences in parallel, the decoder of GLAT has no attention mask and uses global context in decoding. The details of the length predictor is described in Section 2.3.

To reduce the difficulty of training deep models, we also employ dynamic linear combination of layers (DLCL, Wang et al., 2019) in the architecture. With DLCL, the input of each layer is the linear combination of outputs from all the previous layers.

Given the source input $X = \{x_1, x_2, ..., x_N\}$ and the target output $Y = \{y_1, y_2, ..., y_T\}$, we use the glancing language model (Qian et al., 2020) in training. The model performs two decoding during training. In the first decoding, the model generates the sentence $\hat{Y}$ in parallel. Then, the model randomly selects a subset of tokens $\mathbb{GS}(Y, \hat{Y})$ in the target sentence Y:

$$\mathbb{GS}(Y, \hat{Y}) = \text{Random}(Y, S(Y, \hat{Y})) \quad (1)$$

where $\text{Random}(Y, S)$ means randomly sample S tokens in Y. And the sampling number $S(Y, \hat{Y})$ is computed by $S(Y, \hat{Y}) = \alpha \cdot d(Y, \hat{Y})$. $d(Y, \hat{Y})$ is the Hamming distance between the first decoding result $\hat{Y}$ and the target sentence Y, and α is a hyper-parameter for controlling the sampling number more flexibly.

In the second decoding, the model replaces part of the original decoder input representations with the embeddings of tokens in $\mathbb{GS}(Y, \hat{Y})$. Specifically, the token y_i is used to replace the input representation at position i. With the replaced decoder inputs, the model learns to predict the remaining words and compute the training loss:

$$\mathcal{L}_{\text{glm}} = \sum_{y_t \in \overline{\mathbb{GS}(Y,\hat{Y})}} \log p(y_t | \mathbb{GS}(Y, \hat{Y}), X) \quad (2)$$

where $\overline{\mathbb{GS}(Y, \hat{Y})}$ is the subset of tokens in Y that are not selected. In training, the model starts from learning to generate sentence fragments and gradually learning the parallel generation of the whole sequence.

2.2 Auxiliary Decoder

Although the sampled target words in GLAT training help the model learn target word interdependencies, they also introduce a gap between training and inference as the model cannot obtain target word inputs in inference. Therefore, we add an auxiliary non-autoregressive decoder to close the gap. The auxiliary decoder shares the same encoder with the GLAT decoder and directly learns to predict the whole sequence in parallel. With the auxiliary decoder, we compute the loss for predicting the whole sequence:

$$\mathcal{L}_{\text{aux}} = \sum_{t=1}^{T} \log P_{\text{aux}}(y_t | X) \quad (3)$$

where P_{aux} is the output probability of the auxiliary decoder. We jointly train the two decoders and the training loss of model is:

$$\mathcal{L}_{\text{gen}} = \mathcal{L}_{\text{glm}} + \lambda \mathcal{L}_{\text{aux}} \quad (4)$$

Note that the auxiliary decoder is only used in training and has no additional cost in inference.

2.3 Length Prediction

To enable parallel generation, the model predicts the target length before decoding. We use the average of encoder hidden states H_{avg} as the representation to predict the length of target sentence. The probability of the target length is computed by:

$$P_{\text{len}} = \text{softmax}(H_{\text{avg}}^{\top} E_{\text{len}}) \quad (5)$$

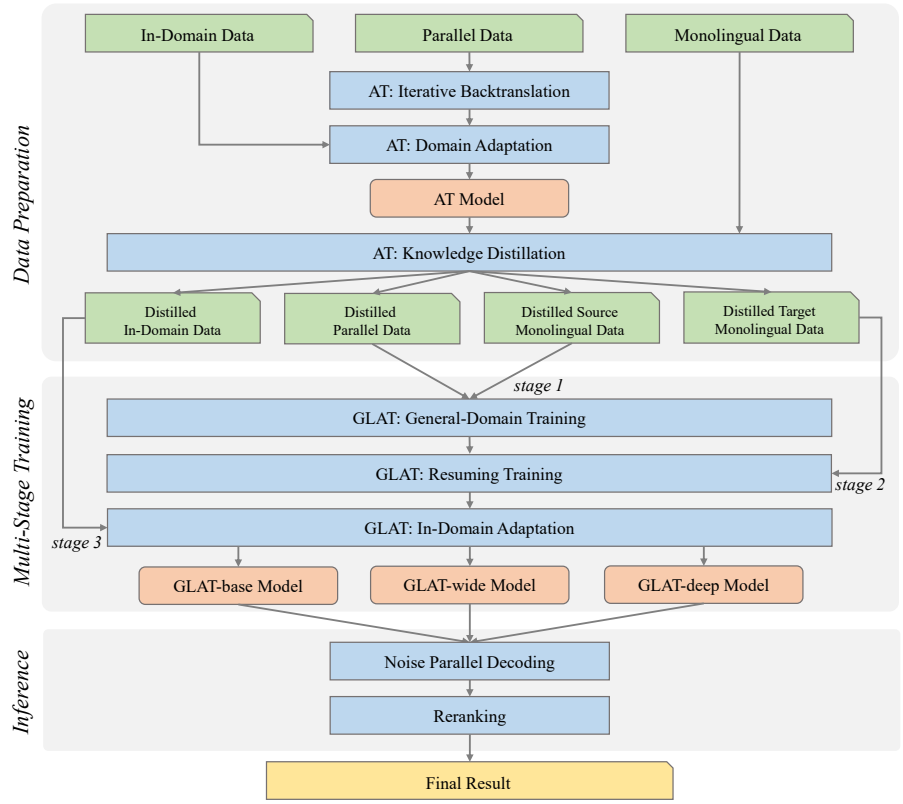

Figure 2: Overview of Volctrans GLAT System. Each grey block denotes a part of the system, the details can be found in Section 3: Data Preparation, Section 4: Multi-Stage Training, and Section 5: Inference.

where E_{len} is the embeddings of length. Instead of directly predicting the target length, the implemented model predicts the length difference between input and output, which is easier to learn. We use cross entropy loss for optimizing P_{len} and train the length predictor with the generation module jointly.

2.4 Model Variants

As shown in Figure 2, in order to increase the diversity of models, we use three model architecture settings for GLAT. The details of the three GLAT architecture variants are:

- GLAT-base: Following Wu et al. (2020);Sun et al. (2019), we increase the number of encoder layers and use 16 encoder layers for GLAT-base. For decoders, we use 6 layers for the original decoder and 2 layers for the auxiliary decoder. As for other model hyperparameters, we use the 1024 hidden dimension and 16 attention heads, which are the same as the setting of Transformer-big.
- GLAT-deep: We further increase the number of encoder layers to 32 for GLAT-deep. To keep the number of model parameters on the same scale, we decrease the hidden dimension to 768.
- GLAT-wide: Following previous work (Wu et al., 2020), we also expand the dimension of the feed-forward inner layer to construct GLAT-wide. We set the feed-forward dimension to 12288 and the encoder layer number to 12.

3 Data Preparation

In this section, we will describe our best practice of distilled data construction by employing AT models. As illustrated in *data preparation* in Figure 2, we will first depict the general procedure of data filtering and preprocessing of the provided raw data, followed by the training details of the AT models. Finally, we will describe how we produced distilled data given the trained AT models. The resulting distilled data will be used for training our GLAT system.

3.1 Data Filtering and Preprocessing

Data quality matters in machine translation systems. To obtain high-quality data, we employ rule-based heuristics, language detection, word alignment and

similarity-based retrieval to filter the provided parallel and monolingual corpora.

Rule-based Data Filtering

Based on experiences and WMT reports in previous years, we first preprocess raw data based on rules:

- Data deduplication.
- Delete parallel data with the same source and target.
- Remove special tokens and unprintable tokens.
- Remove HTML tags and inline URLs.
- Remove words or characters that repeat more than 5 times.
- Delete sentences that are too long (more than 200 words) or too short (less than 5 words), as well as the parallel data whose length-ratios of source and target sentences are out of balance.

Parallel Data Filtering

After completing the rule-based filtering, we further filtered parallel data via language detection and its parallelism. The filtering process consists of three stages:

1. Coarse-grained filtering: We filter parallel corpus according to the results and ratio of language detection. We use the pycld3[1] library to filter German→English sentence pairs with a language likelihood greater than 0.8 and a language ratio greater than 60%.
2. Word alignment learning: We use *fast align* (Dyer et al., 2013)[2] to automatically learn German→English word alignment on the coarsely filtered corpus.
3. Fine-grained filtering: We filter the sentences with an align score greater than five on all parallel corpora and sort them through the vocabulary learned by fast align.

Note that the amount of data in different corpora is not balanced. We split the data into the paracrawl group and the non-paracrawl group. We filter out about 10% of the data in the non-paracrawl group and 20% of the data in the paracrawl group.

Monolingual Data Filtering

For monolingual data, we first use the *pycld3* library to filter the data of low scores, similar to the coarse-grained filtering of parallel data.

Considering that monolingual data is too large, we searched for some of the most relevant sentences in our distilled data through sentence retrieval. We sample news domain sentences from the previous years' dev set and newscrawl corpus, and train a sentence BERT (Reimers and Gurevych, 2019)[3] to retrieve the sentences on the monolingual corpus. In detail, for each sampled news sentence, we calculate the inner product of sentence embedding between it and some random monolingual sentences (as the entire corpus is too large), where the sentence embedding is calculated with the sentence BERT model. We retrieved the top 8000 sentences for each news sample according to the inner product of sentence embedding. Finally, we deduplicate the retrieved sentences to obtain the final monolingual data.

	German (De)	English (En)
parallel data	75M	
monolingual data	86M	105M

Table 1: Statistics of the training data after preprocessing and filtering.

Data Preprocessing

Once we obtained filtered data, we preprocess them through the following steps:

1. Normalization: we use Moses tokenizer to normalize the punctuation.
2. Tokenization: we use Moses tokenizer to tokenize all datasets.
3. Truecasing: we use Moses truecaser to learn and apply truecasing on all datasets.
4. Subword segmentation: we use our proposed VOLT (Xu et al., 2021), which learns vocabularies via optimal transport, to split tokens into subwords, resulting in a joint vocabulary of a size of 12k subwords.

We summarize the statistics of the final datasets in Table 1.

3.2 Training of AT Systems

In this section, we describe our AT systems, which served to distill data for GLAT training. Overall, we first train a pair of German→English and English→German AT systems purely using parallel data. We then exploit source and target monolingual data to create synthetic parallel data to further improve the AT models. Besides, we leverage the

[1] https://pypi.org/project/pycld3/
[2] https://github.com/clab/fast_align
[3] https://github.com/UKPLab/sentence-transformers

testsets from previous years to fine-tune the AT models for in-domain adaptation.

Hyperparameters. The AT models are Transformer models with 12 layers of encoder and decoder. We use the implementations in Fairseq (Ott et al., 2019). All models are trained with Adam optimizer (Kingma and Ba, 2014). We use the inverse sqrt learning rate scheduler with 4000 warm-up steps and set the maximum learning rate to $5 \cdot 10^{-4}$. The betas are (0.9, 0.98). We use multiple GPUs during training, resulting in an approximate total effective batch size of 128k tokens. During training, we employ label smoothing (Szegedy et al., 2016) of 0.1 and set dropout rate (Srivastava et al., 2014) to 0.3.

Iterative Back Translation

Zhang et al. (2018) proposed an iterative joint training method for better usage of monolingual data from the source language (i.e., German) and target language (i.e., English). In each iteration, the German→English model generates forward synthetic data from the German monolingual data, and the English→German model generates backward synthetic data from the English monolingual data. Then, the German→English and English→German models are trained with the new forward and backward synthetic data to improve both models' performance, in which the target-side data are assumed to be the authentic ones from the monolingual corpus. In the next iteration, the German→English and English→German models can generate synthetic data with better quality, and their performance can be further improved . We jointly train the German→English and English→German models for 3 iterations.

In-domain Finetuning

We fine-tune the trained model on the previous years' testsets to obtain in-domain knowledge, which is a widely used technique in previous years' WMT (Li et al., 2019). Specifically, we use WMT19 German→English testset as in-domain data. We set the learning rate to 1e-4 without a learning rate scheduler and the max tokens per batch as 4096. We then fine-tune the model for 30 steps[4].

[4]Since the size of the in-domain data is small, fine-tuning with more steps will overfit the data.

	De-En	En-De
baseline	39.34	35.10
iterative BT	43.56	36.85
in-domain FT	44.00	38.30
forward translation	44.05	39.50
final training	44.15	39.70

Table 2: BLEU scores of AT models on `newstest20` with respect to different training stages.

Forward Translation

Bogoychev and Sennrich (2019) observed that on the sentences that are originally in the source language, which is the case of the test sets of this year's WMT, the forward translation could bring significantly more improvement than back-translation. We thus use the finetuned model, obtained by the aforementioned in-domain finetuning, to translate source monolingual corpus to obtain forward translation data. We then apply these forward translation data to finetune our AT models.

Finally, we combine all the parallel data, back-translation data, and forward translation data to further finetune our AT models. Table 2 shows the performance of the AT models with respect with each training stage. The resulting AT models are ready for constructing distilled data for GLAT training.

3.3 Constructing Distilled Data for GLAT

One of the widely known difficulties of training NAT models is the multi-modality problem (Gu et al., 2018). In the raw training data, the target tokens have strong correlations across different positions, which is hard to capture by NAT models due to the conditional independence assumption. A key ingredient in the training recipe for most of the NAT models is constructing training data via sequence-level knowledge distillation (Kim and Rush, 2016), where the target-side of the training data is replaced by the forward translation of AT models.

Note that previous work did not leverage existing large-scale monolingual data in training GLAT models, either from source or target language. In this work, we applied sequence-level knowledge distillation to parallel data and monolingual data from both source and target languages.

- Parallel data and source monolingual data distillation (119M sentences). We directly use

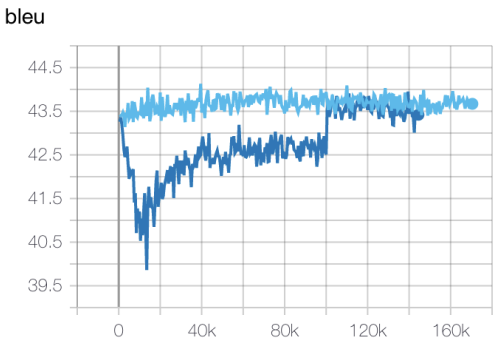

Figure 3: Learning curves of different finetuning strategies, reported on `newstest20`, De→En. The light blue curve denotes training with inverse square root scheduler where the peak learning rate equals $5 \cdot 10^{-4}$, and the initial sampling ratio λ is set to 0.5, the dark blue curve denotes training with a constant learning rate of $1e-4$ and $\lambda = 0.1$.

German→English AT model to obtain the forward translations of the German sentences.

- Monolingual target data distillation (39M sentences). The way to exploiting target monolingual data is not as evident as using the monolingual source data since the purpose of knowledge distillation is to construct a pseudo-parallel dataset where synthetic ones replace the actual target sentences. To this end, we propose a cycle distilling technique. We use the backward English→German AT model to back-translate the monolingual target data, resulting in a translated source dataset. We then used the German→English AT model to get the round-trip forward translation of the translated source dataset, obtaining the cycle distilled data. We will refer to this as *cycle KD data*.

4 Multi-Stage Training

We train our parallel translation system in a multi-stage way (See *Multi-Stage Training* in Figure 2). In the first stage, the model uses the distilled parallel and source monolingual data for training. In the second stage, we train the model with the target monolingual data (aka. *cycle KD data*). After training the model on large-scale distilled data until convergence, we finetune the model on small-scale in-domain data.

4.1 General-Domain Training

All models are trained with Adam optimizer with decoupled weight decay (Kingma and Ba, 2014; Loshchilov and Hutter, 2017). We use the inverse sqrt learning rate scheduler with 4000 warm-up steps and set the maximum learning rate to $5 \cdot 10^{-4}$. The adam betas are $(0.9, 0.999)$.

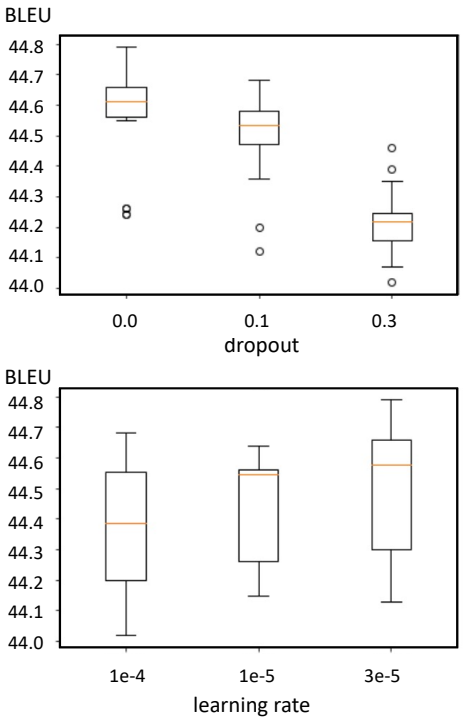

Figure 4: BLEU score versus the dropout and learning rate, reported on `newstest20`, De→En.

4.2 Resuming Training

We often have to load a pre-trained checkpoint and continuously train the model on a new dataset. The loaded checkpoint serves as a good initialization, and the parameters may change significantly in this process.

We found that it is not easy to apply the techniques from auto-regressive translation to GLAT directly. Preliminary experiments show that if we employ the techniques illustrated in (Qian et al., 2020) during the finetuning stage, the BLEU score will degrade dramatically and then increase slowly until convergence. The number of total update steps required for convergence is similar to training from scratch on a new dataset. There are mainly two concerns. Firstly, GLAT employs the inverse square root learning rate scheduler. The learning rate will increase to $5 \cdot 10^{-4}$ linearly and decay exponentially until the training process is over (the learning rate is close to $1e-4$). During the finetuning stage, a constant learning rate no larger than $1e-4$ will stabilize the training process. Secondly, the ini-

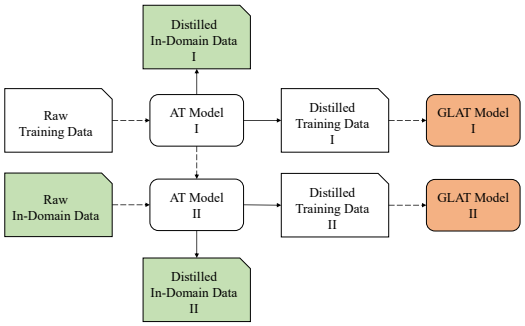

Figure 5: Various pipelines for domain adaptation.

In-Domain Data	GLAT-I	GLAT-II

Distilled I	+0.30	+1.99
Distilled II	+1.56	+2.31

Table 3: Results of different adaptation pipelines. GLAT-I and GLAT-II are models trained with distilled training data generated by AT Model I and AT Model II in Figure 5, respectively. After training, we use the in-domain data Distilled I and Distilled II for fine-tuning.

tial sampling ratio $\lambda = 0.5$ in (Qian et al., 2020) can be too large for finetuning since the model can already do a good job in the translation task. A large sampling ratio may cause the model to suffer from "exposure bias"(Zhang et al., 2019): the gap between training (where some target words are provided) and validation (where no target words are provided). Figure 3 illustrates the comparison between two different finetuning strategies.

4.3 In-Domain Adaptation

When finetuning the model on small-scale in-domain data, which is widely used for domain adaptation (Meng et al., 2020), the parameters of the model do not change significantly.

For domain adaptation, we perform grid search on four group of hyper-parameters: learning rate($1e-5$, $3e-5$, $1e-4$), dropout(0.0, 0.1, 0.3), sampling rate λ (0.3, 0.1), and max number of tokens per batch (2000, 4000, 8000). For each combination, we conduct two experiments to reduce the variance. Experimental results (Figure 4) show that the learning rate and dropout rate are the most significant factors. Interestingly, when dropout is set to 0, the performance is surprisingly great, which indicates the effectiveness of over-fitting on an in-domain dataset.

feature groups	feature number
GLAT score	3
AT 16e6d	3
AT 12e12d	3
Self BLEU	1
Self Chrf	1

Table 4: Selected Features.

Model	BLEU	Self-R	AT-R
GLAT-base (w/o AUX)	42.28	42.54	42.90
+ CTC	41.04	-	-
+ AUX	43.1	43.11	43.52

Table 5: Results of different architectures, reported on `newstest20`, De→En.

There are several feasible pipelines for domain adaptation due to the interaction between auto-regressive and non-autoregressive models. Figure 5 illustrates these pipelines, and the key points are listed as follows:

- Should we finetune the auto-regressive model on the in-domain dataset (AT Model I→AT Model II)?
- Should we use the original in-domain dataset for GLAT's model adaptation or the in-domain dataset distilled by AT model I, or the in-domain dataset distilled by AT Model II?

Table 3 shows the results of different pipelines. Experiments show that making domain adaptation on the autoregressive model can boost the performance of the non-autoregressive model. It is also beneficial to further finetune the non-autoregressive model on the distilled in-domain dataset.

5 Inference

In this section, we introduce two approaches for GLAT's inference: Noisy parallel decoding (NPD) and Reranking (See *Inference* in Figure 2). NPD is easy to integrate into a single model and improve the performance; Reranking can help push the performance to the limit: generating as many candidates as possible and ranking them with as many features as possible.

5.1 Noisy Parallel Decoding

A simple yet efficient inference approach is noisy parallel decoding (NPD) (Gu et al., 2018). We

Table 6: Final results, reported on `newstest20`, De→En. * denotes the submitted system (BLEU=35.0 on `newstest21`, De→En). The baseline is GLAT w/ AUX.

first predict m target length candidates (in Table 5, $m = 5$), then generate output sequences with argmax decoding for each target length candidate. Then we use a model to rank these sequences and identify the best overall output as the final output. If the model for ranking and the one for generation is the same model (GLAT), we call it *Self-Reranking*; if the ranking model is AT, we call it *AT-Reranking*.

5.2 Reranking

We use kbmira[5] to re-rank hypotheses. We first train GLAT model variants of different settings, each of which produces a set of candidates via the various search algorithm in Section 2.4. For each source sentence, every model outputs 7 hypothesis candidates and a total of 252 translations are collected for re-ranking. Then we compute 44 features for each hypothesis, out of which 11 features are finally used. The selected features are listed in Table 4. The kbmira algorithm takes these features to select the best hypothesis from these candidates. Note that the kbmira algorithm is optimized on `newstest19` and validated on `newstest20` to select the best feature combination. Instead of enumerating all the possible combinations (2^{44}), we incrementally add feature groups to kbmira algorithm for fast search.

It is considered as an ablation study to predefined features. After selecting the best feature combination, we further search better kbmira weights to achieve higher BLEU scores on `newstest20`.

6 Experiment

For our parallel translation system, we train three GLAT variants with the distilled data, and get the final outputs by reranking candidate hypothesis obtained from multiple GLAT models.

6.1 Hyperparameters

We implement our models with Fairseq (Ott et al., 2019). Our experiments are carried out on 4 machines with 8 NVIDIA V100 GPUs, each of which has 32 GB memory. The number of tokens per batch is set to $256k$. The dropout rate is set to 0.3 for the first $100k$ steps. We reduce the dropout to 0.1 after $100k$ steps, which can contribute to an improvement of about 1 BLEU score (Figure 3). The hyper-parameter λ for balancing L_{glm} and L_{aux} is set to 1.

6.2 Results

Our models are trained on the distilled parallel data and the distilled source monolingual data firstly. We experiment with various utilization of raw data, but the results show that the usage of raw data has no positive effect. The results of different architectures can be found in Table 5. Self-R and AT-R denote self-reranking and reranking with an autoregressive model, respectively. Experimental results show that the auxiliary decoder (AUX) effectively improves the performance by about 0.6 BLEU scores. For GLAT-base + CTC (Graves et al., 2006), we first set the max output length to twice the source input length and remove the blanks and repeated tokens after generation. We find CTC does not improve the performance and requires about twice the training time for convergence.

Based on GLAT with AUX, we employ three technologies to improve further: continuously training on the cycle KD data, domain adaptation, and reranking with various features. Table 6 shows the final results of our submitted system. Training on the distilled target monolingual data can further improve the performance by about 0.3 BLEU scores. Since the domain adaptation has already been em-

[5] https://github.com/moses-smt/mosesdecoder

ployed in the AT model's training process, the cycle KD data has already contained information of the in-domain data. However, the domain adaptation on GLAT can still gain a slight improvement of about 0.2. Moreover, an additional reranker with more diverse features can boost the performance by about 0.6.

7 Conclusion

In this paper, we introduced our system submitted to the WMT2021 shared news translation task on German→English. We build a parallel translation system based on the Glancing Transformer (Qian et al., 2020). Knowledge distillation, domain adaptation, reranking have proven effective in our system. Our constrained parallel translation system gets first place in the German→English translation task with a 35.0 BLEU score.

Abstract

This paper provides an overview of NVIDIA NeMo's neural machine translation systems for the constrained data track of the WMT21 News and Biomedical Shared Translation Tasks. Our news task submissions for English ↔ German (En ↔ De) and English ↔ Russian (En ↔ Ru) are built on top of a baseline transformer-based sequence-to-sequence model (Vaswani et al., 2017). Specifically, we use a combination of 1) checkpoint averaging 2) model scaling 3) data augmentation with backtranslation and knowledge distillation from right-to-left factorized models 4) finetuning on test sets from previous years 5) model ensembling 6) shallow fusion decoding with transformer language models and 7) noisy channel re-ranking. Additionally, our biomedical task submission for English ↔ Russian uses a biomedically biased vocabulary and is trained from scratch on news task data, medically relevant text curated from the news task dataset, and biomedical data provided by the shared task. Our news system achieves a sacreBLEU score of 39.5 on the WMT'20 En → De test set outperforming the best submission from last year's task of 38.8. Our biomedical task Ru → En and En → Ru systems reach BLEU scores of 43.8 and 40.3 respectively on the WMT'20 Biomedical Task Test set, outperforming the previous year's best submissions.

1 Introduction

We take part in the WMT'21 News Shared Task for English ↔ German, English ↔ Russian, and the Biomedical Shared Task for English ↔ Russian. Our systems are implemented in the NVIDIA NeMo[1] framework (Kuchaiev et al., 2019). They build on baseline sequence-to-sequence transformer models (Vaswani et al., 2017) in the following ways: 1) Checkpoint averaging, 2) Model scaling up to 1B parameters, 3) Data augmentation with large-scale backtranslation (Edunov et al., 2018) of monolingual Newscrawl data and sequence-level knowledge distillation from a right-to-left factorized model (Zhang et al., 2019b), 4) Finetuning models on in-domain news data from WMT test sets made available in previous years, 5) Ensembling models trained on different subsets of the overall data 6) Shallow fusion decoding with transformer language models (Gulcehre et al., 2015) 7) Noisy channel re-ranking of beam search candidate hypotheses (Yee et al., 2019).

Overall, we find each of these components results in a small improvement in BLEU scores with backtranslation results being mixed depending on the language direction and whether the test data contains translationese inputs. Using a combination of these techniques, we achieve 39.5 sacreBLEU scores on the En → De WMT'20 test set, outperforming the best BLEU scores from last year's competition of 38.77.

Training our En ↔ Ru biomedical task submission from scratch using a biomedical vocabulary and similar model improvements to those used for our news task submission, we report a sacreBLEU score of 40.3 on En → Ru and 43.8 on Ru → Enh on the WMT'20 Biomedical Shared Task test dataset. This improves over the best submissions from last year's competition[2] of 39.6 and 43.3 on En → Ru and Ru → En respectively.

2 Datasets

We participated in the constrained data track at this year's news and biomedical competitions and used all the parallel corpora provided by the WMT Shared Tasks for both En ↔ De and En ↔ Ru. We used the provided English, German, and Russian monolingual Newscrawl data for backtranslation and training our autoregressive transformer language models. We filter out monolingual

[1] https://github.com/NVIDIA/NeMo

[2] We compare against all En ↔ Ru Biomedical submissions, not just the ones marked as the final submission.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 197–204
November 10–11, 2021.

Newscrawl data only based on minimum and maximum length criteria, but perform more aggressive filtering of our parallel data described in Section 2.1.

2.1 Parallel Corpus Filtering

We use a combination of the following data filtering steps for all parallel corpora (including pseudo parallel corpora generated via backtranslation and distillation) except for the Biomedical Shared Task provided data.

- **Language ID Filtering** - We use the fastText (Joulin et al., 2016) language ID classifier[3] to remove training examples that aren't in the appropriate language.
- **Length and Ratio Filtering** - We filter out examples where a sentence in either language is longer than 250 tokens before BPE tokenization and where the length ratio between source and target sentences exceeds 1.3.
- **Bicleaner** - Bitexts that were assigned a Bicleaner (Ramírez-Sánchez et al., 2020) score of < 0.6 were removed.

On the news shared task, we keep 60M parallel sentences for En $\leftrightarrow$ De and 26M sentences for En $\leftrightarrow$ Ru after filtering.

2.2 Biomedical Task Data

Our parallel biomedical domain data included a mix of all the En $\leftrightarrow$ Ru parallel training data given by shared task organizers and biomedically relevant examples selected from the provided En $\leftrightarrow$ Ru news task data.

We trained two biomedical domain binary classifiers, one for English and one for Russian. The classifiers were composed of two task-specific fully connected layers on top of pre-trained BERT Base (Devlin et al., 2018) or RuBERT Base (Kuratov and Arkhipov, 2019) for English and Russian respectively. The positive examples were sourced from the WMT'20 Biomedical Shared Task train set. The negative examples were randomly sampled from the parallel En $\leftrightarrow$ Ru news data given for the WMT'21 news task. An equal amount of 45K examples were used for both the positive and negative classes.

We ran our English biomedical domain classifiers on the English half of all approximately 26M parallel En $\leftrightarrow$ Ru WMT'21 news training data. We saved all sentences with predicted biomedical domain probabilities over 50%, collecting around 560k examples. We then ran our Russian classifier on the Russian counterparts to the 560k predicted in domain English sentences. We averaged the classifier scores from the English and Russian domain classifiers and used this average score as our final selection criteria. We set a cut-off threshold of .90 resulting in 208K parallel examples classified from the news domain data. We combined this with the 46k parallel biomedical examples provided for the task, resulting in a total of 256,037 parallel training examples.

2.3 Data Pre-processing and Post-processing

We normalize punctuation[4] and tokenize[5] examples with the Moses toolkit. For En $\leftrightarrow$ De, we train a shared BPE tokenizer with a vocab of 32k tokens using the YouTokenToMe[6] library. For En $\leftrightarrow$ Ru, we train language-specific BPE tokenizers with a vocab of 16k tokens each. For the En $\leftrightarrow$ Ru Biomedical translation task, we learn a separate BPE tokenizer solely on our Biomedical Task Data described in 2.2. We use BPE-dropout (Provilkov et al., 2019) of 0.1 for both language pairs and tasks. We post-process En $\rightarrow$ De model generated translations to replace quotes with their German equivalents - „ and “.

3 System overview

Our systems build on the Transformer sequence-to-sequence architecture (Vaswani et al., 2017). In the subsequent subsections, we discuss model scaling, checkpoint averaging, data augmentation with backtranslation and right-to-left distillation, model finetuning, ensembling, shallow fusion decoding with LMs, and noisy channel re-ranking.

3.1 Model Configurations

We experiment with three different model configurations - Large, XLarge, and XXLarge. The Large configuration corresponds to the "Transformer Large" variant from Vaswani et al. (2017)

[3] https://fasttext.cc/docs/en/language-identification.html

[4] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/normalize-punctuation.perl

[5] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl

[6] https://github.com/VKCOM/YouTokenToMe

and the XLarge and XXLarge scale that base configuration along depth and width. The exact specifications are in Table 1. Following Kasai et al. (2020), we keep the number decoder layers fixed at 6 and scale only the depth of the encoder to 24 layers for the "XLarge" configuration. For stable optimization of deep transformers, we use the "pre-LN" transformer block (Xiong et al., 2020). When scaling to 1 billion parameters (XXLarge), we only increase hidden and feedforward dimensions of the model.

	Large	XLarge	XXLarge
Hidden Dim	1,024	1,024	1,536
Feedforward Dim	4,096	4,096	6,144
Attention Heads	16	16	24
Encoder Layers	6	24	24
Decoder Layers	6	6	6
Pre-LN	✗	✓	✓
Parameters	240M	500M	1B

Table 1: Model Configurations

3.2 Checkpoint Averaging

Over the course of training, we save the top-k checkpoints that obtain the best sacreBLEU scores on a validation set. The final model parameters are obtained by averaging the parameters corresponding to these checkpoints.

$$\theta_{avg} = \frac{1}{k}\sum_{i=1}^{k}\theta_i$$

θ_{avg} are the model parameters after checkpoint averaging and $\theta_1 \ldots \theta_k$ are the individual checkpoints being averaged. Empirically, we didn't observe a difference between averaging the last k checkpoints versus the top-k checkpoints. The former is however more common and implemented in libraries such as fairseq (Ott et al., 2019).

3.3 Data Augmentation with Backtranslation & Right-to-left model distillation

We follow Edunov et al. (2018) in backtranslating monolingual Newscrawl data with noise introduced via topk sampling (k=500). For En $\leftrightarrow$ De, we backtranslate ~250M sentences and filter translations based on the process described in Section 2.1. We observed fairly significant drops in BLEU score when using backtranslated data for En $\leftrightarrow$ Ru and did not apply any data augmentation for this language pair. We use the XLarge model configuration trained only on the News Task provided parallel corpus to generate translations.

We also train an XLarge model for En $\rightarrow$ De and De $\rightarrow$ En on the News Task provided parallel data where the output sequence is factorized from right-to-left. Translations of the training dataset with topk sampling (k=500) using these models are generated and added to the overall training set.

When adding only backtranslated text or data generated from right-to-left factorized models, we use a 2:1 ratio of parallel to pseudo-parallel (model generated) data. When training with a combination of both, we use a 6:3:1 ratio of parallel, right-to-left generated, and backtranslated data. We skew data sampling in this way since training on right-to-left generated data showed better performance on recent WMT test sets as opposed to backtranslation which did better on old test sets that contained translationese inputs (see Tables 2 and 3).

3.4 Mixed Domain Training

For the biomedical task submission, we experiment with different mixed domain training approaches (Zhang et al., 2019a). We train on the concatenated combination of news task and biomedical task data-up-sampling the proportion of biomedical data to make up 30% or 50% of the data-parallel examples seen during training. We also train models on concatenated data with no up-sampling and with purely news task data. The base models trained on exclusively news task data still use the biomedical vocabulary tokenizer.

3.5 Model Finetuning

For our news task submission, we finetuned models on an in-domain parallel corpus consisting of WMT provided test datasets from past years (WMT'08 - WMT'19 for En $\leftrightarrow$ De comprising ~32k examples) for both En $\leftrightarrow$ De and En $\leftrightarrow$ Ru.

We finetuned our biomedical task base models on the 250k parallel sentences obtained via the process described in Section 2.2. Models are finetuned for 1-2 epochs using a fixed tuned learning rate and the top-k checkpoints on a validation dataset (newstest2020 for the News Shared Task) are averaged.

3.6 Ensembling

Given k different models for a particular language direction trained with the same tokenizer, we ensemble them at inference by averaging their probability distributions over the next token.

$$P(y_t|y_{<t}, x; \theta_1 \dots \theta_k) = \frac{1}{k} \sum_{i=1}^{k} P(y_t|y_{<t}, x; \theta_i)$$

Where $P(y_t|y_{<t}, x)$ is the probability distribution over the target token y_t given all previously generated target tokens $y_{<t}$ and the input sequence x. $\theta_1 \dots \theta_k$ are the k different models being ensembled.

Beam search scores are computed using these averaged probabilities at each time step. In practice, we ensemble models trained on different subsets of the available data.

For En $\leftrightarrow$ De, we ensemble a total of 6 models trained on different subsets of the data. Example: News Task provided bitext only, the addition of backtranslated and/or data from right-to-left factorized models and finetuned models.

For En $\leftrightarrow$ Ru, we ensemble a total of 3 identical XLarge models trained with different random seeds on the main parallel corpus.

For the En $\leftrightarrow$ Ru biomedical task, we ensemble 4 finetuned models whose base configurations were trained with different mixed domain sampling ratios. Specifically, each translation direction includes an ensemble of models initially trained on mixed domain data with 50% up-sampling of biomedical data, concatenated biomedical and news data with no up sampling, exclusively news data, and exclusively news data with right-to-left distillation.

3.7 Shallow Fusion Decoding with Language Models

Aside from backtranslation, another way to leverage large amounts of monolingual data is via training language models. We train language-specific 16-layer transformer language models at the sentence level, which is architecturally similar to Radford et al. (2019). They are trained on Newscrawl and use the same tokenizers as our NMT systems.

When generating translations, we decode jointly with our NMT system $\theta_{s\to t}$ and a target side language moel θ_t (Gulcehre et al., 2015). The score of a partially decoded sequence on the beam $\mathcal{S}(y_{1\dots n})$ of length n is given by the following recurrence

$$\mathcal{S}(y_{1\dots n}|x; \theta_{s\to t}, \theta_t) = \mathcal{S}(y_{1\dots n-1}|x; \theta_{s\to t}, \theta_t) + \log P(y_n|y_{<n}, x; \theta_{s\to t}) + \lambda_{sf} \log P(y_n|y_{<n}; \theta_t)$$

where the empty sequence has a score of 0. We tuned the LM importance coefficient λ_{sf} on a validation dataset and found a value between 0.05 - 0.1 to work well in practice.

3.8 Noisy Channel Re-ranking

We re-rank the beam search candidates produced by our ensemble model generated with or without shallow fusion using a neural noisy channel model (Yee et al., 2019). The noisy channel model computes the score of any translation $\mathcal{S}(y_i|x)$ on the beam based on a forward (source-to-target) model, a reverse (target-to-source), and a target language model. The best translation after re-ranking is given by

$$\arg\max_i \mathcal{S}(y_i|x) = \log P(y_i|x; \theta^{ens}_{s\to t}) + \lambda_{ncr}\big(\log P(x|y_i; \theta_{t\to s}) + \log P(y_i; \theta_t)\big)$$

Forward log probabilities are given by an ensemble of source-to-target models $\theta^{ens}_{s\to t}$. We experimented with using an ensemble of target-to-source translation models to compute $\log P(x|y_i)$ but didn't observe any empirical benefits and so all reported results use only a single reverse model $\theta_{t\to s}$ for noisy channel re-ranking. We generate 15 candidates via beam search and tune λ_{ncr} on a validation dataset and found a value between 0.5 - 0.7 to work well in practice.

3.9 Training & Optimization

All En $\leftrightarrow$ De models were trained for up to 450k updates using the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9, \beta_2 = 0.98$ and Inverse Square Root Annealing (Vaswani et al., 2017) with 30k warm-up steps and a maximum learning rate of 4e-4. En $\leftrightarrow$ Ru models were trained for up to 150k updates with 7k warmup steps. We use label smoothing of 0.1 and a dropout of 0.1 on intermediate activations including attention scores to regularize our models.

The "Large" models were trained on NVIDIA DGX-1 machines with 8 32G V100 GPUs. We use a batch size of 16k tokens per GPU for an effective batch size of 128k tokens. The "XLarge" models were trained on 64 GPUs split across 4 NVIDIA DGX-2 nodes with 16 32G V100 GPUs each. These models use an effective batch size of 256k tokens. Finally, our "XXLarge" models were trained on 256 GPUs across 16 DGX-2 nodes with an effective batch size of 512k tokens.

4 News Task Submission

In this Section, we present results for our News Shared Task submission. Tables 2 and 3 contain ablations for En ↔ De and while Tables 4 and 5 has ablations for En ↔ Ru.

Each of the components we describe improves BLEU scores except for backtranslation and scaling our models to 1B params. Both show mixed results on En ↔ De - scores improve significantly on WMT'14 and WMT'18 test sets when adding backtranslated data (possibly because these test sets contain translationese inputs) but hurts or does not improve performance on WMT'19 and WMT'20 test sets. Our 1B parameter model does significantly better on WMT'14, but worse on WMT'19 and is comparable to the 500M parameter model on WMT'18 and WMT'20. We found optimization

with Adam to be unstable and used AdamW with a weight decay of 0.01 instead. Our final En → De model achieves a BLEU score of 39.5 on the WMT'20 test set, which improves over the submission with the best BLEU score from last year's competition of 38.8. We however do not do as well on De → En, with a final BLEU score of 42, compared to last year's best submission of 43.8.

Backtranslation significantly hurt performance in initial experiments on En ↔ Ru so we exclude it from our ensemble. The impact of ensembling, finetuning, and shallow fusion are fairly similar to En ↔ De. Additionally, we also report an "Oracle BLEU" score in Tables 4 and 5 where we compute BLEU scores by cheating and picking the translation on our beam that has the highest sentence BLEU score with respect to the reference. This is a useful indicator of how much there is to gain by re-ranking the beam search candidates.

5 Biomedical translation task submission

We present our Biomedical Shared Task submission in this section. Building on lessons learned from our news task ablation studies, we opted to use the Transformer-XLarge architecture, and average all of the intermediate model checkpoints which helps reduce model variance as a consequence of finetuning. Tables 6 and 7 show our results as we iterated on improving our models.

We trained our BPE tokenizer on biomedical data to mitigate character-level segmentation of words unique to the biomedical domain. We found this had a minimal effect on model performance. This could be because the majority of our parallel biomedical data was selected from news task training data, and thus biomedical words were already adequately accounted for by the news task model's tokenizer. We found that up-sampling in-domain

	Ru → En Biomedical Task Model	WMT'20 Bio	Δ

(16)	(14) + Noisy Channel Re-ranking	42.1	3.4

Table 7: Model iterations for the Biomedical Shared Task Ru → En. All reported scores are checkpoint averaged and are obtained from sacreBLEU. Δ computes the improvement over the Transformer-Large baseline on the WMT'20 Biomedical Shared Task test set. Model 14 is our selected best submission.

biomedical data hurt performance compared to concatenating out-of-domain and in-domain data with no up-sampling. For the En → Ru direction, including any biomedical domain data during initial model training showed improvements over training on exclusively news task data. Up-sampling in-domain data for the Ru → En direction hurt performance compared to our news task model baselines.

Unsurprisingly, finetuning base models on biomedical domain data improved BLEU scores for all models. In-domain finetuning helped models initially trained on news task data overcome performance gaps between themselves and models that had seen a higher amount of biomedical data during training. Neither shallow fusion nor noisy channel re-ranking improved model performance after ensembling for the Ru → En direction. Both techniques individually improved En → Ru performance but failed to do so in combination.

Ensembling our models led to an additional performance boost and allowed us to reach our maximum En → Ru BLEU score of 40.3 and Ru → En BLEU score of 43.8. These scores show a 0.9 and 0.5 improvement over last year's best score of 39.4 and 43.3 (Bawden et al., 2020) respectively.

6 Conclusion

We present Neural Machine Translation Systems for the En ↔ De News Task and En ↔ Ru News and Biomedical shared tasks implemented in the NeMo framework (Kuchaiev et al., 2019). Our systems build on the Transformer sequence-to-sequence model to include backtranslated text and data from right-to-left factorized models, ensembling, finetuning, mining biomedically relevant data using domain classifiers, shallow fusion with LMs, and noisy channel re-ranking. These achieve competitive performance to submissions from previous years.

7 Author Contributions

Sandeep Subramanian: Sandeep implemented and experimented with model scaling, backtranslation, distillation with right-to-left factorized models, model ensembling, and noisy channel re-ranking. He also ran all of the En ↔ De News Shared Task experiments, the right-to-left factorized models for the En ↔ Ru Biomedical task, and wrote parts of the paper.

Oleksii Hrinchuk: Oleksii H implemented the shallow fusion approach and helped with writing backtranslation scripts. He also ran all of the En ↔ Ru News Shared Task experiments and trained the language models used in the Biomedical experiments.

Virginia Adams: Virginia implemented and experimented with the warm-start biomegatron en-

coder, biomedical baselines, classifiers to extract biomedically relevant monolingual and parallel corpora, mixed domain, and finetuning of News models. She ran all of the En ↔ Ru Biomedical experiments.

Oleksii Kuchaiev: Oleksii K advised and managed the project.

Abstract

We describe Facebook's multilingual model submission to the WMT2021 shared task on news translation. We participate in 14 language directions: English to and from Czech, German, Hausa, Icelandic, Japanese, Russian, and Chinese. To develop systems covering all these directions, we focus on *multilingual* models. We utilize data from all available sources — WMT, large-scale data mining, and in-domain backtranslation — to create high quality bilingual and multilingual baselines. Subsequently, we investigate strategies for scaling multilingual model size, such that one system has sufficient capacity for high quality representations of all eight languages. Our final submission is an ensemble of dense and sparse Mixture-of-Expert multilingual translation models, followed by finetuning on in-domain news data and noisy channel reranking. Compared to previous year's winning submissions, our multilingual system improved the translation quality on all language directions, with an average improvement of 2.0 BLEU. In the WMT2021 task, our system ranks first in 10 directions based on automatic evaluation.

1 Introduction

We participate in the WMT2021 shared task on news translation and submit a multilingual translation system. In recent years, multilingual translation has gained significant interest as an alternative to developing separate, specialized systems for different language directions (Firat et al., 2016; Tan et al., 2019; Aharoni et al., 2019; Zhang et al., 2020; Tang et al., 2020; Arivazhagan et al., 2019). Multilingual systems have great potential for simplicity and consolidation, making them attractive options for the development and maintenance of commercial translation technologies. From a research standpoint, studies of transfer learning between related languages and developing methods that incorporate low-resource languages are strong motivators for grouping languages together in one system (Dabre et al., 2019; Fan et al., 2021).

Despite such motivations, existing multilingual translation systems have been unable to show that the translation quality of multilingual systems surpasses that of bilingual. Several works compare to bilingual baselines, but these baselines do not incorporate standard techniques used across the field — such as backtranslation or dense model scaling. Further, multilingual translation systems are often developed on non-standard training datasets and use different evaluation datasets. These factors make it difficult to assess the performance of multilingual translation, particularly when compared to the most competitive bilingual models.

In this work, our aim is to demonstrate against the winning WMT2020 models and our bilingual WMT2021 systems that multilingual translation models have stronger performance than bilingual ones. We focus on 14 language directions: English to and from Czech, German, Hausa, Icelandic, Japanese, Russian, and Chinese. We create an unconstrained system that utilizes both WMT distributed and publicly available training data, apply large-scale backtranslation, and explore dense and mixture-of-expert architectures. We compare the impact of various techniques on bilingual and multilingual systems, demonstrating where multilingual systems have an advantage. Our final multilingual submission improves the translation quality on average +2.0 compared to the WMT2020 winning models, and ranks first in 10 directions based on automatic evaluation on the WMT2021 leaderboard.

2 Data

We participate in translation of English to and from Czech (cs), German (de), Hausa (ha), Icelandic (is), Japanese (ja), Russian (ru), and Chinese (zh). We describe our bitext and monolingual data sources, including additional mined data created for Hausa, and our preprocessing pipeline.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 205–215

2.1 Bitext Data

For all directions, we use all available bitext data from the shared task . For language directions such as English to German or English to Russian, this provides millions of high-quality bitext. However, for low to mid resource languages, such as Hausa and Icelandic, we incorporate additional sources of data from freely available online sources such as ccMatrix (Schwenk et al., 2019), ccAligned (El-Kishky et al., 2020), and OPUS (Tiedemann, 2012). We utilize all available data sources to develop the best quality translation model possible.

For English-Hausa (and Hausa-English), we also mined extra parallel data from the provided monolingual data. We use LaBSE (Feng et al., 2020) to embed Hausa and English sentences into the same embedding space. We then use the margin function formulation (Artetxe and Schwenk, 2019) based on K-nearest neighbors (KNN) to score and rank pairs of sentences from the two languages. Using the mining strategy from Tran et al. (2020), we mined an additional one million pairs of parallel sentences for English-Hausa.

Data Processing. The majority of available bitext represents noisy alignment rather than the output of human translations. We apply several steps of preprocessing to filter noisy data. First, we apply language identification using `fasttext` (Joulin et al., 2017) and retain sentences predicted as the desired language[1]. We then normalize punctuation with `moses`. Subsequently, we removed sentences longer than 250 words and with a source/target length ratio exceeding 3.

2.2 Monolingual Data

Previous work (Ng et al., 2019) shows that using in-domain monolingual data provides the most quality improvement when used for large-scale backtranslation. For high resource languages such as English and German, there are sufficiently large quantities of in-domain data available in Newscrawl, and we do not utilize additional monolingual data. For the remaining languages, the data available in Newscrawl is not sufficient and we follow the strategy in Moore and Lewis (2010); Ng et al. (2019) to examine large quantities of general-domain monolingual data from Commoncrawl[2] and identify a subset that is most similar to the available in-domain news data. For each language, we train an n-gram language model (Heafield, 2011) on all available news-domain data (Newscrawl) and a n-gram language model on a similarly sized sample from general-domain data (Commoncrawl). For each sentence s in Commoncrawl, we compute word-normalized cross entropy scores $H_{\text{news}}(s)$ and $H_{\text{general}}(s)$ using in-domain language model and general-domain language model respectively. We retain sentences that meet the threshold $H_{\text{news}}(s) - H_{\text{general}}(s) > 0.01$. This selects around 5% of total number of sentences in the original Commoncrawl.

Language	Bitext	Monolingual
Czech	185M	140M
German	571M	237M
Hausa	1.7M	7M
Icelandic	28.2M	101M
Japanese	145.7M	218M
Russian	297M	163M
Chinese	166M	123M
English	—	430M

Table 1: **Amount of Data per Language**. The bitext data includes data distributed by the WMT Shared Task, the OPUS repository, ccMatrix, ccAligned, and newly mined data for Hausa. The monolingual data includes data distributed by the WMT Shared Task and CC100.

2.3 Vocabulary

To create our multilingual vocabulary, we first learn a multilingual subword tokenizer on our combined training data across all languages. We use SentencePiece (Kudo and Richardson, 2018), which learns subword units from untokenized text. We train our SPM model with temperature upsampling (with T=5) similar to Conneau et al. (2020), so that low-resource languages are represented. For bilingual models, we used vocabulary size of $32,000$, and for multilingual models, we used $128,000$. Subsequently, we convert the learned SPM units into our final vocabulary.

3 System Overview

We describe step-by-step how we created our final multilingual submission for WMT2021. We detail our bilingual and multilingual model architectures, as well as how we incorporate strategies such as backtranslation, news-domain finetuning, ensembling, and noisy channel reranking.

[1]Note: for Hausa, the language identification system was unreliable, so we did not utilize it.

[2]http://data.statmt.org/cc-100/

3.1 Baseline Bilingual Models

A pre-requisite to creating state-of-the-art multilingual translation systems is establishing strong, competitive bilingual baselines. Our goal is to apply the same set of techniques in data augmentation and modeling scaling to both bilingual and multilingual models, and demonstrate multilingual models have stronger translation quality.

To create baseline bilingual systems, we train a separate Transformer model (Vaswani et al., 2017) for each language direction. For every language pair except Hausa, we use the Transformer 12/12 configurations in Table 2. For Hausa-English (and English-Hausa), since the amount of bitext data is smaller, we use the Transformer-Base architecture similar to Vaswani et al. (2017). We train all our models using `fairseq` (Ott et al., 2019) on 32 Volta 32GB GPUs. We use learning rate of 0.001 with the Adam optimizer, batch size of 768,000 tokens[3], and tune the dropout rate for each language direction independently. For large models

3.2 Backtranslation

Backtranslation (Sennrich et al., 2015) is a widely used technique to improve the quality of machine translation systems using data augmentation. To perform backtranslation for a *forward* language direction (e.g. English to German), we use a system in the backward direction (e.g. German to English), to translate the target German monolingual data into the English source. We then use these *backtranslated* synthetic English to German sentence pairs in conjunction with the original parallel data to train an improved forward translation model.

We use all available filtered monolingual data we have for each language (up to 500 million sentences per language) for backtranslation. Using our baseline bilingual models (described in Section 3.1), we first finetune on in-domain news data (described in Section 3.5), and use an ensemble of 3 models with different seeds to generate backtranslation data using beam search. For Hausa-English and English-Hausa, we applied a round of iterative backtranslation (Hoang et al., 2018; Chen et al., 2019) as the quality improvement is significant.

3.3 Data Sharding and Sampling

Table 1 displays the amount of data for all languages after postprocessing. We divide the data into multiple shards, with each training epoch using one shard. We downsample data from both high resource directions and synthetic backtranslated data by dividing them into a greater number of shards than the real bitext data from low resource directions. We find that downsampling high resource languages works better than upsampling low resource languages, as upsampling contributes more strongly to overfitting.

[3]6000 tokens per GPU * 32 GPUs * 4 update frequency

	12/12	24/24	24/24 Wide
Layers	12	24	24

Attn. Heads	16	16	32
Total Params.	480M	1.2B	4.7B

Table 2: **Dense Transformer Configurations**.

3.4 Model Architectures

We describe several model architectures that we compared using the final dataset with both bitext and backtranslated data.

Scaling Bilingual Models. Based on the baseline architectures described in Section 3.1, we further improve our bilingual models. The two main improvements are: adding backtranslated data, and adding deeper and wider Transformer configurations to take advantage of the increase in data.

Dense Multilingual Models. For the multilingual systems, we train two separate models: *Many to English*, or one system encompassing every language translated into English, and *English to Many*, or one for English into every language. The challenge of multilingual models is often one of capacity — given a fixed number of parameters, a model needs to learn representations of numerous languages rather than just one. To understand the needed capacity and optimal architectural configuration, we experiment with different Transformer architectures, ranging from 480M parameters to 4.7B parameters (see Table 2).

Sparsely Gated MoE Multilingual Models. In multilingual models, languages necessarily compete for capacity and must balance sharing parameters with specialization for different languages. A straightforward way to add capacity to neural architectures is to simply scale the model size in a *dense* manner: increasing the number of layers, the width of the layers, or the size of the hidden dimension.

However, this has a significant computational cost, as each forward pass activates all parameters — at the limit, models become incredibly slow to train and produce translations (Fan et al., 2021).

In this work, we instead focus on *sparse* model scaling, motivated by wanting to increase capacity without a proportional increase in computational cost. We train Sparsely Gated Mixture-of-Expert (MoE) models (Lepikhin et al., 2020) for *English to Many* and *Many to English*. These models aim to strike a balance between allowing high-resource directions to benefit from increased expert model capacity, while also allowing transfer to low-resource directions via shared model capacity. In each Sparsely Gated MoE layer, each token is routed to the top-k expert FFN blocks based on a learned gating function. Thus, only a subset of all the model's parameters is used per input sequence.

We use a Transformer architecture with the Feed Forward block in every alternate Transformer layer replaced with a Sparsely Gated Mixture-of-Experts layer with top-2 gating in the encoder and decoder. As in Lepikhin et al. (2020), we also add a gate loss term to balance expert assignment across tokens with a gate loss weight of 0.01. We use an expert capacity factor of 2.0. We use a learning rate of 0.001 with the Adam optimizer with 4000 warmup updates and a batch size of 1 Million tokens (MoE model with 64 experts) or 1.5 Million tokens (MoE model with 128 experts).

3.5 In-Domain Finetuning

Finetuning with domain-specific data is an effective method of improving translation quality for the desired domain, and thus we curated news-domain data for finetuning. For directions such as German and Russian, we finetune on evaluation datasets from previous years of WMT. For Hausa and Icelandic, as no previous data exists, we use mined data and filter to the subset identified as most likely news domain. Subsequently, we finetune our models on the in-domain data for a maximum of ten epochs, selecting the best model with validation loss on the `newstest2020` dev set. For our submission, we use the settings tuned on `newstest2020` and include `newstest2021` dev set in the final finetuning.

3.6 Checkpoint Averaging

To combat bias toward recent training data, it is common to average parameters across multiple checkpoints of a model (Vaswani et al., 2017). We apply this technique to all models and average the last five checkpoints. To address rapid overfitting during finetuning, we also average the finetuned model with the model after the initial training is complete and select this averaged set of parameters if it performs better on the validation data.

3.7 Noisy Channel Re-ranking

We apply noisy channel re-ranking to select the best candidate translations from n-best hypotheses generated with beam search. We follow Yee et al. (2019); Bhosale et al. (2020) and utilize scores from the direct model $P(tgt|src)$, channel model $P(src|tgt)$, and language model $P(tgt)$. To combine these scores for reranking, for every one of our n-best hypotheses, we calculate:

$$\log P(tgt|src) + \lambda_1 \log P(src|tgt) + \lambda_2 \log P(tgt)$$

The weights λ_1 and λ_2 are determined by tuning them with a random search over 1000 trials on a validation set and selecting the weights that give the best performance. In addition, we also tune a length penalty. The search bounds we use for the weights and the length penalty are [0,2].

Language Models. We trained Transformer-based language models for all languages on the same monolingual data as used for backtranslation. The exception is English, where we trained on the CC100 English data and RoBERTa training data (Conneau et al., 2020; Wenzek et al., 2019; Liu et al., 2019). For the high resource languages, the language models have 12 decoder layers and embedding dimension 4096. For Hausa and Icelandic, we trained smaller language models with 6 decoder layers to prevent overfitting.

3.8 Post-Processing

As a final step, we apply post-processing to the translation outputs for Czech, German, Icelandic, Japanese, and Chinese. For Czech, German, and Icelandic, we convert quotation marks to German double-quote style[4]. For Chinese and Japanese, we convert punctuation marks to the language-specific punctuation characters.

4 Experiments and Results

We conduct experiments to quantify the impact of each of the component in our system. All experiments are evaluated on `newstest20` (Barrault et al., 2020) using `SacreBLEU` (Post, 2018).

Table 3: **Impact of Vocabulary on Bilingual Models**. We compare using a specialized bilingual vocabulary vs. a general multilingual vocabulary and its impact on performance of bilingual systems.

4.1 Creating State-of-the-Art Multilingual Translation Models

We investigate the effectiveness of multilinguality in translation. Compared to bilingual models, which can dedicate their capacity to specializing in specific source and target languages, multilingual systems must learn to effectively share available capacity across all languages while balancing languages of different resource levels. Despite rising research interest, previous WMT submissions have not demonstrated quality improvement of multilingual models over bilingual models. We discuss various choices and comparisons that build our state-of-the-art multilingual translation system. Overall, the best multilingual systems outperform the best bilingual ones in 11 out of 14 directions, with an average improvement of +0.8 BLEU.

4.1.1 Building a Multilingual Vocabulary.

Similar to how multilingual systems must share model capacity, multilingual translation models must also share *vocabulary capacity*. Instead of training specialized subword units for a specific language (often 32k), multilingual models group all languages together to learn a much smaller vocabulary set than 32k * number of languages. We first examine the impact of this multilingual vocabulary, by taking a bilingual system and training it with the multilingual vocabulary. This would indicate a performance difference coming not from architecture, but from the vocabulary itself. Table 3 indicates that across all directions, using a specialized bilingual vocabulary is usually superior, meaning multilingual systems must bridge the performance gap of a potentially subpar vocabulary. However, for some directions such as en-is and en-ja, no difference is observed.

4.1.2 Comparing Model Architectures.

Dense Transformer Models. Overall, we find that dense multilingual models are fairly competitive with dense bilingual models (see Table 4). Importantly, we find multilingual models benefit greatly from additional model capacity. In Table 5, we show comparable dense scaling applied to a bilingual model translating from English to German. While the multilingual model improves up to 1 BLEU point, the bilingual model only improves +0.3 BLEU, indicating diminishing return and possible overfitting in bilingual models. Scaling multilingual translation models has stronger potential for performance improvement.

Sparsely Gated Mixture of Expert Models. If multilingual models benefit from greater capacity, what is the best way to add that capacity? In Table 4, we compare the performance of Dense and MoE multilingual models while keeping the FLOPs per update approximately the same for fair comparison. Due to the conditional compute capacity of MoE layers, MoE models have a greater number of total parameters, but a comparable computational cost with the corresponding dense model.

For Many to English and English to Many, the MoE model with 64 experts per MoE layer gives an average boost of +0.7 BLEU on the dev set. To compare to scaling dense models, increasing dense model size from 12/12 to 24/24 does not correspond to significant improvement for Many to English. However, there is around +1 BLEU improvement in dense scaling on English to Many. We also see a slightly decline or no improvement in the performance of MoE models (MoE-64 12/12 vs MoE-128 24/24) when increasing model dimensionality and increasing the number of experts from 64 to 128. One possible hypothesis is that having 128 experts is largely unnecessary for only 7 languages. Compared to 64 experts, training convergence per expert is slower as each expert is exposed to fewer tokens during training on an average.

After finetuning on in-domain data, we observe a significant improvement in performance across the board. There is a larger improvement from finetuning in MoE models compared to the associated

dense baselines. Furthermore, the MoE model with 128 experts, which previously lagged behind the MoE model with 64 experts, now gives the best results for all but two directions. A possible hypothesis is that expert capacity in MoE models can retain specialized direction-specific finetuning better than dense models, where all language directions must share all model capacity while finetuning.

4.1.3 Effects of In-Domain Finetuning

Finetuning Improves Multilingual More than Bilingual. Table 6 compares the impact of finetuning across a variety of models. Multilingual systems benefit more from in-domain finetuning. As a result, the best multilingual system always outperforms the best bilingual system.

Multilingual Finetuning is better than Bilingual Finetuning. For multilingual models, there are two possible finetuning schemes (Tang et al., 2020). The multilingual model could be finetuned to specialize to the news domain in a multilingual fashion, concatenating the news data for all languages, *or* could be finetuned for each direction separately by training on bilingual news domain data. We compare *multilingual in-domain finetuning* with *bilingual in-domain finetuning* in Table 6. We find that multilingual finetuning is almost always better than bilingual finetuning, indicating that it is not necessary to take a multilingual system and specialize it to be bilingual via bilingual finetuning — a completely multilingual system still has the strongest performance.

4.1.4 Human Evaluation.

While a number of studies have been conducted on bilingual models to understand how BLEU correlates with human-perceived quality, few studies

have investigated multilingual ones. Given a bilingual system and a multilingual system with the same BLEU scores, we want to understand if there is anything intrinsically different in the multilingual system output that would impact human evaluation.

We study two directions: English to German and English to Russian. We ask human annotators who are fluent in source and native in target language to evaluate the translation quality between a bilingual system output and a multilingual system output. Both systems have similar BLEU scores, within decimal point difference. The translations are generated on the same English source sentence. We find no statistically significant difference between human evaluations of both systems, indicating that human evaluators have no innate preference for bilingual or multilingual systems.

4.2 Impact of Large-scale Backtranslation

Large-scale backtranslation has contributed to improvements in performance in machine translation models (Edunov et al., 2018), even when measured in human evaluation studies (Edunov et al., 2019; Bogoychev and Sennrich, 2019) — it is a component integrated into most modern translation systems. However, backtranslation also has downsides. Research has indicated that systems trained with large scale backtranslation data tend to overfit to the synthetically generated source sentences, producing lower quality translations when translating original source sentences (Marie et al., 2020). Further, backtranslation is fundamentally a form of data augmentation, which could have increasingly marginal effect when large-scale mined bitext is directly incorporated into training datasets. Beyond mining, multilingual translation can also be seen as an inherent form of data augmentation, as language directions can benefit from the training data

Table 9: **Full Results of Submitted Models**. Starting with a bilingual baseline, we depict the incremental gain of different techniques across language pairs. Our final submission is a multilingual ensemble with noisy channel reranking, trained on all available data including backtranslation. On all language pairs, we observe improvement compared to the previous WMT20 winning models. The column *MMT* denotes if the model is multilingual. Note Hausa and Icelandic were not present in WMT20.

of other directions. Thus, we analyze further in this section the continued importance of backtranslation, even in multilingual systems.

Backtranslation in Bilingual Systems. First, we investigate if backtranslated data is still helpful, even after we augment the training dataset with mined and publicly available training data, beyond what is distributed in the WMT Shared Task. Our results in Table 7 show that backtranslation is helpful for 10 out of 14 directions, especially for low resource directions such as ha-en and is-en. However, for high resource directions such as de-en, ru-en, zh-en, bilingual systems trained with backtranslation had slightly lower validation BLEU compared to those trained without backtranslation.

Finetuning Corrects Overfitting to Translationese We further investigate the anomaly that high-resource directions can suffer from adding backtranslated data. Figure 1 shows that the minor BLEU degradation from adding backtranslation mostly disappears after applying in-domain finetuning. For zh-en and cs-en after in-domain finetuning, the system trained with backtranslation has stronger performance (+0.4 BLEU) compared to the system trained without backtranslation. Previous studies of this effect have indicated that backtranslation produces *translationese*, which has distinct qualities compared to original training data (Marie et al., 2020; Zhang and Toral, 2019; Graham et al., 2020). We hypothesize that in-domain finetuning, which trains the model on non-backtranslated data, can have a *corrective* effect that counteracts overfitting on translationese.

Backtranslation in Multilingual Systems. Table 8 summarizes the performance improvement from adding backtranslation to multilingual models in an ablation study. Overall, despite creating a fully unconstrained system with substantially greater training data and leveraging the data sharing potential of multilingual translation, we find that backtranslation still improves the performance. We believe this is influenced by the fact that backtranslation fully utilizes available monolingual data. While data mining techniques can identify potentially parallel sentences, it is naturally limited to identifying only a subset of the full monolingual data the algorithms utilize to mine.

4.3 Ablation on Components of Final Submission

Finally, we end by analyzing each aspect in our final submission and the cumulative effect. The effect of each component is shown in Table 9.

Bilingual Baselines. We find that our bilingual baselines have high BLEU scores, particularly for ru-en where our bilingual baseline is already stronger than the WMT20 winner. Overall, we observe that only en-ha and ha-en are significantly lower than 20 BLEU, indicating that curating a large amount of high quality bitext data is likely the most important basis of a strong system.

Backtranslation. Subsequently, we add backtranslated data. We observe that ha, is, and ja in particular observe large improvements in BLEU after adding backtranslated data, while other directions can actually slightly decrease in quality as a possible effect of translationese.

In-Domain Finetuning. We next evaluate the impact of in-domain finetuning and find an almost 3 BLEU improvement across directions for translation into English and 0.7 BLEU improvement for translation out of English. Across all language directions, finetuning is almost universally helpful.

Multilingual. Compared to bilingual models, multilingual models have stronger performance in every direction. Multilingual models benefit much more from scaling model size, as our largest architecture (MoE-128 24/24) has the best performance.

Ensembling. The effect of ensembling on average is fairly minor, but specific directions can see large improvements (such as +1 BLEU on zh-en).

Reranking. We then apply noisy channel reranking to the outputs of our final system. It is helpful across almost all directions, but does not have a huge effect on BLEU. On average, performance improves around 0.3 to 0.5 BLEU.

Postprocessing. Finally, we observe that postprocessing translated output to use standardized punctuation in each language is very important for BLEU scores when translating out of English. For example, Chinese in particular has a number of specific periods and double width punctuation characters, and properly using these produces almost +5 BLEU. However, we note that these techniques likely only improve BLEU score, and the effect on human evaluation is not well understood.

5 Conclusion

In this paper, we describe Facebook's multilingual model submission to the WMT2021 shared task on news translation. We employed techniques such as large scale backtranslation, bitext mining, large scale dense and sparse multilingual models, in-domain finetuning, ensembling, and noisy channel reranking. We provide extensive experiment results to quantify the impact of each technique, as well as how well they cumulatively stack to produce the final system. Our results demonstrate that multilingual translation can achieve state-of-the-art performance on both low resource and high resource languages, beating our strong bilingual baselines and previous years' winning submissions.

Acknowledgements

We'd like to thank Michael Auli and Halil Akin for helping getting this project started, help and advice along the way. We'd like to thank Holger Schwenk and Vishrav Chaudhary for their help in getting training data.

Tencent AI Lab & Cloud Xiaowei

Abstract

This paper describes Tencent Translation systems for the WMT21 shared task. We participate in the news translation task on three language pairs: Chinese⇒English, English⇒Chinese and German⇒English. Our systems are built on various Transformer models with novel techniques adapted from our recent research work. First, we combine different data augmentation methods including back-translation, forward-translation and right-to-left training to enlarge the training data. We also apply language coverage bias, data rejuvenation and uncertainty-based sampling approaches to select content-relevant and high-quality data from large parallel and monolingual corpora. Expect for in-domain fine-tuning, we also propose a fine-grained "one model one domain" approach to model characteristics of different news genres at fine-tuning and decoding stages. Besides, we use greed-based ensemble algorithm and transductive ensemble method to further boost our systems. Based on our success in the last WMT, we continuously employed advanced techniques such as large batch training, data selection and data filtering. Finally, our constrained Chinese⇒English system achieves 33.4 case-sensitive BLEU score, which is the highest among all submissions. The German⇒English system is ranked at second place accordingly.

1 Introduction

In this year's news translation task, our translation team at Tencent AI Lab & Cloud Xiaowei participated in three shared tasks, including Chinese⇒English, English⇒Chinese and German⇒English. We used the same data strategies, model architectures and corresponding techniques for all tasks.

We hypothesized that different models have their own strengths and characteristics, and they can complement each other. Thus, we built various advanced NMT models which mainly differ in training data and model architectures. These models (i.e. DEEP, LARGE and LARGE-FFN) are empirically designed based on Transformer-Deep which has proven more effective than the Transformer-Big models (Li et al., 2019). In addition to the original multi-head self-attention, we also proposed a mixed attention strategy by combining relative position with the original one, which extends the self-attention to efficiently consider representations of the relative positions. We use a variation of relative position, the random attention (RAN) (Zeng et al., 2021). As a results, we combined these models at transductive fine-tuning stage.

In terms of data augmentation, we adapt back-translation (BT) (Sennrich et al., 2016a), forward-translation (FT) (Zhang and Zong, 2016) and right-to-left (R2L) (Zhang et al., 2019) techniques to generate large-scale synthetic training data. Different from the standard back-translation, we add noise to the synthetic source sentence in order to take advantage of large-scale monolingual text. In addition, we used tagged BT mechanism (i.e. add a special token to the synthetic source sentence) to help the model better distinguish the originality of data. All the parallel data and a large amount of monolingual data are used in corresponding data augmentation methods, and finally we combine them together to build strong baseline models.

To enhance the domain-specific knowledge, we introduced approaches at both data and model levels. First, we employed a hybrid data selection method (Wang et al.) to produce different fine-tuning datasets. More specifically, we apply language coverage bias (Wang et al., 2021a), data rejuvenation (Jiao et al., 2020) and uncertainty-based sampling (Jiao et al., 2021) to select content-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 216–224
November 10–11, 2021.

relevant and high-quality data from parallel and monolingual corpora. The news texts contain a number of sub-genres such as COVID-19 and government report. Thus, we fine-tuned a domain-specific model translate each sub-genre of text in the test set (i.e. "one domain one model").

We take advantage of the combination methods to further improve the translation quality. The "greedy search ensemble algorithm" (Li et al., 2019) is used to select the best combinations from single models. Furthermore, we propose an multi-model & multi-iteration transductive ensemble (m^2TE) method based on the translation results of the ensemble models. First, we divided models into two parts. Second, each part produced syntactic parallel testsets which is used to fine-tune another part of models. We repeated this procedure for N times.

This paper is structured as follows: Section 2 describes our advanced model architectures. We then present the data statistics and processing methods in Section 3. The methods and ablation study are detailed in Section 4 followed by final experimental results in Section 5. Finally, we conclude our work in Section 6.

2 Model Architecture

In this section, we mainly introduced three model architectures, which are empirically adapted from Transformer (Vaswani et al., 2017).

2.1 General Configurations

All models are implemented on top of the open-source toolkit Fairseq (Ott et al., 2019). Each single model is carried out on 8∼16 NVIDIA V100 GPUs each of which have 32 GB memory. We use the Adam optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. The gradient accumulation is used due to the high GPU memory consumption. We also employed large batching (Ott et al., 2018), which has significantly outperformed models with regular batch training. To speed up the training process, we conduct training with half precision floating point (FP16). We set max learning rate to 0.0007 and warmup-steps to 16000. All the dropout probabilities are set to 0.3. The detailed hyper-parameters of each model are summarized in Table 1.

2.2 Deep Model

Deep transformer has shown more effective performance than the TRANSFORMER-BIG models (Dou et al., 2018; Wang et al., 2019). We mainly modified the TRANSFORMER-BASE model by using a 40-layer encoder. To stabilize the training of deep model, we use the Pre-Norm strategy (Li et al., 2019), which is applied to the input of every sub-layer. The layer normalization was applied to the input of every sub-layer which the computation sequence could be expressed as: normalize → Transform → dropout → residual-add. The batch size is 5120 with 16 GPUs and "update-freq" is 1. We totally train models with 400K updates.

Module	DEEP	LARGE	LARGE-FFN
Encoder Layer	40	24	20
Attention Heads	8	16	16
Embedding Size	512	1024	1024
FFN Size	2048	4096	8192
Model Size	232M	514M	652M

Table 1: Hyper-parameters and model sizes of different models used in our systems.

2.3 Large Model

The large model is empirically designed based on TRANSFORMER-BIG models (Vaswani et al., 2017; Yang et al., 2020) with 24 encoder layers. More specifically, the batch size is 4096 with 8 GPUs and the "update-freq" is 4. We totally train models with 400K updates.

2.4 Large-FFN Model

We train Larger Transformers, the inner FFN dimension of which is twice as big as that of large Transformer. Specifically, in this setting, the FFN dimension is set to 8192. The number of encoder and decoder layers are 20 and 6 respectively. The number of head is 16. In addition to the original multi-head self-attention, we use a mixed attention strategy, where the random attention (Zeng et al., 2021) is combined with the original attention. In this way, the self-attention mechanism can efficiently consider representations of the relative positions, or distances between sequence elements. In training Large-FFN models, we set the batch size to 8192 toknes per GPU and the "update-freq" parameter is set to 8. The models are trained on 8 GPUs for about 3 days.

3 Data and Processing

3.1 Overview

Table 2 lists statistics of parallel and monolingual data we used in training our systems. The details

D.	L.	Parallel Data		Monolingual Data	
		# Sent.	# Word	# Sent.	# Word
In.	En	6.7M	128.2M	641.3M	13.1B
	Zh		116.0M	18.4M	466.0M
Out.	En	24.8M	613.8M	1.8B	35.5B
	Zh		550.3M	1.1B	28.4B
In.	En	58.5M	1.1B	641.3M	13.1B
	De		1.1B	353.8M	7.2B
Out.	En	3.4M	78.0M	1.8B	35.5B
	De		74.4M	417.0M	1.5B

Table 2: Data statistics of parallel and monolingual data. We combine sub-corpora according to in-domain (*In.*) and out-of-domain (*Out.*).

are as follows.

Chinese ⇔ English The bilingual data include all the available corpora provided by WMT2021: CCMT Corpus, News Commentary v16, ParaCrawl v7.1, Wiki Titles v3, UN Parallel Corpus V1.0 and WikiMatrix (except for Back-translated news). The monolingual English data consist of News crawl, News discussions, Common Crawl. The Chinese data consist of News crawl, News Commentary, Common Crawl and Extended Common Crawl.

English ⇒ German The bilingual data includes News Commentary v16, Europarl v10, ParaCrawl v7.1, Common Crawl, Wiki Titles v3, Tilde Rapid and WikiMatrix. For monolingual German data, we used News Crawl, News Commentary, Common Crawl and Extended Common Crawl. The monolingual English data are same as Chinese⇔English.

3.2 Pre-Processing

To process raw data, we applied a series of open-source/in-house scripts (Wang et al., 2014; Lu et al., 2014), including non-character filter, punctuation normalization, and tokenization/segmentation. The English and German languages are tokenized by Moses toolkit,[1] while the Chinese sentences are segmented by Jieba.[2] Furthermore, we generated subwords via BPE (Sennrich et al., 2016b) with 35K merge operations. The BPE models are trained on all the data in corresponding parallel and monolingual corpora instead of only parallel data. The vocabulary sizes of Chinese⇔English are 59100 and 48772, respectively. The vocabulary sizes of English⇒German are 41812 and 40948.

3.3 Filtering

To improve the quality of data, we filtered noisy sentences (pairs) according to their characteristics in terms of language identification, duplication, length, invalid string and traditional-simplified Chinese conversation. First, we filtered sentences whose language identification is invalid especially for English⇒German. Second, we removed similar sentences by comparing MD5 values of skelectons (i.e. removing stop words from sentences). About length, we filter out the sentences with length longer than 150 words. For more noisy corpora (e.g. ParaCrawl), we added hard filtering rules on special symbol, digital number, word length, punctuation number, HTML tags. Regarding bingling data, we further considered source-target ratio. For instance, the word ratio between the source and the target must not exceed 1:1.3 or 1.3:1. According to our observations, our method can significantly reduce noise issues including misalignment, translation error, illegal characters, over-translation and under-translation.

After filtering noisy training data, we used several data manipulation approaches to further improve the quality of the training data. We first followed Wang et al. (2021a) to identify the original languages of the bilingual sentence pairs, and explicitly distinguished between the source- and target-original training data using the bias-tagging strategy. We also identified the inactive training examples which contribute less to the model performance, rejuvenated them with self-training (Jiao et al., 2020). For the data augmentation with back-translation and forward-translation, we selected the most informative monolingual sentences by computing the uncertainty of monolingual sentences using the bilingual dictionary extracted from the parallel data (Jiao et al., 2021).

3.4 Evaluation

We regarded the WMT2019 test set as the validation set, and WMT2020 test set as the test set for all experiments. We ranked checkpoints according to either loss or BLEU on validation set. We used sacreBLEU score[3] as our evaluation metrics which is officially recommended. We also con-

Table 3: Effects of data augmentation methods on Chinese⇒English translation task. We used generally the same amount of monolingual data with the bilingual corpus. We used the DEEP model trained on the original bilingual data to construct the synthetic data, which is used together with the bilingual data to train the NMT models.

ducted post-processing such as *detokenizer.perl* on system output before sacreBLEU.

4 Method and Ablation Study

In this section, we conducted a comprehensive ablation study of the techniques used in this competition. We reported results on the Chinese⇒English task using the constrained data.

4.1 Data Augmentation

In this evaluation, we used three commonly-used data augmentation methods, namely *back-translation* (BT), *forward-translation* (FT) and *right-to-left training* (R2L), to exploit the useful monolingual data. All the synthetic parallel data is used together with the original parallel data to train NMT models.

Back-Translation This method first trains an intermediate target-to-source NMT system, which is used to translate monolingual target sentences into source language. Then the synthetic parallel corpus is used to train models together the bilingual data. In this work, we apply the noise back-translations method as introduced in Lample et al. (2018). When translating monolingual data we use an ensemble of two models to get better source translations. We follow Edunov et al. (2018) to add noise to the synthetic source data. Furthermore, we use a tag at the head of each synthetic source sentence as Caswell et al. (2019) does. To filter the pseudo corpus, we translate the synthetic source into target and calculate a Round-Trip BLEU score, the synthetic pairs are dropped if the BLEU score is lower than 30.

Forward-Translation This method is similar to BT but performs in a reverse manner. Recent studies showed that back-translation harms the translation performance, while forward-translation improves the performance (Edunov et al., 2020; Marie et al., 2020). Our preliminary experiments reconfirm their findings. Accordingly, we use forward-translation to construct the synthetic parallel data by translating the monolingual source sentences by the source-to-target NMT model, which is trained on the original bilingual data.

Right-to-Left Training The approach is proposed to address the error propagation problem in autoregressive generation task (Zhang et al., 2019). The main idea is to improve the agreement between translations generated by Right-to-Left (R2L) models and Left-to-Right (L2R) models. Following this work, we translate the source-side sentences in both parallel and monolingual corpora with both a R2L model and a L2R model, and use the translated pseudo corpus to improve the L2R model. For the right-to-left training, we trained another DEEP model on the bilingual data, whose target side is reversed. We drop the pseudo parallel data if the BLEU score lower than 15.

Experimental Results As shown in Table 3, we systematically investigated effects of 1) WMT20/WMT21 training data and 2) individual/combined data augmentation methods on Chinese⇒English translation task. For a comparison between the different training corpora of WMT20 and WMT21, we also reported results on the WMT20 training data ("WMT20 Data") used in last year (Wu et al., 2020b), and it consists of 12.4M sentence pairs after filtering. As seen, WMT21 extended around 19M sentence pairs, which improves the baseline model by +2.1 BLEU points. About data augmentation methods,

Source	Description	# Sent.

+ DS	44.9	35.4
+ DA	42.5	35.8
+ ODOM	n/a	36.1

Table 5: Finetune results on the corresponding datasets.

we selected domain-relevant and high-quality sentences from all available monolingual data as listed in Table 2. To construct the new training data (i.e. combining authentic and synthetic data), we selected the same amount of monolingual data with the bilingual corpus. As seen, individually using FT and R2L can significantly improve the baseline model by around +1 BLEU point. About BT, we fount that it failed to outperform baseline in "WMT20 Data" while performs slightly better than baseline in "WMT21 Data". Finally, we trained the NMT models on the WMT21 training data augmented with the synthetic data generated by different data augmentation methods (up to 99.8M sentence pairs in total). We can further improve the performance by combining them together, demonstrating complementarity of different methods.

4.2 Fine-Tuning

We use in-domain finetune to further improve the model performance, which has proven effective on the WMT19∼20 news translation tasks (Sun et al., 2019; Meng et al., 2020; Li et al., 2020; Wu et al., 2020b). We construct different types of finetune data with the following approaches. Table 4 lists the statistics of data used for fine-tuning.

Previous Test Sets We follow the common practices to use WMT test sets in previous years as the finetune data. Specifically, we use WMT2017 development set, WMT2017 test set, WMT2018 and WMT19 test set.[4] Previous studies have shown that current NMT models suffer from the *language coverage bias* problem, which indicates the content-dependent differences between sentence pairs originating from the source and target languages, because the target-original data[5] can not improve translation performance (Wang et al., 2021a). Accordingly, we select the source-original examples (SO) from the test sets as the finetune data. Besides the WMT test sets, we also use the test sets from the CWMT competitions, which are available in the released data of WMT21 competition. In the CWMT testsets, each source sentence has four references, therefore we construct four sentence pair for each instance in the CWMT test sets.

In-Domain Training Data We employed data selection and data augmentation methods to select in-domain data from WMT/CWMT test sets and training corpus, respectively. More specifically, we employed BM25 algorithm to select relevant sentence pairs by regarding source-side of WMT20 test set as queries. As shown in Table 4, the "Data Selection" is a subset of WMT test sets. On the other hand, we extend the finetuning set by selecting in-domain data from the tranining corpus. We further use the RT and R2L approaches in Section 4.1 to augment the finetune data with the TRANSFORMER-DEEP model. Since the data augmentation approaches only require source-side sentences, we also construct the synthetic data for the WMT19 and WMT20 test sets.[6] We finetune the NMT model on the mixture of the additional synthetic corpus and the selected previous test sets.

One Domain One Model Li et al. (2020) argued that low-frequency words contain more domain information than high-frequency words, since low-

[4]In our final submission, we include WMT2019 and WMT2020 test sets in the fine-tune data.

[5]Target-original data are sentence pairs that are translated from the target language into the source language.

[6]In the final submission, we augment the WMT21 test set.

frequency words are mostly domain-specific nouns, etc., which may indicate the topic directly. Therefore, they adapt the TF-IDF algorithm to search and filter on the whole training set and then use them to train domain-specific models. We automatically to assigned domain labels to each source-side document in the test set. First, we used K-means clustering to obtain keywords of each document. Then, we proposed a rule-based method to classify each document in three categories: COVID-19, government report and other. In this experiment, we only focused on two specific domains and thus we trained two domain-specific models to translate COVID-19 and government report documents, respectively. The other documents are still dealt with a general-domain model.

Experimental Results As shown in Table 5, we investigated effects of different fine-tuning methods on Chinese⇒English translation task. As seen, source-original data is more effective than combining non-source-original one into finetuning dataset (35.5 vs. 35.7 BLEU). However, the CMWT dataset instead decrease the BLEU scores (-0.6 BLEU). The data reduction ("+DS") and expansion ("+DA") methods can not further improve the performance of baseline model (-0.3 and + 0.1 BLEU). Encouragingly, the "One Domain One Model" method can significantly improve the baseline model by +0.4 BLEU point.

4.3 Model Ensemble

Model ensemble is a widely used technique in previous WMT shared tasks, which can boost the performance by combining the predictions of several models at each decoding step (Li et al., 2019; Sun et al., 2019; Wang et al., 2018). In our work, we use two kinds of ensemble methods and finally the two are combined for further improvements.

Checkpoint Average For one model (same architecture and training data), we stored checkpoints according to their BLEU scores (instead of PPL or training time) on validation set. Then we combined top-L checkpoints (generate a final checkpoint) by averaging their weights to avoid stochasticity. To combine different models, we further ensembled the averaged checkpoint of each model. In our empirical experiments (Wang et al., 2020a), we find that this hybrid combination method outperforms solely combining checkpoints or models in terms of robustness and effectiveness.

Algorithm 1: Multi-Model & Multi-Iteration Transductive Ensemble

Input: Single Model M_n,
In-domain Seed D=$\{D_s, D_t\}$,
Ensemble N models E_N.
Output: New Model $M_n^{'}$

$t := 0$
while *not convergence* **do**
  Translate D_s with E_N and get $D_t^{E_N}$
  Train M_n on $D \cup D^{E_N}$ and get $M_n^{'}$,
  then $M_n = M_n^{'}$
  $t := t + 1$
end

Greedy Based Ensemble This method is proposed by Li et al. (2019), which adopts an easy operable greedy-base strategy to search for a better single model combinations on the development set. For more detail, please refer to the original paper. We also train single models with different hyper parameters to ensure the diversity. We refer to this method as Ensemble in the following.

Multi-Model & Multi-Iteration Transductive Ensemble Transductive ensemble (TE) is proposed by Wang et al. (2020b). The key idea is that source input sentences from the validation and test sets (in-domain seed) are firstly translated to the target language space with multiple different well-trained NMT models, which results in a pre-translated synthetic dataset. Then individual models are finetuned on the generated synthetic dataset. We propose an variation of TE, namely Multi-Model & Multi-Iteration TE (m^{2}TE) which is shown in Algorithm 1. The main difference from Iterative Transductive Ensemble (Wu et al., 2020b) is that E_N can be different groups of ensembled models (Deep, Large and Large-FFN models).

5 Final Results

In this section, we combined all the presented methods and techniques (detailed in Section 4) together and showed the final results in Table 6.

5.1 Chinese⇔English Translation Tasks

We train multiple single models in each settings. We found that the R2L method can significantly improve the baseline by about 1 BLEU score. It is surprising to find a gain of 2 BLEU improvement when combining all data augmentation meth-

ods. After we boost the in-domain corpus, we can further achieve 1∼2 more BLEU points on the different models, illustrating the effectiveness of fine-tuning. Specifically, we used corresponding development and test datasets and selected parallel data as in-domain corpus D. After training an NMT model M with the above methods, we finetune W on D with the same hyper parameters of training M. When testing on the WMT2020 test set, we achieve about 1.5 BLEU improvement. As the in-domain corpus is very limited, we propose a boosted finetune method by using the R2L training method to boost the finetune process. In our final submission, we add the WMT2020 test set to D, the batch size is set to 2048, the finetune finished after 3K training steps.

In our experiments, the ensemble models consists of 5 single models: 1 DEEP, 2 LARGE, 2 LARGER-FNN models. The simple ensembled model can outperform the best single model by 0.5∼2.0 BLEU scores. We then apply transductive ensemble to each group of models and the performance achieves 36.8 BLEU on Chinese⇒English task. Finally, we employed two fine-grained domain-specific models to translate COVID-19 and government report texts, respectively. This can further improve the model by +0.5 BLEU point. We also find that the single models that applied TE cannot bring further improvement to ensemble results. We do not apply re-ranking to this task, as we find that the improvement is insignificant.

5.2 German⇔English Translation Tasks

The baseline model are trained on bilingual data and R2L data. This boosts the BLEU score from 41.6 to 42.1. After adding BT and FT, we further improve the BLEU score by 1.3 BLEU scores.

For finetuning English⇒German models, we select the document whose source side is originally in German from all previous development and test dataset as in-domain corpus D. Single models are trained with the above methods are then fine-tune on D for one epoch with a fixed learning rate of 1e-4. In our final submission, the WMT2020 test set is added to D for better performance improvement. The fine-tuning can further achieve 0.93 BLEU improvement on the DEEP model.

In this task, the ensemble models consists of 3 single models: 1 DEEP, 1 LARGE, 1 LARGER-FNN models. The ensemble models outperform the best single model by 1.5 BLEU scores. Furthermorem we apply a rule-based post-processing procedure on punctuation and this can improve the BLEU score on development set by 0.5 point.

5.3 Official Results

The official automatic results (in terms of sacreBLEU) of our submissions for WMT 2021 are presented in Table 7. Among participated teams, our primary systems achieve the first and the second BLEU scores on Chinese⇔English and German⇔English, respectively. The experimental results demonstrates that our models can achieve the state-of-the-art performance.

In the future, we will integrate these useful techniques in the Tencent TranSmart (Huang et al., 2021), Mr. Translator (https://fanyi.qq.com), and Tencent Simultaneous Translation systems.

6 Conclusion

This paper presents the Tencent Translation systems for WMT2021 news translation tasks. We investigate various deep architectures to build strong baseline models. Then popular data augmentation

System	Zh-En	En-Zh	De-En
Best Official	33.4	36.9	35.0
Our System	33.4	36.5	34.9

Table 7: Official sacreBLEU scores of our submissions for WMT21 news task. The "Best Official" denotes the best performance among all participant teams.

methods such as BT, FT and R2L are combined to improve their performances. We demonstrate that in-domain fine-tuning and fine-grained domain modelling are effective to further improve domain-specific quality. Besides, our proposed greed-based ensemble algorithm and transductive ensemble method play key roles in our systems. Among participated teams, our primary systems achieve the first and the second BLEU scores on Zh⇒En and De⇒En, respectively. In the future, we will adopt useful methods to our advanced non-autoregressive translation models (Ding et al., 2021b,a) and investigate the effects of pre-training on NMT (Liu et al., 2021a,b).

It is worth mentioning that most advanced technologies reported in this paper are also adapted to our systems for biomedical translation task (Wang et al., 2021b), which achieve three 1st ranks in German/French/Spanish⇒English tasks.

Abstract

This paper presents the submission of Huawei Translate Services Center (HW-TSC) to the WMT 2021 News Translation Shared Task. We participate in 7 language pairs, including Zh/En, De/En, Ja/En, Ha/En, Is/En, Hi/Bn, and Xh/Zu in both directions under the constrained condition. We use Transformer architecture and obtain the best performance via multiple variants with larger parameter sizes. We perform detailed pre-processing and filtering on the provided large-scale bilingual and monolingual datasets. Several commonly used strategies are used to train our models, such as Back Translation, Forward Translation, Multilingual Translation, Ensemble Knowledge Distillation, etc. Our submission obtains competitive results in the final evaluation.

1 Introduction

This paper introduces our submission to the WMT 2021 News Translation Shared Task. We participate in seven language pairs including Chinese/English (Zh/En), German/English (De/En), Japanese/English (Ja/En), Hausa/English (Ha/En), Icelandic/English (Is/En), Hindi/Bengali (Hi/Bn), and Xhosa/Zulu (Xh/Zu) in both directions. We consider that the officially provided dataset has the acceptable size and quality and therefore only participate in the constrained evaluation. Our method is mainly based on previous works but with fine-grained data cleansing techniques and language-specific optimizations.

For each language pair, we perform multi-step data cleansing on the provided dataset and only keep a high-quality subset for training. At the same time, several strategies are tested in a pipeline, including Backward (Edunov et al., 2018) and Forward(Wu et al., 2019a) Translation, Multilingual Translation (Johnson et al., 2017), Right-to-Left Models (Liu et al., 2016), Iterative Joint Training (Zhang et al., 2018), Ensemble Knowledge Distillation (Freitag et al., 2017; Li et al., 2019) , Fine-Tuning (Sun et al., 2019), Ensemble (Garmash and Monz, 2016), and PostProcess.

We combined all the techniques mentioned above and the overall training process is shown in Figure 1. Section 2 focuses on our data processing strategies while section 3 describes our training techniques, including model architecture and iterative training, etc. Section 4 explains our experiment settings and training processes and section 5 presents our experiment results.

2 Data

2.1 Data Source

For all language pairs, we follow the constrained data requirements and take full advantages of the bilingual and monolingual training data available. Table 1 lists the data sizes of each language pair before and after filtering.

2.2 Data Pre-processing

We use following operations to pre-process the data:

- Filter out repeated sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Convert XML escape characters.
- Normalize punctuations using Moses (Koehn et al., 2007).
- Delete html tags, non-UTF-8 characters, unicode characters and invisible characters.
- Filter out sentences with mismatched parentheses and quotation marks; sentences of which punctuation percentage exceeds 0.3; sentences with the character-to-word ratio greater than 12 or less than 1.5; sentences of which the source-to-target token ratio higher

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 225–231

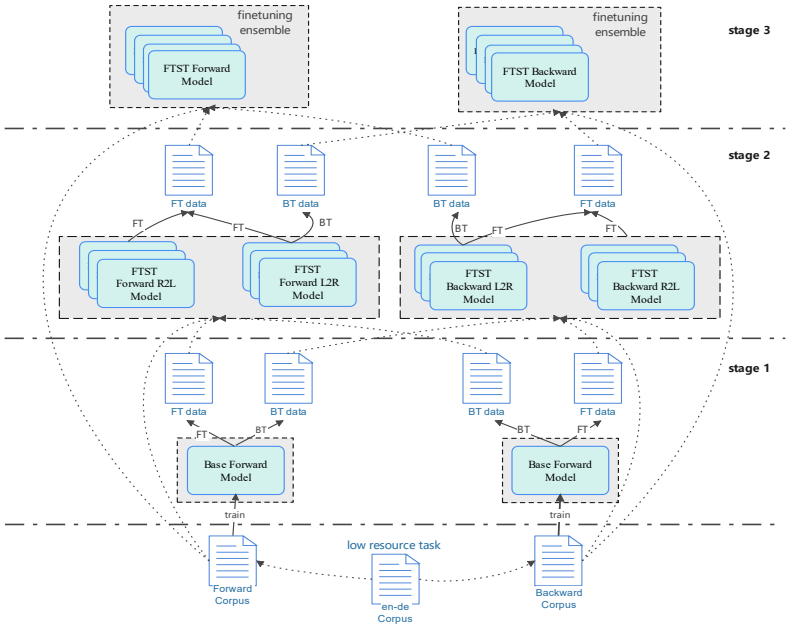

Figure 1: This figure shows the training process for the WMT 2021 News Translation Shared Task, which consists of three stages. In stage 1, one forward model and one backward model are trained. In stage 2, the synthetic data by FTST is used to train L2R and R2L models. In stage 3, the synthetic data by enhanced models are used to train models. Finally, model ensemble is used to boost the performance.

than 3 or lowers than 0.3; sentences with more than 120 tokens.

- Apply langid (Joulin et al., 2016b,a) to filter sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter sentence pairs with poor alignment.

We perform the additional steps to process Chinese data:

- Convert traditional Chinese characters to simplified ones.
- Convert fullwidth forms to halfwidth forms.

Data sizes before and after cleansing are listed in Table 1.

2.3 Data Selection

Since the news (in-domain) monolingual data in some tasks is not sufficient, it is necessary to obtain data from Common Crawl. We use Fasttext (Joulin et al., 2016a) to train a binary classification model to distinguish between in-domain and out-domain data.

3 System Overview

3.1 Model

Transformer (Vaswani et al., 2017) has been widely used for machine translation in recent years, which has achieved good performance even with the most primitive architecture without much modifications. Therefore, we choose to start from Transformer-Big and consider it as a baseline. Four variants of Transformer are also evaluated during the experiments, which are the model with wider FFN layers proposed in (Ng et al., 2019), and the deeper encoder version proposed in (Sun et al., 2019). Here, we use the following four variants:

- Deep 25-6 model: The number of the encoder layers is adjusted to 25 based on the transformer base model architecture and layer normalization is added. The other settings remain the same as the base model.
- Deep 35-6 model: The number of the encoder layers is adjusted to 36 based on the transformer base model architecture and layer normalization is added. The other settings remain the same as the base model.

language pairs	Raw bi data	Filter bi data	Used mono data
Zh/En	37.8M	16.5M	En: 150M, Zh:150M
De/En	95M	79M	En: 230M, De: 317M
Ja/En	18M	13.5M	En: 300M, Ja: 300M
Ha/En	0.73M	0.59M	En: 8M, Ha:8.65M
Is/En	5.69M	4.04M	En: 20M, Is: 18M
Hi/Bn	3.53M	3.4M	Bn: 59.3M, Hi: 45.8M

Table 1: Bilingual data sizes before and after filtering, and monolingual data used in tasks.

- Deep 35-6 big model: This model features 35-layer encoder, 6-layer decoder, 768 dimensions of word vector, 3076 dimensions of FFN, 16-head self-attention, and pre-norm.
- Deep 25-6 large Model: This model features 25-layer encoder, 6-layer decoder, 1024 dimensions of word vector, 4096 dimensions of FFN, 16-head self-attention, and pre-norm.

3.2 Data Augmentation

Back-translation (Edunov et al., 2018) is an effective way to boost translation quality by using monolingual sentences to generate synthetic training parallel data. As described in (Wu et al., 2019b), similar to back translation, the monolingual corpus in source language can also be used to generate forward translation text with a trained MT model, and the generated forward and backward translation data can both be merged with the authentic bilingual data. This strategy can increase the data size to a large extent.

We take full advantages of the officially provided monolingual data for data augmentation. In terms of back translation, we adopt top-k sampling for high-resource languages, and adopt beam search for low-resource languages. With regard to forward translation, we translate monolingual data using beam search. Through sampling, we ensure that the sizes of data generated by forward and back translation are relatively equal. In this paper, we refer to the combination of forward and sampling back translation as FTST.

3.3 Iterative Joint Training

Zhang et al. (2018) propose a new iterative joint training method, that is, using monolingual data from both source and target sides to train a source-to-target (forward) model and a target-to-source (backward) model at the same time. The two models generate synthetic data for each other. The advantage of such method is that both of the two models gain improvement after each iteration with the synthetic data provided by the other, and then can generate synthetic data with higher quality. Such training procedure is repeated after the two models converge.

3.4 Multilingual Translation

Johnson et al. (2017) propose a simple solution to use a single neural machine translation model to translate among multiple languages, and the model requires no change to the model architecture. Instead, the model introduces an artificial token at the beginning of the input sentence to specify the required target language. All languages use a shared vocabulary. There is no need to add more parameters. In low-resource tasks, we select a portion of the En-De bilingual data and conduct a joint training. The experiment shows that a multilingual model can improve the translation quality of low-resource languages to a large extent.

3.5 Right-to-Left Models

The approach of Right-to-Left is proposed by (Liu et al., 2016). The main idea is to integrate information of Right-to-Left (R2L) models to Left-to-Right (L2R) ones. Following this strategy, we translate the source sentences of the monolingual data with both R2L models and L2R models. In the Zh/En and De/En tasks, we use the R2L model to synthesize forward translation data using beam search and mix the synthetic data with the L2R synthetic data for iterative joint training.

3.6 Ensemble Knowledge Distillation

Ensemble Knowledge Distillation (Freitag et al., 2017; Li et al., 2019) improves the performance of a student model by distilling knowledge from a group of trained teacher models. Comparing with some soft label distillation methods, the EKD for NMT is relatively straightforward, which can be implemented by training the student models on the combination of the original training set and the

translation from the ensembled teacher model on the training set. In our experiments, we ensemble models as the teacher model to translate the wmt21 test set, and use the translate results to further fine-tune models.

3.7 Fine-tuning

Previous works have demonstrated that fine-tuning a model with in-domain data, such as last year's test set, could effectively improve the performance of this year (Sun et al., 2019). We use the dev and test sets from previous years, coupled with data generated by ensemble knowledge distillation and noises added to the target side, to fine-tune models and achieve further improvements.

3.8 Ensemble

Model ensemble is a widely used technique in previous WMT workshops (Garmash and Monz, 2016), which can improve the performance by combining the predictions of several models at each decoding step. In our work, we ensemble models with different architectures to further improve system performances. For Zh/En and De/En, we experimented with a combination of the Deep 35-6 big model and the Deep 25-6 large model to ensemble. For all language pairs, we train multiple models to ensemble by shuffle the data.

4 Experiment Settings

4.1 Settings

We use the open-source fairseq (Ott et al., 2019) for training and sacreBLEU (Post, 2018) to measure system performances. The main parameters are as follows: Each model is trained using 8 GPUs. The size of each batch is set as 2048, parameter update frequency as 32, and learning rate as 5e-4 (Vaswani et al., 2017). The number of warmup steps is 4000, and model is saved every 1000 steps. The architectures we used are described in section 3.1. We adopt dropout, and the rate varies across different language pairs. Marian (Junczys-Dowmunt et al., 2018) is used for decoding during inference.

4.2 Training Process

We employ iterative training and phase-based data augmentation. Figure 1 shows our training process in details. The specific steps are as follows:

1) Process data using methods described in section 2.2. Train one forward model and one backward model.

System	en2zh	zh2en
baseline	39.1	26.5
FTST	45.1 (+6.0)	32.4 (+5.9)
in-domain FTST + R2L	46.2 (+1.1)	34.4 (+2.0)
finetuning	46.5 (+0.3)	34.8 (+0.4)
ensemble	46.7 (+0.2)	34.9 (+0.1)
wmt21 final submit	35.1	28.9

Table 2: The experimental result of Zh/En tasks

2) Generate back translation and forward translation data. Mix the data with parallel training data and train three forward L2R models and three backward models. At the same time, train three R2L models for generating R2L forward translation data, in order to improve the diversity of synthetic data.

3) Split monolingual data into several sets. Generate back translation and forward translation data using models trained in step 2. Mix sampled synthetic data with bilingual training data and train four forward models and four backward models.

4) Average the last five checkpoints of each model and fine-tune it. Ensemble models to produce the final system.

5 Results and analysis

5.1 Zh/En

We use methods described in Section 2.2 for data processing. Four model architectures mentioned in Section 3.1 are employed to increase system diversity. On the basis of bilingual baselines model, we use FTST data augmentation to further enhance model performance.

Table 2 lists the results of our submission on WMT 2020 News Task test set. Comparing with the baseline model, FTST leads to 6.0 BLEU increase on en2zh direction and 5.9 BLEU increase on the opposite direction. We conduct data distillation on source sentences from WMT 2017 and 2018 news test sets, mix the generated data with the original data, and add noises to the target side. We fine-tune the model using the mixed data and achieve 1.1 BLEU and 2.0 BLEU increases on en2zh and zh2en directions, respectively. We then conduct a second-round FTST data augmentation on the fine-tuned model. In this round, we adopt the R2L model. We conduct data distillation on source sentences from WMT 2017-2018 news test sets, mix

System	en2de	de2en
baseline	33.1	39.7
FTST	34.2 (+1.1)	40.8 (+1.1)
FTST + R2L	34.5 (+0.3)	41.1 (+0.3)
finetuning	38.2 (+3.7)	43.1 (+2.0)
ensemble	38.3 (+0.1)	43.4 (+0.3)
postprocess	39.7 (+1.4)	-
wmt21 final submit	29.8	34.7

Table 3: The experimental result of De/En tasks

System	en2ja	ja2en
baseline	36.4	21.4
iterative FTST	39.2 (+2.8)	23.1 (+2.7)
finetuning	42.9 (+3.7)	25.3 (+2.2)
ensemble	43.6 (+0.7)	26.0 (+0.7)
wmt21 final submit	45.4	26.5

Table 4: The experimental result of Ja/En tasks

the generated data with the WMT 2017-2018 test sets, and add noises to the target side. We fine-tune the model using the mixed data and achieve 0.3 BLEU and 0.4 BLEU increases on en2zh and zh2en directions, respectively. Finally, ensemble further leads to 0.2 BLEU increase on the en2zh direction and 0.1 BLEU increase on the opposite direction. When submitting the final results, we further fine-tune the model with WMT 2019 and 2020 test sets. Our models achieve 35.1 BLEU on the en2zh direction and 28.9 BLEU on the zh2en direction when measuring with the WMT 2021 News Task test set.

5.2 De/En

For the En-De task, we adopt the Deep 36-5 big model and Deep 25-6 large model, as described in section 3.1. We use Moses for English and German word segmentation. The training data are segmented by a shared SentencePiece model. The source and target side each has a vocabulary with 32K words. We process all data using filter methods described in section 2.2.

Table 3 lists the results of our submission on WMT 2020 News Task test set. Comparing with the baseline model, two rounds of FTST data augmentation contribute to 1.4 BLEU increase on each directions. We conduct data distillation on source sentences from WMT 2020 news test sets, mix the generated data with the WMT 2018 and WMT 2019 test sets after adding noises to the target side. We fine-tune the model using the mixed data and achieve 3.7 BLEU and 2.0 BLEU increases on en2de and de2en directions, respectively. Ensemble further leads to 0.1 BLEU increase on the en2de direction and 0.3 BLEU increase on the opposite direction. Ensemble does not have significant impact on this task. It should be noted that we find that the quotation marks generated by the en2de model does not comply with the German standard, so we add a correction script to the post-processing(just convert English quotation marks to German quotation marks), which surprisingly leads to 1.4 BLEU increase. When submitting the final results, we further fine-tune the model with WMT 2020 test set. Our submitted models achieve 29.8 BLEU on the en2de direction and 34.7 BLEU on the de2en direction when measuring with the WMT 2021 News Task test set.

5.3 Ja/En

For Ja/En task, we adopt the same settings as that for the Zh-En task. The dropout rate is set to 0.1. The training data are segmented by a shared SentencePiece model. The source and target side each has a vocabulary with 32K words. The size of parallel data after cleansing is 13.5M. We sampled 150M English monolingual data from News Crawl and 300M Japanese monolingual data from News Crawl and Common Crawl (150M from each source).

Table 4 lists the results of our submission on WMT 2020 News Task test set. Comparing with the baseline model, iterative FTST data augmentation contribute to 2.8 BLEU and 1.7 BLEU increases on the en2ja and ja2en directions respectively. We conduct data distillation on source sentences from WMT 2020 news test sets, mix the generated data with the WMT 2020 dev set after adding noises to the target side. We fine-tune the model using the mixed data and achieve 3.7 BLEU and 2.2 BLEU increases on en2ja and ja2en directions, respectively. We train four models on each direction and ensemble further leads to 0.9 BLEU increase on the en2ja direction and 1.0 BLEU increase on the opposite direction. When submitting the final results, we further fine-tune the model with WMT 2021 dev set. Our submitted models achieve 45.4 BLEU on the en2ja direction and 26.5 BLEU on the j2en direction when measuring with the WMT 2021 News Task test set.

System	en2ha	ha2en	en2is	is2en	hi2bn	bn2hi	xh2zu	zu2xh
baseline	2.8	7.7	18.3	25.1	7.4	18.0	2.1	6.2

iFTBT	19.7	23.2	23.5	32.4	10.4	19.4	9.3	9.2
wmt21 final submit	20.3	17.5	27.5	38.4	13.0	21.9	11.8	9.9

Table 5: The experimental result of low resource tasks. iBTFT indicates that multiple rounds of BTFT are used for data enhancement.

5.4 Low resource tasks

We use the same strategy to deal with low resource tasks (En-Ha, En-Is, Bn-Hi and Xh-Zu). We train a bilingual baseline model and a monolingual baseline model for each direction. Every multilingual model is trained with 10x bilingual data sampled from the training corpora and 50M En-De parallel data. For en2ha, en2is, hi2bn and xh2zu, we use en2de data for training. For other language directions, we use de2en data for training.

Table 5 lists the results of our submission on dev set. On the eight language directions, all multilingual models gain huge improvements when comparing with the bilingual baseline model. Particularly, En-Ha achieves the greatest improvements: 12.1 BLEU on en2ha direction and 11.20 on ha2en direction. Bn-Hi achieves the slightest improvements: 0.4 BLEU on bn2hi direction and 1.78 on hi2bn direction. The results demonstrate that the fewer the bilingual data, the greater impact a multilingual model has. In other extremely low-resource scenarios, the improvement gained by a multilingual model for En-Ha is greater than that for the Xh-Zu task. We think the reason lies in the differences of language similarities. On the basis of multilingual models, we conduct data augmentation as described in section 3.2. We adjust sampling ratios according to the monolingual data size of each languages. Our data augmentation strategy achieves improvements on all eight language directions, from 1.1 BLEU to 4.4 BLEU increase. When conduct the second-round FTST data augmentation, we only get a slight increase on the En-Ha task: 0.2 BLEU on en2ha direction and 0.9 on ha2en direction. We also leverage fine-tuning and ensemble techniques to further improve our model performances. Finally, we get the highest BLEU score on the xh2en direction and the second highest BLEU score on the en2ha direction.

6 Conclusion

This paper presents the submissions of HW-TSC to the WMT 2021 News Translation Task. For each direction in all pairs, we perform experiments with a series of pre-processing and training strategies. The effectiveness of each strategy is demonstrated. Our experiments show that in low-resource scenarios, multilingual model that utilizing data from other languages can improve system performance to a large extent. Data augmentation strategy is still effective for multilingual models. Our submissions finally achieves competitive results in the evaluation.

Abstract

This paper describes LISN's submissions to two shared tasks at WMT'21. For the biomedical translation task, we have developed resource-heavy systems for the English-French language pair, using both out-of-domain and in-domain corpora. The target genre for this task (scientific abstracts) corresponds to texts that often have a standardized structure. Our systems attempt to take this structure into account using a hierarchical system of sentence-level tags. Translation systems were also prepared for the News task for the French-German language pair. The challenge was to perform unsupervised adaptation to the target domain (financial news). For this, we explored the potential of retrieval-based strategies, where sentences that are similar to test instances are used to prime the decoder.

1 Introduction

This paper describes LISN's[1] submissions to the translation shared tasks at WMT'21, where we took part in two shared tasks. For the biomedical translation tasks, we have developed resource-heavy systems for the English-French language pair, using a diversity of out-of-domain and in-domain corpora, thus continuing the efforts reported in (Abdul Rauf et al., 2020). Like for previous years shared task, the target genre (scientific abstract) corresponds to texts that often have a standardized structure comprising typical subsections of one to five lines. Standard subsections report the OBJECTIVE, the METHOD, or the RESULTs of the study. Our systems for this year attempt to take this structure into account using sentence-level tags, with the hope to capture some of the document structure and the phraseology of the domain into account. These systems are documented in Section 2.

Translation systems were also prepared for the News task for the French-German language pair. The challenge this year was to perform unsupervised adaptation to the target domain (financial news), with no further detail regarding the test data. In particular, the organizers did not release any development data to tune systems. In this setting, we explored the potential of using a retrieval-based strategy, where sentences that are similar to the test instances are used to help the decoding. In this approach, introduced in (Bulte and Tezcan, 2019) and further explored in (Xu et al., 2020; Pham et al., 2020), translation is a two-step process: a retrieval phase, which identifies sentences that resemble the source test sentence in parallel corpora. These sentences and their translation are then used to *prime* the decoder: inserting relevant translations examples in the decoder's context should help to select the right translations, especially for words and terms from the test domain. These systems are described in Section 3.

2 MT for biomedical texts

In this section, we describe our participation to the biomedical task for WMT'21, in which we participated in both English to French and French to English directions. English-French is a reasonably resourced language pair with respect to biomedical parallel corpora, allowing us to train our Neural Machine Translation (NMT) systems (Vaswani et al., 2017) with in-domain corpora as well as large out-of-domain data that exists for this language pair. Like for last year (Abdul Rauf et al., 2020), our first goal is to make the best of all the available data, including supplementary in-domain monolingual data. Our corpora are described in Section 2.1.

For this year's participation, we also attempt to take the internal structure of biomedical abstracts into account. Many of these abstracts follow what is often refered to as the "IMRAD format", comprising the following subparts: INTRODUCTION,

METHODS, RESULTS, and DISCUSSION (Sollaci and Pereira, 2004). This structure can be explicit in documents through dedicated headings or remain implicit. Our experiments aim to explore how to use this information in NMT and to measure the correlated impact. We notably expect that by informing the system with sub-document information, it will learn the typical style and phraseology of sentences occurring in each part.

For this purpose, we identified in our data all the abstracts that were conforming to this basic structure and worked to make this structure as explicit and standardized as possible. This notably implied to normalize the mains headings, as some variation was observed: for instance, ANALYSIS may be replaced with DISCUSSION, and additional subparts (OBJECTIVES, CONCLUSION) are also be observed. To incorporate the standard IMRaD format we mapped each subheading to the corresponding IMRaD subpart using a system of tags. Details regarding this process are given in Section 2.2.

All systems are based on the Transformer architecture of Vaswani et al. (2017). We were able to achieve appreciable gains both from back-translation and document structure processing. The results are discussed in Section 2.4.

2.1 Corpus and preprocessing

We trained our baseline systems on a collection of in domain biomedical texts as well as out-of-domain parallel corpus. Table 1 details the corpora used in training.

2.1.1 Parallel corpora

We gathered parallel and monolingual corpora available for English-French in the biomedical domain. The former included the biomedical texts provided by the WMT'20 organizers: Edp, Medline abstracts and titles (Jimeno Yepes et al., 2017), Scielo (Neves et al., 2016) and the Ufal Medical corpus[2] consisting of Cesta, Ecdc, Emea (OpenSubtitles), PatTR Medical and Subtitles. In addition, we used the Cochrane bilingual parallel corpus (Ive et al., 2016)[3], the Taus Corona Crisis corpus[4] and the Mlia Covid corpus.[5] We finally experimented with additional in-domain data selected using Information Retrieval (IR) techniques from general domain corpora including News-Commentary, Books and Wikipedia corpus obtained from the Open Parallel Corpus (OPUS) (Lison and Tiedemann, 2016). These were selected using the data selection scheme described in (Abdul-Rauf and Schwenk, 2009). Medline titles were used as queries to find relevant sentences. We used the `2-best` sentences returned from the IR pipeline as additional corpus.

Our out-of-domain corpora include the parallel data provided by the WMT14 campaign for French-English: Gigafr-en, Common Crawl, Europarl, News Commentary and the UN corpora.

For development purposes, we used Medline test sets of WMT'18 and 19, while Medline 20 was used as internal test data.[6]

[4] https://md.taus.net/corona

[5] http://eval.covid19-mlia.eu/task3/

[6] These testsets were sentence-aligned with in-house

2.1.2 Monolingual sources

The back-translation of monolingual sources has often been effectively used to cater for parallel corpus shortage in the Biomedical domain in (Stojanovski et al., 2019; Peng et al., 2019). We also adopt this approach here.

Supplementary French data from three monolingual sources were collected from public archives: abstracts of medical papers published by Elsevier from the Lissa portal[7] and from the national ISTEX archive[8]; a collection of research articles collected from various sources[9] henceforth referred to as Med_Fr (Maniez, 2009). These documents were automatically translated into English with an NMT system trained on biomedical corpora, with a BLEU score of 33.6 on Medline20 testset.

The English side of Medline German and Spanish corpora is used as supplementary English data for back translation. Duplicate documents were removed based on the document id. For these, the internal structure of documents is often available and has been tagged as for the parallel data. These texts were then split into sentences[10] and translated into French using a NMT system trained on all Biomedical corpora with a BLEU score of 36.4 on Medline20 testset. All back-translated data is tagged using the proposal of Caswell et al. (2019).

Parallel and monolingual data are further processed using SentencePiece (Kudo and Richardson, 2018) tokenisation and detokenisation scheme to segment texts into subword units using a vocabulary of 32K subwords. These units were learned on all the in-domain corpora.

2.2 Sentence tagging: a three-level scheme

2.2.1 Tagging domains and corpora

As explained above, our training data is diverse, comprising in-domain parallel, out-of-domain parallel, and in-domain monolingual that is automatically back-translated. Some are made of lists of isolated sentences, while others retain the document information. Even within the in-domain data, some texts precisely match the genre of the testset (scientific abstracts) - this is the case for instance of Medline and to a lesser extent, Cochrane; while others are more remote (eg. the Ufal collection, or the Mlia corpus). In order to reflect this diversity, we designed a three-level sentence tagging scheme that is used for the experiments in Section 2.4.2. These tags appear as prefix of each source sentence.

The first level of tags distinguishes between out-of-domain data (<G>), and in-domain data (tagged <M>). The second level of tag aims to distinguish between data sources, hence the use of one dedicated tag for each corpus, except for the monolingual data, which is simply tagged with <BT>.

2.2.2 Tagging sections within documents

The third level of annotation is indented to enhance the translation context with information regarding the position of a sentence within the abstract. The structure of scientific abstracts in the medical domain often obey the IMRAD structure, and the third tag aims to include this structural information as an additional document-level context. Document level information is necessary to model long-range dependencies between words, phrases, or sentences, or document parts. For a translation system, the ability to model the context may notably improve certain translation decisions, e.g. a better or most consistent lexical choice (Kuang et al., 2018) or a better translation of anaphoric pronouns (Voita et al., 2018; Bawden et al., 2019). A recent review of these themes is in (Maruf et al., 2021).

For this purpose, we further pre-processed 6 corpora containing scientific abstracts. These corpora had different subheadings and structures as given below, which were mapped to a restricted set of section tags listed in Table 2:

1. Medline and Scielo: Abstracts and sub headings often without title. We identified a total of 189 subheadings including spelling variations. Examples include: Presenting Concerns of the Patient, Sources of Information, Novel finding, Study Selection etc.

2. Edp: Abstracts and sub headings mostly contain titles. 45 subheadings where found, such as: Case report, Observation, Subjects and Methods, Commentary, Pedagogical objectives etc.

3. Cochrane: only 10 different subheadings were found, including: Abs selection criteria, abs search strategy, abs data collection, summary title etc.

The identification and standardization of subheading information was a tedious process, involving a lot of rule-based processed to take the variability of sub-headings into account. In order to reconstruct fully parallel versions with subheadings, we also had to reinsert explicit headings in

tools and are shared at https://github.com/fyvo/WMT-Biomed-Test.

the source or the target files. Also note that this information was not available for all abstracts. After preprocessing files for which the full subheading information was available, we obtained the 6 fully-tagged corpora (see statistics in Table 3). A similar process was used for test sets (see Table 4).

medline20	735	580
medline18	321	347
medline19	493	469

Table 4: Number of test sentences after alignment

Finally, we also introduced a third tag in all other documents as follows: sentences within an abstract where tagged as <ABS>, while all remaining sentences from other corpora where simply tagged as "unspecified subheading" (<US>).

2.3 Translation framework

Our translation systems mostly used the basic Transformer models, while a few contrastive systems used the large version (Vaswani et al., 2017). They all rely on Facebook's seq-2-seq library (fairseq) (Ott et al., 2019) with parameters settings borrowed from `transformer_wmt_de_en`.[11]. The ReLU activation function was used in all encoder and decoder layers. We optimize with Adam (Kingma and Ba, 2015), set up with a maximum learning rate of 0.0005 and an inverse square root decay schedule, as well as 4000 warmup updates. We share the decoder input and output embedding matrices. Models are trained with mixed precision and a batch size of 4096 tokens on 4 V100 GPUs for 300k updates. Systems were trained until convergence based on the BLEU score on the development sets. Evaluation was performed using SacreBleu (Post, 2018). Scores are chosen based on the best score on the development set (Medline 18, 19) and the corresponding scores for that checkpoint are reported on Medline 20 test set.

For fine-tuned systems, the process starts with models trained to convergence, based on BLEU score on dev sets. Training then resumes using a selected portion of the training corpus using the same parameters and criterion as for the base systems. In our results corresponding systems are post-fixed with `*-ft`.

2.4 Results

We present our results for the two directions in two tables, Table 5 and 6, differentiating the normal versus the *tag-based* systems. Base systems are given on the left, ($\Rightarrow$) identifies the derived (fine-tuned) systems.

2.4.1 Regular MT systems

Results for the untagged systems are reported in Table 5 and are denoted by `X*`, with `E*` and `F*` representing the English to French and French to English systems respectively.

We first built baseline systems. `X0` denotes the systems built using only the in-domain data provided by the organizers. `X1` are our baseline systems built using all in-domain parallel data. We see good improvement in both directions amounting to 4.2 and 4.8 BLEU points, which is obtained by adding around $1M$ sentences of additional Cochrane and Taus corpora to the already available $3.4M$ sentences from WMT'20. This hints at the relevance of the additional in-domain parallel corpora used.

We used the `X1` systems as strong in domain baselines to study the effect of adding back-translated in domain data. These appear as `X2` and `X3` in Table 5. Adding around 0.8M French to English and around 0.2M English to French back translated sentences did not help as much as we were expecting. We saw similar results last year and increased the amount of back translations this

Table 6: Results for systems with sentences tagged with our 3 level tagging scheme. Test sets are decoded 3 times, where the third tag is varied from the more specific (<SUBHEAD>) to the more generic (<US>). Superscripts ^{*n} denote the runs submitted.

year. `X3` denote systems built using the tagging scheme proposed by Caswell et al. (2019), where back translations are prefixed with the <BT> tag on the source side.

Indicating that a training sentence is back-translated allows the model to separate the helpful and harmful signal. This proved particularly true for English into French where adding tag to back translations improved the BLEU score by 0.8 points; but it was not helpful in the reverse direction where the amount of back translated data was may be too small (0.2M lines). back-translations as compared to the baseline corpora.

Finally, systems were built by initialising the parameters from huge out-of-domain corpora and later fine tuned on in-domain corpora (`X4`), where in-domain sub words learned from all the Biomedical data are used to segment the out-of-domain data. The initial systems were trained for 4 epochs on general domain WMT14 EN-FR corpora. The FR-EN system (`F4`) is the best system in this direction, reaching a BLEU score of 35.8.

2.4.2 Tagged Systems

As our 3-level tagging scheme, described in Section 2.2, is adding information about the domain of each sentence, we specifically focused on larger systems by using all the available in- and out-of-

domain corpora.

Results are summarized in Table 6 with TE* representing the Tagged English to French systems and TF* representing the French to English systems. TE1 is the baseline system for EN-FR built with all the available in domain and out-domain data. TE4 is the corresponding baseline using a Large Transformer[12]. We then fine-tune these systems with all the in-domain data including the back translations, these are represented by TE2 and TE5 respectively. This gives an appreciable gain of 2.5 and 2.3 BLEU points for Transformer and Transformer large systems. As we saw no major difference in scores for Transformer versus Transformer large, so we continue the rest of experiments with the simple Transformer architecture. Fine-tuning further with just abstracts from Cochrane and Medline did not yield any further improvement.

French to English results display similar trends. The baseline (TF1) using all available (in domain + out-of-domain) data tagged with our 3 level scheme yielded a BLEU score of 32.1. Fine-tuning it further with all in-domain data (TF2) gives an improvement of 3.6 BLEU points which does not improve further when fine-tuning continues with just Cochrane and Medline abstracts (TF3).

To measure whether the model learned document domain and/or sentence origin information, we tested by tagging the test set with three different tags in the third position, using either the exact subheading, or abstract or UnSpecified for sentences for which the sub-section is unknown. Table 6 reports the scores for the three cases. Though the difference in scores for the three cases is minute, in-domain systems{TE2, TE3, TE5} and {TF2, TF3} achieve their best results when the test set is tagged with the subheading or the abstract tag, typical feature of the biomedical corpora. Conversely, for out-of-domain systems {TE1, TE4, TF1}, the best scores are always for the test set tagged with <US>. This strongly hints that the system is using the extra-information provided by the tag. These observations need to be confirmed using other metrics, as BLEU may not properly reflect these differences.

For English to French direction we got better scores with the tagged systems, with the best system (TE2 = 38.7) achieving 2.1 BLEU points more than the best un-tagged system (E3 = 36.6). This was however not the case for French-English where both tagged and un-tagged systems had more or less similar scores.

[12]hidden size of 1024 and a feed forward size of 4096. Rest of the parameters same as for other systems.

		EN-FR		
E2	base+bt	34.8		
E3	base+bt-tag	36.6		
		<SUBHEAD>	<ABS>	<US>
TE	Indomain+bt	**37.3**	37.0	37.0
		FR-EN		
F2	base+bt	33.5		
F3	base+bt-tag	32.4		
		<SUBHEAD>	<ABS>	<US>
TF	Indomain+bt	**34.4**	34.4	34.4

Table 7: Comparison of our 3 level tagged systems with the corresponding untagged systems. Systems {E2,F2} are built by adding back-translated data to the baseline. In systems {E3,E3}, the added back-translated data start with <BT> tag. Systems {TE, TF} use our 3-level tagging scheme for all sentences.

Systems in Tables 5 and 6 have different baselines, thus to establish a fair comparison we report numbers for comparable systems in Table 7. Systems {E2,E3,F2,E3} are copied from Table 5, whereas {TE and TF} are the corresponding systems using our tagging scheme on the sole biomedical data. We see here a clear gain for French-English when we use a 3-level tagging scheme (TF) compared to just adding the <BT> tag (F3); results for the reverse direction are more even and having one or three tags does not make a difference.

2.5 Conclusion

In this section, we have presented our work for the biomedical task. We notably have tried to incorporate document origin and structure information and improve strong baseline systems that were using a wealth of in-domain and out-of-domain data. . Overall, our systems for this year are significantly better than last year's, even though the benefits of adding document structures as tags need to be confirmed by more experiments and analyses.

3 News translation task: De ↔ Fr

In the 2021 News translation task, we focused on the German-French language pair in which the participants are asked to build MT systems for News in the financial domain. In this section, we discuss details of our approach and the rationale behind it.

3.1 Unsupervised adaptation

As the training and development data do not contain domain information, the supervised domain adaptation paradigm is not suitable here. However, non-parametric adaptation (Bapna and Firat, 2019), example-based guided machine translation (Zhang et al., 2018), unsupervised domain adaptation (Farajian et al., 2017) or priming NMT (Xu et al., 2020; Pham et al., 2020) have showed promising results for this problem. These approaches retrieve translation examples that are similar to the input source sentence, and use them to guide the inference and to reproduce existing translations or to locally adapt the pre-trained NMT system to the input sentence.

Even though all of the approaches mentioned above have merits of their own, we decided to focus on computationally cheaper methods such as (Bulte and Tezcan, 2019; Xu et al., 2020) where the retrieved instances provide an extra conditioning context for the decoder. Pham et al. (2020) further improved these techniques by proposing to simultaneously prime the source and the target side of the retrieved examples (see Section 3.4.1) and has been our main source of inspiration.

3.2 Data and preprocessing

We use all available parallel data for De $\leftrightarrow$ Fr, with the exception of the ParaCrawl data, for training. We also use monolingual data to improve translation quality. For both languages, we choose Newscrawl 2020. We additionally use Newscrawl 2018 and 2019 French data at inference time to explore the ability of our priming model to make use of extra data. Details are in Section 3.4.2. We use *newstest2019* as development set and test our models on *newstest2020*.

We filter out sentence pairs with invalid language tag using `fasttext` language id model[13] (Bojanowski et al., 2017). We use Moses tools to normalize punctuation, to remove non-printing characters and to tokenize into words. The final parallel data contains 5.6M sentences.[14] We use a shared source-target vocabulary built with 40K Byte Pair Encoding (BPE) units using the `subword-nmt` implementation (Sennrich et al., 2016b).[15]

[14] https://github.com/moses-smt/mosesdecoder

[15] https://github.com/rsennrich/subword-nmt

3.3 Baseline systems

We build our Transformer-based (Vaswani et al., 2017) systems using `fairseq`[16] (Ott et al., 2019). Our baseline system is a large Transformer with a hidden size of 1024 and a feedforward size of 4096. We optimize with Adam (Kingma and Ba, 2015), set up with a maximum learning rate of 0.0007 and an inverse square root decay schedule, as well as 4000 warmup updates. We tie the encoder and decoder input embedding matrices with the decoder output embedding matrix and we apply layer normalization before each block. Models are trained with mixed precision and a batch size of 4096 tokens on 4 V100 GPUs for 300k updates.

3.4 Submitted systems

3.4.1 Boosting NMT by similar translations

Our approach comprises 2 steps: similar translation retrieval and inference where the priming example is processed in forced-decoding mode.

The retrieval of relevant examples for a given source sentence is based on their distance in some high-dimensional numerical representation space. These representations are computed using the encoder of the baseline system (see Section3.3) so as to keep our systems in the "constrained" track, as the use of large pre-trained models such as BERT (Devlin et al., 2019), XLM (Conneau and Lample, 2019), etc., was only allowed in unconstrained submissions. More precisely, for each sentence, we average the contextualized embeddings output at the last layer of the encoder. From the training dataset, we create a datastore of pairs (K, V) in which the key K is the sentence embedding of some source sentence $\mathbf{f}$ and the value is the sentence pair $(\mathbf{f}, \mathbf{e})$ whose source sentence is $\mathbf{f}$. For each query, we retrieve k keys ($k = 10$ in all experiments).

The similarity between two sentences is the cosine similarity and the retrieval of the nearest neighbor(s) is performed using FAISS (Johnson et al., 2017). In order to search through a large datastore, we divide it into shards containing at most 500K data points; we conduct the k nearest neighbor search on each shard, gather all the retrieved keys from all shards into a list and reduce it to the k nearest keys. Given an input sentence and the list of its k nearest neighbours, we append m ($m \leq k$) retrieved source sentences to the input sentence and initialize the target side by the concatenation of the

[16] https://github.com/pytorch/fairseq

m corresponding target sentences. We use a special token to separate sentences.

During training, we train the NMT model with two types of examples (with and without retrieval): this means that each training sample will occur twice, once with and once without priming. The former examples have the following format:

$$\mathbf{f}_1 * \cdots * \mathbf{f}_m || \mathbf{f}$$

$$\mathbf{e}_1 * \cdots * \mathbf{e}_m || \mathbf{e}$$

while the latter is presented as the original data.

During inference, we use the same format as for the source-side, while we initialize the decoder with the prefix $\mathbf{e}_1 * \cdots * \mathbf{e}_m ||$. We therefore call this initialization "force-decoding". The special tokens, which serve as joiners between the retrieved sentences and the source/target sentence, are carefully chosen so that they never occur in the real text to avoid ambiguity. As discussed in Pham et al. (2020), it is possible to concatenate several similar sentences i.e. use $m > 1$; we however only report results with $m = 1$, since our preliminary experiments did not show superior results with $m > 1$.

3.4.2 Monolingual retrieval

Pham et al. (2020) suggested that monolingual texts in the target language can also be helpful to inform the inference. To make use of monolingual data, we create pseudo translation pairs with back-translation to generate the missing source language side. For this step, we leverage the baseline NMT system in Section 3.3 for one direction to back-translate the monolingual target text in the inverse direction. We use Newscrawl 2020 as monolingual resource for both directions. The monolingual French data contains approximately 10M sentences while the German data is much larger. We randomly extract 10M sentences from the German monolingual data as the pseudo corpus. The back-translated corpora are added to the real parallel corpora to create a larger datastore for retrieval.

3.5 Evaluation

3.5.1 Priming and Back-translation

We mainly evaluate our method on the De→Fr direction. Results on both Newstest2019 and 2020 are in Table 8. Our priming model is able to improve for 0.4 BLEU on newstest2019. However, the same improvement is not observed for newstest2020. As indicated in Pham et al. (2020), monolingual back-translated data could be directly applied during inference without any additional training. We thus search similar sentences on both original and synthetic data for the test sets. As shown in Table 8 (+ bt inference), searching on synthetic data directly improves our results by 0.6 BLEU point on newstest2019.

Model	newstest2019	newstest2020
baseline	35.7	32.8
+ bt	37.5	33.7
+ tag	37.5	34.3
priming	34.6	33.2
+ bt inference	35.2	33.2
priming + bt	37.4	33.9
+ tag	36.9	34.1
+ min sim 0.85	37.5	34.3

Table 8: BLEU scores of models for De→Fr direction. Our best submitted system obtained a BLEU score of 28.1 on newstest2021.

Even though priming model could benefit from back-translated data at inference time, training with synthetic data has proven to be effective in many previous works (Sennrich et al., 2016a; Edunov et al., 2018; Ng et al., 2019). Therefore, we also experiment by adding back-translated data to the original data and retrain a translation model. Results (+ bt) demonstrate that training with synthetic data clearly improves the performance on both test sets. Caswell et al. (2019) reports that using explicit tags to distinguish original from back-translated data provides further gains; however in our experiments, tagging BT data was not very helpful.

Our model using priming with synthetic data was not able to surpass the baseline model trained with additional back-translated data. One possible reason is that similar sentences retrieved with low similarity scores may be too noisy, and therefore decrease the overall performance. Filtering out noisy similar sentences (with a threshold of 0.85)[17] help to further improve the performance and makes it our best system (+ min sim 0.85). This setting was used for our primary submission for both directions.

We directly apply the best settings found for De→Fr to the reverse direction (Fr→De) and report the corresponding results in Table 9.

[17]Thresholding the minimum similarity score is the result of a trade-off: using a high threshold selects good sentences for priming, at the risk of leaving many examples without any priming data, while a low threshold retrieves more examples, many of which are of poor quality. Our preliminary experiments showed that that 0.85 was a reasonable value.

Model	newstest2019	newstest2020
baseline	27.7	27.2
+ bt	32.4	32.9
+ tag	30.9	31.0
priming + bt	29.8	29.3
+ tag	29.5	29.6
+ min sim 0.85	30.4	30.1

Table 9: BLEU scores of models for Fr→De. Our best submitted system obtained a BLEU score of 37.2 on newstest2021.

3.5.2 Priming and domain adaptation

In this section, we try to assess the relationship between domain adaptation (DA) and priming, and question our initial assumption that priming performs some kind of unsupervised adaptation. Our test set for this part contains 1000 lines extracted from the European Central Bank (ECB) corpus, also available from OPUS website.

As an alternative to priming, we first consider a simple unsupervised domain adaptation technique, where we retrieve $k = 10$ most similar sentences for each test sample, yielding a corpus of $10 \times k$ sentences that we use to fine-tune for two epochs the baseline systems. Again, filtering based on a similarity scores helps to accumulate a smaller number of sentences that are closer to the test domain.

We then try to combine priming and fine-tuning in the following manner: for each test sentence, we use the k nearest examples $(\mathbf{f}_1, \mathbf{e}_1) \ldots (\mathbf{f}_k, \mathbf{e}_k)$ to derive k *domain-adaptation examples with priming* as follows: the first primes $\mathbf{f}_2$ with $\mathbf{f}_1$, the second $\mathbf{f}_3$ with $\mathbf{f}_2$, and so on, until finally $\mathbf{f}_1$ is primed with $\mathbf{f}_k$ (the target part is built accordingly). This corpus is used for fine-tuning, and decoding proceeds as before (with $\mathbf{f}_1$ as prime).

These approaches (priming, unsupervised DA, and priming+DA) are compared in Table 10. We first see that using back-translated data is detrimental to the BLEU score of the baseline system, an effect that might be due to the difference between News texts and ECB domain. We also see that unsupervised adaptation with highly similar sentences yields a small gain. Priming alone achieves the same result as the baseline, but can also benefit somewhat from unsupervised DA. Our best results are obtained when we mix the two strategies, only keeping highly similar sentences.

Model	ECB
baseline	26.7
baseline + bt + tag	25.9
+ FT min sim 0.7	26.3
+ FT min sim 0.8	26.1
priming + bt + tag	25.9
+ FT	25.6
+ FT min sim 0.7	26.3
+ FT min sim 0.8	26.0
priming + bt + tag + min sim 0.7	26.3
+ FT min sim 0.7	26.5
priming + bt + tag + min sim 0.8	26.3
+ FT min sim 0.8	26.3

Table 10: BLEU scores for De→Fr on ECB.

3.6 Conclusion

In this section, we have reported our attempt to perform domain adaptation through priming, a technique which uses sentences that are similar to the test instances to provide additional context in training and decoding. In our experiments with the translation of News between French and German, we had little success with this technique, even when using massive amounts of back-translated data to search for relevant primes. This suggests that priming is not so useful for "open" domains such as News (Pham et al., 2020), and should better be used for standardized types of texts that occur in more specialized domains. We also tried to compare unsupervised DA and priming, showing that, in our context, the former was yielding better results that than the latter and also proposed a promising way to combine these two complementary techniques.

4 Conclusion and outlook

In this paper, we have described the systems prepared for this year's participation to WMT shared tasks. For the biomedical track, most of our efforts have been invested in the development of high resource systems, trying to take the structure of medical abstracts into account. In the News task, we have explored ways to perform unsupervised domain adaptation using retrieval based techniques and back-translated data.

Abstract

This paper introduces WeChat AI's participation in WMT 2021 shared news translation task on English→Chinese, English→Japanese, Japanese→English and English→German. Our systems are based on the Transformer (Vaswani et al., 2017) with several novel and effective variants. In our experiments, we employ data filtering, large-scale synthetic data generation (i.e., back-translation, knowledge distillation, forward-translation, iterative in-domain knowledge transfer), advanced fine-tuning approaches, and boosted Self-BLEU based model ensemble. Our **constrained** systems achieve 36.9, 46.9, 27.8 and 31.3 case-sensitive BLEU scores on English→Chinese, English→Japanese, Japanese→English and English→German, respectively. The BLEU scores of English→Chinese, English→Japanese and Japanese→English are the highest among all submissions, and that of English→German is the highest among all constrained submissions.

1 Introduction

We participate in the WMT 2021 shared news translation task in three language pairs and four language directions, English→Chinese, English↔Japanese, and English→German. In this year's translation tasks, we mainly improve the final ensemble model's performance by increasing the diversity of both the model architecture and the synthetic data, as well as optimizing the ensemble searching algorithm.

Diversity is a metric we are particularly interested in this year. To quantify the diversity among different models, we compute Self-BLEU (Zhu et al., 2018) from the translations of the models on the valid set. To be precise, we use the translation of one model as the hypothesis and the translations of other models as references to calculate an average BLEU score. A higher Self-BLEU means this model is less diverse.

For model architectures (Vaswani et al., 2017; Meng and Zhang, 2019; Yan et al., 2020), we exploit several novel Transformer variants to strengthen model performance and diversity. Besides the Pre-Norm Transformer, the Post-Norm Transformer is also used as one of our baselines this year. We adopt some novel initialization methods (Huang et al., 2020) to alleviate the gradient vanishing problem of the Post-Norm Transformer. We combine the Average Attention Transformer (AAN) (Zhang et al., 2018) and Multi-Head-Attention (Vaswani et al., 2017) to derive a series of effective and diverse model variants. Furthermore, Talking-Heads Attention (Shazeer et al., 2020) is introduced to the Transformer and shows a significant diversity from all the other variants.

For the synthetic data generation, we exploit the large-scale back-translation (Sennrich et al., 2016a) method to leverage the target-side monolingual data and the sequence-level knowledge distillation (Kim and Rush, 2016) to leverage the source-side of bilingual data. To use the source-side monolingual data, we explore forward-translation by ensemble models to get general domain synthetic data. We also use iterative in-domain knowledge transfer (Meng et al., 2020) to generate in-domain data. Furthermore, several data augmentation methods are applied to improve the model robustness, including different token-level noise and dynamic top-p sampling.

For training strategies, we mainly focus on scheduled sampling based on decoding steps (Liu et al., 2021b), the confidence-aware scheduled sampling (Mihaylova and Martins, 2019; Duckworth et al., 2019; Liu et al., 2021a), the target denoising (Meng et al., 2020) method and the Graduated Label Smoothing (Wang et al., 2020) for in-domain finetuning.

For model ensemble, we select high-potential

* Equal contribution.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 243–254
November 10–11, 2021.

candidate models based on two indicators, namely model performance (BLEU scores on valid set) and model diversity (Self-BLEU scores among all other models). Furthermore, we propose a search algorithm based on the Self-BLEU scores between the candidate models with selected models. We observed that this novel method can achieve the same BLEU score as the brute force search while saving approximately 95% of search time.

This paper is structured as follows: Sec. 2 describes our novel model architectures. We present the details of our systems and training strategies in Sec. 3. Experimental settings and results are shown in Sec. 4. We conduct analytical experiments in Sec. 5. Finally, we conclude our work in Sec. 6.

2 Model Architectures

In this section, we describe the model architectures used in the four translation directions, including several different variants for the Transformer (Vaswani et al., 2017) .

2.1 Model Configurations

Deeper and wider architectures are used this year since they show strong capacity as the number of parameters increases. In our experiments, we use multiple model configurations with 20/25-layer encoders for deeper models and the hidden size is set to 1024 for all models. Compared to our WMT20 models (Meng et al., 2020), we also increase the decoder depth from 6 to 8 and 10 as we find that gives a certain improvement, but deeper depths give limited performance gains. For the wider models, we adopt 8/12/15 encoder layers and 1024/2048 for hidden size. The filter sizes of models are set from 8192 to 15000. Note that all the above model configurations are applied to the following variant models.

2.2 Transformer with Different Layer-Norm

The Transformer (Vaswani et al., 2017) with Pre-Norm (Xiong et al., 2020) is a widely used architecture in machine translation. It is also our baseline model as its performance and training stability is better than the Post-Norm counterpart.

Recent studies (Liu et al., 2020; Huang et al., 2020) show that the unstable training problem of Post-Norm Transformer can be mitigated by modifying initialization of the network and the successfully converged Post-Norm models generally outperform Pre-Norm counterparts. We adopt these initialization methods (Huang et al., 2020) to our training flows to stabilize the training of deep Post-Norm Transformer. Our experiments have shown that the Post-Norm model has a good diversity compared to the Pre-Norm Model and slightly outperform the Pre-Norm Model. We will further analyze the model diversity of different variants in Sec. 5.1.

2.3 Average Attention Transformer

We also use Average Attention Transformer (AAN) (Zhang et al., 2018) as we used last year to introduce more model diversity. In the Average Attention Transformer, a fast and straightforward average attention is utilized to replace the self-attention module in the decoder with almost no performance loss. The context representation g_i for each input embedding is as follows:

$$g_i = FFN(\frac{1}{i}\sum_{k=1}^{i} y_k) \quad (1)$$

where y_k is the input embedding for step k and i is the current time step. $FFN(\cdot)$ denotes the position-wise feed-forward network proposed by Vaswani et al. (2017).

In our preliminary experiments, we observe that the Self-BLEU (Zhu et al., 2018) scores between AAN and Transformer are lower than the scores between the Transformer with different configurations.

2.4 Weighted Attention Transformer

We further explore three weighting strategies to improve the modeling of history information from previous positions in AAN. Compared to the average weight across all positions, we try three methods including decreasing weights with position increasing, learnable weights and exponential weights. In our experiments, We observe exponential weights perform best among all these strategies. The exponential weights context representation g_i is calculated as follows:

$$c_i = (1-\alpha)y_i + \alpha \cdot c_{i-1} \quad (2)$$

$$g_i = FFN(c_i) \quad (3)$$

where α is a tuned parameter. In our previous experiments, we test different alpha, including 0.3, 0.5, and 0.7, on the valid set and we set the alpha to 0.7 in all subsequent experiments as it slightly outperform the others.

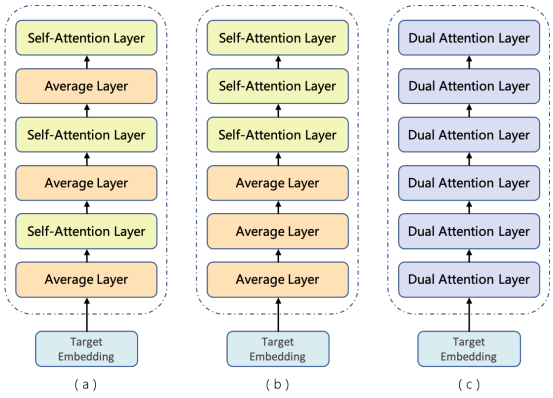

Figure 1: Mixed-AAN Transformers.

2.5 Mixed-AAN Transformers

Our preliminary experiments show that the decoder structure is strongly related to the model diversity in the Transformer. Therefore, we propose to stack different types of decoder layers to derive different Transformer variants. As shown in Figure 1, we mainly adopt three Mixed-AAN Transformer architectures: a) Alternately mixing the standard self-attention layer and the average attention layer, b) Continuously stacking several average attention layers on the bottom layers and then stacking self-attention layers for the rest layers. c) Stacking both the self-attention layer and average attention layer at each layer and using their average sum to form the final hidden states (named as 'dual attention layer').

In the experiments, Mixed-AAN not only performs better but also shows strong diversity compared to the vanilla Transformer. With four Mixed-AAN models, we reach a better ensemble result than the result with ten models which consist of deeper and wider standard Transformer. We will further analyze the effects of different architectures from performance, diversity, and model ensemble in Sec. 5.1

2.6 Talking-Heads Attention

In Multi-Head Attention, the different attention heads perform separate computations, which are then summed at the end. Talking-Heads Attention (Shazeer et al., 2020) is a new variation that inserts two additional learned linear projection weights, W_l and W_w, to transform the attention-logits and the attention scores respectively, moving information across attention heads. The calculation formula is as follows:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}}W_l)W_wV \quad (4)$$

We adopt this method in both encoders and decoders to improve information interaction between attention heads. This approach shows the most remarkable diversity among all the above variants with only a slight performance loss.

3 System Overview

In this section, we describe our system used in the WMT 2021 news shared task. We depicts the overview of our NMT system in Figure 2, which can be divided into four parts, namely data filtering, large-scale synthetic data generation, in-domain finetuning, and ensemble. The synthetic data generation part further includes the generation of general domain and in-domain data. Next, we proceed to illustrate these four parts.

3.1 Data Filtering

We filter the bilingual training corpus with the following rules for most language pairs:

- Normalize punctuation with Moses scripts except Japanese data.
- Filter out the sentences longer than 100 words or exceed 40 characters in a single word.
- Filter out the duplicated sentence pairs.
- The word ratio between the source and the target words must not exceed 1:4 or 4:1.
- Filter out the sentences where the fast-text result does not match the origin language.
- Filter out the sentences that have invalid Unicode characters.

Besides these rules, we filter out sentence pairs in which Chinese sentence has English characters in En-Zh parallel data. The monolingual corpus is also filtered with the n-gram language model trained by the bilingual training data for each language. All the above rules are applied to synthetic parallel data.

3.2 General Domain Synthetic Data Generation

In this section, we describe our techniques for constructing general domain synthetic data. The general domain synthetic data is generated via large-scale back-translation, forward-translation and knowledge distillation to enhance the models' performance for all domains. Then, we exploit

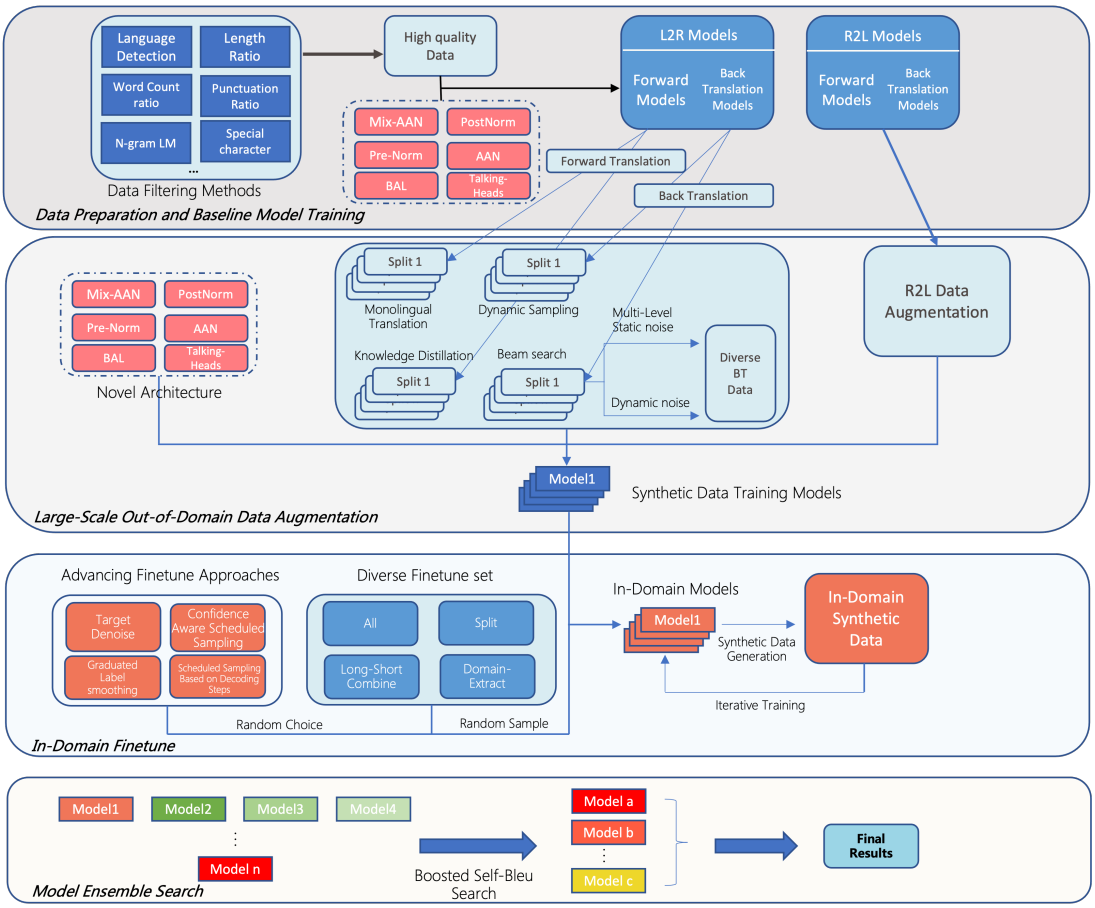

Figure 2: Architecture of our NMT system.

the iterative in-domain knowledge transfer (Meng et al., 2020) in Sec 3.3, which transfers in-domain knowledge to the vast source-side monolingual corpus, and builds our in-domain synthetic data. In the following sections, we elaborate the above techniques in detail.

3.2.1 Large-scale Back-Translation

Back-translation is the most commonly used data augmentation technique to incorporate the target side monolingual data into NMT (Hoang et al., 2018). Previous work (Edunov et al., 2018) has shown that different methods of generating pseudo corpus has a different influence on translation quality. Following these works, we attempt several generating strategies as follows:

- Beam Search: Generate target translation by beam search with beam size 5.
- Sampling Top-K: Select a word randomly from top-K (K is set to 10) words at each decoding step.
- Dynamic Sampling Top-p: Selected a word at each decoding step from the smallest set whose cumulative probability mass exceeds p and the p is dynamically changing from 0.9 to 0.95 during data generation.

Note that we also use Tagged Back-Translation (Caswell et al., 2019) in En→De and Right-to-Left (R2L) back-translation in En↔Ja, as we achieve a better BLEU score after using these methods.

3.2.2 Knowledge Distillation

Knowledge Distillation (KD) has proven to be a powerful technique for NMT (Kim and Rush, 2016; Wang et al., 2021) to transfer knowledge from the teacher model to student models. In particular, we first use the teacher models to generate synthetic corpus in the forward direction (i.e., En→Zh). Then, we use the generated corpus to train our student models.

Notably, Right-to-Left (R2L) knowledge distillation is a good complement to the Left-to-Right (L2R) way and can further improve model performance.

3.2.3 Forward-Translation

Using monolingual data from the source language to further enhance the performance and robustness of the model is also an effective approach. We use the ensemble model to generate high quality forward-translation data and obtain a stable improvement in En→Zh and En→De directions.

3.3 Iterative In-domain Knowledge Transfer

Since in-domain knowledge transfer (Meng et al., 2020) delivered a massive performance boost last year, we still use this technique in En↔Ja and En→De this year. It is not applied to En→Zh because no significant improvement is observed. We guess the reason is that the in-domain finetuning in the En→Zh direction does not bring a significant improvement compared to the other directions. And in-domain knowledge transfer is aiming at enhancing the effect of finetuning, so this does not have a noticeable effect in the English-Chinese direction.

We first use normal finetuning in Sec. 3.5 to equip our models with in-domain knowledge. Then, we ensemble these models to translate the source monolingual data into the target language. We use 4 models with different architectures and training data as our ensemble model. Next, we combine the source language sentences with the generated in-domain target language sentences as pseudo-parallel corpus. Afterwards, we retrain our models with both in-domain pseudo-parallel data and general domain synthetic data.

3.4 Data Augmentation

Once the pseudo-data is constructed, we further obtain diverse data by adding different noise. Compared to previous years' WMT competitions, we implement a multi-level static noise approach for our pseudo corpus:

- Token-level: Noise on every single subword after byte pair encoding.
- Word-level: Noise on every single word before byte pair encoding.
- Span-level: Noise on a continuous sequence of tokens before byte pair encoding.

The different granularities of noise make the data more diverse. The noise types are random replacement, random deletion and random permutation. We apply the three noise types in a parallel way for each sentence. The probability of enabling each of the three operations is 0.2.

Furthermore, an on-the-fly noise approach is applied to the synthetic data. By using on-the-fly noise, the model is trained with different noises in every epoch rather than all the same along this training stage.

3.5 In-domain Finetuning

A domain mismatch exists between the obtained system trained with large-scale general domain data and the target test set. To alleviate this mismatch, we finetune these convergent models on small scale in-domain data, which is widely used for domain adaption (Luong and Manning, 2015; Li et al., 2019). We take the previous test sets as in-domain data and extract documents that are originally created in the source language for each translation direction (Sun et al., 2019). We also explore several advanced finetuning approaches to strengthen the effects of domain adaption and ease the exposure bias issue, which is more serious under domain shift.

Target Denoising (Meng et al., 2020). In the training stage, the model never sees its own errors. Thus the model trained with teacher-forcing is prune to accumulated errors in testing (Ranzato et al., 2016). To mitigate this training-generation discrepancy, we add noisy perturbations into decoder inputs when finetuning. Thus the model becomes more robust to prediction errors by target denoising. Specifically, the finetuning data generator chooses 30% of sentence pairs to add noise, and keeps the remaining 70% of sentence pairs unchanged. For a chosen pair, we keep the source sentence unchanged, and replace the i-th token of the target sentence with (1) a random token of the current target sentence 15% of the time (2) the unchanged i-th token 85% of the time.

Graduated Label-smoothing (Wang et al., 2020). Finetuning on a small scale in-domain data can easily lead to the over-fitting phenomenon which is harmful to the model ensemble. It generally appears as the model over confidently outputting similar words. To further preventing overfitting of in-domain finetuning, we apply the Graduated Label-smoothing approach, which assigns a higher smoothing penalty for high-confidence predictions, during in-domain finetuning. Concretely, following the paper's setting, we set the smoothing penalty to 0.3 for tokens with confidence above 0.7,

zero for tokens with confidence below 0.3, and 0.1 for the remaining tokens.

Confidence-Aware Scheduled Sampling. Vanilla scheduled sampling (Zhang et al., 2019) simulates the inference scene by randomly replacing golden target input tokens with predicted ones during training. However, its critical schedule strategies are only based on training steps, ignoring the real-time model competence. To address this issue, we propose confidence-aware scheduled sampling (Liu et al., 2021a), which quantifies real-time model competence by the confidence of model predictions. At the t-th target token position, we calculate the model confidence $conf(t)$ as follow:

$$conf(t) = P(y_t|\mathbf{y}_{<\mathbf{t}}, \mathbf{X}, \theta) \tag{5}$$

Next, we design fine-grained schedule strategies based on the model competence. The fine-grained schedule strategy is conducted at all decoding steps simultaneously:

$$y_{t-1} = \begin{cases} y_{t-1} & if\ conf(t) \leq t_{golden} \\ \hat{y}_{t-1} & else \end{cases} \tag{6}$$

where t_{golden} is a threshold to measure whether $conf(t)$ is high enough ($e.g.$, 0.9) to sample the predicted token $\hat{y}_{t-1}$.

We further sample more noisy tokens at high-confidence token positions, which prevents scheduled sampling from degenerating into the teacher forcing mode.

$$y_{t-1} = \begin{cases} y_{t-1} & if\ conf(t) \leq t_{golden} \\ \hat{y}_{t-1} & if\ t_{golden} < conf(t) \leq t_{rand} \\ y_{rand} & if\ conf(t) > t_{rand} \end{cases} \tag{7}$$

where t_{rand} is a threshold to measure whether $conf(t)$ is high enough ($e.g.$, 0.95) to sample the random target token $\hat{y}_{rand}$.

Scheduled Sampling Based on Decoding Steps. We propose scheduled sampling methods based on decoding steps from the perspective of simulating the distribution of real translation errors (Liu et al., 2021b). Namely, we gradually increase the selection probability of predicted tokens with the growth of the index of decoded tokens. At the t-th decoding step, the probability of sampling golden tokens $g(t)$ is calculated as follow:

Algorithm 1 Boosted Self-BLEU based Ensemble

Input:
List of candidate models M = $\{m_0, ..., m_n\}$
Valid set BLEU for each model B = $\{b_i, ..., b_n\}$
Average Self-BLEU for each model S = $\{s_i, ..., s_n\}$
The number of models n
The number of ensemble models c

Output: Model combinations C

for $i \leftarrow 1\ to\ n$ **do**
  $score_i = (b_i - min(B)) \cdot weight + (max(S) - s_i)$
  $weight = \frac{(max(S) - min(S))}{(max(B) - min(B))}$
end for
Add the highest score model to candidates list C = { m_{top} }
while $|C| < c$ **do**
  $index = \arg\min_i \frac{1}{|M-C|} \sum_{i \in M-C, j \in C} BLEU(i, j)$
  Add m_{index} to candidate list C
end while
return C

- Linear Decay: $g(t) = \max(\epsilon, kt + b)$, where ϵ is the minimum value, and $k < 0$ and b is respectively the slope and offset of the decay.
- Exponential Decay: $g(t) = k^t$, where $k < 1$ is the radix to adjust the decay.
- Inverse Sigmoid Decay: $g(t) = \frac{k}{k + e^{\frac{t}{k}}}$, where e is the mathematical constant, and $k \geq 1$ is a hyperparameter to adjust the decay.

Following our preliminary conclusions (Liu et al., 2021b), we choose the exponential decay and set k to 0.99 by default.

3.6 Boosted Self-BLEU based Ensemble (BSBE)

After we get numerous finetuned models, we need to search for the best combination for ensemble model. Ordinary random or greedy search is over-simplified to search for a good model combination and enumerate over all combinations of candidate models is inefficient. The Self-BLEU based pruning strategy (Meng et al., 2020) we proposed in last year's competition achieve definite improvements over the ordinary ensemble.

However, diversity is not the only feature we need to consider but the performance in the valid

set is also an important metric. Therefore, we combine Self-BLEU and valid set BLEU together to derive a Boosted Self-BLEU-based Ensemble (BSBE) algorithm. Then, we apply a greedy search strategy in the top N ranked models to find the best ensemble models.

See algorithm 1 for the pseudo-code. The algorithm takes as input a list of n strong single models M, BLEU scores on valid set for each model B, average Self-BLEU scores for each model S, the number of models n and the number of ensemble models c. The algorithm return a list C consists of selected models. We calculate the weighted score for each model as line 2 in the pseudo-code. The weight calculated in line 3 is a factor to balance the scale of Self-BLUE and valid set BLEU. Then the list C initially contains the model m_{top} has a highest weighted score. Next, we iteratively re-compute the average Self-BLEU between the remaining models in $|M - C|$ and selected models in C, based on which we select the model has minimum Self-BLEU score into C.

In our experiments, we save around 95% searching time by using this novel method to achieve the same BLEU score of the Brute Force search. We will further analyze the effect of Boosted Self-BLEU based Ensemble in section 5.2.

4 Experiments And Results

4.1 Settings

The implementation of our models is based on Fairseq[1] for En→Zh and EN→De, and OpenNMT[2] for En↔Ja. All the single models are carried out on 8 NVIDIA V100 GPUs, each of which has 32 GB memory. We use the Adam optimizer with β_1 = 0.9, β_2 = 0.998. The gradient accumulation is used due to the high GPU memory consumption. The batch size is set to 8192 tokens per GPU and we set the "update-freq" parameter in Fairseq to 2. The learning rate is set to 0.0005 for Fairseq and 2.0 for OpenNMT. We use warmup step = 4000. We calculate sacreBLEU[3] score for all experiments which is officially recommended.

4.2 Dataset

The statistics of all training data is shown in Table 1. For each language pair, the bilingual data is the combination of all parallel data released by WMT21. For monolingual data, we select data from News Crawl, Common Crawl and Extended Common Crawl, it is then divided into several parts, each containing 50M sentences.

	En→Zh	En→De	En↔Ja
Bilingual Data	30.7M	74.8M	12.3M
Source Mono Data	200.5M	332.8M	210.8M
Target Mono Data	405.2M	237.9M	354.7M

Table 1: Statistics of all training data.

For general domain synthetic data, we use all the target monolingual data to generate back-translation data and a part of source monolingual data (about 80 to 100 million for different languages) to get forward translation data. For the in-domain pseudo-parallel data, we use the entire source monolingual data and bilingual data. All the test and valid data from previous years are used as in-domain data.

We use the methods described in Sec. 3.1 to filter bilingual and monolingual data.

4.3 Pre-processing and Post-processing

English and German sentences are segmented by Moses[4], while Japanese use Mecab[5] for segmentation. We segment the Chinese sentences with an in-house word segmentation tool. We apply punctuation normalization in English, German and Chinese data. Truecasing is applied to English↔Japanese and English→German. We use byte pair encoding BPE (Sennrich et al., 2016b) with 32K operations for all the languages.

For the post-processing, we apply de-truecaseing and de-tokenizing on the English and German translations with the scripts provided in Moses. For the Chinese translations, we transpose the punctuations to the Chinese format.

4.4 English→Chinese

The results of En→Zh on newstest2020 are shown in Table 2. For the En→Zh task, filtering out part of sentence pairs containing English characters in Chinese sentences shows a significant improvement in the valid set. After applying large-scale Back-Translation, we obtain +2.0 BLEU score on the baseline. We further gain +0.62 BLEU score after applying knowledge distillation and +0.24 BLEU from Forward-Translation. Surprisingly, we observe that adding more BT data from different

+ BSBE	**50.94** ⋆	**45.35** ⋆	**28.24** ⋆	40.59
+ Post-Process	–	–	–	**41.88** ⋆

Table 2: Case-sensitive BLEU scores (%) on the four directions *newstest2020*, where '⋆' denotes the submitted system. Mix BT means we use multiple parts of Back Translation data with different generation strategies. The *Advanced Finetune* methods outperform the normal *Finetune* and we report the best results in single model. BSBE outperforms Normal Ensemble in all four directions.

shards with different generation strategy can further boost the model performance to 48.17. The fine-tuned model achieves a 49.81 BLEU score, which demonstrates that the domain of the training corpus is apart from the test set domain. The *advanced* finetuning further brings about 0.41 BLEU score gains compared to normal finetune. Our best single model achieves a 50.22 BLEU score.

In preliminary experiments, we select the best performing models as our ensemble combinations obtaining +0.4 BLEU score. On top of that, even after searching hundreds of models, no better results are obtained. With BSBE strategies in Sec. 3.6, a better model combination with less number of models are quickly searched, and we finally achieve 50.94 BLEU score. Our WMT2021 English→Chinese submission achieves a SacreBLEU score of 36.9, which is the highest among all submissions and chrF score of 0.337.

4.5 English→Japanese

The results of En→Ja on newstest2020 are shown in Table 2. For the En→Ja task, we filter out the sentence pairs containing Japanese characters in the English side and vice versa. The Back-Translation and Knowledge Distillation improve the baseline from 35.78 to 36.66. Adding more BT data further brings in 0.56 improvements. The improvement by finetuning is much larger than other directions, which is 5.32 BLEU. We speculate that this is because there is less bilingual data for English and Japanese than for other languages, and the test results for Japanese are char level BLEU so this direction is more influenced by the in-domain finetuning. Two In-domain knowledge transfers improve BLEU score from 37.22 to 43.69. Normal finetune still provides 0.54 improvements after in-domain knowledge transfer. Then, we apply *advanced* finetuning methods to further get 0.19 BLEU improvements. Our final ensemble result outperforms baseline 9.57 BLEU.

4.6 Japanese→English

The Ja→En task follows the same training procedure as En→Ja. From Table 2, we can observe that Back-Translation can provide 1.11 BLEU improvements from baseline. Knowledge Distillation and more BT data can improve the BLEU score from 20.82 to 22.11. The finetuning improvement is 3.8 which is slightly less than the En→Ja direction but still larger than En→Zh and En→De. We also apply two-turn in-domain knowledge transfer and further boost the BLEU score to 25.89. After normal finetuning, the BLEU score achieves 26.27. The *advanced* finetuning methods provide a slight improvement on Ja→En. After ensemble, we achieve 28.24 BLEU in newstest2020.

Table 4: Self-BLEU scores (%) between different architectures. For simplicity, we refer to these models as Transformer (Pre-Norm Transformer), Post-Norm (Post-Norm Transformer), AAN (Average Attention Transformer), Weighted (Weighted Attention Transformer), Avg-First (Average First Transfromer), Avg-Bot (Average Bottom Transformer), Dual (Dual Attention Transformer), TH (Talking-Heads Attention). The model with '∗' is the Mix-AAN variants.

4.7 English→German

The results of En→De on newstest2020 are shown in Table 2. After adding back-translation, we improve the BLEU score from 33.28 to 35.28. Knowledge Distillation further boosts the BLEU score to 36.58. The finetuning further brings in 2.63 improvements. After injecting the in-domain knowledge into the monolingual corpus, we get another 0.31 BLEU gain. We apply a post-processing procedure on En→De. Specifically, we normalize the English quotations to German ones in German hypotheses, which brings in 1.3 BLEU improvements.

5 Analysis

To verify the effectiveness of our approach, we conduct analytical experiments on model variants, finetune methods, and ensemble strategies in this section.

5.1 Effects of Model Architecture

We conduct several experiments to validate the effectiveness of Transformer (Vaswani et al., 2017) variants we used and list results in Table 3. We also investigate the diversity of different variants and the impacts on the model ensemble. The results is listed in Table 4 and Table 5. Here we take En→Zh models as examples to conduct the diversity and ensemble experiments. The results in other directions show similar trends.

Performance. As shown in Table 3, AAN performs slightly worse than other variants in En→Zh but Mixed-AAN variants outperform normal Transformer. Weighted Attention Transformer provides noticeable improvement compare to AAN and sometimes better than vanilla Transformer.

Diversity. The Self-BLEU scores in Table 4 demonstrate the difference between two models, more different models generally have lower scores. As we can see, AAN and all the variants with AAN have an absolutely lower Self-BLEU score with the Transformer. The Talking-Heads Attention has the minimum scores among all the variants.

Ensemble. In our preliminary experiments, we observe that more diverse models can significantly help the model ensemble. The results are listed

MODELS	newstest2020
Deeper & Wider Transformer	50.31
Weighted & Mixed-AAN	50.44
Ensemble with all models above	**50.62**

Table 5: Ensemble results with different architectures. The first row is the ensemble results with 10 deeper and wider models searched from dozens of ones. The second row is the ensemble results with only 4 Weighted Attention Transformer and Mixed-AAN models.

ALGORITHM	BLEU	Number of Searches
Greedy	50.19	$2n$
Brute Force	50.44	$\sum_{i=1}^{n} C_n^i$
BSBE	**50.44**	$n+1$

Table 6: Results of different search algorithm. n is the total number of models used for the search. The number of searches is number that the methods need to translate the valid set. Our BSBE achieves comparable BLEU score as Brute Force search and significantly reduces the searching time.

in Table 5. We get a more robust ensemble model with only four models using our novel variants than searching from dozens of Deeper and Wider Transformer models. Even these four models are trained with the same training data. After we combine the four models with Deeper and Wider Transformer, we can further get a significant improvement.

Take En→Zh as an example, our final submission consist of 1 Average First Transformer, 1 Average Bottom Transformer, 1 Dual Attention Transformer, 1 Weighted Attention Transformer and 1 Transformer with Post-Norm.

5.2 Effects of Boosted Self-BLEU based Ensemble

To verify the superiority of our Boosted Self-BLEU based Ensemble (BSBE) method, we randomly select 10 models with different architecture and training data. For our submitted system, we search from over 500 models. We use a greedy search algorithm (Deng et al., 2018) as our baseline. The greedy search greedily selects the best performance model into candidate ensemble models. If the selected model provides a positive improvement, we keep it in the candidates. Otherwise, it is added to a temporary model list and still has a weak chance to be reused in the future. One model from the temporary list can be reused once, after which it is withdrawn definitely. We compare the results of greedy search, BSBE and Brute Force and list the ensemble model BLEU and the number of searches in Table 6. Note that n is the number of models, which is 10 here. For BSBE, we need to get the translation result of every model to calculate the Self-BLEU. After that, we only need to perform the inference process once.

5.3 Effects of Advanced Finetuning

In this section, we describe our experiments on advanced finetuning in the four translation directions. As shown in Table 7, all the advanced finetuning methods outperform normal finetuning. For En→Zh, Scheldule Sampling Based on Decoding Steps with Graduated Label Smoothing improves the model performance from 49.81 to 50.20. For En↔Ja, Target Denoising with Graduated Label Smoothing provides the highest BLEU gain, which are 0.19 and 0.11. For the En→De direction, Confidence-Aware Scheldule Sampling with Graduated Label Smoothing performs the best, improving from 39.21 to 39.42. These findings are in line with the conclusion of Wang and Sennrich (2020) that links exposure bias with domain shift.

6 Conclusion

We investigate various novel Transformer based architectures to build robust systems. Our systems are also built on several popular data augmentation methods such as back-translation, knowledge distillation and iterative in-domain knowledge transfer. We enhance our system with advanced finetuning approaches, i.e., target denoising, graduated label smoothing and confidence-aware scheduled sampling. A boosted Self-BLEU based model ensemble is also employed which plays a key role in our systems. Our constrained systems achieve 36.9, 46.9, 27.8 and 31.3 case-sensitive BLEU scores on English→Chinese, English→Japanese, Japanese→English and English→German, respectively. The BLEU scores of English→Chinese, English→Japanese and Japanese→English are the highest among all submissions, and that of English→German is the highest among all constrained submissions.

Small Model and In-Domain Data are All You Need

Hui Zeng
Independent Researcher
felix_zeng_ai@aliyun.com

Abstract

I participated in the WMT shared news translation task and focus on one high resource language pair: English and Chinese (two directions, Chinese to English and English to Chinese). The submitted systems (ZengHuiMT) focus on data cleaning, data selection, back translation and model ensemble. The techniques I used for data filtering and selection include filtering by rules, language model and word alignment. I used a base translation model trained on initial corpus to obtain the target versions of the WMT21 test sets, then I used language models to find out the monolingual data that is most similar to the target version of test set, such monolingual data was then used to do back translation. On the test set, my best submitted systems achieve 35.9 and 32.2 BLEU for English to Chinese and Chinese to English directions respectively, which are quite high for a small model.

1 Introduction

I participated in the WMT shared news translation task and focus on the English and Chinese language pair. This language pair is challenging due to the plentiful in-domain bitext training data and abundant monolingual data. High resource means fierce competition, many high-tech companies and universities chose this language pair also. My neural machine translation system is developed using base transformer (Vaswani et al., 2017) architecture and the toolkit I used is THUMT (Zhang et al., 2020). Rules and word aligning model are used to clean parallel data. Language model is used to clean monolingual data. I use a base transformer (Vaswani et al., 2017) architecture since I have only one GPU. The following techniques are used on model training: a. Increase the number of encoder layers to 12 to further improve the encoder's representation capability; b. Back translation (Sennrich et al., 2016) are applied to fully utilize the monolingual corpus. c. Shared vocabulary is used for better performance. d. Four different models using diversified data are trained for ensemble decoding.

2 Data Filtering and Selection

The parallel data is mainly from CCMT Corpus[1], and the monolingual data is collected from the internet. I did not use any other datasets since I think they are not highly related to this news translation task. To evaluate my model's performance, I merged the test set from WMT2017 to WMT2020 to build a big development set.

2.1 Monolingual Data Filtering Using Language Model

In terms of monolingual data, I collected more than 20 million Chinese sentences and more than 15 million English sentences from various websites.
The Chinese text are collected from the following websites:
http://www.chinanews.com/
https://cn.reuters.com/
http://news.ifeng.com/

[1]http://mteval.cipsc.org.cn:81/agreement/description

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 255–259

https://www.sohu.com/
The English text are collected from the following websites:
https://www.bbc.com/news
www.theguardian.com
https://www.telegraph.co.uk/
https://www.washingtonpost.com/
https://www.latimes.com/
https://www.smh.com.au/
https://www.brisbanetimes.com.au/
https://www.dailymail.co.uk/
https://www.rt.com/
https://time.com/
https://www.euronews.com/
https://www.msnbc.com/
https://www.cbsnews.com/
https://www.nytimes.com/
https://www.newsweek.com/
https://www.foxnews.com/
https://www.standard.co.uk/

The following rules are used for a simple cleaning:
•Remove duplicated sentences.
•Remove the sentences containing special characters.
•Remove the sentences containing html addresses or tags.

Afterwards, language models are used to filter the monolingual data. For English sentences, lm-scorer [2] is used to calculate a score for each sentence, which is the mean of tokens' probabilities. The pre-trained model used for English is GPT-2 (Radford et al., 2019). [3] For Chinese sentences, a pre-trained Chinese GPT-2 (Radford et al., 2019)[4] model is used to calculate a score for each sentence. Then, the English and Chinese sentences are filtered by their scores.

GPT-2 (Radford et al., 2019) is a large transformer-based language model with 1.5 billion parameters, trained on a dataset of 8 million web pages. GPT-2 (Radford et al., 2019) is trained with a simple objective: predict the next word, given all of the previous words within some text.

The threshold I used is determined based on my personal evaluation on the text. After calculating the scores for all the sentences, I sampled the sentences by their scores and perform a language quality check. I started from the extremely low scores and the extremely high scores, and then gradually move the scale from the two ends to the middle until I find that the language quality is up to my standard.

There are about 16 million Chinese sentences and 10 million English sentences left after filtering using language model.

2.2 Parallel Data Filtering Using Rules

For CCMT parallel Corpus and synthetic parallel corpus from back translation, I used the following rules to filter data.

a. Remove duplicated sentence pairs.
b. Remove the lines having identical source and target sentences.
c. Remove the sentence pairs containing special characters.
d. Remove the sentence pairs containing html addresses or tags.
e. Remove the sentence pairs with empty source or target side.

2.3 Parallel Data Filtering Using Word Alignment

In order to get word alignment results, fast_align (Dyer et al., 2013) is used on the CCMT Corpus filtered by rules, then extract-lex [5] is used to generate bilingual phrase tables. The phrase tables are then pruned according to probabilities. Afterwards, I use the pruned phrase table to measure the confidence of the sentence pairs being mutual translations. The confidence score is calculated like this: check each token of the target sentence to find if it has a counterpart in the source side, then perform this operation in the reverse direction, the final confidence score is calculated by summing up the two percentages from two respective directions and then getting the average.
Then the confidence score is used to remove bad sentence pairs. The sentence pairs with confidence scores below 0.6 are discarded. In this way, I finally got a high quality parallel CCMT Corpus.

3 System Description

This section illustrate how I train the model step by step.

[2]https://github.com/simonepri/lm-scorer
[3]https://openai.com/blog/better-language-models/
[4]https://huggingface.co/uer/gpt2-chinese-cluecorpussmall
[5]https://github.com/marian-nmt/extract-lex

3.1 Data pre-processing

For data preprocessing, I use the tokenizer developed on my own to process both Chinese and English. Chinese text (including punctuations and numbers) is split to single character level. I keep the upper and lower case letters of English as they are, since I believe they are also important features for the model. Numbers in English text are also split into single digits. I use byte pair encoding (BPE) (Sennrich et al., 2016) to create a shared vocabulary, so that the vocabulary size is reduced to 45467. I also wrote a post-processor to restore the Chinese and English text to normal form.

3.2 Normal Model Training

To evaluate my model's performance, I merged the test set from WMT2017 to WMT2020 into a big development set. First, I use the CCMT parallel Corpus filtered by rules and word aligning model to train base transformer (Vaswani et al., 2017) English to Chinese and Chinese to English translation models. Two sets of training parameters were used with only one difference: the number of encoder layers. The detailed parameters are as follows:

batch_size=15000,
max_length=384,
hidden_size=512,
filter_size=2048,
num_heads=8,
num_encoder_layers=6 or 12,
num_decoder_layers=6
max_relative_dis=16,
layer_preprocess="layer_norm",
eval_steps=2000,
warmup_steps=4000

Validation is performed every 2000 steps, the training is terminated if there is no gain in BLEU for 20 consecutive validations.

As shown in Table 1, using the same filtered CCMT Corpus, the BLEU scores of models with deeper encoder (12-layer-encoder, 6-layer-decoder) are slightly higher than that of the base version.

Back translation (Sennrich et al., 2016) is a useful data augmentation technique to boost model performance with target side monolingual data. The technique starts from training a target to source translation model using initial bilingual corpus, which is later used to translate the monolingual data in the target language back to source language. Then the synthetic back-translated corpus is concatenated with the original bilingual corpus to train the source to target translation model. After the source to target model is enhanced, the same method can be applied

Model + Corpus	**BLEU EN2 ZH**	**BLEU ZH to EN**
filtered CCMT Corpus base transformer 6-layer-encoder, 6-layer-decoder, base transformer	32.7	21.0
filtered CCMT Corpus base transformer 12-layer-encoder, 6-layer-decoder, base transformer	32.9	21.1
filtered CCMT Corpus half of the filtered monolingual data multiple rounds of back translations 12-layer-encoder, 6-layer-decoder, base transformer	35.3	24.5
filtered CCMT Corpus in-domain monolingual data extracted using test set multiple rounds of back translations 12-layer-encoder, 6-layer-decoder, base transformer best single model	38.3	28.0
filtered CCMT Corpus in-domain monolingual data extracted using test set multiple rounds of back translations 12-layer-encoder, 6-layer-decoder, base transformer ensemble of four models	39.5	29.1

Table 1: Different models and their BLEU scores
I merged the test set from WMT2017 to WMT2020 into a big development set.
The BLEU scores are calculated on this big development set.

again to train the back-translation system in the reversed direction.

I repeat this process using **half** of the filtered monolingual data for several iterations until the BLEU is not increasing.

3.3 Training on In-domain Data

BERT (Devlin et al., 2019) is designed to pre-train deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers. Before feeding word sequences into BERT (Devlin et al., 2019), 15% of the words in each sequence are replaced with a [MASK] token. The model then attempts to predict the original value of the masked words, based on the context provided by the other, non-masked, words in the sequence.

After the WMT2021 test set was released, I first translated the Chinese and English test sentences to target versions using the above models, then I generated feature representations for the target versions of the test sentences using pre-trained English BERT (Devlin et al., 2019)[6] and Chinese BERT (Devlin et al., 2019)[7] models.

The example representations are shown in Figure 1 and Figure 2.

```

Figure 2: The BERT representation of "我非常喜欢这个竞赛。", the tensor shape is [1, 12 , 768]

I also generated feature representation for each sentence in the **other half** of the filtered monolingual data. These features are then used to calculate the cosine similarity scores between the target versions of test sentences generated by the previous trained models and the monolingual sentences that are not used in previous training.

Then, the similarity scores are used to find out monolingual sentences that are most similar to the WMT2021 test set.

For each test set sentence, hundreds of monolingual sentences are extracted. In order to determine a threshold score, I randomly sampled 100 test set sentences and their extracted counterparts. Then I checked their similarities and scores using my personal linguistic competences in these two languages. The determined threshold score was then used to automatically extract in-domain data.

Finally, I extracted around 550 thousand Chinese sentences and 420 thousand English sentences as in-domain monolingual data. These sentences are then divided into four equal portions. On the basis of the best models using back translation and the first half of monolingual data, I use four portions of in-domain English data and four portions of in-domain Chinese data to do back translation until the BLEU stops increasing. Therefore, I get four in-domain English to Chinese and four in-domain Chinese to English translation models. These models are then ensembled to build two most powerful models for each direction.

3.4 Results

The BLEU scores on the aforesaid big development set (I merged the test set from WMT2017 to WMT2020 to build a big development set) for each corpus plus model combination are shown in Table 1.

On the WMT 2021 test set, my best submitted systems achieve 35.9 and 32.2 BLEU for English to Chinese and Chinese to English directions respectively, which are even higher than most of the systems from famous high-tech companies.

4 Conclusion

This paper describes Hui Zeng's translation systems (ZengHuiMT) for the WMT2021 news translation shared task. The potential of small model plus in-domain data is explored. I am pleased to argue that, with high quality in-domain data, small model could achieve BLEU scores comparable to that of huge models.

The Mininglamp Machine Translation System for WMT21

Shiyu Zhao, Xiaopu Li, Minghui Wu, Jie Hao
Mininglamp Technology, Beijing, China
{zhaoshiyu, lixiaopu, wuminghui, haojie}@mininglamp.com

Abstract

This paper describes Mininglamp neural machine translation systems of the WMT2021 news translation tasks. We have participated in eight directions translation tasks for news text including Chinese↔English, Hausa↔English, German↔English and French↔German. Our fundamental system was based on Transformer architecture, with wider or smaller construction for different news translation tasks. We mainly utilized the method of back-translation, knowledge distillation and fine-tuning to boost single model, while the ensemble was used to combine single models. Our final submission has ranked first for the English→Hausa task.

1 Introduction

This paper describes the Mininglamp submissions to the WMT2021 news translation tasks for eight directions including four high-resource Chinese↔English, German↔English, two medium-resource French↔German and two low-resource Hausa↔English. Furthermore, all of our systems were built with constrained data sets.

For this participation, we experimented with some smaller or wider Transformer (Vaswani et al., 2017) architectures to reach a reliable baseline based on different resource scales, sampling or beam search in back-translation to generate more suitable pseudo bilingual sentences. Particularly in the low-resource tasks, Hausa↔English, the Transformer-Small neural machine translation was built for the baseline, we presented iterative between back-translation and fine-tuning pattern which significantly improve the BLEU score on the validation set, and it worked well on English→Hausa task. Due to time constraints, we did not experiment on Hausa→English task. This path could be an experiment in the future work.

As for the data augmentation aspect, we experimented with several back-translation methods (Sennrich et al., 2016a), including the beam search, unrestricted sampling and sampling-topK (Edunov et al., 2018), to leverage the target-side monolingual data. We also applied knowledge distillation (Freitag et al., 2017) to leverage the source-side monolingual data.

Our systems followed four main steps:1) data filtering and preprocessing, 2) back-translation to generate pseudo bilingual data, 3) knowledge distillation by monolingual data, 4) fine-tuning with in-domain.

It should be emphasized that we used Marian[1] (Junczys-Dowmunt et al., 2018) to implement only for Hausa↔English baseline systems, and Fairseq[2] (Ott et al., 2019) for the rest, include Hausa↔English back-translation and knowledge distillation models.

2 System Overview

2.1 Data Filtering and Preprocessing

In this section, we discuss the preprocessing, normalization and filter techniques carried out in an attempt, in order to reduce spurious uncertainty in the modeling problem.

2.1.1 Text Preprocessing

Generally, we carried out the following text preprocessing steps prior to use in every model:

- Normalization: Unicode canonicalization, replacement of common multiple encoding errors present in training data, standardization of quotation marks into directional variants, conversion of any traditional Chinese characters into simplified forms, conversion of any Chinese full-width characters and segmental Chinese full-width punctuation into half-width forms. Normalize punctuation in all data by using Moses[3] (Koehn et al., 2007)

[1] https://github.com/marian-nmt/marian
[2] https://github.com/pytorch/fairseq
[3] https://github.com/moses-smt/mosesdecoder

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 260–264

(`normalize-punctuation.perl`) script except for every language pair.

- Segmentation: Chinese was segmented using the Jieba[4] segmentation tool, and tokenizer using Moses (`tokenizer.perl`) script for English, German, French and Hausa. For the Hausa tokenizer, we used English tokenizer instead.

- True-case: The word, at the start of a sentence, containing only an initial capital letter was replaced with the capitalized variant. That occurred most frequently in other positions of the English monolingual training data. Thus, in the previous sentence, the initial token would be "words" rather than "Words". We used Moses' script for true-case.

- Subword: The neural machine translation system is capable of open-vocabulary translation by representing rare and unseen words as a sequence of subword units. The model was trained based on subword-nmt[5] on the parallel training corpus.

2.1.2 Data Filtering

For all language pairs, the data filtering process for the training bilingual corpus stayed to the principle with the following rules:

- Filter out the sentence pairs that contain blank lines either from the source side or the target side.

- Filter out the sentence pairs that the source side and the target side at the same.

- Filter out the sentences with the length ratio falling outside from 0.4 to 2.5.

- Filter out the sentences whose punctuation and foreign words taking more than 40 percent.

- Remove the sentences which are longer than 200 words, or exceed a single word with 30 characters.

- Filter out the sentences which contain HTML tags or duplicated translations.

- Filter out the sentences which its word ratio between the source and the target exceeds 1:2.5 or 2.5:1.

- Identify language and delete foreign languages. Filter parallel and monolingual data by language detection using cld2[6].

The rules described above were also employed when cleaning monolingual and back-translation data. In the monolingual data particularly there were some lines that include two or more sentences, we cut them into several sentences by writing a script.

2.2 Data Augmentation

2.2.1 Back-Translation

Back-translation (Sennrich et al., 2016a) is an essential method to integrate the target side monolingual synthetic knowledge when building a state-of-the-art neural machine translation system. Especially for low-resource language tasks, it's indispensable to augment the training data by mixing the pseudo corpus with the parallel part. In that the target side, lexicon coverage was insufficient. The nucleus sampling (Holtzman et al., 2020) in back-translation to generate more suitable pseudo bilingual sentences. We attempted several data augmentation methods as follow, with different single technologies or combinations.

- Beam search: Generated target translation by beam search with beam 5.

- Sampling: Selected a word randomly from the whole distribution in each step, which increases the diversity of pseudo corpus with low precision, compared with beam search.

- Sampling Top-K: Selected a word in a restricted way that only top-K (we set K as 16) words could be chosen.

2.2.2 Forward Translation to Generate Synthetic Parallel Sentence

For Chinese↔English tasks. To generate a more diverse pseudo-parallel corpus, we use forward-translated to do generated synthetic parallel sentences on source monolingual data only by our own ensemble model.

[4] https://github.com/fxsjy/jieba

[5] https://github.com/rsennrich/subword-nmt

[6] https://github.com/CLD2Owners/cld2

2.2.3 Knowledge Distillation

We used knowledge distillation (Kim and Rush, 2016) to do distillation on the original dataset. Specifically, we translated the source-side of the bilingual data using previously trained proposal models, and generated distilled candidates. We then trained models on filtered data along with the original bilingual data and back-translation data.

2.3 Iterative Back-translation and Fine-tuning

A process which iterative twice between back-translation and fine-tuning was implemented by following steps for the low-resource Hausa↔English tasks.

2.4 Reranking

For German↔English, French↔German tasks, we followed noisy-channel (Yee et al., 2019) reranking using one neural language model and three reverse translation models.

3 Experiment

3.1 Experiment Settings

In order to demonstrate the experiments of the system, there some experiment details should be clarified. To train all of the models used in our system, we made use only of the constrained data sets provided to shared news translation task participants. On the other side, the baseline models were trained on parallel corpus only by cleaned corpus. In terms of model evaluation, the main indicator for the report was calculated according to sacreBLEU[7] (Post, 2018) based on the results which has been removed parts of post-preprocessing such as removed BPE symbols, detruecased, detokenized, etc.

The Transformer-Small was implemented based on Marian (Junczys-Dowmunt et al., 2018) as our baseline for Hausa↔English tasks. For Chinese↔English, German↔English and French↔German tasks, we implemented the Transformer-Big FFN-8192 based on Fairseq (Ott et al., 2019) as our baseline model. We used Adam optimizer (Kingma and Ba, 2014) during training, learning rate was 5e-4, $\beta_1 = 0.9$, $\beta_2 = 0.98$, weight decay was 0.0001, label smoothing was 0.1. Specifically, the learning rate warmed up over the 8,000 steps for pre-normalize architectures Transformer-Big FFN-8192 model. The system shuffled the training data before generating the training batch for each epoch, so the document context information was not considered in this case. FP16 was applied to accelerate training with few performance damage during the training process.

3.2 Chinese↔English

For Chinese↔English system, our parallel corpus included CCMT, wikititles-v3, wikimatrix-v1, para-crawl-v7.1, news-commentary-v16 corpus. While Chinese were segmented by Jieba word segmentation toolkit, English was tokenized by Moses tokenizer script. Based on the result of data Filtering, we used 17 million Chinese↔English parallel data corpus for training the baseline model. As the next step after the preprocessing, we trained BPE (Sennrich et al., 2016b) models which were learned with 32,000 merge operations for joined English and Chinese on the parallel data. We built separately vocabularies for each language, and the final vocabulary size of Chinese was 42K and English was 22K. Baseline train data we followed drop-BPE (Provilkov et al., 2020). We trained the Transformer-Big FFN-8192 model for Chinese↔English.

For back-translation, we selected 20 million News Crawl 2020 English monolingual data for Chinese→English task. All News Crawl Chinese monolingual data and selected 20 million Extended Common Crawl Chinese monolingual data were combined for English→Chinese task. Back-translation data were combined by sampling top-16 and beam search. At the same time, there was a combination between back-translation data and parallel data corpus in order to train Chinese↔English models. We selected 10 million Chinese and English sentences respectively for forward translation and knowledge distillation to generate synthetic parallel sentences.

Our final submissions consisted of three Transformer-Big FFN-8192 models with different configurations, using the beam search with a beam size of 5, and set lenpen 2.0. Table 1 shows that the translation quality was improved by using the proposed techniques.

3.3 Hausa↔English

The parallel corpus for Hausa↔English system included para-crawl-v8, wikititles-v3, Khamenei and Opus corpus, which was tokenized by Moses tokenizer script. It should be clear that Hausa used tokenizer by English mode. After the data filter-

+ Fine-tuning	34.7	47.8
+ Ensemble	35.5	48.6

Table 1: SacreBLEU scores on newstest2020 Chinese↔English tasks.

ing, we used 550 thousand Hausa↔English parallel data corpus for training the baseline model. A joint BPE model was applied with 10,000 merge operations. Moreover, shared vocabularies were selected for Hausa↔English language pairs.

We used Marian trained Transformer-Small[8] model for Hausa↔English baseline, with learning rate ranging from 0.0008 to 0.001, warmup steps fixing at 48,000. Three models(3e3d, 4e4d, 6e4d) were trained under different architectures on single 2080Ti GPU.

For English↔Hausa back-translation, the standard Transformer-Big model implemented in Fairseq. We selected 4.5 million Hausa monolingual data by data filtering and language detection, and 20 million English monolingual data from the News Crawl 2020 were filtered as the back-translation dataset. Every time we handled the back-translation process, the beam search was applied. Then the back-translation and the fine-tune were executed twice. For Hausa→English, due to time constraints, it was limited to one back-translation and fine-tune.

In the fine-tuning stage, 200 sentences from the newsdev2021 were kept randomly as the validation set, and other sentences were attributed to fine-tune the model.

Table 2 shows that the translation quality was improved by using the proposed techniques. Our final submissions consisted of two Transformer-Big models.

3.4 German↔English

For German↔English task, the provided parallel sentences were completely joined together so as to get about 95 million sentence pairs. Then, sentences with lots of punctuation masks and non-alpha-number characters were removed, as well as the sentences whose length ratio was larger than 2. As a result, 52 million sentences were selected to be candidates. After that, BPE was learned jointly with 32k as the merge operations, and the size of the vocabulary was 32,168. The model's parameters for both directions were copied from the Transformer-Big in the paper "Attention is all you need" (Vaswani et al., 2017). Finally, we got three English→German models and two English↔German models for ensembling and reranking. The language model used for reranking was trained with GPT-3 using data cleaned from news 2020. All the models were trained using Fairseq. The overview of our German↔English system is listed in Table 3.

[8]The dimension of word embedding was 256, the dimension of the feed-forward network was 1024, multi-head was 4, encoder and decoder layer was 4.

3.5 French↔German

For French↔German task, about 7 million sentences were left after removing the sentences with invalid characters or punctuations from the original parallel sentences. We trained the BPE codes with 32k as the merge operations. The final vocabulary size for German was 32,144 and for French was 32,176. We introduced forward translation in German→French direction using models trained from the original parallel dataset. In both directions, the models were based on the Transformer-Big as the basic architecture. At last, three French→German models and two German→French models, trained from forward-translation, were applied to ensembling and reranking. The language model used for reranking was

trained with GPT-3 using data cleaned from news 2020. The models from this system were completely trained by Fairseq. Check the overview of our German↔French systems in Table 4.

4 Conclusions

This paper described the Mininglamp submissions to the WMT2021 eight news translation tasks, and our main exploration was using more diversified architectures, back-translation, fine-tuning and ensemble. We used a similar data preprocess and filtering strategy for all the tasks, containing statistical information-based rules. And we experimented with back-translation by different decoding strategies, using the Transformer-Small model and iterative between back-translation and fine-tuning for low-resource.

Abstract

This paper describes NiuTrans neural machine translation systems of the WMT 2021 news translation tasks. We made submissions to 9 language directions, including English↔{Chinese, Japanese, Russian, Icelandic} and English→Hausa tasks. Our primary systems are built on several effective variants of Transformer, e.g., Transformer-DLCL, ODE-Transformer. We also utilize back-translation, knowledge distillation, post-ensemble, and iterative fine-tuning techniques to enhance the model performance further.

1 Introduction

Our NiuTrans team participated in the WMT 2021 news translation shared tasks, including English↔Chinese (EN↔ZH), English↔Japanese (EN↔JA), English↔Russian (EN↔RU), English↔Icelandic (EN↔IS) and English→Hausa (EN→HA), nine submissions in total. All of our systems were built with constrained data sets. We adopt some effective models and useful methods, which have been witnessed the success in previous papers (Wang et al., 2018; Li et al., 2019; Zhang et al., 2020; Meng et al., 2020; Wu et al., 2020b; Chen et al., 2020; Yu et al., 2020; Wu et al., 2020a; Wei et al., 2020).

To enhance the performance of the single model, we choose pre-normalized Transformer-DLCL (Wang et al., 2019) and ODE-Transformer (Li et al., 2021a) as the backbone. All systems are built upon the relative position representation (Shaw et al., 2018) due to its strong performance when models are deep (Li et al., 2020). For the system combination, we adopt the post-ensemble (Kobayashi, 2018) to find the most similar hypothesis among several ensemble outputs, which could be regarded as a reranking technique without pre-training. Previous works have emphasized the importance of diversity when building ensemble systems. Besides the architecture diversity, we also adopt iterative ensemble knowledge distillation leveraging the source-side monolingual data to enlarge the diversity. More details please refer to (Li et al., 2019).

Our data preparation pipeline consists of threefold: (i) For the data filtering. We use a stricter cleaning process than last year (Zhang et al., 2020). Details will be discussed in Section 2.1. (ii) For the data augmentation, both iterative back-translation (Sennrich et al., 2016a) method, and iterative knowledge distillation (Freitag et al., 2017) method are employed to take the full advantage of monolingual data provided by the WMT organization. In the back-translation stage, we leverage target-side monolingual sentences to generate source-side pseudo sentences and use a nucleus sampling (Holtzman et al., 2019) decoding strategy to improve the generalization ability. Furthermore, we leverage in-domain source-side monolingual data by applying iterative knowledge distillation. (iii) For data selection, it's hard to find massive in-domain data for low-resource languages to train a neural language model, so we use a statistical n-gram language model (XenC toolkit3[1]) instead.

Domain finetuning is quite essential to improve the translation system given a certain target domain. We use domain adaptation to migrate the models from the general domain to the news domain by iterative finetuning. After in-domain finetuning, we use multiple ensemble combinations by the post-ensemble method.

This paper is structured as follows: In Section 2, we introduce several effective techniques, including data preprocessing, deeper and wider Transformer models, iterative back-translation, itera-

tive knowledge distillation, fine-tuning and post-ensemble. In Section 3, we show the experiment settings and report the experimental results of the validation set (newstest2020). Finally, we draw the conclusion in Section 4.

2 System Overview

2.1 Data Preprocessing and Filtering

For word segmentation, we use different tools in six languages. English, Russian, Hausa and Icelandic sentences were segmented by Moses (Koehn et al., 2007), while Chinese and Japanese used NiuTrans (Xiao et al., 2012) and MeCab[2] separately. Then BPE (Sennrich et al., 2016b) with 32K operations is used for five languages sides independently, except for 36K operations in Russian.

The quality of the parallel training data is crucial to the performance of the models, so we use rigorous data filtering scheme as the suggestion in Zhang et al. (2020)'s work. For most language pairs, rules are as follows:

- Filter out sentences that contain long words over 40 characters or over 150 words.
- The word ratio between the source word and the target word must not exceed 1:3 or 3:1.
- Use Unicode to filter sentences with more than 10 other characters.
- Filter out the sentences which contain HTML tags or duplicated translations.
- In monolingual data, some sentences contain two or more sentences. We write a script to cut them into several sentences.

We use these rules to filter bilingual and monolingual data, detecting low-quality sentences with misalignment, translation errors, illegal characters, and missing translation.

[2]https://github.com/taku910/mecab

2.2 Model Architectures

As shown in previous work (Li et al., 2019; Zhang et al., 2020; Meng et al., 2020), deep Transformers bring significant improvements than the baseline on various machine translation benchmarks. In their work, the performance of the model was significantly improved by increasing the encoder depth. We keep the decoder depth unchanged as the brought benefit is marginal when the encoder is strong enough (Li et al., 2021b).

Hence, we train two deep models in our experiment: Transformer DLCL (Wang et al., 2019) and ODE Transformer (Li et al., 2021a) with a larger filter size. ODE Transformer is designed from the ordinary differential equations (ODE) perspective. Higher-order ODE solutions can gain fewer truncation errors, thus reducing the global error and improving the model performance. The details of several models we mainly experimented with are summarized in Table 1.

In addition, we incorporate relative position representation (RPR) into the self-attention mechanism on both the encoder and decoder sides. Preliminary experiments demonstrate that only relative key information is enough, and we set the relative window size to 8.

2.3 Large-scale Back-Translation

Back-translation (BT) is an effective data augmentation technique to boost the performance of NMT models, which use monolingual data to generate pseudo-training parallel data. Back-translation is divided into three stages:

- Using bilingual parallel data to train a target-to-source intermediate ensemble of models.
- Utilizing the ensemble of reverse direction models to translate the target monolingual corpus into the source corpus.

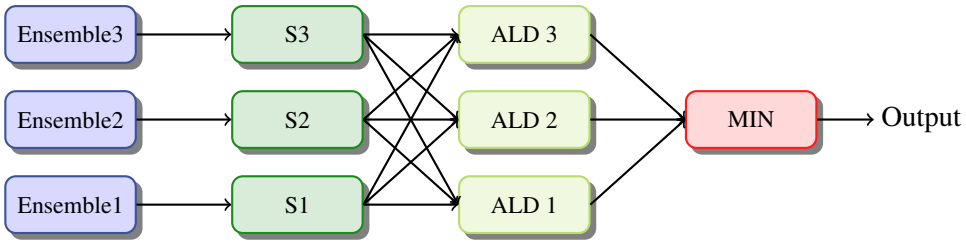

Figure 1: Process of the post-ensemble method. Sn denotes the sentence generated by the n-th ensemble of models. ALD denotes the average Levinstein distance of a sentence with other sentences. For example, $ALD\,1 = \frac{1}{2} * (Levinstein\_distance(S1, S2) + Levinstein\_distance(S1, S3))$. Finally, we select the sentence of the smallest ALD.

- Training models with the bilingual parallel corpus and the synthetic parallel corpus together.

Select in-domain monolingual data during back-translation can significantly alleviate domain adaptation problems (Zhang et al., 2020). Our in-domain data consist of the test sets released in recent years and the News Commentary high-quality monolingual data. Due to insufficient data in the domain, we used a statistical method to select in-domain data, the XenC toolkit. Furthermore, to avoid the high ranking of short sentences, we choose the in-domain source side sentences according to the distribution of sentence tokens number in the previous years' test set.

For all tasks, we employ the beam search and Nucleus Sampling approaches to generate pseudo corpus and the scale of the pseudo corpus was about 1:1 to the real corpus.

2.4 Iterative Knowledge Distillation

Knowledge distillation (KD) has been proven to be a powerful technique to improve the performance of the student model by transferring knowledge from the teacher model (Li et al., 2019; Zhang et al., 2020). Here, we regard the ensemble models as a teacher model and single models as student models. Specifically, we first use the ensemble model to generate synthetic corpus in the forward direction. Then, we merge the synthetic parallel corpus with the bilingual parallel corpus to teach student models. And by searching for better model ensemble combinations, we can provide stronger teacher models for the next round of knowledge distillation. Our experiment found that the gap between the single model and the integrated model gradually narrowed as the iteration progressed. So for the nine tasks we participated in, two iterations of knowledge distillation deliver the best performance.

2.5 Finetuning

Domain adaptation plays an important role in improving the performance of the models. A practical method of domain adaptation is to train models on large-scale out-domain corpus and then fine-tune the models with in-domain corpus (Luong and Manning, 2015). For all tasks, we mainly reuse an iterative fine-tuning process (Zhang et al., 2020) and use the development sets and the test sets of previous years as in-domain corpus.

It is worth noting that, in order to be consistent with the composition of the test set, we select parallel sentences pair from the previous development sets and test sets in which the source side is real and the target side is manually translated. Moreover, we found that iterative fine-tuning can better improve the translation quality of the names of news organizations in the news field.

2.6 Post-ensemble

Ensemble learning is a technique widely used in several WMT shared tasks, which improves performance by using multiple single models. In neural machine translation, a practical method of the model ensemble is to combine the probability distribution on the target vocabulary of different models in each step of sequence prediction. Here, we adopted their method, which uses a greedy-based strategy to find a better combination of models on the development set. However, enumerating all combinations of candidate models is an inefficient and cumbersome way.

In our ensemble experiments, we set the number of the ensemble to four and six. We observed that simply expanding the scale of the ensemble does not necessarily improve translation performance.

Besides, brute force search for all models is costly and unrealistic. As the number of models increases, the ensemble easily exceeds the computer capacity limit. Therefore, for all tasks, we finally search for four single models as an ensemble.

In addition, we use a simple but effective unsupervised ensemble method, post-ensemble, which uses a clustering method to select a majority-like output from multiple ensembles. As shown in the figure 1, we first choose several ensemble combinations composed of different models to obtain more diversity. Then we use these ensembles to generate multiple sentences, respectively. Next, we calculate the Levinstein distance between each sentence, and finally, we select the sentence of the smallest average Levinstein distance with other sentences.

For more detailed content, please refer to the original paper (Kobayashi, 2018). This technology can further improve the performance of the system based on ensemble learning.

3 Experiment

3.1 Experiment Settings

The implementation of our models is based on Fairseq (Ott et al., 2019). All models were trained on 8 RTX 2080Ti GPUs. We selected the pre-norm Transformer-base as the baseline for all tasks and enhanced our deep or wide models by enlarging the model depth and the hidden size, respectively. We used Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.997$ during training. As suggested in Ott et al. (2018) and Wang et al. (2019)'s work, models with larger capacities tend to perform much better within large batch size and learning rate. Due to the high GPU memory consumption, accumulated gradients every two steps where each batch contains 2048 tokens. Training for 15 epochs is sufficient for most tasks, and models have shown convergence in validation perplexity. The max learning rate and warmup step were set to 0.002 and 8000 for deep models, and 0.0016 and 16000 for deep and wide models, e.g., Transformer-DLCL, whose hidden dimension is 768. All the dropout probabilities were set to 0.1, including the residual dropout, attention dropout, and the ReLu dropout. We also used FP16 mix-precision training to accelerate further the training process with almost no loss in BLEU.

3.2 EN↔ZH

For EN↔ZH tasks, the training data consists of ParaCrawl, News Commentary v16, WikiMatrix, UN Parallel Corpus V1.0, and the CCMT Corpus. We regarded the newstest2019 as the valid set and the newstest2020 as the test set to tune the hyperparameters. After filtering the data, we sampled the top 12 and 20 million data according to the XenC score as the bilingual dataset. For the ZH→EN task, we used 12 and 20 million data to train the baseline model, respectively, and found that the model trained by 12 million data is 1 and 1.2 BLEU point higher than the model trained by 20 million data in the valid and test set. We found that the data quality of the bottom 8 million is lower and also selected the 12 million data as our training data.

During the first-step back-translation, we sampled 8 million monolingual data from the combination of News crawl, News Commentary, News discussions, and News crawl. Then we used the baseline model to generate the hypotheses via the beam search strategy as the pseudo dataset. In the second-step back-translation, we utilized the same amount of pseudo data while using nucleus sampling, whose p is 0.9. For ZH→EN and EN→ZH, we got BLEU improvements of 1.8 and 2.9 in the first back-translation and further BLEU improvements of 0.5 and 0.8 in the second back-translation, respectively.

In addition, we implemented knowledge distillation twice to iteratively enhance the single model with the ensemble outputs. The main goal is to make the single student mimic the behavior of the ensemble models, thus obtaining stronger ensemble teachers in the next step. We used the test sets in previous years as in-domain data in EN→ZH and EN→ZH directions respectively, and we used the XenC tool to sample 3 million from the large scale monolingual data based on in-domain data. Then we used the best ensemble of models to construct pseudo data by decoding them and merge them to the original training data to continue training for each model. We got BLEU improvements of 1.1 and 0.6 in the first knowledge distillation and further BLEU improvements of 0.6 and 0.3 in the second knowledge distillation in ZH→EN and EN→ZH.

After knowledge distillations, we used the newstest2017-2019 to fine-tune our models for five epochs with the 0.0001 learning rate and got 2 and 0.4 BLEU improvements in EN→ZH and EN→ZH

System	EN→ZH	ZH→EN	EN→JA	JA→EN	EN→HA
Baseline	41.9	30.1	34.5	21.4	10.9
DLCL30-RPR	42.8	31.0	35.6	21.6	11.9
+Iteratively BT	46.5	33.3	38.4	21.7	16.5
+Iteratively KD	47.4	35.0	41.8	25.9	18.2
+Fine-tune	47.8	37.0	42.0	26.4	-
+Ensemble	48.8	37.2	42.7	27.4	18.5
+Post-ensemble & Post edit	49.0	37.5	43.6	27.4	-

Table 2: BLEU evaluation results on the WMT 2020 EN↔ZH, EN↔JA test sets and WMT 2021 EN→HA development sets.

directions, respectively. In the final stage, we add newstest2020 to the fine-tuning data. Finally, we searched for the best five combinations of 4 out of 12 models for post-ensemble to ensure the diversity of the models. Based on the ensemble method, post-ensemble further brought us +0.2 and +0.3 BLEU in ZH→EN and EN→ZH directions. Our main results showed in table 2, we find that iterative back-translation, iterative knowledge distillation, and iterative fine-tune are effective methods to get significant improvements.

3.3 EN↔JA

For EN↔JA tasks, we chose ParaCrawl v7.1, News Commentary v16, WikiMatrix, Japanese-English Subtitle Corpus, The Kyoto Free Translation Task Corpus, TED Talks total of six parallel data corpora about 17.5 million. For the ParaCrawl v7.1, we only selected 8.5 million data according to the score of sentences provided by the dataset. We chose all of News Crawl and News Commentary and 12 million data sampled from Common Crawl for the Japanese monolingual data. After merging corpora into training data, we found that there were many-to-one situations in both the target side and the source side. Therefore, we sorted sentences and calculated the Levenshtein ratio of two adjacent sentences to remove duplication sentences. We applied this method to all version data before training models and removed 10 percent of the total data. We randomly selected one out of many sentences in which Levenshtein ratios are greater than or equal to 0.9.

We also implemented tagged back-translation, which brought us +2.8 BLEU in the EN→JA task. In addition, beam search and nucleus sampling were used to generate two parts of translations to increase data diversity, and each part contains 12 million data. An interesting phenomenon is that back-translation is useful for EN→JA task while knowledge distillation is helpful for JA→EN task. We suspect this is because the domain of Japanese monolingual more fits the field of the test set.

We also implemented knowledge distillation and fine-tuned iteratively. During the knowledge distillation phase, we used FDA[3] and XenC to select monolingual data more like newstest2020 and generated pseudo data by using both post-ensemble and ensemble methods. During the fine-tuning phase, we used the WMT 2020 valid set and opposite direction test set. After performance stopped increasing at the second fine-tune, we utilized the best ensemble models to regenerate pseudo data by back-translation and knowledge distillation. Then, we retrained multiple deep models. Finally, we put all models together to greedy search for the best combination of 13 models. And this method brought us +0.7 BLEU in JA→EN task. Our main results are shown in table 2.

3.4 EN↔RU

For EN↔RU tasks, we used only two parallel datasets, including ParaCrawl v8 and News Commentary. After the data filter, about 12M sentence pairs were left to build our system. Additionally, we set the merge operations of BPE to 36K.

We also used iterative back-translation, iterative knowledge distillation, and fine-tuned to enhance the model. During the back-translation, English monolingual data is the same as the EN↔JA part, and Russian monolingual data sources consist of News Crawl and News Commentary. During the knowledge distillation, we used FDA to select 4 million sentence pairs from the monolingual dataset according to the newstest2020 and newstest2019. Then we merged them with the official development set to continue training our

Task	Submission	Task	Submission
EN→ZH	35.8	EN→RU	28.4
ZH→EN	31.9	RU→EN	41.8
EH→JA	46.2	EH→IS	30.6
JA→EN	27.2	IS→EN	39.2
EH→HA	19.7	-	-

Table 4: Our final submission results in nine tasks.

models for five epochs. After KD, we used the newstest2019 and newstest2018 to fine-tune our models for five epochs with the 0.0001 learning rate and got 1.1 and 0.5 BLEU improvements in EN→RU and RU→EN.

The detailed and full results can be described in Table 3. Iterative BT, KD, and fine-tune are still very effective and improved 2.8 and 4.3 compared with the base model in EN→RU and RU→EN tasks, respectively.

3.5 EN↔IS

The process of EN↔IS tasks is similar to EN→HA task but more complicated. Concretely, we used four parallel datasets, including ParaCrawl v7.1, Wiki Titles v3, WikiMatrix, and ParIce. After the data filtering, about 5.5 million sentence pairs were left to build the baseline system. The experimental results are listed in Table 3. We obtained significant improvements of 6.1 and 4.4 BLEU in EN→IS and IS→EN directions, respectively.

Then we implemented iterative KD two times and sampled 3 million in-domain source data according to WMT2021 development sets. Table 3 shows that it's a very effective method to get 2.2 and 1.1 improvements. Furthermore, we fine-tuned models iteratively twice to transfer the knowledge into the target domain. Due to implementing two ensemble combinations to decode sentences, the model ensemble still gained 0.7 and 0.8 improvements.

3.6 EN→HA

In the EN→HA direction, we used ParaCrawl v8, Khamenei corpus, and English-Hausa Opus corpus three data sets, obtaining 1.43M parallel data after cleaning. We collected News crawl, Extended Common Crawl, and Common Crawl for the monolingual data, resulting in 5.7M Hausa monolingual data. Considering the insufficient scale of Hausa, we used all monolingual data in each round of back-translation. The implementation details of iterative knowledge distillation and back-translation are almost the same as the EN↔ZH tasks.

Table 2 summarized the results. We can observe that the wide and deep models were still effective in low-resource language pairs. Through the back-translation and knowledge distillation techniques, we gain 4.6 and 1.7 BLEU improvements, respectively.

3.7 Submission Results

The results we finally submitted are shown in table 4. We participated in nine tasks this year. On the whole, all of our systems performed competitively, especially in EH→IS and RU→EN directions.

Through all the experimental results, we found that different methods perform differently on nine tasks. Among them, iterative BT is effective for almost all tasks, except for the JA→EN task. Iterative KD performs better for EN↔ZH, EN↔JA and EH↔IS tasks, while fine-tune is more suitable for ZN→EN and EN→RU tasks.

4 Conclusion

This paper introduced our submissions on WMT21 nine tasks. Our main exploration is using a new effective architectures ODE Transformer and utilizing post-ensemble technology to enhance the system. And we experimented with iterative back-translation by different decoding strategies, iterative knowledge distillation, iterative fine-tuning, model ensembling and post-ensemble.

Improving Similar Language Translation With Transfer Learning

Ife Adebara **Muhammad Abdul-Mageed**
Natural Language Processing Lab
The University of British Columbia
{ife.adebara,muhammad.mageed}@ubc.ca

Abstract

We investigate transfer learning based on pre-trained neural machine translation models to translate between (low-resource) similar languages. This work is part of our contribution to the WMT 2021 Similar Languages Translation Shared Task where we submitted models for different language pairs, including French-Bambara, Spanish-Catalan, and Spanish-Portuguese in both directions. Our models for Catalan-Spanish (82.79 BLEU) and Portuguese-Spanish (87.11 BLEU) rank top 1 in the official shared task evaluation, and we are the only team to submit models for the French-Bambara pairs.

1 Introduction

We present the findings from our participation in the WMT 2021 Similar Language Translation shared task 2021, which focused on translation between similar language pairs in low-resource settings. The similar languages task focuses on building machine translation (MT) systems for translation between pairs of similar languages, without English as a pivot language.

Similarity between languages interacts with MT quality, usually positively (Adebara et al., 2020). Languages described as similar usually share certain levels of mutual intelligibility. Depending on the level of closeness, certain languages may share orthography, lexical, syntactic, and/or semantic structures which may facilitate translation between pairs. However, **(a) scarcity of parallel data** that can be used for training MT models remains a bottleneck. Even high-resource pairs can suffer from **(b) low-data quality**. That is, available data is not always guaranteed to be actual bitext with target standing as a translation of source. In fact, some open resources such as OPUS (Tiedemann, 2012a; Tiedemann et al., 2015) can suffer from noise such as when the source and target sentences belong to the same language. In this work, we tackle both **(a) scarcity** and **(b) low-data quality**. For **a**, we use simple knowledge transfer from already trained MT models to the downstream pair. For **b**, we use a simple procedure of language identification to remove noisy bitext where both the source and target are detected to be the same language or where source or target is identified as a different language from what it is expected to be.

The models we develop are for Spanish to Catalan (ES-CA), Catalan to Spanish (CA-ES), Spanish to Portuguese (PT-ES), Portuguese to Spanish (PT-ES), French to Bambara (FR-BM), and Bambara to French (BM-FR) language pairs[1]. Whenever possible, we choose an available MT model trained with the same source and target languages as our pair of interest. In cases where no such a model exists, we pick a model with either the source or the target language as our intended pair (Section 5). To show the utility of our transfer learning approach to the problem, we also train on one pair from scratch (which we treat as a *baseline*).

We experiment with tokenized **(primary models)** and untokenized **(contrastive models)** settings and compared the settings with models developed by fine-tuning pre-trained models as well as models trained from scratch. Our experiments show that the tokenized settings perform better than the untokenized settings for all language pairs. The model fine-tuned on top of the pre-trained MT model has higher performance than our baseline model from the first epoch compared with the model trained from scratch (for six epochs). Our models for the CA-ES and PT-ES language pairs *achieve top 1 rank in the offical shared task results*, with 82.96 and 47.71 BLEU scores respectively. In addition, we are the only team that submitted for the rest of the language pairs (i.e., ES-PT, FR-BM, and

[1] All models are available on https://github.com/fenimi/Similar-Languages-MT

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 273–278

BR-FR).

The rest of our paper is organized as follows: we discuss related work in Section 2. We describe the data and pre-processing in Section 3. Next, we describe the data cleaning process in Section 4. In Section 5, we describe the models we developed for this task and we discuss the various experiments we perform. We also describe the architectures of the models we developed. Then we discuss the evaluation criteria in Section 6. Evaluation is done on both the validation and test sets. In section 7 we perform error analysis on the output of our models for some language pairs to determine the types of errors the models make. We conclude with discussion of the insights we gained from the shared task in Section 8.

2 Related Work

In recent times, there has been an increase of research interest in low-resource MT scenarios (Jawahar et al., 2021; Baziotis et al., 2020). NMT models, specifically those based on the Transformer architecture, have been shown to perform well when translating between similar languages (Przystupa and Abdul-Mageed, 2019; Adebara et al., 2020; Barrault et al., 2019, 2020), low resource scenarios (Adebara et al., 2021), and in contexts not involving English (Fan et al., 2021).

Furthermore, pre-training techniques have been successful for many NLP tasks (Zoph et al., 2016; Durrani et al., 2021) including NMT (Aji et al., 2020; Weng et al., 2020). Self-supervised pre-training acquires general knowledge from a large amount of unlabeled monolingual or multilingual data to improve the training process of downstream tasks (Aji et al., 2020; Devlin et al., 2018). The pre-trained model acquires some syntactic and semantic knowledge which can be transferred as initialized parameters to improve NMT models and translation quality (Goldberg, 2019; Jawahar et al., 2019; Aji et al., 2020). The intuitive justification for using pre-trained models is that the embedding space becomes more consistent, with semantically similar words closer together.

The knowledge from pre-trained language models (LMs) can be used to initialize the NMT model before training it on parallel data. However, there are certain limitations for MT tasks. First, LMs cannot be easily fine-tuned for MT tasks. Second, there is a discrepancy between pre-training objectives for LMs and the training objective in MT. Existing pre-training approaches such as mBART rely on auto-encoding objectives to pre-train the models, which are different from MT. Furthermore, LMs learn to reconstruct all source tokens with some noises, while NMT learns to translate most source tokens and copy only a few of them. LM pre-training is said to copy about 65% of tokens, while NMT training needs to copy less than 10% (Knowles and Koehn, 2018). The unexpected knowledge/bias can be therefore propagated to the NMT model via pre-training, which may result in NMT models mistakenly copying source tokens to the target side (Liu et al., 2021). For instance, because copying behaviours can be learned, a source word such as "shoe" may be copied to the target by pre-training based NMT models instead of providing a translation. Therefore, fine-tuning MT models on pre-trained LMs still do not achieve adequate improvements.

In order to address the difference in training objectives that using pre-trained language models results in, we use pre-trained MT models to initialize our models. This is still a type of *transfer learning*.

Following the justification for pre-trained models, we hypothesize that two linguistically similar languages will share closer semantic and syntactic relationships. This is based on the assumption that the more similar the source and target languages, the more similar the syntax and semantic properties and the higher the gains from using pre-trained models will be. We now introduce our data.

3 Data

For our experiments, we use parallel data from OPUS (Tiedemann, 2012b). Our data are from the following language pairs Spanish and Catalan, Spanish and Portuguese, and French and Bambara. We use data in the two directions from each of these three pairs. Details about our data is in Table 1.

Pair	Lang	Sent	Words
ES-CA	**ES**	10M	284.6M
	CA	10M	273.3M
ES-PT	**ES**	4.1M	86.6M
	PT	4.1M	82.7M
FR-BM	**FR**	9.9K	179.3K
	BM	9.9K	202.9K

Table 1: Number of sentences and words for the training data used for each language pair. We also report the type token ratio (TTR) before and after tokenization.

3.1 Pre-Processing

We perform pre-processing using the Moses toolkit (Koehn et al., 2007). For each language not supported by Moses, we use the tokenization setting of the language it is translated to. This applies only to Bambara, for which we used tokenization for the French language. We perform data cleaning, as we explain next.

4 Data Cleaning & Analysis

We perform data cleaning on the ES-CA, CA-ES, ES-PT, and PT-ES language pairs. We do not clean the French and Bambara pairs because we had very few training sentences for these. For cleaning, we run the langid tool (Lui and Baldwin, 2012) on the concatenation of the source and target and remove sentences that are not identified as belonging to one or both of the language pair. In Table 2, we provide some examples of data points we remove from the training data during data cleaning. These examples are removed because the claimed language is different from the language predicted by langid. After cleaning, we are left with $\sim$ 10M clean sentences out of $\sim$ 18.3M sentences for the Spanish and Catalan pair, and $\sim$ 3.1M clean sentences out of $\sim$ 4.2M sentences for the Spanish and Portuguese pair, respectively. We note that removed data comprise large portions of each dataset, thus confirming our concerns about data quality.

Sentence	Claimed	Predicted
Animal Crossing: Pico de Santo Tomés	Spanish	English
Quinto Sereno Sammonico	Portug.	Portug.
La sombra del caudillo	Catalan	Italian
Cultura del Nepal	Catalan	Spanish
Morts a Rāwalpindi	Catalan	Spanish

Table 2: Examples removed from our training data. "Claimed" refers to the expected language as coming from source, while "predicted" is what langid.py identified.

5 Models

5.1 Primary and Contrastive Models

We developed our *primary* and *contrastive* models using Transformers from HuggingFace library (Wolf et al., 2019). The primary models were developed using tokenized data while the contrastive models employed untokenized data. For the tokenized setting, we used Moses tokenizer (as explained earlier) while the untokenized setting used the data just as they were made available to us by shared task organizers.

Hyperparameter	Values
encoder layers	6
decoder layers	6
attention heads	8
hidden layers	6
embedding dimension	512
dropout	0.0
vocab size	49,621

Table 3: Hyperparameter settings for the HuggingFace Marian Transformer models.

	Model	#Epochs	#Highest
FR-BM	tok	100	55
BM-FR	tok	100	60
ES-CA	untok	6	3
	tok	8	3
CA-ES	untok	7	7
	tok	8	8
ES-PT	untok	17	15
	tok	35	13
PT-ES	untok	18	16
	tok	34	23

Table 4: Description the number of epochs for training each model and the epoch with the highest BLEU score.

Pair	Untokenized	Tokenized
es-ca	77.3	86
ca-es	87.7	87.8
es-pt	46.9	47.3
pt-es	52.9	53.6
fr-bm	-	6.6
bm-fr	-	6.07

Table 5: BLEU scores on our Dev set.

We used the pre-trained NMT models developed by Helsinki-NLP on HuggingFace. We used pre-trained models closest to the language pairs we trained. For language pairs without existing pre-trained models, we used a close language pair with either the source or target matching one of our downstream task languages in a given pair. Specifically, we used the following Marian models released by Helsinki-NLP: es-ca (for ES-PT), ca-es (for CA-ES and PT-ES), fr-en (for FR-BM), and en-fr (for BM-FR).

As an example, we report the hyperparameters for the CA-ES *primary* model in Table 3. This model had the best BLEU and RIBES score for this

Pre-Trained Model	Pair	Untokenized System			Tokenized System		
		BLEU	RIBES	TER	BLEU	RIBES	TER
ca-es	ca-es	76.8	95.19	15.421	**82.79**	**96.98**	**10.918**
es-ca	es-pt	35.61	82.48	52.61	38.10	85.35	46.556
ca-es	pt-es	43.86	85.10	43.801	**47.71**	**87.11**	**39.213**
fr-en	fr-bm	-	-	-	1.32	24.79	97.89
en-fr	bm-fr	-	-	-	3.62	36.17	101.52

Table 6: BLEU, RIBES and TER Scores on the Test set for the Tokenized (primary) and untokenized (contrastive) configurations. The models for CA-ES and PT-ES language pairs were the best performing models highlighted in bold type.

Table 7: Examples sentences from the various pairs and corresponding translations based on the untokenized and tokenized models. Examples are from the Dev set. We highlight the differences between the outputs from the untokenized model and the reference text with blue highlights and the differences between the tokenized model and the reference text in red highlights. It can be observed that the number of errors in the untokenized model (based simply on the number of blue highlights here) is larger than that in the tokenized model (less errors/red highlights

language pair. We trained each model for different number of epochs due to time and GPU constraints. We show the number of epochs each model is trained for and the epoch with the highest BLEU score in Table 4. We did not train any *contrastive* models for FR-BM and BM-FR pairs, so we report the training for the primary (tokenized) models only.

5.2 Baseline

We developed a single baseline model based on Transformers as implemented in Fairseq. This model does not use any pre-trained MT models nor tokenization. This model was developed for the ES-PT pair for six epochs and it achieved a BLEU score of 37.6. For comparison, we developed a model for the same pair (i.e., ES-PT) based on an already available pt-es pre-trained MT model. After six epochs, this ES-PT model employing transfer learning achieved 52.18 BLEU (thus significantly outperforming our baseline). Based on this result, we resumed with experiments for all other language pairs *without* including a baseline. Ideally, we would train such baseline models for all

the pairs. However, due to limited time and GPU resources, we only trained a baseline for a single pair.

6 Evaluation

We evaluated our models on both the Dev and Test sets. We used the checkpoint with the best BLEU score as evaluated on DEV as our best model. We used a beam size of four during evaluation on both Dev and Test and evaluated on de-tokenized data.

Evaluation on Dev set. We report the results on the Dev sets for each language pair in Table 5. As explained, the models were trained with both tokenized and untokenized data. As Table 5 shows, the tokenized setting yielded the highest performance for *all* language pairs. We show sample outputs from our tokenized models (from Dev data) in Table 7.

Evaluation on Test set. Our Test set performance was evaluated by the shared task organizers using BLEU (Papineni et al., 2002), RIBES, and TER (Snover et al., 2009). We report the scores in Table 6. Each of our CA-ES and PT-ES models ranked top 1 based on the official shared task results. In addition, we were the only team to submit models in the official competition for the French-Bambara pairs. As with the Dev set, the tokenized setting gave the highest performance for all language pairs.

7 Effect of Language Similarity

In order to gain some insight into the interference of similarity between languages of a given pair, we performed an analysis based on Levenstein distance that allows us to identify the percentage of cognates shared between the languages. We then compared system output to the reference sentences, trying to quantify how much the system is able to translate cognates correctly (in this case the correct translation will have the same cognate word in the target as it is in the source). We performed this analysis for one language pair: CA-ES and found that the model learned the cognates correctly up to 80% of the time.

8 Conclusion

We describe our contribution to the WMT2021 Similar Languages Translation Shared Task. We develop models for ES-CA, CA-ES, ES-PT, PT-ES, FR-BM, and BM-FR and show the improvement our models make with tokenized data when compared to untokenized data. We also show the utility of transfer learning based on fine-tuning NMT pre-trained models. Future work can investigate how the choice of pre-trained models affects the downstream tasks.

T4T Solution: WMT21 Similar Language Task for the Spanish-Catalan and Spanish-Portuguese Language Pair

Miguel Canals
miguelknals@gmail.com

Marc Raventós Tato
marcraven@gmail.com

Abstract

This system description describes the participation in the EMNLP 2021 Sixth Conference on MT (WMT21) - Shared Task: Similar translation for the language pairs SPA<>CAT and PTG<>SPA for our T4T solution. The main objective has been to prove that good data with a good standard NMT toolkit, as OpenNMT, is able to provide good results. We have focus in the corpus cleaning (both from the physical and from the statistical side), try to find some alternatives to subword segmentation (syllabic and byte-pair-enconding), and finally use OpenNMT as out-box system with a transformer model. The results have been pretty close to the best ones, if not the best.

1 Introduction

Current available NMT systems have become so complex and resource computing demanding, that the idea behind this project is try to find out if simple logical solutions and standard tools are able to provide good results at least in close languages (according Ethnologue Lexical similarity coef for the language pairs are 0.85 CA<>ES and 0.89 for PT<>ES) (Collin, 2010).

The first thing that come with a little surprise is how we can explain that so similar languages have persistently get so different BLEU (Papineni et al., 2002) scores in previous WMT years, as stated in Table 1 for WMT2020.(Barrault et al., 2020)

ES-CA	CA-ES	ES-PT	PT-ES
86.44	77.08	32.69	33.82

Table 1: Results WMT 2020 for similar languages CA-ES/PT-ES best BLEU score.

We suspect this 50 BLEU score difference is direct result of corpus quality or diversity. CA<>ES corpus provided by the organization uses a very reliable source, the DOG (The official Catalan Government Diary) (approx 40% of words), and even though PT<>ES uses also a similar domain (mainly news and legal), its legal composition (Europarl/JARC) is based in probably a mix of indirect translations. We think one of the best ways to improve a NMT system, is to use the best data you can.

We have have focused in the physical cleaning of the corpus (duplicate strings, unusual sentences, tokenized text in some sources, deal with the UTF-8 universe coding for punctuation, numerical data and the upper/lower casing issue). We have developed a set of python programs for these cleaning tasks and an adhoc tokenizer.

We also have tried also to run some cleaning procedure based in some basic statistical information of the bitext corpus. As there is a quite large source-target, we have scored word probabilities in bitext corpus sentences, and then somehow score sentence probabilities and decide to use or not these sentences. This simple cleaning has indeed increased the score of the model for corpus in-data, but is not so clear if it helps with data out of the corpus.

The last step in data preparation, to deal with the vocabulary size issue, has been the subword segmentation. We have used python standard tools for syllabic segmentation with good results (corpus data has achieved best score than BPE (byte-pair-enconding), but again, with data outside of the corpus, BPE (Sennrich et al., 2015) has proven better. At the end, we have used Google SentencePiece (Kudo and Richardson, 2018) BPE implementation.

After that, we have used what we think a proven toolkit for NMT, OpenNMT (Klein et al., 2017), out of the box, without any modification, using its web publish options for the Transformer model. In the last step we have used the inverse python programs in order to generate the final version of the test source translated file.

We have focused the system from a practical engi-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 279–283

neering point of view. The whole project has been based in currently available local only mid size system, with consumer grade multi-gpu environment. Following this fast approach, and due the nature of the main focus on the corpus, we have used simple models that OpenNMT provides (2-layer LSTM with 500 hidden units on both the encoder and decoder) in order to choose several options and parameters used later for the final transformer model, as this last model is close to the limit a midsize system can provide.

2 Cleaning the corpus

In our approach we have joined all data sources (all monolingual sources and the matching language for the bilingual text corpus) in order to create a mono corpus, and the bilingual text corpus. For the model training we have used the dev data provided by the organization. The typical size for this file in OpenNMT is around 2000 lines, so we have used data from the bilingual text corpus in order to reach this typical size.

2.1 Physical cleaning steps for the bilingual corpus

These are the direct "physical" tasks in order to prepare a corpus with what they look "standard" sentences.

- Removal of duplicated sentences.
- As many strings are already tokenized we have detokenize all the corpus with the Moses (Koehn et al., 2007) detokenizer, as our custom tokenizer works with untokenized text. (Some punctuation is changed, but indeed fixes many punctuation format errors as coma not correctly joined to the words).
- Perform physical cleaning. These are some steps based on the manual inspection of the corpus in order to remove noise sentences or fix others. For instance, remove all left chars until an alphabetic char is found, remove some keywords leftovers, sentences should have at least a spell correct word (Németh, 2010), remove any text between parenthesis or remove duplicates.
- Using python nltk (Bird et al., 2009) package we have removed all sentences that probably are made up of more than one sentence.

2.2 Statistical cleaning for the bilingual corpus

Using the bitext corpus we have created source/target dictionary and all instances of where source word and target word appears in the same sentence pair. Using simple rules we can try to score the probability of the source word given a target word, and somehow score words and sentences. Then create a list and remove the ones with worst scores. Most of this cleaning is based in heuristic parameters.

The clean is indeed effective as for instance, score for corpus data for PT->ES using this cleaning can raise from 49,38 BLEU score to 67.27, but these gains are not matched when we have used test data outside the corpus. We suspect, this cleaning creates an ideal statistical data set that cannot explain "real" data outside the corpus. So we have used this feature in a moderate way, removing 15% of the low matching sentences. Many of these sentences are indeed removed for a good reason, but many times too are not, because translators many times do not follow a statistical behavior.

We suspect this is an open field. This "cleaning" is close related to word alignment, so probably it would have been wiser use some GIZA++(Och and Ney, 2003) or fastalign word based solution.

3 Tokenization

One of the big issues to deal with real data, is the tokenization. After reviewing several available tools, we ended creating a python custom tokenizer that has the following features.

- It uses a list of split chars (comma, dot, hyphen, ...). The number of these chars that are not alphabetic can be quite large, and is a source of many problems. This list of split chars is generated by the tokenizer itself in a first scanning phase.
- Numbers are replaced by variables (as ((n0)), ((n1)). These numbers are kept in an independent file in order to be used if detokenization is required. This will avoid the use of numbers, another big source of undesired vocabulary.
- Casing is indicated with special tags before the upper word in to ways, ((up)) for first uppercase only first letter words, or ((aup)) for

all uppercase letter words. This avoids most of casing issues and allow us to work with a full lowercase input in the neuronal toolkit.

- Tokenizer also keeps track of the spaces for words and split chars.

These features provide a robust tokenization <> detokenization reversibility.

Sentence example:

> Vista la Directiva 91/494/CEE del Consejo, de 26 de junio de 1991, sobre ...

is tokenized as:

> ((up)) vista la ((up)) directiva ((n0)) @@/@@ ((n1)) @@/@@ ((aup)) cee del ((up)) consejo @@, de ((n2)) de junio de ((n3)) @@, sobre

4 Word segmentation: BPE and syllabic

Word segmentation is further step in order to to reduce neuronal network vocabulary.
We have followed two approaches, the well know BPE subword segmentation, but also an uncommon one, a syllabic segmentation. We have used again a known python tool (https://pyphen.org/) to split words in syllables.
Results are quite interesting as they have been quite consistent. Using a syllabic segmentation:

- BLEU scores for corpus test data in all NTM models (LSTM or Transformer) have been better.
- BLEU scores for external data have been worst.

So the promising syllabic segmentation, has not responded so well with data outside de corpus. Due this, BPE has been chosen for final models.

5 Evaluation

After testing in more simple neuronal network models (LSTM) the final setup has consisted of a corpus cleaned (in the physical sense, and also in an statistical sense removing approx 15% of sentence corpus sentences with the highest perplexity). This clean corpus has been detokenized with our adhoc tokenizer (that lowercase the corpus, replaces numbers by variables, and handles punctuation and upper/lower casing).

After this cleaning, the number of words for ES<>PT has been around 2M lines (55.3M words) and ES<>CA around 9.5M lines (176M words).

Then we have used 16000 terms SentencePiece BPE vocabulary on this detokenized corpus in order to reduce vocabulary. We have removed sentences with more than approx 170 tokens for the sentences the neuronal network has ingested (This length has kept the model below the memory limit of each one of the GPU cards).

We have set the model configuration using the published Transformer(Uszkoreit, 2017) model in the OpenNMT site (https://opennmt.net/OpenNMT-py/FAQ.html#how-do-i-use-the-transformer-model). According OpenNMT documentation, this setup mimic the Google (Vaswani et al., 2017) setup that replicate its WMT results.

We have tested our models against test data form our corpus (23_SP_TRANSF_Statclean_3,5 for PT<>ES and 25_SP_CAES_2_TRANSF_Statclean_3.5 for CA<>ES) and also from the test data from WMT2020 (test20 for PT<>ES and test20.v2 CA<>ES).

In Figure 1 we can see the results for the PT<>ES for both test sets and both directions. The transformer model converges really fast after 30-40K steps (as the size of the corpus is not very large). We have used the best score (PT->ES BLEU score 55.96 at 55K steps and ES->PT BLEU score 54.68 at 60K steps) for the final evaluation.

In Figure 2 we can see the results for the CA<>ES for both test sets and both directions. We have used the best score (CA->ES BLEU score 84.34 at 70K steps and ES->PT BLEU score 83.77 at 85 steps) for the final.

6 Results

In Table 2 we can compare the best score of each one of the 3 teams that have submitted results for this WMT 2021 task (http://www.statmt.org/wmt21/similar.html).

7 Conclusions

We think we have accomplish the objective to achieve good results with good data and out of box toolkit as OpenNMT.
It has proven more difficult than expected find recipes to improve the corpus quality beyond the physical cleaning. What we have found suggest (without prove) that:

- Cleaning the corpus trying to remove sentences with low translation probability to be correct looks to us that can improve the corpus for sure, but is not so clear will happen the same for data outside the corpus. The idea of find correct paired translated sentences in the bitext, is a translation/alignment problem by itself, and probably the simple statistical system we have used has much room to improve.
- Syllabic word sub segmentation can improve greately the corpus quality, but has not improved the score with data outside the corpus. The reason is unknown.

Abstract

The neural machine translation approach has gained popularity in machine translation because of its context analysing ability and its handling of long-term dependency issues. We have participated in the WMT21 shared task of similar language translation on a Tamil-Telugu pair with the team name: CNLP-NITS. In this task, we utilized monolingual data via pre-train word embeddings in transformer model based neural machine translation to tackle the limitation of parallel corpus. Our model has achieved a bilingual evaluation understudy (BLEU) score of 4.05, rank-based intuitive bilingual evaluation score (RIBES) score of 24.80 and translation edit rate (TER) score of 97.24 for both Tamil-to-Telugu and Telugu-to-Tamil translations respectively.

1 Introduction

Machine translation (MT) works as an interface that handles language ambiguity concerns via automatic translation between two different languages. Neural machine translation (NMT) attains state-of-the-art results for both high and low-resource language pairs translation (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015; Pathak et al., 2018; Pathak and Pakray, 2018; Laskar et al., 2019; Laskar et al., 2020a). The NMT utilizes an artificial neural network to predicts the likelihood of a sequence of words. But NMT requires a sizeable parallel corpus to get effective MT output, challenging for low-resource pair translation. In this WMT21 shared task, we have participated on a similar language pair translation task of Tamil–Telugu pair using NMT. We aim to utilize similarity features among such a similar language pair and monolingual data to overcome the less availability of parallel corpus. The transformer model (Vaswani et al., 2017) based NMT is considered in this work, since it outperforms RNN based NMT. Moreover, NMT performance can be enhanced utilizing monolingual data (Weng et al., 2019; Wu et al., 2019; Ramachandran et al., 2017; Variš and Bojar, 2019; Qi et al., 2018). To evaluate the performance of our system's output, WMT21 organizer used standard evaluation metrics, namely, BLEU (Papineni et al., 2002), RIBES (Isozaki et al., 2010) and TER (Snover et al., 2006) which are reported in Section 4.

2 Related Work

There are limited works on the Tamil–Telugu pair (Chakravarthi et al., 2021). The literature survey found similar works on Indian similar language pairs, such as Hindi–Nepali (Laskar et al., 2019) and Hindi–Marathi (Laskar et al., 2020b) at WMT19 and WMT20. Both (Laskar et al., 2020b, 2019) used transformer model based NMT. Moreover, Ramachandran et al. (2017); Variš and Bojar (2019); Qi et al. (2018) pre-trained methods are incorporated in NMT to utilize advantage of monolingual data for low-resource pairs translation. In this work, GloVe (Pennington et al., 2014) pre-trained word embeddings are used in transformer model (Vaswani et al., 2017) based NMT for both Tamil-to-Telugu and Telugu-to-Tamil translation.

3 System Description

Our system mainly consists of the following parts: data preprossessing, model training and testing. These have been described in the following subsections. The dataset description is presented in Section 3.1. For our system, we have used the OpenNMT-py toolkit (Klein et al., 2017) for the data preprocessing, training and testing.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 284–287

	Telugu	47877462	574131374		

Table 1: Dataset Statistics

3.1 Dataset

The parallel corpus for Tamil-Telugu pair is provided by the WMT21 organizer[1]. It consists of 40147, 1261, 1735 sentence pairs for train, validation and test set. Apart from this, we also collected Monolingual data from the IndicNLP[2] corpus. It consists of 31542481 Tamil sentences and 47877462 Telugu sentences. This monolingual corpus is specifically used for deriving pretrained embeddings to use in the model. The dataset statistics are described in the table 1.

3.2 Data Preprocessing

The OpenNMT-py toolkit is used to preprocess the parallel data and then generates a vocabulary of size: 50002 for the source-target sentences by tokenizing and indexing in a dictionary. It was done in both ways independently, considering Tamil as source and Telugu as target and then with Telugu as source and Tamil as the target to train models for both ways for translation in either direction. We have used GloVe (Pennington et al., 2014) to pretrain on the monolingual corpora to obtain word vectors. These word vectors are specifically used in the form of word embeddings in the transformer model during the training process.

3.3 System Training

After the data preprocessing, the pre-trained embeddings and parallel dataset are used for training our model for both Tamil-to-Telugu and Telugu-to-Tamil. We have adopted a transformer model to implement both of the trained models separately. The transformer model consists of a self-attention mechanism, encoder, and decoder layers. The self-attention comes into play, where the relevancy of one word to other words of the sentence is represented as an attention vector that contains the context between words in that sentence. Multiple such attention vectors are calculated, and the weighted average is taken so that the interactions with other words are captured properly rather than their value. More specifically, the embeddings are converted into three spaces: query, key, and value. The dot product of its query vector and all the key vectors are calculated for every embedding. Since the hidden state of the previous embedding is not needed in calculating the current embedding's hidden state, the self-attention can be done in parallel for all embeddings. Thus, it can be run in parallel for all embeddings simultaneously. This speeds up the training and translation process a lot. Now, the target sentences are passed to the decoder layers similarly to the encoders and then passed to the self-attention block. The difference is that in attention layers, the next word of the target sentence is masked so that the word will be predicted using previous results for learning. It is called a masked multi-head attention block. The attention vectors thus produced and the outputs from the encoder layers are then passed to another attention block called encoder-decoder attention block. The attention vectors for every word in the sentences are the output. Then we pass it through a feed-forward network for making output acceptable for further layers.

Our transformer model consists of six layers for both encoders and decoders and eight attention heads. We used adam optimizer with a learning rate 0.001 and a drop-out of 0.1 for normalization. The rest of the parameters were selected as the default configuration of the toolkit. This configuration is used for both models, the Tamil-to-Telugu and vice versa.

3.4 System Testing

The obtained trained models are used in system testing, where the test data is used to obtain the predicted translation for both Tamil-to-Telugu and vice-versa independently.

Translation	System Type	BLEU	RIBES	TER
Tamil to Telugu	Primary	4.05	24.80	97.24
Telugu to Tamil	Primary	4.05	24.80	97.24

Table 2: Our System results for Tamil-Telugu pair at WMT21

4 Result

Our system's outputs were submitted to the organizer for evaluation. Consequently, the results of the shared task on "Similar Language Translation" were announced separately for Tamil-to-Telugu[3] and Telugu-to-Tamil[4]. The ranking of the systems is mainly based on BLEU score, while the RIBES and TER scores are also given. Our team name is CNLP-NITS. For the Tamil-to-Telugu translation system, we achieved 4th rank with a BLEU score of 4.05 and 6th rank with a BLEU score of 4.05 for the Telugu-to-Tamil translation. The results of our system are reported in the Table 2. The system performance is identical for both translation directions. We need to perform a human evaluation in future work to identify the test set and predicted output are identical or not.

5 Conclusion and Future Work

This work reports our system description along with results, which we have participated in the WMT19 shared task of similar language pair: Tamil-Telugu. Both direction of translations, transformer model based NMT is used and utilized monolingual data through pre-trained word embeddings. We will investigate multilingual NMT approach in future to improve such low-resource translation quality.

Acknowledgement

Authors would like to thank WMT21 Shared task organizers for organizing this competition and also, thank Center for Natural Language Processing (CNLP) and Department of Computer Science and Engineering at National Institute of Technology, Silchar for providing the requisite support and infrastructure to execute this work.

Abstract

This paper describes the participation of team oneNLP (LTRC, IIIT-Hyderabad) for the WMT 2021 task, similar language translation[1]. We experimented with transformer based Neural Machine Translation and explored the use of language similarity for Tamil-Telugu and Telugu-Tamil. We incorporated use of different subword configurations, script conversion and single model training for both directions as exploratory experiments.

1 Introduction

Machine Translation (MT) is a field of Natural Language Processing which aims to translate a text from one natural language to another. The meaning of the source text must be fully preserved in the resulting translated text in the target language. Recent years have seen significant quality advancements in machine translation with the advent of Neural Machine Translation. For the translation task, different types of machine translation systems have been developed and they are mainly categorized into Rule based Machine Translation (RBMT)(Forcada et al., 2011), Statistical Machine Translation (SMT) (Koehn, 2009) and Neural Machine Translation (NMT) (Bahdanau et al., 2014).

Neural machine translation (NMT) shows high quality in terms of output fluency and translation quality, when large amounts of parallel data are available (Barrault et al., 2020). Unfortunately, for most language pairs, parallel data is either scare or non-existent. To overcome this, unsupervised MT (UMT) (Artetxe et al., 2020) focuses on utilising monolingual data to generate synthetic parallel training data. Other techniques like back-translation(Sennrich et al., 2015),(Hoang et al., 2018), (Feldman and Coto-Solano, 2020) or denoising(Kim et al., 2019) also rely on parallel corpora of other language pairs and/or large quantities of monolingual data.

This paper describes our experiments for very low resourced similar language translation. For our work, we focused only on Tamil-Telugu language pair (both directions) and participated in a constrained setting.

We experimented only with Transformer (Vaswani et al., 2017) based Neural Machine Translation throughout. Along with it, to tackle high agglutination of both languages, we explored the morph (Virpioja et al., 2013) induced sub-word segmentation with byte pair encoding (BPE)(Sennrich et al., 2016).

Similar to Multilingual Neural Machine Translation (MNMT), we explored the use of a tag trick, where a token like "< 2xx >" (xx is language code) is prefixed to each source sentence to indicate the desired target language(Dabre et al., 2020). Here, we trained a single model for both directions (Tamil-Telugu and Telugu-Tamil) on given parallel data and monolingual data under MNMT setting.

The sections of the paper are organised as following: Section 2 describes Data, Section 3 and 4 describe pre-processing and Training Configuration and in Section 5 we talk about results and we conclude in section 6.

2 Data

We utilised provided parallel corpora for Tamil<->Telugu MT task. Apart form parallel corpus, we randomly selected 0.1M monolingual corpora from IndicCorp monolingual corpus[2] for Tamil and Telugu. Table-1 describes the training and development data (parallel and monolingual) used in all our experiments under constrained setting.

Data	Sents	Token	Type
Train			
Tamil (Parallel)	40,147	0.68M	74K
Telugu (Parallel)	40,147	0.72M	90K
Development			
Tamil (Parallel)	1261	29K	9K
Telugu (Parallel)	1261	30K	10K
Tamil (Mono)	0.1M	-	-
Telugu (Mono)	0.1M	-	-

Table 1: Tamil-Telugu WMT2021 Training data

3 Data Pre-Processing

To tokenize and clean both Tamil and Telugu corpora (train, test, valid and monolingual), we used IndicNLP Tool[3] with in-house tokenizer as a first step. Following subsections explain other pre-processing steps of experiments.

3.1 Morph + BPE Segmentation

Based on token/type ratio, both Tamil and Telugu are morphologically rich languages from Table-1. Translating from (and to) morphologically-rich agglutinative language is more difficult due to their complex morphology and large vocabulary. We address this issue with morphology and BPE(Sennrich et al., 2016) based segmentation method as prescribed in (Mujadia and Sharma, 2020). We utilized unsupervised Morfessor (Virpioja et al., 2013) by training it on monolingual data of Tamil and Telugu. We then applied this trained Morfessor model on our corpora (train, test, development) to get meaningful stem, morpheme, suffix segmented sub-tokens for each word in a sentence. Subsequently, we applied the subword algorithm on top of the morph segmentation and used the derived sequence in training.

3.2 Training as Multilingual Neural Machine Translation (MNMT)

As an exploratory experiment, we configure a similar low resource machine translation problem as a multilingual machine translation problem. For both translation directions (Tamil-Telugu and Telugu-Tamil) we trained a single model to take advantage of language similarity among these languages. First, we converted both languages into Roman script using litcm[4]. Second, we prefixed "<2TE>" for Tamil to Telugu and "<2TA>" for Telugu to Tamil to the respective source sentences. Apart from this, we also utilised monolingual data as a monolingual translation. For this we prefixed "<2TE>" for Telugu to Telugu and "<2TA>" for Tamil to Tamil translation.

4 Training Configuration

Throughout all experiments, we used Transformer sequence to sequence architecture with the following configuration.

- Morph + BPE based subword segmentation, Embedding size : 512 Transformer for encoder and decoder, rnn_size 512, heads 4 encoder - decoder layers : 2, label smoothing : 1.0, dropout : 0.30, Optimizer : Adam, Beam size : 4 (train) and 10 (test), training steps : 20K

For these experiments, we used shared vocab across trainings. We used Opennmt-py (Klein et al., 2020) toolkit with above configuration for our experiments.

Using the above described pre-processing and configuration, we performed experiments on word level, BPE level and morph + BPE level for input and output. The results are discussed in following Result section.

5 Result

Feature	**BPE**	**Dev**
Script Conversion (ta to te)	-	0.57
Word	-	5.12
BPE	20K	6.07
Morph + BPE	20K	6.25
Morph + BPE (MNMT)	20K	6.65

Table 2: BLEU scores for Tamil-Telugu on Development set. BPE stands for byte pair encoding (subword), Morph for Morphological segment and MNMT for Multilingual Neural Machine Translation based method as discussed in Section-3.2

Table-2 and Table-3 show performance of our systems with different configurations in terms of BLEU score (Papineni et al., 2002) for Tamil-Telugu and Telugu-Tamil respectively on the development data. To get trivial, non-translation baseline, we used aksharamukha[5] script conversion

[3]http://anoopkunchukuttan.github.io/indic nlp library/
[4]https://github.com/irshadbhat/litcm
[5]https://aksharamukha.appspot.com/converter

Feature	BPE	Dev
Script Conversion (te to ta)	-	0.41
Word	-	5.72
BPE	20K	6.37
Morph + BPE	20K	6.45
Morph + BPE (MNMT)	20K	6.76

Table 3: BLEU scores for Telugu-Tamil on Development set. BPE stands for byte pair encoding (subword), Morph for Morphological segment and MNMT for Multilingual Neural Machine Translation based method as discussed in Section-3.2

tool to convert script from Tamil-Telugu (both direction). We achieved highest 6.65 and 6.76 development and 3.67 and 5.03 test BLEU scores for Tamil-Telugu and Telugu-Tamil systems respectively (all are of MNMT based systems).

Table-2 and Table-3 show that non-translation baselines are also low in terms of BLEU scores which indicates that the task much harder even though languages are similar. The results show that for low resource settings, transformer network based MT models can be improved with morph based segmentation along with byte pair encoding for morph rich languages. Also, forming it as a Multilingual machine translation problem, along with monolingual data, it improves the quality of MT models. This may be due to language similarity and use of monolingual data, as it is helping models to do better generalization by learning better source language encoding and target language fluency.

6 Conclusion

From our experiments, we conclude that linguistic feature such as morph based segmentation with subword segments along with MNMT is a promising approach for similar language translation.

reinhardrapp@gmx.de

Abstract

This paper describes the SEBAMAT contribution to the 2021 WMT Similar Language Translation shared task. Using the Marian neural machine translation toolkit, translation systems based on Google's transformer architecture were built in both directions of Catalan–Spanish and Portuguese–Spanish. The systems were trained in two contrastive parameter settings (different vocabulary sizes for byte pair encoding) using only the parallel but not the comparable corpora provided by the shared task organizers. According to their official evaluation results, the SEBAMAT system turned out to be competitive with rankings among the top teams and BLEU scores between 38 and 47 for the language pairs involving Portuguese and between 76 and 80 for the language pairs involving Catalan.

1 Introduction

In recent years, neural machine translation (NMT) has become the state of the art in machine translation (MT). Using toolkits such as Marian NMT (Junczys-Dowmunt et al., 2018), it is relatively straightforward to construct end-to-end NMT systems which need only little pre-processing of the training corpora and post-processing of the system output. As NMT is a supervised approach to MT based on machine learning technology, training is usually conducted using sentence aligned human translations. Given a large number of source/target-language sentence pairs, the neural system fully automatically learns how to translate.

The SEBAMAT submission to the Similar Language Translation (SLT) task[1] of the 6th Conference on MT is based on work conducted as part of the SEBAMAT project[2] (semantics-based machine translation; Rapp & Tambouratzis, 2020). This project has a focus on experiments introducing semantics into MT but, for comparative purposes, also deals with standard NMT systems. The latter were used as the basis for the current shared task. During the SEBAMAT project a number of MT systems had been developed for language pairs involving English, French, German, Greek and Spanish, but there had been no prior work on Catalan and Portuguese. The aims of the participation in the SLT shared task were the following:

- See in how far the SEBAMAT-based MT systems are competitive.
- Extend the number of SEBAMAT languages by Catalan and Portuguese.
- Find out whether systems for new language pairs can be developed in a very short time.
- See whether reasonably well working systems can be developed without much proficiency of the respective languages on the developer side.

2 Resources

2.1 Corpora

For the training of the NMT systems sentence-aligned parallel corpora are required. We used all parallel corpora suggested by the SLT shared task organizers who in their task description explicitly stated that no additional parallel corpora were allowed for training.

For Catalan–Spanish the following parallel corpora were used:

- Wiki Titles v3 (476,475 sentence pairs) (Barrault et al., 2020)[3]
- ParaCrawl (6,870,183 sentence pairs) (Bañón et al., 2020)
- DOGC v2 (10,933,622 sentence pairs) (Tiedemann, 2012).

[3] http://data.statmt.org/wikititles/README

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 292–298

For Portuguese–Spanish, these parallel corpora were used:

- Europarl v10 (1,801,845 sentence pairs) (Koehn, 2005)
- News Commentary v16 (48,259 sentence pairs) (Tiedemann, 2012)
- Wiki Titles v3 (649,833 sentence pairs) (Barrault et al., 2020)
- Tilde MODEL (13,464 sentence pairs) (Rozis & Skadiņš, 2017).
- JRC-Acquis (1,650,126 sentence pairs) (Steinberger et al., 2006; Tiedemann, 2012)[4]

The above length specifications were taken from the SLT 2021 website's corpus download page. We did not use any of the comparable corpora provided by the SLT task organizers which, among others, included about 65 million sentences of Spanish news crawl.[5] The reason is that in the SEBAMAT project we achieved fairly good translation results when training with the Europarl corpus only. For example, we obtained BLEU scores (Papineni et al., 2002) well above 40 for Spanish–English and Greek–English when evaluated with randomly held out data. The Europarl corpus comprises in the order of 2 million sentences per language pair for many languages. As the parallel corpora for the shared task were much larger than this (with the Portuguese–Spanish language pair even including the respective language parts of the Europarl corpus), we saw no need to extract additional parallel sentences from comparable corpora. Such sentences are usually much noisier than parallel sentences based on human translations and could therefore possibly even reduce the quality of the NMT training in this high resource scenario.

Given the good quality of the training data provided by the shared task organizers, we only had to convert some of the files from a two-column translation memory format to the standard Moses format, and then concatenate all files of the source language as well as all files of the target language to form a large parallel training set. The concatenation was done in the order as listed above. However, as Marian NMT by default randomly shuffles the sentence pairs for training, the order of concatenation should not be of importance in our scenario.

2.2 Hardware

Marian NMT supports training using CPUs or GPUs. According to our experiments in the SEBAMAT project, training times in NMT can typically be reduced by about two orders of magnitude by conducting the training on a current GPU rather than on a (single) CPU. We therefore used a PC with an nVidia RTX 3090 GPU, supported by an i9 CPU. With 24 GB of memory, 28.3 billion transistors and 35.58 TFLOPS FP32 (float) performance, this GPU is state of the art in 2021, so – depending on parameter settings – with a single GPU we typically had training times of only a few hours per language pair. As our operating system we used Ubuntu 20.04 LTS.

As a side note, let us mention that performance in CPU-based training can be increased by using several CPU cores in parallel, which is supported by Marian NMT. With the 16 cores of the i9 processor, this looks promising if an appropriate GPU is not at hand. However, according to our experiments, each of the processors requires the full amount of memory. Therefore, if we assume 8 GB of memory per CPU core (which is typically the minimum for serious NMT work), we would require a total of 128 GB of RAM if we wished to use all 16 cores.

2.3 Software

As the translation engine we used the Marian NMT toolkit as it is well established and, for the reason that it is implemented in the C++ programming language, runs very fast (Kim et al., 2019), thereby substantially reducing training times. This is a particularly important consideration in a shared task where time tends to be very limited.

Marian NMT was installed on the above PC together with the nVidia driver and CUDA software. Our pre-processing pipeline involves the following steps: tokenization, cleaning, i.e. removal of very long sentences and sentence pairs with very different lengths, true-casing, and byte-pair encoding. For the first three steps we used the Moses tools *tokenizer*, *clean-corpus-n*, and *truecase* (Koehn et al., 2007).[6] For byte-pair encoding we used Rico Sennrich's Python program *bpe* (Sennrich et al., 2016). For post-processing of the translations, the tokenization and true-casing was reversed using the Moses tools *detruecase* and *detokenizer*.

Table 1: Parameters for Marian NMT training (Portuguese → Spanish).

The Moses tokenizer works well for Spanish and Portuguese, but has some problems with Catalan as there are some peculiarities in this language, most notably the interpunct (as used e.g. in the word *cel·la*). An insightful discussion on this can be found on GitHub.[7] As we did not have time to adapt the tokenizer to Catalan, to account for a few obvious errors, we did some minimalistic automatic post-processing (replacing a few short character sequences) as described in Section 4.

3 Experiments

To obtain any information on the training data and on the development and test sets, it was required to register for the shared task. We did so on July 13, 2021, so had seven days until July 19 when the submission of the results was due. This did not leave us much time for parameter optimization which is why we mostly took the standard parameters as suggested in the Marian NMT documentation for the Transformer architecture (Vaswani et. al, 2017).

We only did a few test runs with various settings concerning the number of merge operations in byte pair encoding (later to be referred to as *vocabulary size*), but did not have time to systematically optimize it. In our primary submissions, this parameter is set to 40,000, whereas in the comparative submissions, as in some previous SEBAMAT work, it is set to 85,000. For all language pairs and data sets (development and test), the smaller size performed better in terms of BLEU scores, although the exact size appears to be not very critical within a wide range of values.

To provide details on the core part of our experiments, in Table 1 we show the script for the Marian NMT training. As the parameters are well described in the Marian NMT documentation, we do not discuss them here. Let us only mention that during training BLEU scores are computed periodically on the development set, and that the training stops if the best score cannot be improved within ten iterations.

4 Results

We pre-processed the corpora as described in section 2 and trained the system for the language pairs Catalan→Spanish, Spanish→Catalan, Portuguese →Spanish and Spanish→Portuguese. We then inspected the translation results. For all language pairs the translations looked ok except for Spanish→Catalan. For this language pair we noticed, apparently because the tokenizer was not well suited for Catalan, the following three types of systematic errors in the output:

- There were extra spaces within Catalan words such as *paral·lel* because the *interpunct* (*punt volat*) was incorrectly interpreted as a separator between words rather than between syllables, which is why during tokenization blanks were inserted around it. We corrected this by replacing all «␣·␣» sequences («␣» stands for blank) in the translation output by «·».
- We found extra spaces before the apostrophe in phrases such as «l'efectiu» or after the apostrophe in phrases such as «d'informes». We therefore removed all spaces before and after apostrophes in the translation output.
- We noticed that whereas in the translated output «'» was used as the apostrophe, the sample translations in the development set used «´» instead. The reason is probably a discrepancy between training corpora and development sets. Assuming that the test set would have the same characteristics as the development set, we replaced in the translation output all occurrences of the former by the latter.

Vocabulary size	Language pair	BLEU score
40,000 (primary submission)	ca–es	80.72
	es–ca	83.32
	pt–es	50.37
	es–pt	44.96
85,000 (contrastive submission)	ca–es	79.40
	es–ca	81.21
	pt–es	47.29
	es–pt	42.77

Table 2: Results for the development sets. ca = Catalan, es = Spanish, pt = Portuguese. Without the interpunct and apostrophe substitutions, the BLEU score of es–ca (primary) is 69.40 and the BLEU score of es–ca (contrastive) is 68.01.

Vocabulary size	Language pair	BLEU	RIBES	TER	Rank
40,000 (primary)	ca–es	78.65	94.76	15.805	2
	es–ca	79.69	95.76	14.632	1
	pt–es	46.51	86.31	41.235	2
	es–pt	40.35	84.99	45.258	2
85,000 (contrastive)	ca–es	76.78	94.46	17.067	5
	es–ca	77.32	95.35	16.744	3
	pt–es	43.12	84.99	45.068	4
	es–pt	38.90	83.89	47.044	3

Table 3: Shared task results for the test sets as computed by the shared task organizers.

Especially the substitution of the apostrophes resulted in an improvement of several BLEU points, whereas the effects of blank removal before and after apostrophes differed depending on the software used for automatic evaluation. When using *Tilde's interactive BLEU score evaluator*[8] this change had no effect, whereas with the Moses *multi-bleu-detok.perl* tool, which we used in our scripts, a small improvement was obtained. The discrepancy can be explained by assuming that tools for computing BLEU scores often introduce some forms of tokenization or de-tokenization by themselves, and that these operations can slightly differ between tools.

Table 2 shows the BLEU scores obtained with the *multi-bleu-detok.perl* tool on the development sets for the four language pairs and the two parameter settings (byte pair encoding vocabulary sizes of 40,000 vs. 85,000). Table 3 shows the official BLEU scores for the test sets as computed by the shared task organizers who also provided scores for the RIBES (Isozaki et al., 2010) and TER (Snover et al., 2006) measures on the evaluation section of the SLT webpage. These scores we cite in Table 3. The last column shows our submissions' ranks among the other teams participating in the competition. As can be seen, our primary submissions (byte pair encoding vocabulary size of 40,000) won the competition for Spanish → Catalan, and ranked second for the other three language pairs.

As can be expected from the evaluation scores, the translation quality is to the most part very good. This is particularly true for the language pairs involving Catalan. Table 4 shows a translation example for Portuguese → Spanish which is harder than Catalan → Spanish. For all language pairs, we

[8] https://www.letsmt.eu/Bleu.aspx

found a few occurrences of hallucinations (Raunak et al., 2021), mainly of the type where the beginning of a long sentence is translated well but towards the end a phrase translation is repeated over and over again. To give an idea how often this happened: manual inspection of the results for Catalan → Spanish (vocabulary size 85,000) showed that such hallucinations occurred in 7 of the 970 sentence translations of the development set.

FIRST THREE SEGMENTS OF TEST SET (PORTUGUESE)	SEBAMAT TRANSLATION (SPANISH)
O plano pretende contribuir para a realização dos objetivos da política comum das pescas e, em especial, para garantir que a exploração dos recursos biológicos marinhos vivos restabeleça e mantenha as populações das espécies exploradas acima de níveis que possam produzir o rendimento máximo sustentável (MSY).	El plan pretende contribuir a la consecución de los objetivos de la política pesquera común y, en particular, garantizar que la explotación de los recursos biológicos marinos vivos restablezca y mantenga a las poblaciones de especies explotadas por encima de niveles que puedan producir el rendimiento máximo sostenible (RMS).
Coordenar, em consulta com a Comissão, os métodos de diagnóstico da doença de Newcastle nos Estados-Membros, nomeadamente, mediante:	Coordinar, en consulta con la Comisión, los métodos de diagnóstico de la enfermedad de Newcastle en los Estados miembros, en particular mediante:
Por conseguinte, atualmente é preciso cofinanciamento da União para assegurar que a Finance Watch e a Better Finance recebam os recursos necessários para atingirem os objetivos pretendidos nos próximos anos, e para proporcionar estabilidade financeira a ambas as organizações, aos seus peritos e ao seu pessoal administrativo, que até agora conseguiram lançar as suas atividades relevantes em pouco tempo.	Por lo tanto, hoy es necesario cofinanciar la Unión para garantizar que Finance Watch y Better Finance reciban los recursos necesarios para alcanzar los objetivos deseados en los próximos años y para proporcionar estabilidad financiera a ambas organizaciones, a sus expertos y a su personal administrativo, que hasta ahora han logrado lanzar sus actividades relevantes en poco tiempo.

Table 4: First three Portuguese segments of the SLT 2021 test set and their translations to Spanish as produced by the primary SEBAMAT NMT system.

The hallucinations could be detected by looking at the ratio of sentence lengths between a source language sentence and its translation, and/or by detecting repetitive phrases towards the end of a sentence translation. However, according to Raunak et al. (2021), hallucinations are a problem of training data quality, which to improve would have been too time-consuming. We thought of greedy solutions such as cutting off repetitive sentence ends, but did not implement them for lack of time and as they would be hard to justify.

5 Discussion and conclusions

Given the observation that the language pairs involving Catalan achieved considerably higher evaluation scores than those involving Portuguese, the question arises how this can be explained. Our somewhat speculative answer is as follows: As Catalan's grammar and sentence structure is very similar to Spanish, with differences mainly on the vocabulary side, extremely high scores can be achieved because in many cases, often in the form of a word-by-word translation, there is just one obvious way how to translate a sentence for both man and machine. This is only to a lesser extend true for Spanish–Portuguese, so the lower scores are likely caused by more variability in acceptable translation options, rather than by lower translation quality.

When comparing the BLEU scores in Tables 2 and 3, it can be seen that our system performed significantly worse on the test sets than it did on the development sets. From this we conclude that probably the test data is less representative of the training data than the development data. Problems with overfitting seem unlikely as in the previous SEBAMAT work we had usually used randomly held out sentences of the training data for both development and testing. In such a scenario, the results were very similar in both cases, with only minor unsystematic discrepancies in BLEU scores.

Finally, let us try to answer the questions raised in the introduction. As it was ranked first for Spanish → Catalan and second for the other three language pairs, it appears that especially our primary systems (with vocabulary size 40,000) are competitive. Let us mention, however, that all participating systems showed similarly convincing evaluation scores, so that minor differences in parameter choice (such as vocabulary size) or in the organizers' selection of the test set may have had a noticeable impact on the rankings.

Like many other studies, this work provides once again evidence how powerful NMT is, and how well the Marian toolkit works: Within a week it was possible for a single developer to add two new language pairs (in two directions each) to the SEBAMAT portfolio, despite mediocre proficiency of Spanish and hardly any proficiency of Catalan and Portuguese. Of course, achieving good translation quality was considerably facilitated by the similarity of the languages and by the good quality and size of the training data provided by the shared task organizers.

Acknowledgments

This work was funded by the Marie Curie Individual Fellowship SEBAMAT (grant agreement number 844951) within the European Commission's Horizon 2020 Framework Programme. I would like to thank my colleagues at Athena R.C., the SLT and the WMT organizers, and all researchers who generously made available the tools and resources used in this work.

Abstract

In this work, two Neural Machine Translation (NMT) systems have been developed and evaluated as part of the bidirectional Tamil-Telugu similar languages translation subtask in WMT21. The OpenNMT-py toolkit has been used to create quick prototypes of the systems, following which models have been trained on the training datasets containing the parallel corpus and finally the models have been evaluated on the dev datasets provided as part of the task. Both the systems have been trained on a DGX station with 4 - V100 GPUs.

The first NMT system in this work is a Transformer based 6 layer encoder-decoder model, trained for 100000 training steps, whose configuration is similar to the one provided by OpenNMT-py and this is used to create a model for bidirectional translation. The second NMT system contains two unidirectional translation models with the same configuration as the first system, with the addition of utilizing Byte Pair Encoding (BPE) for subword tokenization through the pre-trained MultiBPEmb model. Based on the dev dataset evaluation metrics for both the systems, the first system i.e. the vanilla Transformer model has been submitted as the Primary system. Since there were no improvements in the metrics during training of the second system with BPE, it has been submitted as a contrastive system.

1 Introduction

Tamil is a language, predominantly spoken in Tamil Nadu, a state in Southern India, along with countries with a large Tamil speaking diaspora such as Sri Lanka, Malaysia and Singapore, to name a few. Telugu on the other hand is the official language of two Southern states in India, namely Andhra Pradesh and Telangana. It is also spoken among the Telugu speaking immigrant population in the USA, Canada and the UK. Both languages belong to the Dravidian family of languages which comprise of Tamil, Telugu, Kannada and Malayalam as the major languages spoken in South India. Despite belonging to the same family of languages, there are many differences between Tamil and Telugu, such as the script used for writing and linguistic differences in terms of phonology, morphology, syntax among others. Tamil belongs to the Southern branch of Dravidian languages, which has a rich literary tradition spanning more than 2000 years. Telugu, on the other hand, belongs to the South Central branch of Dravidian languages and has a considerable amount of different linguistic characteristics when compared to Tamil as described by Krishnamurthy (2019).

As part of the similar language translation's subtask for Dravidian Languages, namely Tamil (TA) and Telugu (TE), we have attempted to build Neural Machine Translation (NMT) models using the OpenNMT-py toolkit [1], which helps to generate quick prototypes for the NMT models with the desired configurations. The first NMT system (submitted as the primary system) in this work is a Transformer based 6 layer encoder-decoder model which provides a single model for bidirectional translation between Tamil and Telugu using the datasets provided for this shared task. The second NMT system (submitted as the contrastive system) consists of two unidirectional translation models with the same configuration as the first system, but with the addition of utilizing Byte Pair Encoding (BPE) for subword tokenization using the pre-trained MultiBPEmb model (Heinzerling and Strube, 2018).

The rest of the work is described in sections that pertain to the related work, data, system descrip-

2 Rationale for Selecting the Models and Related Work

There has been a significant amount of work done on developing machine translation systems for Indian languages, with some notable examples for Dravidian languages such as Tamil and Malayalam described in Kumar et al. (2019). This shared task provides a unique challenge in terms of the constraint on the parallel aligned language pair data made available for training. The other challenges include the linguistically rich and domain specific content present in the Prime Minister of India (PMI) and the Mann ki baat (MKB) datasets, where topics related to India's domestic and foreign policy issues can be found.

In order to address the challenge of lengthy input (samples containing more than 300 space delimited tokens), the Transformer model described by Vaswani et al. (2017) was adopted. This model provides the multi head attention mechanism which helps retain context for longer length sentence samples. To reduce the vocabulary, reduce the training time and possibly improve the translation quality (through sub word tokenization), a MultiBPEmb model trained with a vocabulary of 100000 tokens from 275 languages has been utilised (Heinzerling and Strube, 2018).

Other methods to improve translation quality, that have not been explored as part of this work are the use of back translation using monolingual corpus or corpora, on the lines of the one described by Sennrich et al. (2016). Factored NMT (which uses data tagged on the basis of morphology and Parts of Speech (POS)) such as the one described by García-Martínez et al. (2016) is another possible candidate suitable for the kind of challenge provided by the similar language translation task, as the use of POS and morphological information can reduce the number of tokens and make the models more generalizable in terms of predictions.

3 Data

The datasets used in the NMT systems for this work are the parallel aligned Tamil and Telugu (TA-TE) language pairs provided as part of the Dravidian Language sub task of the Similar Language Translation shared task[2]. Some statistics about the dataset are outlined in Table 1.

3.1 Dataset preprocessing

Due to the moderate size of the training dataset, which contains 40147 samples, along with the topic

Model Configuration Name	Model Configuration Value
Corpus Weights for PMI dataset	23
Corpus Weights for News dataset	19
Corpus Weights for MKB dataset	3
Source and Target Sequence Length	1600
Save checkpoint after steps	500
Number of training steps	100000
Number of validation steps	5000
Training batch size	4096
Dev(validation) batch size	16
Optimizer	Adam
Number of Encoder Decoder Layers	6 (each)
Number of Attention heads	8

Table 3: Training Configuration for Transformer based Encoder-Decoder Model (Primary System).

overlap of sentence samples between the training and dev datasets as well as test set (to a certain extent) on topics such as the Indian Prime Minister's statements on domestic issues and foreign policies in the PM India dataset, the entire training dataset has been utilized in its original form.

The length wise statistics of the dataset (in terms of space delimited tokens) is given in Table 2, this was taken as the deciding factor in fixing the maximum input length as 1600 for the NMT systems developed. The tokenization for the primary system was done as space delimited tokens which yielded a shared Tamil-Telugu vocabulary of 194860 tokens. On the other hand on using the MultiBPEmb model for subword tokenization gave a vocabulary of 14056 tokens for Tamil (TA) and 13170 tokens for Telugu (TE), which included some words in English as well.

4 System Description

As mentioned in section 1, the PyTorch based toolkit OpenNMT-py has been used to create rapid prototypes for NMT models (the motivations for the same can be seen in section 2), which have then been trained on the datasets provided, validated against the provided dev sets and finally translations for the test sets described in section 3 have been obtained and submitted to the committee for evaluating the Similar Language Translation task.

A DGX station with 4 - V100 GPUs have been used to train the models utilized in this task. A Transformer based 6 layer encoder-decoder model on the lines of the NMT system described by Vaswani et al. (2017), was trained for 100000 training steps as the first NMT system to be evaluated. The configuration for this model is the same as that provided by OpenNMT-py. In order to save time, a single bidirectional translation model for TA-TE language pair has been created, which can translate from Tamil to Telugu and vice versa. The datasets used in this system were doubled in terms of the number of samples when compared to the second NMT system (constrastive submission), by reversing the position of the TA-TE language pair and appending them to the original datasets. No special tagging identifiers were used as the Tamil and Telugu scripts are distinct.

Basic space delimited tokenization was applied on the datasets, which resulted in a combined TA-TE vocabulary of 194860 tokens being generated, the relevant key configuration for this model are listed in Table 3.

The corpus weights help assign varied importance to the particular datasets used in this task, the values for these weights were determined after visual analysis of the dev(validation) dataset which indicated the dev dataset's contents had a greater overlap with PMI, News and (Mann ki Baat - which roughly translates to "From the heart") MKB in that particular order. The training time for the entire model was 18 hours.

The second NMT system consists of two unidirectional translation models with the same configuration as the first system, with the addition of utilizing Byte Pair Encoding (BPE) for subwords using the pretrained MultiBPEmb model (Heinzerling and Strube, 2018). The intuition behind using BPE was to reduce the vocabulary size using subword tokenization. The choice of the pre trained BPE model was based on the relevance of content

System Name	Source Language	Target Language	BLEU	RIBES	TER
Primary System (Transformer Based)	TA	TE	4.321	7.4	99.1
Contrastive System (Transformer Based + BPE subword)	TA	TE	0.003	0.0	130.6
Primary System (Transformer Based)	TE	TA	3.908	9.0	98.7
Contrastive System (Transformer Based + BPE subword)	TE	TA	0.029	3.0	105.0

Table 4: Dev dataset BLEU, RIBES and TER Corpus level scores using the VizSeq library.

System Name	Source Language	Target Language	BLEU	RIBES	TER	System Rank
Primary System	TA	TE	6.09	17.03	-	1
Contrastive System	TA	TE	0.00	0.03	-	9
Primary System	TE	TA	6.55	19.61	98.356	4
Contrastive System	TE	TA	0.04	1.00	-	9

Table 5: Test dataset BLEU, RIBES, TER scores and BLEU based System Rank in the Shared Task

used for BPE model training, languages supported and size of the vocabulary. Heinzerling and Strube (2018) describes a MultiBPE model with a 100000 vocabulary which was deemed suitable for this task as it supported Tamil and Telugu, was trained on WikiNews and could use a single vocabulary like the first NMT system used in this work. During training it was found that the translations for the Dev set couldn't distinguish between Tamil and Telugu subwords correctly, due to the failure in vocabulary matching for the candidates used in the evaluation and possibly due to the vocabulary shared between the languages. Hence, this system was trained twice generating two unidirectional models for TA-TE and TE-TA translations. The training time for each model was 5 hours, which is less when compared to the primary system due to the number of samples used (the primary system uses double the number of samples) and the vocabulary size (the contrastive system has a smaller and fixed vocabulary as a pre trained BPE model has been used).

5 Results

The evaluation metrics used to evaluate the systems in this task are BiLingual Evaluation Understudy (BLEU) score as described by Papineni et al. (2002), Rank-based Intuitive Bilingual Evaluation (RIBES) score as described by Isozaki et al. (2010) and Translation Error Rate (TER) as described by Snover et al. (2006).

Corpus level metrics for the dev dataset were computed using the VizSeq python library which is an implementation of several metrics described by Wang et al. (2019).The metrics for the dev dataset are listed in Table 4.

Based on the evaluation metrics of the Dev (validation) dataset translations for both the systems evaluated in this work, the first system i.e. the vanilla Transformer model has been submitted as the Primary system. Since there were no improvements in the metrics (the reason for it can be seen in section 6), during training of the second system which consists of the Transformer model along with the use of MultiBPEmb model for sub word tokenization, hence the second system has been submitted as a contrastive system.

Table 5 lists the evaluation metrics[3] applied on the test dataset and the BLEU based system rank in the shared task provided by the evaluation committee [4,5].

6 Conclusion and Future Work

The analysis of the evaluation metrics, from section 5, on the dev dataset indicates that the primary system, which is a Transformer based Encoder-

[3]The results of the TER metrics for the test set translations have been marked as - (refer Table 5), when the values exceed 100.0

[4]https://mzampieri.com/workshops/wmt/2021/TA_TE.pdf

[5]https://mzampieri.com/workshops/wmt/2021/TE_TA.pdf

Decoder model, performs better than the contrastive system which contains Transformer based NMT models with BPE for subword tokenization. The reason for this is possibly due to the lack of vocabulary matching the candidates being evaluated and also due to the shared vocabulary of the MultiBPEmb model. The choice of a pre trained MultiBPE model was to reduce effort on the embeddings, but in hindsight training the MultiBPE model using the given datasets or fine tuning the pre trained MultiBPE model on the given datasets would have been a better choice.

As seen from the evaluation of translations obtained using the Dev and Test datasets using BLEU, RIBES and TER metrics in section 5, there is a considerable scope of improvement in the scenario where a constraint is placed on the number of datasets containing parallel corpus language pair samples, that can be used for training. The possible reason for the low BLEU scores in the primary system is the relatively small number of samples used along with the presence of a large variety in the linguistic forms present in the datasets. In the case of the contrastive system, the low BLEU scores can be attributed to the use of the pre trained MultiBPE model (a pre trained BPE model fine tuned on the given datasets would have helped improved the scores). Some approaches that have the potential to improve the results are, the use of back translation using monolingual corpus (through training corpus augmentation and providing more training examples for the model to learn), utilizing domain specific corpora from the shared machine translation task for Indian Languages described in section 2. Factored NMT, an NMT which uses input tagged on the basis of morphology and Parts of Speech (POS) to reduce the number of tokens, the use of alternative BPE models trained on content which are a close match to the dataset used in the shared task, are other promising alternatives.

Abstract

In this paper, we describe our submissions for the Similar Language Translation Shared Task 2021. We built 3 systems in each direction for the Tamil $\Longleftrightarrow$ Telugu language pair. This paper outlines experiments with various tokenization schemes to train statistical models. We also report the configuration of the submitted systems and results produced by them.

1 Introduction

Machine translation is a process of translating text from a source to a target language. There are multiple ways of building such a system - Rule-based, Data-driven, Hybrid etc. In this shared task, we use data-driven method to create machine translation system for Tamil $\Longleftrightarrow$ Telugu. Due to low-resource setting of this language pair in the shared task, we use Statistical Machine translation method (Koehn et al., 2003),(Koehn and Knowles, 2017) to build systems.

Tamil Telugu language pair comes under the bracket of similar languages. Similar languages show similarity in their lexical and syntactical properties (Kunchukuttan et al., 2014a). This may be due to them being in close proximity of each other for long time. This can also be due to common ancestry. In the current digital context, translation between similar languages is of importance. But there can be scarcity of good quality parallel text. In the current shared task, we have a language pair which is morphologically rich and with $\simeq$39K parallel sentences. So, following Kunchukuttan and Bhattacharyya (2017) and Kunchukuttan et al. (2014b) we use sentencepiece[1] (Kudo and Richardson, 2018) and morfessor[2] (Virpioja et al., 2013) to segment tokens in the dataset into subwords. And due to the size of parallel text ($\simeq$39K parallel text) coming under purview of low resource, we make use of Moses[3](Koehn et al., 2007) to create statistical machine translation models(Koehn and Knowles, 2017).

For this shared task we developed 3 translation systems (1 Primary and 2 Contrastive) in each direction Tamil $\Longleftrightarrow$ Telugu. For each output we post-processed and detokenized translation output depending on the tokenization scheme for target language. To choose a primary and 2 contrastive systems, we compared BLEU (Papineni et al., 2002) scores on output of development dataset for each system using sacrebleu[4] (Post, 2018). The Following sections give more details about the systems developed.

2 SMT systems using different schemes

We used various tokenization schemes to build translation systems. Evaluated these systems on the development dataset. After post-processing, detokenizing and scoring each translation output, we submit output systems as primary and contrastive submissions accordingly.

2.1 Data and preprocessing

We used parallel data provided by the organizers to train all the models. IndicNLP[5] (Kunchukuttan, 2020) was used to normalize and tokenize datasets. 2 Subword models were trained on tokenized text for each language. Sentencepiece(Kudo and Richardson, 2018) was used to prepare a subword tokenizer model with vocabulary size set to 32000 and character coverage set to 0.9995. Another alternative tokenization model was trained on morfessor(Virpioja et al., 2013). To create 3 systems for each translation direction, we used the

following tokenization schemes,

- basicTok: bitext is tokenized with IndicNLP.
- morf: each training file in the parallel text is tokenized into subwords with the respective morfessor model.
- spm: each training file in the parallel text is tokenized into subwords with the respective sentencepiece model

Table 1 shows the statistics of the Tamil and Telugu dataset for each tokenization scheme after using `clean-corpus-n.perl` script with 1,70 as min,max line length for training text. No additional monolingual dataset was used in building any of the models.

2.2 MT Systems

We build a trigram language model with kneser ney smoothing for each language in each tokenization scheme using KenLM (Heafield, 2011). And used Moses (Koehn et al., 2007) to train an SMT system. MERT (Och, 2003) is used for tuning the trained model on development datasets. The performance of all systems, for each language direction on respective tokenized development datasets, is given in Table 2. For this shared task, we submit 3 systems (1 PRIMARY and 2 CONTRASTIVE) for each language direction for evaluation. Depending on scores on development dataset, systems build were submitted as,

	Tamil ->Telugu	Telugu ->Tamil
basicTok	7.7	9.9
spm	5.2	9.0
morf	7.7	9.8

Table 2: BLEU score on development dataset for each system

- For Telugu to Tamil,

2.3 Results

This subsection compares the results of our systems, which we received from organizers, in terms of BLEU scores. Table 3 shows the BLEU scores for Telugu to Tamil systems. In comparison with other systems, all of our system outputs score highest. We were hoping that, in test cases, models using subwords for training and translating would prove to be better than basicTok, but that was not the case. Instead models trained on basicTok fared better.

System Type	BLEU	RIBES	TER
PRIMARY (basicTok)	8.37	43.55	95.884
CONTRASTIVE1 (morf)	7.89	46.24	95.627
CONTRASTIVE2 (spm)	7.43	42.54	94.964

Table 3: Scores on test dataset for each Telugu to Tamil system

Table 4 shows the BLEU score we received for Tamil to Telugu systems. Our system outputs from

System Type	BLEU	RIBES	TER
CONTRASTIVE1 (basicTok)	5.54	40.58	98.082
PRIMARY (morf)	5.23	42.37	98.662
CONTRASTIVE2 (spm)	3.32	34.42	-

Table 4: Scores on test dataset for each Tamil to Telugu system

CONTRASITVE1 and PRIMARY submission are in the top 3 in comparison with other systems. Here again, we see basicTok model fared a bit better than model trained on morf segmented dataset. And sentencepiece model was $\simeq$2 BLEU points behind both the systems. These BLEU scores (CONTRASTIVE1, PRIMARY) are in the top 3. Again, we were hoping, that in test cases, models using subwords for training and translating would prove to be better. But as was case in Telugu to Tamil, here also models trained on basicTok dataset fared better, followed by models trained on morfessor segmented dataset.

Netmarble AI Center

Abstract

This paper describes Netmarble's submission to WMT21 Automatic Post-Editing (APE) Shared Task for the English-German language pair. First, we propose a Curriculum Training Strategy in training stages. Facebook Fair's WMT19 news translation model was chosen to engage the large and powerful pre-trained neural networks. Then, we post-train the translation model with different levels of data at each training stages. As the training stages go on, we make the system learn to solve multiple tasks by adding extra information at different training stages gradually. We also show a way to utilize the additional data in large volume for APE tasks. For further improvement, we apply Multi-Task Learning Strategy with the Dynamic Weight Average during the fine-tuning stage. To fine-tune the APE corpus with limited data, we add some related subtasks to learn a unified representation. Finally, for better performance, we leverage external translations as augmented machine translation (MT) during the post-training and fine-tuning. As experimental results show, our APE system significantly improves the translations of provided MT results by -2.848 and +3.74 on the development dataset in terms of TER and BLEU, respectively. It also demonstrates its effectiveness on the test dataset with higher quality than the development dataset.

1 Introduction

Automatic Post-Editing (APE) aims to improve the quality of an existing Machine Translation (MT) system by learning from human-edited samples (Chatterjee et al., 2019, 2020). With the continuous performance improvements of Neural Machine Translation (NMT) systems along with deep learning advancements, developing APE systems has faced a big challenge. Simple translation errors are hard to find in machine translation outputs, and the remaining errors are still hard to solve. In recent years, transfer learning and data augmentation techniques have shown their efficiency when training models on datasets with limited size (Devlin et al., 2019). Therefore, such approaches are also adopted in APE tasks (Lopes et al., 2019).

Participants in WMT21 APE shared tasks are required to develop systems to automatically post-edit the translation outputs from an unknown MT system. In this year, the same data has been re-post-edited to improve the quality. As a result of performing statistics on the development set, the evaluation scores are 19.057 and 68.79 in terms of TER and BLEU, which are much higher than the scores of last year, 31.374 and 50.37, respectively. The central distribution of TER has shifted to the left compared to last year. We find that the section in the range of 5 to 10 has the most examples, which indicates that over-correction problems should be considered during the APE tasks. In addition, the dataset has been changed in terms of the domain (from IT to Wikipedia), which results in the change in data distribution. Therefore, directly using previous datasets or officially provided synthetic corpus (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018) to enlarge the training set of APE tasks might not be appropriate under such circumstances. In work by Yang et al. (2020), considering the change of data distribution, they select to use additional MT candidates as the data augmentation method to improve feature diversity in their APE systems, which significantly improves the APE performance.

Inspired by this idea, we decided to solve the APE task as NMT alike task and utilize the external MT at the fine-tuning stage. However, because of the limited size of the APE corpus and the improvement of MT quality, fine-tune the model only on the APE data, easily reach the performance ceiling in spite of using external translation. To solve the aforementioned issues, existing works for other

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 307–314
November 10–11, 2021.

Natural Language Processing (NLP) tasks have adopted several Multi-task Learning (MTL) methods with the auxiliary task (Whang et al., 2021; Oh et al., 2021). We wondered whether it is possible to apply MTL mechanism with APE task to the fine-tuning stage since MTL trains the model to encourage representation sharing and improve generalization performance. Furthermore it aims to alleviate the data sparsity problem with a limited number of data in each task (Zhang and Yang, 2021). Therefore, we add some related NLP tasks along with the APE task. Our experiment results demonstrate that such approaches can further improve performance.

As mentioned above, large-volume data, such as news translation data and artificial synthetic data, can not be used to enlarge the APE corpus directly during the fine-tuning because of the large gap in data distribution. We wondered if there is a way to apply any learning method to the post-training so that we can utilize more data to train a more robust and powerful model. In work by (Xu et al., 2020), they applied Curriculum Learning according to the difficulty of each example on a single training stage. Inspired by the research, we try to apply Curriculum Learning across multiple training stages. As the training stage increases, we make the system learn to solve the different tasks by gradually providing extra information, described in Section 3 in detail. Extensive experiments show the effectiveness of applying the Curriculum Learning Strategy during the training phase. Finally, We combined these two approaches to make our final APE system, which significantly improves the performance of the APE task.

Our APE system is built based on Transformer (Vaswani et al., 2017) and is post-trained on WMT21 News-Translation Data (Koehn, 2005; Tiedemann, 2012; Rozis and Skadiņš, 2017; Bhatia et al., 2016; Tiedemann, 2012) and artificial synthetic data (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018) provided by APE Task with Curriculum Learning Strategy. For fine-tuning, MTL is applied with related NLP subtasks such as Part-Of-Speech (POS), Named Entity Recognition (NER), Masked Language Model (MLM), and Keep/Translate are added to the model to reduce the over-fitting as well as achieve better performance, described in Section 4 in detail. For better training efficiency, the Dynamic Weight Average (DWA) mechanism (Liu et al., 2019) is applied during the MTL to keep the correct balance between these subtasks. Here we summarize our contributions as follows:

- We design Multi-task Learning Strategy (MLS) with DWA to the fine-tuning stage, which improves the training efficiency and the performance significantly.
- We adapt Curriculum Training Strategy (CTS) to our APE system during the post-training across the multiple training stages, which shows the effectiveness in performance. In addition, we showed a way to utilize the additional data in large volumes in APE tasks.

2 Base System

Our system is based on Facebook FAIR's WMT19 News Translation Model (Ng et al., 2019), which used the big Transformer (Vaswani et al., 2017) and provided the pre-trained weights. We use both of them as our base system. In addition, we utilize data augmentation with external MT, which has been proposed by Yang et al. (2020) to generate the external translated sentence (mt_ext) and help generate the post-editing sentence (pe). An input sentence X that contains a source sentence (src), a translated sentence by the machine translation system (mt), and an external translated sentence (mt_ext) is defined as,

$$X = [src \texttt{<SEP>} mt \texttt{<SEP>} mt\_ext], \quad (1)$$

and output a sequence, $H = [h_{src_0}, h_{src_1}, ..., h_{src_n}, h_{\texttt{<SEP>}}, h_{mt_0}, ..., h_{mt_m}, h_{\texttt{<SEP>}}, h_{mt\_ext_0}, ..., h_{mt\_ext_l}] \in \mathbb{R}^{d_h \times (n+m+l+2)}$, where d_h represents a dimension of the encoder, and n, m, l represents the number of tokens for src, mt, mt_ext, respectively. We represent the parameters of the encoder as Θ_s. Then, H is fed into the decoder, and the decoder target is defined as $Y = [pe]$.

3 Curriculum Training Strategy (CTS)

CTS has been inspired by Curriculum Learning (Xu et al., 2020) that is applied according to the difficulty of each example on a single training stage, which has already been applied to our baseline architecture by Ng et al. (2019). In addition, we propose CTS, which applied Curriculum Learning across multiple training stages. CTS aims at step-by-step learning. In an early stage, the system learns to solve easy problems or something that needs to know beforehand and complex problems or target tasks in the later stages.

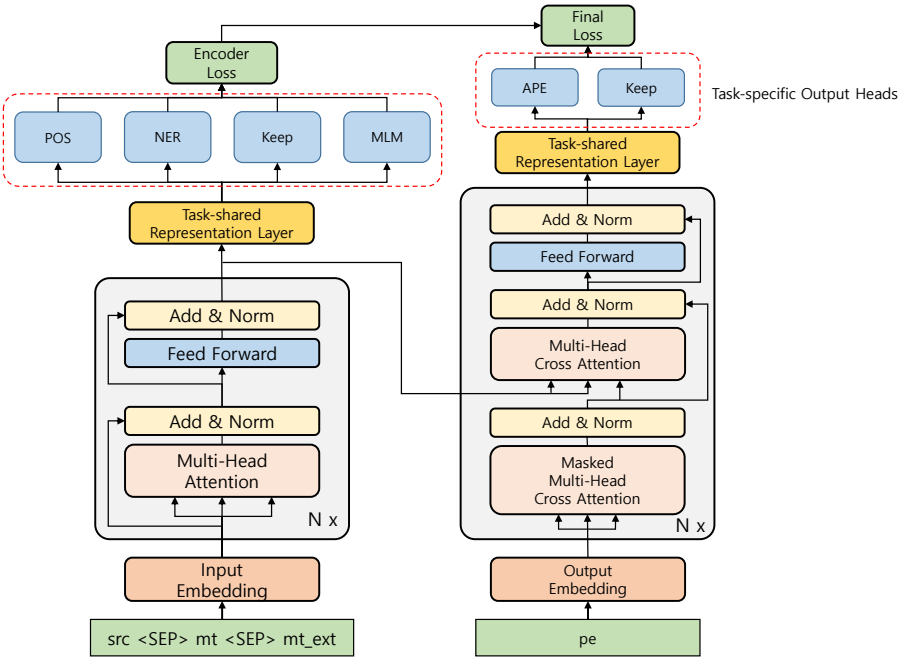

Figure 1: Overall architecture

3.1 Step 1: Understanding for Machine Translation

$$X = [src], \tag{2}$$

The APE task has to understand the machine translation system because the APE task modifies the mt results. Therefore, we designed the first step of the curriculum with the input as Equation 2 and the target as pe.

3.2 Step 2: Learning about Post-Editing

$$X = [src \texttt{<SEP>} mt], \tag{3}$$

After the first step, our system understands as the machine translation system. In this step, we make our system learn how to edit mt to pe with the input as Equation 3 and the target as pe.

3.3 Step 3: Post-Editing with External MT

For the second step, our system learns about the post-editing mechanism. In this step, we make the system learn to take the External MT into account with the input as Equation 1 and the target as pe.

3.4 Fine-Tuning

Finally, we fine-tune the APE system using the data given in the challenge with the input as Equation 1 and the target as pe.

4 Multi-task Learning Strategy (MLS)

Existing works for MTL propose jointly learning methods among related tasks. MTL aims to improve the generalization performance of the whole tasks by sharing knowledge representations of other tasks and can also alleviate the data sparsity problem where each task has limited labeled data (Zhang and Yang, 2021). Therefore, we utilize MLS for our system because WMT21 APE shared task provides only 7,000 train sentences. In NMT, existing works for MTL applied POS, NER, or MLM as subtasks and provided improved results (Chatterjee et al., 2017; Wang et al., 2020). Despite the impressive results, they applied only a few subtasks, such as one or two. Since we defined the APE task as NMT alike problem in our work, it would be helpful to leverage these subtasks into our work to achieve better performance. We find out that all these subtasks are cooperative with each other and benefit our system. Inspired by the word-level quality estimation task, we also add the Keep/Translate classification tasks for encoder and decoder to handle the high-quality APE task, which is described in Section 4.2 in detail. Since utilizing multiple subtasks, we have to consider the loss ratio between these subtasks. In our work, we apply the Dynamic Weight Average method described in Liu et al. (2019), and more details are described in Section 4.4. Our final system based on the model

post-trained using CTS with fine-tuning the APE data with MLS.

4.1 Architecture

Our architecture is described in Figure 1. The overall flow of the APE task is the same in Section 2. In this section, we explain five auxiliary subtasks consisting of POS, NER, MLM, Keep/Translate for the encoder, and Keep/Translate for the decoder. For the encoder, the encoding vector H is fed into Task-shared Representation Layer in Figure 1 like a Fully-connected Neural Network (FNN), and the output is represented as,

$$H_s = (W_1 H + b_1), \tag{4}$$

where $W_1 \in \mathbb{R}^{d_h^s \times d_h}$, and d_h^s represents a dimension of the Task-shared Representation Layer.

4.2 Subtasks

POS & NER POS and NER task aims to predict parts of speech and named entities about an input sequence, respectively. Task-shared Representation Layer H_s is fed into Task-specific Output Heads on Figure 1 like a FNN, and the output is represented as,

$$\hat{Y}^{pos} = \text{softmax}(W_2 H_s + b_2), \tag{5}$$

where $W_2 \in \mathbb{R}^{C_{pos} \times d_h}$ is trainable parameters and C_{pos} is the number of class of POS task. The parameters of Task-specific Output Heads for POS task are represented as Θ_{pos}. Likewise, $\hat{Y}^{ner}$ is obtained as in Equation 5 for NER task, where the parameters are represented as Θ_{ner}.

MLM In MLM task, we copy the input tokens from X to X^{mlm}, which is represented by $X^{mlm} = \{x_1, ..., x_{n+m+l+2}\}$, where n, m, l represents the number of tokens for src, mt, mt_ext, respectively. Then, we randomly mask 15% of the tokens X^{mlm} using the special token $mask$, and define the target as original input tokens. X^{mlm} is fed into the encoder. Then, the output representation is used to the input for Task-specific Output Heads for MLM task as,

$$\begin{aligned} \hat{Y}^3 &= \text{softmax}(W_3 H_s + b_3), \\ \hat{Y}^{mlm} &= \{\hat{Y}_r^3 | x_r = mask, \\ &\quad \forall\, r \in \{0, ..., n+m+l+2\}\} \end{aligned} \tag{6}$$

where $W_3 \in \mathbb{R}^{C_{mlm} \times d_h}$ represents trainable parameters and C_{mlm} is the number of vocab for the encoder. The parameters of a linear projection layer are represented as Θ_{mlm} for MLM task.

Keep/Translate Considering the characteristics of the APE data with relatively low TER scores, we decide to add Keep/Translate classification subtask to both Encoder and Decoder in our APE system. Keep/Translate subtask aims to predict the labels of the input sequence, where is $\hat{Y}^{kt} \in \{Keep, Translate\}$. In this subtask, each token in the input will be labeled with $Keep$ or $Translate$. For label generation, we apply to the pair of src-mt and src-mt. First, we use SimAlign (Jalili Sabet et al., 2020) to perform word alignment on the pe-mt pair. To each aligned word pair, we labeled them with Keep if they are equal. Otherwise, they will be marked as Translate. As for the pair of src-mt, we also do word alignment to find the correspondence between the source and target side. On the src side, the tokens are labeled with the same name as the corresponding words on the mt side. In our case, the same procedure on pe-mt is conducted for the pair of mt_ext and pe because we use the mt_ext as our data augmentation method. Figure 2 shows an example of label generation in the Keep/Translate task for better understanding. The output is represented as,

$$\hat{Y}^{kt} = \text{softmax}(W_4 H_s + b_4), \tag{7}$$

where $W_4 \in \mathbb{R}^{C_{kt} \times d_h}$ is trainable parameters and C_{kt} is the number of class of Keep/Translate task. The parameters of Task-specific Output Heads for Keep/Translate task are represented as Θ_{kt} and $\hat{Y}^{kt}$ is obtained as in Equation 7 for Keep/Translate task.

4.3 Loss

As described above, five subtasks are used in our system, and most of them have data with imbalanced labels. The imbalanced ratio reaches 1:2160, 1:15, and 1:6 between minority and majority classes in POS Tagger, NER, and Keep/Translate subtasks, respectively. With such imbalanced data, the Cross-Entropy loss used in classification problems may result in performance degradation in some tasks. To improve the performance, the Focal loss (Lin et al., 2017) is considered as an alternative candidate because a Focal Loss function addresses class imbalance during training in tasks. It applies a modulating term to the cross-entropy loss in order to focus on learning the hard negative examples. It reduces the relative loss for well-classified examples ($p_t > 0.5$), putting more focus on hard, misclassified examples. Equation 8 describes the

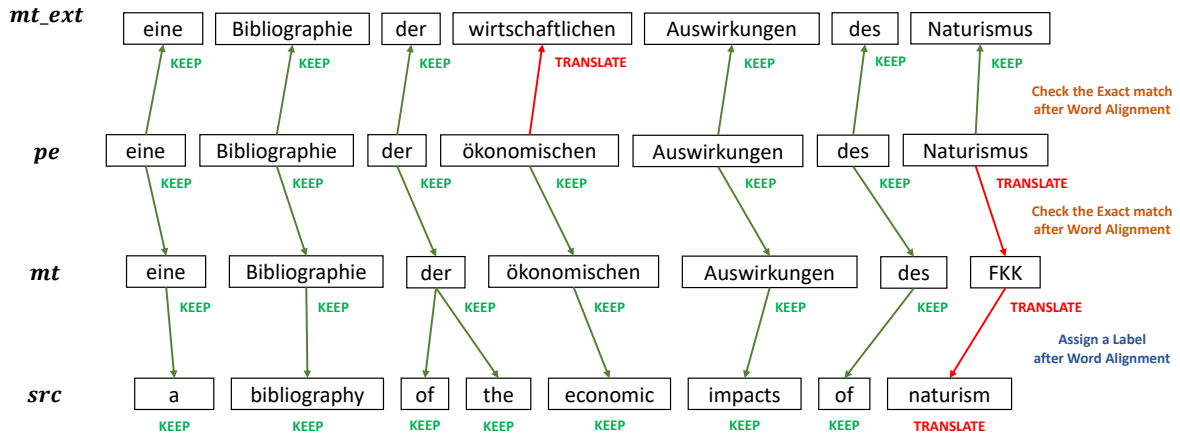

Figure 2: A label generation example in the Keep/Translate task

Focal Loss, where p_t is the probability of each class predicted by the model and γ represents the focusing parameter. Considering the imbalanced property of each task, we apply the Focal Loss to three of our subtasks, such as POS Tagger, NER, and Keep/Translate in the decoder.

$$FL(p_t) = -(1-p_t)^{\gamma} log(p_t) \tag{8}$$

Class Balanced Loss is designed to use a re-weighting scheme that uses the effective number of samples for each class to re-balance the loss, thereby yielding a class-balanced loss (Cui et al., 2019). As the number of samples increases, there is information overlap among data. Therefore, the marginal benefit that a model can extract from the data diminishes. The effective number of samples, which played as the expected volume of samples, is used to capture the diminishing marginal benefits by using more data points of a class. For Keep/Translate task in the decoder, it just considered the PE as input, so we applied the Focal Loss to the subtask. However, for Keep/Translate task in the encoder, as one of the data augmentation methods, the external MT is also considered as input along with the src and mt. As the information of input increases, we think it may cause information overlap among data because mt and the mt_ext have the most in common. Therefore, we apply the Class-Balanced Loss as our loss function in Keep/Translate subtask in the encoder. Equation 10 describes the Class-Balanced Loss (L_{cb}), where C is the total number of classes, z_y is the output from the model for class y, n_y is the number of samples in the ground-truth class and $\beta \in [0, 1)$ is a hyperparameter which can be calculated in Equation 9. In Equation 9, i denotes the class index, $i \in \{1, 2, ..., C\}$, and N is the number of samples.

As for the MLM task, since it does not suffer from the data imbalance problem, we use the Cross-Entropy loss in our work as other works do.

$$\begin{aligned} N_i &= N, \\ \beta_i &= \beta = (N-1)/N \end{aligned} \tag{9}$$

$$L_{cb} = -\frac{1-\beta}{1-\beta^{n_y}} \log\left(\frac{\exp(z_y)}{\sum_{j=1}^{C}\exp(z_j)}\right) \tag{10}$$

4.4 Dynamic Weight Average

For most Multi-Task learning networks, it's difficult to find the best ratio between each task in subtasks manually. Therefore, we apply the Dynamic Weight Average (DWA) (Liu et al., 2019) to our work, which adapts the task weighting over time by considering the rate of change of the loss for each task.

Equations 11 and 12 describe DWA. Here, $\lambda_k(\cdot)$ represents the weighting for task k, $w_k(\cdot)$ calculates the relative descending loss rate for each task in each epoch, t is an iteration index, and T represents a temperature that controls the softness of task weighting. $\mathcal{L}$ in Equation 12 is the loss value, calculated as the average loss in each epoch over several iterations.

$$\lambda_k(t) := \frac{Kexp(\omega_k(t-1)/T)}{\sum_i Kexp(\omega_i(t-1)/T)} \tag{11}$$

$$\omega_k(t-1) = \frac{\mathcal{L}_k(t-1)}{\mathcal{L}_k(t-2)} \tag{12}$$

Table 1: CTS results on WMT21 APE development dataset. CTS-best (ensemble) is built by two similar single models. we submitted CTS-best (ensemble) as CONTRASTIVE result.

4.5 Joint Learning Procedure

All tasks are jointly trained, and the objective is defined as,

$$\mathcal{L} = \frac{1}{K}\sum_{i}^{K} \lambda_{\text{i}} \mathbb{L}(Y_i, f(X_i)), \qquad (13)$$

where λ is a dynamic weight determining the degree of subtasks and f is the training classifier. Note that the parameter K is the number of subtasks. $\mathbb{L}(Y, f(X))$ is the loss of f w.r.t. the target Y.

5 Experiments

5.1 Datasets

Following existing works, we utilize additional resources (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018), which have source sentences (src), machine translation sentences (mt), and post-editing sentences (pe). Moreover, we also utilize some of News-Translation data for the WMT21 (Koehn, 2005; Tiedemann, 2012; Rozis and Skadiņš, 2017; Bhatia et al., 2016; Tiedemann, 2012), which has source sentences (src) and translated sentences that can be used as pe. For evaluation and fine-tuning, we use the data for WMT21 automatic post-editing shared task. Moreover, we utilize translated sentences using Google Translate and Quality Estimation NMT Model (Fomicheva et al., 2020). The former is used to make mt_ext from the additional resources and the data for WMT21 automatic post-editing. The latter is used to make mt from News-Translation data. We filtered all the training data based on and number checking logic, which filters the pairs with different numbers in source and target side.

MLS w/o DWA	16.37	72.34

Table 2: Ablation analysis of DWA on the WMT21 APE development dataset.

5.2 Experimental Settings

For the first step of CTS, we utilize WMT19 en-de weights by Fairseq (Ng et al., 2019). In the second step, we utilize News-Translation data with translated sentences with Quality Estimation NMT Model as mt. In the third step, we make our system learn with Junczys-Dowmunt and Grundkiewicz (2016); Negri et al. (2018) and Google Translate as mt_ext. Finally, when learning the fine-tuning step, which contains MLS, we utilize the data for WMT21 Automatic Post-Editing shared task.

5.3 Results: CTS

To study the effectiveness of CTS, we conduct ablation experiments on WMT21 Automatic Post-Editing development dataset. We set the $baseline$, which is a system that leaves all the test instances unmodified. As shown in Table 1, we can observe that the $step$ 3 is more effective than the $step$ 2, and that using only $step$ 2 doesn't help APE. As our system is learning step by step with CTS, it allows that our system has strengths in the APE task.

5.4 Results: MLS

Table 2 presents the ablation analysis about DWA when fine-tuning with MLS on WMT21 APE development set. From the result, we can observe that MLS with DWA has better performance than the one without applying it. For that reason, we adopt DWA at a fine-tuning stage with MLS in our APE Task.

To find the best combination of subtasks in MLS, we conducted an ablation analysis on the same development dataset. Vanilla in the table is a system without adding any subtasks. We add the subtasks one by one during the fine-tuning to see the effect of each subtask on the performance. As shown in Table 3, the one using all the subtasks performs best among all the combinations, which means that these subtasks are cooperative in the APE task.

Netmarble_PRIMARY	17.97	70.53
baseline	18.05	71.07

Table 4: Official results on WMT21 APE test dataset.

5.5 Official Results

Table 4 shows the official results of our proposed methods on WMT21 test dataset. The test dataset has baseline scores of 18.05 and 71.07, which is higher than the development dataset with 19.06 and 68.79 in terms of TER and BLEU, respectively. Despite its high quality, our proposed methods showed effectiveness on this test dataset.

5.6 Implementation Details

We set the batch size to 256 for the *step* 2 and *step* 3 in CTS at each GPU, 16 for the fine-tuning and MLS. We set the initial learning rate to 1e-4 using scheduler in Fairseq (Ng et al., 2019) for all experiments. The average runtime of one epoch for each approach was about 360 minutes for the *step* 2, 90 minutes for the *step* 3, and 40 seconds for MLS. We train our models using AdamW (Loshchilov and Hutter, 2019) optimizer and conduct experiments with 16 Tesla A100 GPUs for CTS, Tesla V100 GPU for MLS.

6 Conclusion

In this paper, we propose an APE system based on CTS and MLS. CTS allows understanding between machine translation and automatic post-editing, and shows a way using additional data in large volume in APE task. MLS learns a shared unified representation from related subtasks to improve the performance. We submitted the system, which Fine-tunes with MLS, as our primary version and the ensembled CTS as our contrastive version. The experimental results show that our system is able to effectively detect and correct the errors made by a high-quality NMT system, improving the score by -2.848 and +3.74 on the development dataset in terms of TER and BLEU, respectively. Our proposed methods also achieved performance improvement on the test dataset with higher quality.

Abstract

Automatic post-editing (APE) models are used to correct machine translation (MT) system outputs by learning from human post-editing patterns. We present the system used in our submission to the WMT'21 Automatic Post-Editing (APE) English-German (En-De) shared task. We leverage the state-of-the-art MT system (Ng et al., 2019) for this task. For further improvements, we adapt the MT model to the task domain by using WikiMatrix (Schwenk et al., 2021) followed by fine-tuning with additional APE samples from previous editions of the shared task (WMT-16,17,18) and ensembling the models. Our systems beat the baseline on TER scores on the WMT'21 test set.

1 Introduction

Automatic Post-Editing (APE) is the task of automatically correcting machine translation (MT) outputs. Along with fixing systematic errors in MT outputs, APE models can adapt general purpose MT systems to new domains and provide better translations to reduce the human post-editing effort (Chatterjee et al., 2015). APE has seen significant progress with Transformer based models (Yang et al., 2020; Lopes et al., 2019; Chatterjee et al., 2019, 2020) dominating the landscape as opposed to the earlier Statistical Machine Translation (SMT) based models (Simard et al., 2007; Béchara et al., 2012) and RNN based sequence-to-sequence models (Junczys-Dowmunt and Grundkiewicz, 2017). To track this progress, WMT has been conducting APE shared tasks since 2015 on different data domains and language pairs (Bojar et al., 2015, 2016, 2017; Chatterjee et al., 2018, 2019, 2020).

WMT 2021's shared task focused on English-German and English-Chinese language pairs. We participated in the English-German sub-task and describe our submission in this paper. Participants were provided a training set with 7000 instances and a development set with 1000 instances. Each dataset consisted of *source*, *machine-translation*, *post-edit* triplets. The source sentences came from the English Wikipedia, the MT outputs were generated with a black-box state-of-the-art MT system and the post-edits were created by professional translators correcting MT outputs. The test set consisted of 1000 pairs of source and MT outputs for which the participants had to submit the post-edits generated by their systems. The task organisers provided two additional synthetic post-editing datasets – 'artificial training data' (Junczys-Dowmunt and Grundkiewicz, 2016) and 'eSCAPE corpus' (Negri et al., 2018) and permitted using additional data to train the model. TER scores (Snover et al., 2006) and BLEU (Papineni et al., 2002) scores were used as primary and secondary evaluation metrics respectively.

Last year's entries primarily focused on transfer learning (Yang et al., 2020; Lee, 2020; Wang et al., 2020) and novel data augmentation techniques (Lee et al., 2020b,a; Wang et al., 2020). The winning submission (Yang et al., 2020) was based on fine-tuning a pre-trained machine translation model for the APE task.

We take a similar line of approach by leveraging an existing state-of-the-art machine translation model. We first fine-tune an MT model on WikiMatrix (Schwenk et al., 2021) — a mined bitext from Wikipedia — to bridge the domain gap, followed by further tuning to the APE task with post-editing samples. To deal with the limited training data, we exploit APE data from the previous editions of the WMT shared tasks. We describe the details of our experiments in Section 3 with gains and observations from individual tuning steps mentioned above.

2 Related Work

The last year's WMT'20 APE shared task saw methods using transfer learning with data augmentation techniques perform well. Yang et al. (2020) fine-tune state-of-the-art transformer-based MT system on APE data using bottleneck adapter layers (Houlsby et al., 2019) to avoid overfitting. They additionally use outputs from an external MT system as input to the model and converged to ensembling to achieve 66.89 BLEU score on the WMT'20 development set to make it to the top of the final leaderboard.

Data augmentation techniques where post-edits are synthesized to augment human-edited data was shown to be effective in the last year's submissions for addressing the training data limitation. However, data augmentation must be done carefully to prevent a mismatch between the error distributions in gold and synthetic data (Yang et al., 2020). Wang et al. (2020) use data augmentation along with dual conditional cross-entropy model (Junczys-Dowmunt, 2018) based filtering to ensure data quality, model adaptation to target domain, and ensembling to achieve 56.06 BLEU on the development set and the second rank on the leaderboard. Similarly, Lee et al. (2020b) performed data augmentation by creating a novel noising scheme to synthesize four kinds of errors for APE training, namely, insertion, deletion, substitution and shifting/reordering noise to attain 53.77 BLEU score.

The other submissions to the WMT'20 task used variations of the language models to generate edits. Lee et al. (2020a) trained a model by jointly optimizing losses for masked language and translation language models while Lee (2020) tailored a language model to make corrections by replacing poor quality words to improve the overall sentence-level quality. These two submissions were able to get 55.67 and 53.82 BLEU scores respectively on the WMT'20 development set.

In comparison, our model is a pre-trained MT model adapted to the target domain and further fine-tuned on the APE data. These improvements give us about five absolute points gain over the no post-editing baseline (that returns MT output without changes) on the BLEU score to arrive at 55.85 which is competitive with all but one of last year's submissions on the WMT'20 development set.

Dataset	Train	Dev	Test	Domain

Table 1: WMT APE shared task data for En-De

3 Method

We describe our baseline model followed by the details of domain and task adaptation in this section.

3.1 Baseline translation model

Limited by availability of training data, we used transfer learning approach (as is common in related tasks with few samples, see Ruder et al. (2019)) beginning with a pre-trained MT model. We used the MT models from FAIR's WMT'19 submission[1] (Ng et al., 2019) that is an ensemble trained for the News Translation task using fairseq (Ott et al., 2019) library. It takes a single source sentence as input and returns translation in the target language. To use this model for the APE task, we concatenated the *source* and the *machine-translation* with a special token to make the input. Thus, we fine-tune the NMT model on the APE dataset with `source <sep> machine-translation` as input and `post-edited` reference as the output.

3.2 Pre-training on domain-specific data

FAIR's WMT'19 NMT model was trained on Newscrawl and Commoncrawl datasets while the source of this year's APE data is Wikipedia. To fix the domain mismatch in NMT model's training data and our task, we fine-tune the NMT model on WikiMatrix (Schwenk et al., 2021) before fine-tuning the model with APE data. WikiMatrix is mined from Wikipedia using the multi-lingual sentence embeddings from the LASER toolkit (Artetxe and Schwenk, 2019). We ensure that the model is fine-tuned on only high-quality parallel data by using a higher threshold of 1.1 for extracting parallel sentences (rather than the default 1.04) to get $64k$ parallel sentences.

3.3 Fine-tuning on APE data

To further address the data limitation, we use samples from earlier editions of the APE shared task; WMT'16, WMT'17 and WMT'18. Although the

Do Nothing	68.79	19.06
MT fine-tuned on WMT'21	68.74	18.45
MT fine-tuned on (WMT'16-18 + WMT'21) (A)	69.34	18.27
MT fine-tuned on WikiMatrix and further on (WMT'16-18 + WMT'21) (B)	69.12	18.34
Ensemble (A + B)	**69.38**	**18.18**

Table 2: Results on the WMT 2021 APE development set. Higher BLEU and lower TER is better. The "Ensemble" model is the ensemble of the two best performing single models (the ones with 69.12 and 69.34 BLEU scores).

Model	BLEU↑	TER↓
Do Nothing	**71.07**	18.05
Model (A)	70.54	**17.74**
Ensemble (A + B)	70.50	17.85

Table 3: Results on the WMT 2021 APE test set. Higher BLEU and lower TER is better. The Model (A) is the one described in the same from Table 2 and the "Ensemble" model is the ensemble of the two best performing single models.

domain of the data in the previous editions of this shared task challenge is different from the current one, we preferred using this data over synthetic APE data similar to (Yang et al., 2020). We prefer this because unlike in WMT datasets where the post-edits are human revisions of the MT output, synthetic APE datasets have post-edited sentences independent of the MT output, causing the error patterns and data distributions to vary significantly. Hence, we combine the WMT'16, WMT'17 and WMT'18 datasets to get $45k$ *source*, *machine-translation* and *post-edit* triplets. We present the details of the data in Table 1.

4 Results and conclusion

We report the results of our model on the WMT'21 development and test set. We use BLEU scores (Papineni et al., 2002) [2] for quality estimates relative to a human reference and TER scores (Snover et al., 2006) for quantifying human post-editing effort.

We report improvements over the `Do Nothing` baseline. This baseline refers to the system that returns the base machine translation output as the post-edit without any changes. We submitted the best performing single model and the ensemble model in Table 2 for evaluation. In Table 3 we present the results reported by the organizers for baseline, our model fine tuned on WMT'16-18 + WMT'21 (model A) and our ensemble model (A + B). The Do Nothing baseline from last year (Chatterjee et al., 2020) was reported at 50.21 BLEU score and this year it is reported at 71.07 BLEU score. These numbers suggest that the baseline machine translation engine used in this year's task proved to be of very high quality for the dataset used; leaving very little room for APE models to improve the translation similar to the observation made in (Chatterjee et al., 2018). This is the only logical conclusion we could draw since the data used last year and this year are the same with human post-editing re-done. Using data from previous years' tasks clearly improves both BLEU and TER scores on the development set. While fine-tuning on WikiMatrix data itself has not led to improvements on the development set, it helps improve performance when used in ensemble with the other model. The model A beats the baseline on TER metric by 0.31 points on the test set while both our model A and ensemble system manage to outperform previous year's best entry.

Further extending this work, we wish to study more carefully the impact of adaptation by switching the order of domain and task adaptation, effect of noise in training sample by tuning threshold (Wieting and Gimpel, 2018), and evaluate if synthetic data can be selectively augmented for greater metric gains.

ISTIC's Triangular Machine Translation System for WMT' 2021

Hangcheng Guo, Wenbin Liu, Yanqing He*, Tian Lan,

Abstract

This paper describes the ISTIC's submission to the Triangular Machine Translation Task of Russian-to-Chinese machine translation for WMT' 2021. In order to fully utilize the provided corpora and promote the translation performance from Russian to Chinese, the pivot method is used in our system which pipelines the Russian-to-English translator and the English-to-Chinese translator to form a Russian-to-Chinese translator. Our system is based on the Transformer architecture and several effective strategies are adopted to improve the quality of translation, including corpus filtering, data pre-processing, system combination, model averaging, model ensemble and reranking.

1 Introduction

The Institute of Scientific and Technical Information of China (ISTIC) participated in the Triangular Machine Translation Task of Russian-to-Chinese in the Sixth Conference on Machine Translation[1] (WMT' 2021). This paper demonstrates the overall framework of the ISTIC's submission and its technical details.

In this evaluation, we adopted the neural machine translation architecture of Google Transformer(Vaswani et al., 2017) as a part of our system. We use the three parallel corpora released by the evaluation organizer and adopted a two-stage method for data pre-processing. Several filtering methods of the corpus are explored to reduce the data noise and improve the data quality. As for model construction, we use the pivot method to get a Russian-to-Chinese translator by bridging the trained Russian-to-English translator and English-to-Chinese translator. Model averaging(Claeskens and Hjort, 2008), model ensemble(Lutellier et al., 2020) and reranking(Ng et al., 2019) strategies are adopted to generate the final output translation. We removed spaces between words and restored the target language translation results to the prescribed file format in data post-processing. In our experiment, the performance of the system under different settings was compared and further analyzed the experimental results.

The structure of this paper is as follows: the second part introduces the technical architecture of our machine translation system; the third part describes the data pre-processing, parameter settings, experimental results, and related analysis; the fourth part gives the conclusion and future work.

2 System Overview

The overall framework of the ISTIC's triangular machine translation system is shown in Figure 1.

2.1 Single Transformer System

Our baseline single system used in participated evaluation tasks is the Transformer based encoder-decoder architecture. Transformer is completely based on a self-attention mechanism. It can achieve algorithm parallelism, speed up model training, further alleviate long-distance dependence and improve translation quality(Zhang and Zong, 2020). The encoder and the decoder are formed by stacking N identical layer blocks, where N is set to 6.

2.2 Context-based Combination System

As shown in Figure 2, based on the Transformer model, our team adopts a context-based(Voita et al., 2018) system combination method, which is an encoder-decoder structure composed of n identical network layers, where n is set to 6. Two different methods of system combination are designed according to the fusion in different positions, which are Encoder Combination method and Decoder Combination method. Both of them adopt multi-encoder(Li et al., 2020) to encode the source sen-

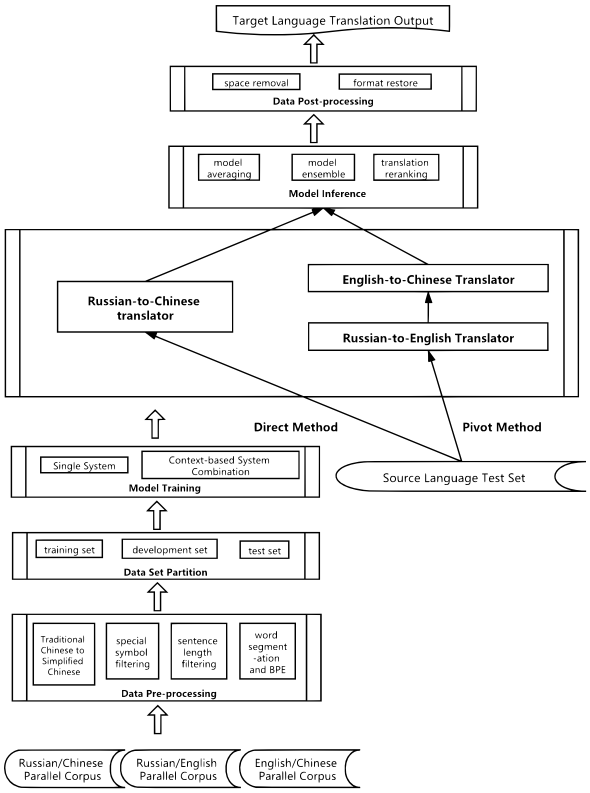

Figure 1: Overall framework

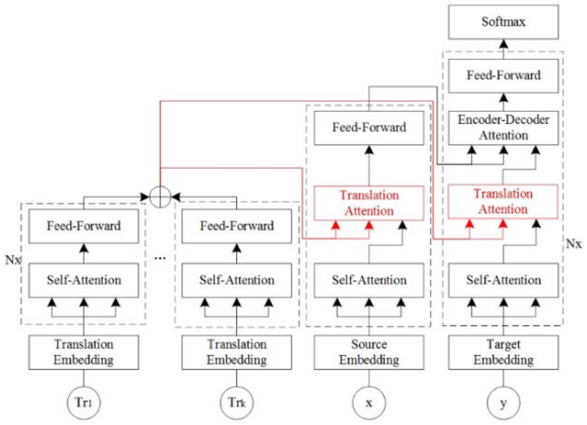

Figure 2: Context-based combination system

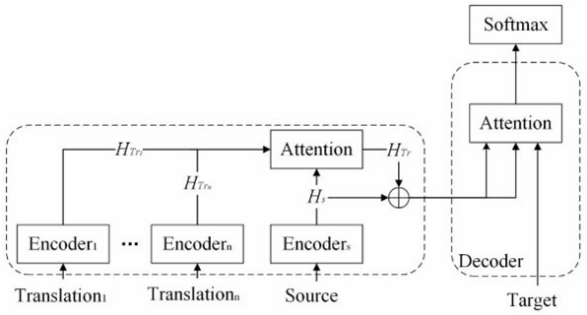

Figure 3: Encoder combination model

tences and the context information from machine translation results of the source sentence. In the Encoder Combination method, the hidden layer information of context (multi-system translation) is transformed into new representation through attention network, and merges the hidden layer information of source sentence through gating mechanism at encoder end; In Decoder Combination method, the hidden layer information of multi-system translation and the hidden layer information of source sentence is calculated at the decoder to obtain the fusion vector. The attention calculation method is the same as the original transformer model, to obtain a higher quality fusion translation.

The Encoder Combination model (see Figure 3) uses multiple system translations, and then converts the system translations into new representations through the attention network, integrating the hidden layer information of homologous language sentences for attention fusion through the gating mechanism in the Encoder. In the Encoder Combination mode and the Self-Attention of the multi-system translation Encoder, Q, K, and V are all from the upper layer output of the multi-system translation Encoder; in the Self-Attention of the source language Encoder, Q, K, and V are all from the upper layer output of the source language Encoder; in the Translation Attention of the source language Encoder, both K and V come from the upper hidden layer state H_{T_r} of the multi-system translation Encoder, and Q comes from the upper layer hidden state H_s of the source language Encoder. H_s represents the hidden state of the source language sentence, H_{T_r} represents the hidden state of the multi-system translation, and H represents the hidden state of the Translation Attention part of the Encoder.

$$H_{T_r} = Concat(H_{T_r1}, ..., H_{T_rn}) \quad (1)$$

$$H = MutiHead(H_{T_r}, H_s) \quad (2)$$

The Decoder Combination model (see Figure 4) combines the hidden layer information of multiple encoders with attention in the decoder. The Decoder can process multiple encoders separately, and then fuse them using the gating mechanism inside the Decoder to obtain the combined vector. In the Decoder Combination mode and the Self-Attention of the target language Decoder, Q, K, and V are all from the output of the previous layer of the target language Decoder; in the Translation Attention of the target language Decoder, Q comes from the

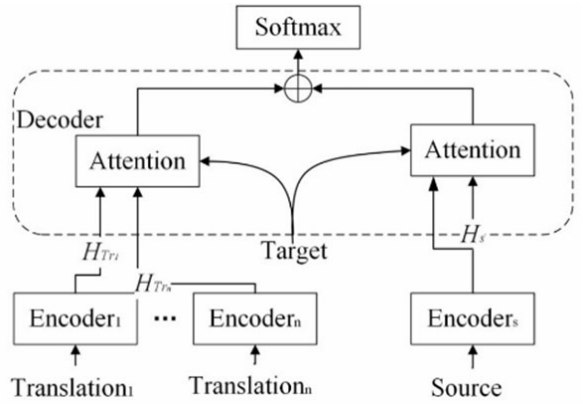

Figure 4: Decoder combination model

output of the upper layer of the target language Decoder, K comes from the upper hidden layer state H_s of the source language Encoder, and V comes from the upper hidden layer state H_{T_r} of the multi-system translation Encoder; in the Encoder-Decoder Attention of the target language Decoder, Q comes from the upper layer output of the target language Decoder, K, V come from the previous output of the source language Encoder. H_s represents the hidden layer state of the source language sentence, H_{T_r} represents the hidden layer state of the multi-system translation, $H_{Decoder}$ represents the hidden layer state of the upper layer output of the Decoder, and H represents the hidden state of the Translation Attention part of the Decoder.

$$H = MutiHead(H_{T_r}, H_s, H_{Decoder}) \quad (3)$$

2.3 Direct Method

In the direct method (see Figure 5), we use the pre-processed Russian/Chinese parallel corpus to train a direct Russian-to-Chinese translator by means of the single Transformer System or the context-based Combination System, depending on which kind of system performs best.

2.4 Pivot Method

In the pivot method (see Figure 5)(Park and Zhao, 2019), firstly, we use the pre-processed Russian/English parallel corpus to train a Russian-to-English translator; secondly, we use the pre-processed English/Chinese parallel corpus to train an English-to-Chinese translator; finally, we pipeline them to form a pivot Russian-to-Chinese translator. All translators can be trained by means of the single Transformer System or the context-based Combination System. By comparing the

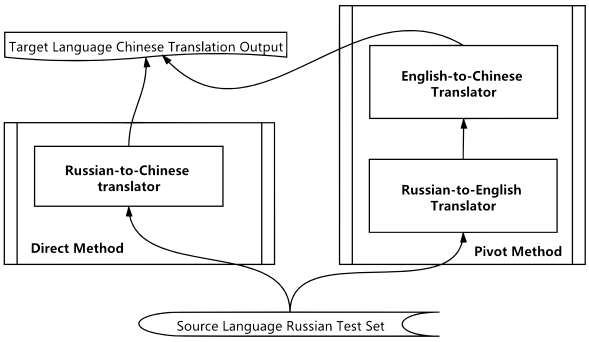

Figure 5: Direct and pivot method

experimental results, the system with optimal performance is accepted for Russian-to-Chinese translation.

3 Experiments

3.1 Data Pre-processing

The evaluation organizers provide three parallel corpora: the Chinese/Russian corpus is crawled from the web and aligned at the segment level, and combined with different public resources; the Chinese/English corpus combines several public resources; the Russian/English corpus gathers multiple public resources. A two-stage method(Wei et al., 2020) is used for data pre-processing, consist of a general pre-processing stage and a specific pre-processing stage. The general pre-processing stage includes conversion from traditional Chinese to simplified Chinese by the hanziconv[2] package , conversion between full angle and half-angle, special character filtering, same content filtering, sentence length filtering, and sentence length ratio filtering. Among them, sentence length of the Chinese language is calculated in the unit of "character" and sentence length of non-Chinese language is calculated in the unit of "token". Sentence length filtering removes sentence pairs which source sentence length or target sentence length exceeds the range of [5, 200]. Sentence length ratio filtering excludes the sentence pairs whose ratio of source sentence length and target sentence length exceeds the range of [0.2, 20]. In the specific pre-processing stage, the word segmentation of English and Chinese sentences is implemented using the lexical tool Urheen[3] and the word segmentation of Russian sentences is implemented using the lexical

After data preprocessing, we split the corpora into training set, development set and test set. The scales of the data partition are shown in Table 2.

3.2 System Settings

The open-source project fairseq[5](Ott et al., 2019) is chosen for this evaluation system. The main parameters are set as follows. Each model uses 1-3 GPUs for training, and the batch size is 2048. The embedding size and hidden size are set to 1024, the dimension of the feed-forward layer is 4096. We use six self-attention layers for both encoder and decoder, and the multi-head self-attention mechanism has 16 heads. The dropout mechanism(Provilkov et al., 2020) was adopted, and dropout probabilities are set to 0.3. BPE(Sennrich et al., 2016) is used in all experiments, where the merge operations is set to 32000. The maximum number of tokens is set to 4096. The loss function is set to "$label\_smoothed\_cross\_entropy$". The parameter "$adam\_betas$" is set to (0.9, 0.997). For the baseline system, the initial learning rate is 0.0007, the warm-up steps are set to 4000, and the maximum epoch number is set to 15. For the Encoder Combination system and Decoder Combination system[6], the initial learning rate is 0.0001, the warm-up steps are set to 4000, and the maximum epoch number is set to 10.

3.3 Experimental results

In the training of Russian-to-English translator, English-to-Chinese translator and Russian-to-Chinese translator, the single Transformer systems

are trained for 15 epochs. The context-based combination systems with Encoder Combination model or Decoder Combination model are trained for 10 epochs. The best epoch model and the last epoch model are ensembled to generate better results. The BLEU(Papineni et al., 2002) scoring results on the self-built test set are shown in Table 3.

The context-based combination systems with Decoder Combination model are used as our final submission since they outperform other systems.

Our primary submission uses the pivot method, which use English translation as the bridge. The Russian sentences are translated into English intermediate results by the well-trained Russian-to-English translator and then the English intermediate results are translated into Chinese output by the well-trained English-to-Chinese translator. Our contrast submission uses the direct method, which uses the well-trained Russian-to-Chinese translator to generate the target output.

As a result, our primary submission achieves a BLEU score of 19.2 and ranked the fourth among all participating teams. Our contrast submission achieves a BLEU score of 18.1 (shown in Table 4).

4 Conclusions

This paper introduces the main technologies and methods of ISTIC's submission in WMT 2021. To sum up, our model is constructed on the Transformer architecture of self-attention mechanism and context-based system combination method. In the aspect of data pre-processing, we explore several corpus filtering methods. In the process of translation output, the strategies of model ensemble and reranking are adopted. Experimental results show that these methods can effectively improve the quality of translation. It is worth mentioning that the pivot language translation bridge method

outperforms the direct translation method.

Abstract

This paper presents the submission of Huawei Translation Service Center (HW-TSC) to WMT 2021 Triangular MT Shared Task. We participate in the Russian-to-Chinese task under the constrained condition. We use Transformer architecture and obtain the best performance via a variant with larger parameter sizes. We perform detailed data pre-processing and filtering on the provided large-scale bilingual data. Several strategies are used to train our models, such as Multilingual Translation, Back Translation, Forward Translation, Data Denoising, Average Checkpoint, Ensemble, Fine-tuning, etc. Our system obtains 32.5 BLEU on the dev set and 27.7 BLEU on the test set, the highest score among all submissions.

1 Introduction

This paper introduces our submission to the WMT21 Triangular task. We adopt Transformer (Vaswani et al., 2017) architecture and strictly obey the constrained condition in terms of data usage. On one hand, we perform multiple data filtering strategies to enhance data quality; on the other hand, we leverage multilingual model (Johnson et al., 2017), pivot language, forward (Wu et al., 2019) and back translation (Edunov et al., 2018), and data denoising (Wang et al., 2018) strategies to further enhance training effects. In addition, we also adopt fine-tuning (Sun et al., 2019) and ensemble (Garmash and Monz, 2016), two widely used strategies, to further enhance system performance. We compare and contrast different strategies based on our experiment results and give our analysis accordingly.

The overall training process is illustrated in Figure 1. Section 2 mainly focuses on our training techniques, including model architecture, data processing and training strategies. Section 3 describes our experiment settings and training process. Section 4 presents the experiment results while section 5 analyze how our multilingual, data denoise and data augmentation strategies influence system performances.

2 Method

2.1 Model Architecture

Our system uses Transformer (Vaswani et al., 2017) model architecture, which adopts full self-attention mechanism to realize algorithm parallelism, accelerate model training speed, and improve translation quality. In this shared task, Transformer-Deep (Wang et al., 2019) is used, which features 35-layer encoder, 6-layer decoder, 768 dimensions of word vector, 3072-hidden-state, 16-head self-attention, and pre-norm.

2.2 Data Processing an Augmentation

We strictly comply with the constrained condition and use only the officially provided data.

2.2.1 Data Filtering

We perform the following steps to cleanse all data:

- Filter out repeated sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Convert XML escape characters.
- Normalize punctuations using Moses (Koehn et al., 2007).
- Delete html tags, non-UTF-8 characters, unicode characters and invisible characters.
- Filter out sentences with mismatched parentheses and quotation marks; sentences of which punctuation percentage exceeds 0.3; sentences with the character-to-word ratio greater than 12 or less than 1.5; sentences of which the source-to-target token ratio higher

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 325–330

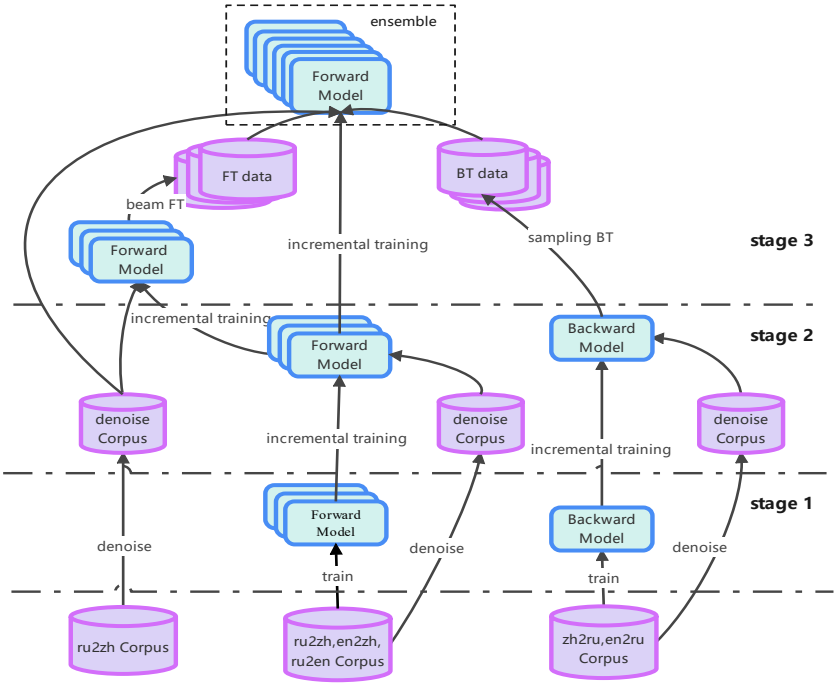

Figure 1: This figure shows the training process for the WMT 2021 Triangular MT Shared Task, which consists of three stages. In stage 1, three forward models and one backward model are trained. In stage 2, denoise corpus is used to train models incrementally. In stage 3, the synthetic data by FTST and denoise corpus are used to train models incrementally. Finally, model ensemble is used to boost the performance.

than 3 or lowers than 0.3; sentences with more than 120 tokens.

- Apply langid (Joulin et al., 2016b,a) to filter sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter sentence pairs with poor alignment, about 10% of the data is filtered.

We perform the additional steps to process Chinese data:

- Convert traditional Chinese characters to simplified ones.
- Convert fullwidth forms to halfwidth forms.

Data sizes before and after cleansing are listed in Table 1.

2.2.2 Data Augmentation

Back-translation (Edunov et al., 2018) is an effective way to boost translation quality by using monolingual data to generate synthetic training parallel data. As described in (Wu et al., 2019), similar to back translation, the monolingual corpus in source language can also be used to generate forward translation text with a trained MT model, and the generated forward and backward translation data can both be merged with the authentic bilingual data. This strategy can increase the data size to a large extent.

Since there is no officially provided monolingual data, we use the target side of en2zh data and the source side of zh2ru data filtered out in section 2.2.1 for back translation. We adopt the top-k sampling method. Then, we use the source side of ru2en data for forward translation, which is done based on beam search. Through sampling, we ensure that the sizes of data generated by forward and back translation are relatively equal. In this paper, we refer to the combination of forward and sampling back translation as FTST.

2.2.3 Filter Using LaBSE

Apart from the commonly used data cleansing methods, we also explore other techniques based on neural networks. LaBSE (Feng et al., 2020) is a multilingual BERT embedding model that can measure semantic similarities across languages. In our experiment, we notice that traditional data cleansing methods described in section 2.2.1 are unable to produce high-quality data, so we further filter the data using pre-training model LaBSE. For all parallel data, we calculated the similarity scores and

language pair	Raw data	Data Filtering	Filter Using LaBSE
en-zh	28.6M	14.7M	13.3M
en-ru	69.2M	45.1M	36.0M
ru-zh	33.4M	19.1M	14.7M

Table 1: Data sizes before and after filtering by different methods.

filtered out sentence pairs below a threshold. For Russian-Chinese data, the threshold is set to 0.7. For Russian-English and English-Chinese data, the threshold is set to 0.8. Our experiment integrates data denoising into the training process. The data size filtered by LaBSE is shown in table 1.

2.3 Multilingual Model

Johnson et al. (2017) proposes a simple solution that uses a single Neural Machine Translation (NMT) model to translate among multiple languages, and the model requires no change to the model architecture. Instead, the model introduces an artificial token at the beginning of the input sentence to specify the required target language. All languages use a shared vocabulary. There is no need to add more parameters. Surprisingly, experiments show that such model design can achieve better translation qualities across languages. In our experiment, we use two multilingual systems: forward model using ru2zh, en2zh, and ru2en data, and backward model using zh2ru and en2ru data.

2.4 Denoising Training

Wang et al. (2018) find that during training, dynamically adjusting noise data can boost system performance. The core idea is to train the model with noisy data at the initial stages and clearer data at later stages till the model converges. The quality of training data in this task is relatively poor as most of the data are crawled from website. We consider denoising training is suitable in this scenario. We simplify the denoising training process in our experiment, divide the training process into several stages.

For forward model, the training is divided into three steps: 1) Use all official provided data in three directions (ru2zh, en2zh, and ru2en) for training; 2) Use all clean data selected by LaBSE for incremental training; 3) Finally, use ru2zh clean data selected by LaBSE for incremental training.

For backward model, we only perform two steps: 1) Use all data (en2ru, zh2ru) for training; 2) Use zh2ru clean data selected by LaBSE for incremental training.

2.5 Fine-tuning and Ensemble

To achieve better results, fine-tuning with small-size in-domain data is necessary (Sun et al., 2019). An effective strategy for fine-tuning is to leverage the dev set available in this task. The fine-tuning strategies employed in our experiment include: 1) Add noise to the target side of the dev set to generate synthetic training data (Meng et al., 2020); 2) Use multiple models to generate synthetic data through beam search decoding, and then add synthetic data to the dev test for fine-tuning.

Model ensemble is also a widely used technique in previous WMT workshops (Garmash and Monz, 2016), which can boost the performance by combining the predictions of several models at each decoding step. We selected the best four models from the six we trained for ensemble.

3 Settings

3.1 Experiment Settings

We use the open-source fairseq (Ott et al., 2019) for training, and use sacreBLEU (Post, 2018) to measure system performances instead of the BLEU script mentioned in the task. The main parameters are as follows: Each model is trained using 8 GPUs. The size of each batch is set as 2048, parameter update frequency as 32, learning rate as 5e-4 (Vaswani et al., 2017) and label smoothing as 0.1 (Szegedy et al., 2016). The number of warmup steps is 4000, and the dropout is 0.1. We employ joint sentencepiece model (Kudo and Richardson, 2018; Kudo, 2018) for word segmentation, with the size of the vocabulary set to 32k. Jieba tokenizer is used for Chinese word segmentation while Moses tokenizer for English and Russian word segmentation. The three languages share a vocabulary of 45K words. In the inference phase, we use the open-source marian (Junczys-Dowmunt et al., 2018) to perform decoding. The beam-size is 4 and the length penalty is set to 1.2.

System	BLEU
Data Filter	26.6
Multilingual model	29.3 (+2.7)
Full data denoise	30.0 (+0.7)
FTST + ru-zh denoise	31.9 (+1.9)
Ensemble	32.5 (+0.6)
2021 Final submit	27.7

Table 2: The experimental result of system

Training Strategy	Train Data	BLEU
Baseline	ru2zh	26.6
Enhanced target	+en2zh	28.7 (+2.1)
Enhanced target and source	+ru2en	29.3 (+0.6)
All Direction	+zh2ru zh2en en2ru	29.2 (-0.1)

Table 3: The experimental result of Multilingual Model

3.2 Training Process

We combine multi-stage denoising training with data augmentation methods. Figure 1 illustrates our training process:

1) We cleanse the training data using methods mentioned in 2.2.1 and train three forward models and one backward model.

2) We further denoise data using LaBSE (as mentioned in 2.2.3) and conduct denoising training until the model converge on the dev set.

3) We perform data augmentation as described in 2.2.2. We collect a total of 45M Russian monolingual data and split them into three sets, each with 15M sentences. We use three different forward models to generate three sets of training data. Hoping to add diversity to incremental training, we use the data synthesized by one model to train the other two models. For example, we use the synthetic data generated by forward model A to incremental train forward model B, C and so on. We also collect a total of 15M Chinese monolingual data and back translate the data using the backward model. We repeat back translation for three times and obtain three sets of back translation data. We incrementally train six models using the above synthetic data.

4) We average the last 5 checkpoints of each model and select the best four from the six models we trained for final ensemble.

4 Experiment Result

Our overall training strategy is to train a baseline model, conduct incremental training with techniques such as multilingual model, denoise training, data augmentation, and fine-tuning. Our submitted results come from ensembled models. Table 2 lists the results of our submission on dev set. Comparing with the baseline model, our final submission achieves an increase of 5.9 BLEU. Our baseline model is trained with data processed with methods mentioned in section 2.2.1. The BLEU score of the baseline model on the dev set is 26.6. Comparing with the baseline model, our multilingual strategy leads to a huge improvement of 2.7 BLEU. Our simplified denoising training strategy contributes to an increase of 0.7 BLEU. It should be noted that data augmentation techniques (FTST method and LaBSE denoising on ru2zh data) also result in a significant increase of 1.9 BLEU. Finally, an increase of 0.6 BLEU is gained via ensemble. Our submitted system gain 32.5 BLEU on the dev set, which demonstrate the effectiveness of our multiple strategies. According to the organizer's feedback, our submitted model gains 27.7 BLEU on the WMT21 test set.

5 Analysis

5.1 Multilingual Model and Model Performance

Our experiment results demonstrate that multilingual model has positive effects on system performance. We have experimented on different multilingual models and compare their results. Table 3 lists the results of different multilingual models. Compared with the baseline model, the multilingual model obtains 2.1 BLEU increase after adding en2zh data for training. A further 0.6 BLEU is achieved after adding the ru2en data, demonstrating that adding Russian data at the source side can optimize the encoder.

However, our experiment shows no improvement after adding data of other three directions. We adopt the enhanced target and source strategy for faster training, as training with all data might be considerably slow.

Training Strategy	BLEU
Baseline	26.6
+ru2zh denoise	28.0 (+1.4)
Enhanced target and source	29.3
+Full-data denoise	30.0 (+0.7)
+ru-zh denoise	30.5 (+0.5)

Table 4: The experimental result of denoising training

Training Strategy	BLEU
Enhanced target and source	29.3
Sampling BT	30.0
Beam BT	29.7
FT	29.7
Pivot FT	29.5
FTST	30.5

Table 5: The experimental result of data augmentation

5.2 Denoising Training and System Performance

Our experiment also demonstrates the contribution of denoising training to system performance. Table 4 compares the results of baseline and denoising training model, from which we can see an increase of 1.4 BLEU. We further compare the results measured at the three stages of denoising training. We use the enhanced target and source model to conduct simplified denoising training. Our experiment shows that full-data denoising training leads to an increase of 0.7 BLEU while ru2zh data denoising further leads to an increase of 0.5 BLEU. The experimental results show that the denoise strategy is effective and can lead to at least 1 BLEU improvement even after multilingual model enhancement.

5.3 Data Augmentation and System Performance

Data augmentation strategy also leads to huge BLEU improvements. We try multiple data augmentation strategies, including back translation (BT), forward translation (FT), FTST (2.2.2). Sampling BT means sampling from the model conditional distribution and beam BT means using beam search, when generating synthetic data. Table 5 shows the effects of different data enhancement methods. Our results show that sampling back translation can lead to better results (about 0.3 BLEU in our experiment). We also conduct two forward translation experiments: FT is translating Russian to Chinese directly, and Pivot FT is using English as the pivot language, which achieve only an undesirable result. We then using the FTST method and gain the best result with a BLEU score of 30.5. The experimental results show that the combination of sampling BT and FT data (FTST) can produce the best data augmentation effect.

6 Conclusion

This paper presents HW-TSC's submission to WMT21 Triangular Machine Translation Task. In general, we use Transformer architecture and explore multiple data filtering and selection methods. In terms of training and data processing strategies, multilingual model, denoising training, data augmentation, and FTST we used can effectively improve system performance. Our final result achieves an increase of 5.9 BLEU when comparing baseline model on the dev set and gain a BLEU score of 27.7 on the test which is the highest among all submissions.

Abstract

This paper describes DUT-NLP Lab's submission to the WMT-21 triangular machine translation shared task. The participants are not allowed to use other data and the translation direction of this task is Russian-to-Chinese. In this task, we use the Transformer as our baseline model, and integrate several techniques to enhance the performance of the baseline, including data filtering, data selection, fine-tuning, and post-editing. Further, to make use of the English resources, such as Russian/English and Chinese/English parallel data, the relationship triangle is constructed by multilingual neural machine translation systems. As a result, our submission achieves a BLEU score of 21.9 in Russian-to-Chinese.

1 Introduction

The WMT2021 Shared Task on translating sentences from Russian into Chinese provides a challenging mixed-genre test for machine translation systems and a triangular relationship for researchers to evaluate new techniques. The task focuses on translation between non-English languages and optimally mixing direct and indirect parallel resources. In this task, the participants must use only the provided parallel training data and use of other data is not allowed. The provided data is shown in Table 1, including parallel data in three directions. Given the language pair (Russian-to-Chinese), the bulk of previous NMT work has pursued one of two strategies that are illustrated in Figure 1:

Direct: Collect parallel Russian-to-Chinese data from the public resource, and train a Russian-to-Chinese translator.

Pivot: Collect parallel Russian-to-English and English-to-Chinese data (usually larger than direct data), train two translators (Russian-to-English + English-to-Chinese), and make a cascade translator from Russian to Chinese.

Direction	# SENT
Russian/Chinese	33,388,455
Russian/English	69,155,404
English/Chinese	28,528,290

Table 1: The provided training data in the constrained data track.

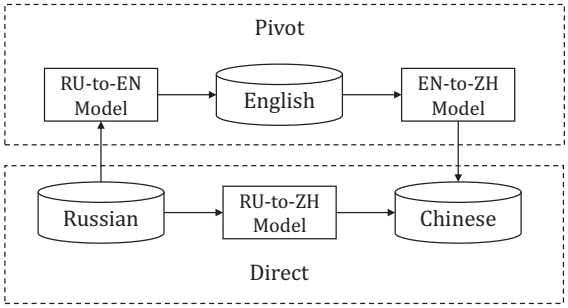

Figure 1: The illustration of two strategies for triangular machine translation.

The DUTNLP submission to the constrained data track is based on the mainstream architecture Transformer (Vaswani et al., 2017). According to the scale of datasets, this shared task should be considered as the high-resource translation direction. We use the Transformer-big setting for better performance, on the contrary, a low-resource translation task often utilizes the Transformer-base due to the limited parallel training data. Moreover, to enhance the baseline model and investigate the usage of triangular direction data, we utilize two pipelines for combining English related resources: 1) incorporates English-to-Chinese translator into direct translation process to normalize the translation of rare words. 2) adopts a multilingual training strategy to make use of English ↔ X parallel resources. Besides, some of the provided Russian ↔ Chinese parallel corpora are crawled from the

web, which has many noise issues. We filter the training bilingual corpora with several techniques, including language model and constrained rules.

This paper is structured as follows: Section 2 describes variants of models we used in the shared task. In Section 3, we introduce the system overview using several techniques for model enhancement, including data pre-processing and filtering, triangular translation strategy and fine-tuning. In Section 4, this paper presents experimental settings, main results and analysis. Finally, in Section 5 we draw a brief conclusion of our work in the WMT2021 Triangular Translation Task.

2 Model

2.1 Transformer

Recent advances in Transformer (Vaswani et al., 2017) have led to significant improvement of Neural Machine Translation (NMT) and achieve human parity on Automatic Chinese to English News Translation (Hassan et al., 2018). The Transformer adopts a sequence-to-sequence structure, using stacked encoder and decoder layers of self-attention. Each encoder layer consists of a self-attention mechanism and a feed-forward network. Each decoder layer consists of a masked self-attention layer, a cross self-attention layer, and a feed-forward network layer. Moreover, the Transformer leverages positional embedding, residual connections and layer normalization for enhancement (Ba et al., 2016). In this paper, we adopt the Transformer-big as the baseline model, in which both the encoder and decoder have 6 layers, the hidden size is 1024, and the feed-forward inner size is 4096.

2.2 Multilingual Architecture

Multilingual neural machine translation (mNMT) handles the translation between multiple languages by joint training in a multi-task setup (Johnson et al., 2017), which greatly eases the model deployment. Previous works (Lakew et al., 2018; Tan et al., 2019) show that the mNMT model can facilitate cross-lingual knowledge transfer between languages. It also enables zero-shot translation between unseen language pairs (Johnson et al., 2017; Al-Shedivat and Parikh, 2019; Zhang et al., 2020). Following Johnson et al. (2017), we build our multilingual translation system based on the advanced Transformer model by adding a pretending language token to each source sentence, which indicates the language to be translated into. And the multilingual model is also fine-tuned on pre-trained mNMT models such as mBART(Liu et al., 2020) and mRASP(Lin et al., 2020).

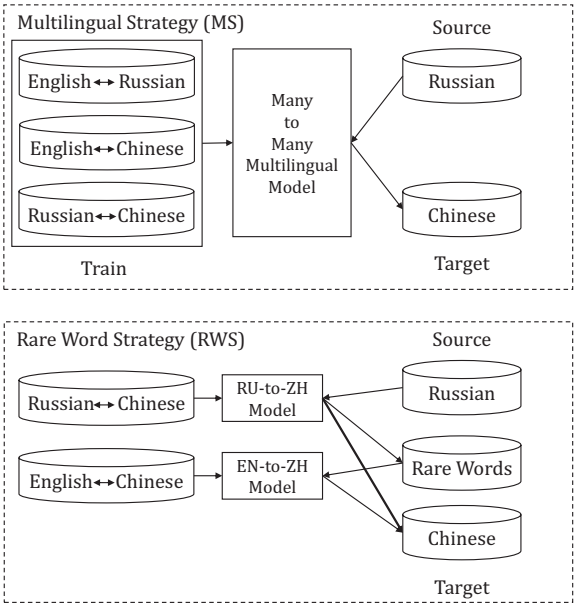

Figure 2: The illustration of two strategies for incorporating English resources into the baseline systems.

3 System Overview

3.1 Data Pre-processing and Filtering

To improve the quality of data, especially the Russian ↔ Chinese parallel data, we filter noisy data with several techniques. The flow of all training data pre-processing and filtering is set to step by step as follows:

- Punctuation normalization with Moses scripts (Koehn et al., 2007) for all language pairs.
- Chinese word segmentation using the open segmentation tool (Huang et al., 2020). Splitting the English and Russian words using clearly delimiter by Moses "tokenizer" script.
- True-casing. The uppercase letter may influence the generation of vocabulary dictionaries. We transfer the uppercase letter into lower case automatically by Moses scripts.
- Filtering out the sentence pairs longer than 256 or duplicated translation.
- Filtering out the sentences by the multilingual parallel data filter tools LASER [1].

[1]https://github.com/facebookresearch/LASER

- Filtering out the sentence according to their characteristics in terms of language identification and length ratios, in particular, the sentence pairs whose length ratio between the source and target are not in range of 1:2.5 and 2.5:1 are abandoned.

- The bilingual direct translator utilizes BPE to encode text into sub-word unit (Sennrich et al., 2016). In the multilingual translator, the system applies sub-word processing using SentencePiece tool (Kudo and Richardson, 2018).

3.2 Triangular Translation Strategy

In this task, we exploit two strategies to incorporate English resources into the baseline systems, which are shown in Figure 2.

Rare Word Strategy According to the official provided data, the performance of the direct translator is better than the pivot. And the provided parallel Russian ↔ Chinese training data can be considered as the high-resource. The baseline model can be trained successfully with the bilingual training data and can achieve competitive performance in most cases. However, the translations of rare words are always terrible by the direct translator, for example, most Russian names will be translated into English. We utilize an English ↔ Chinese translator to alleviate this issue. The external translator only works in the specific case to reduce the error propagation and redundant computational cost. This strategy is to complement the direct baseline model and improve the performance in an interpretable way.

Multilingual Strategy The mNMT models are effective in low resource settings due to knowledge transfer. To make use of all provided parallel data, we train a multilingual many-to-many models with 3 language pairs(i.e., 6 directed translation direction). However, it is expensive to train different parameter sets to get the best translation result in the target direction. According to Lin et al. (2020), mRASP can obtain more improvements with rich-resource language pairs than multilingual many-to-many models, so multilingual strategy (MS) is based on fine-tuning large-scale pre-training models. We fine-tune on two pre-trained models respectively: mBART(Liu et al., 2020) and mRASP(Lin et al., 2020). In particular, we use MS-mBART and MS-mRASP for the two methods in section 4. We use mBART to continue training on the filtered parallel data subset, and select the appropriate checkpoints according to the performance on the validation set. The mRASP model pre-trained on a dataset contains 32 English-centric language pairs, including English-Russian and English-Chinese, and Russian-Chinese are not the direct training objective of it. We stop the fine-tune process when the loss on validation does not decrease for 5 consecutive steps (measured every 50 updates). The experiment shows that fine-tuning on mRASP with filtered parallel data achieves anticipated improvements.

Models	VALID.	TEST.
Direct	20.2	17.0
Baseline	24.92	20.4
+RWS	26.40	21.8
+MS-mBART	19.47	-
+MS-mRASP	25.21	21.7

Table 2: The BLEU-4 scores in the constrained data track.

4 Experiment

4.1 Experimental Settings

The implementation of our models is based on Fairseq (Ott et al., 2019). All the models are carried out on 2 NVIDIA 3090 GPUs each of which has 24 GB of memory. The parameters of Transformer-Big, mBART, and mRASP are all followed by the architectures themselves. We use the Adam optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. The batch size is set to 4096 tokens and the "update-freq" parameter in Fairseq is set to 2. In particular, for pre-trained language models settings (i.e., mBART and mRASP), the batch size is 2048 and "update-freq" is 4. The initial learning rate is set to $5e^{-4}$ for training and $3e^{-5}$ for fine-tuning. The learning scheduler is inverse_sqrt and all the dropout probabilities are set to 0.1. We select the checkpoint with the average of the top 5 sacreBLEU scores on the development set as the final checkpoint in each training. We calculate the BLEU-4 score for all experiments, which is officially recommended.

4.2 Main Results

Table 2 shows the Triangular translation results on validation and test set. We train multiple models in each setting and report the best scores in Table

MS-mRASP: **坦布夫地区**是一个农业地区，但面临着严重的农业问题。

Figure 4: The results by different NMT systems. The rare words are bold.

2. In particular, the direct model is trained with all available data, and the Baseline utilizes the clean parallel data after filtering to train. It improves the direct method by 4.72 and 3.4 BLEU scores on validation and test set, respectively. Moreover, to make use of the English resources, we propose two triangular training strategies to investigate the effect of the triangle relationship. The rare word strategy (RWS) can effectively improve the baseline from 24.92 to 26.40 in terms of BLEU scores. And the multilingual strategy (MS) improves the baseline from 24.92 to 25.21 in terms of BLEU scores.

4.3 Triangular Translation Analysis

The official results do not open the reference on the test set. So we investigate the experiments further on the validation set.

Multilingual Models In this task, we utilize the multilingual training strategy which is fine-tuned on mBART and mRASP. It is surprising to find that the model trains failed on this dataset, which is fine-tuned on mBART, shown in Figure 3. However, the mRASP worked in this scenario. Follow by Lin et al. (2020), the mRASP is beneficial to fine-tune the high-resource language pairs. And this method (MS-mRASP) achieves the best BLEU-4 scores on the validation set. Although the training curve of MS-mBART is more stable, the overall loss has remained relatively high level and cannot be effectively declined.

Results Discussion Figure 4 shows the results from different models. The two multilingual translation strategies can effectively improve the performance of baseline model, especially for the rare words. In the baseline model, some rare words are translated into English, and most of the words are translated correctly depends on the direct training method. It is worth mentioning the two multilingual translation strategies can alleviate this issue effectively.

5 Conclusion

This paper presents the DUTNLP Translation systems for WMT2021 Russian-to-Chinese triangular translation tasks. We investigate various neural architectures and data filtering to build strong baseline systems. Then the two triangular translation strategies are used to improve the baselines. We also prove that in-domain finetuning is very effective for this translation task. Finally, we discuss the results carefully and analyze the influence of different triangular strategies for further improvement. A number of advanced technologies reported in this paper focus on alleviating the issue of triangle translation. As a result, our system outperforms the strong baseline by 1.48 and 1.4 BLEU scores on the validation set and test set, respectively. In the future, we will investigate the technologies in the low-resource scenario and continue to improve the performance of this task through post-evaluation submissions.

Abstract

In this paper, we discuss the various techniques that we used to implement the Russian-Chinese machine translation system for the Triangular MT task at WMT 2021. Neural Machine translation systems based on transformer architecture have an encoder-decoder architecture, which are trained end-to-end and require a large amount of parallel corpus to produce good quality translations. This is the reason why neural machine translation systems are referred to as *data hungry*. Such a large amount of parallel corpus is majorly available for language pairs which include English and not for non-English language pairs. This is a major problem in building neural machine translation systems for non-English language pairs. We try to utilize the resources of the English language to improve the translation of non-English language pairs. We use the pivot language, that is English, to leverage transfer learning to improve the quality of Russian-Chinese translation. Compared to the baseline transformer-based neural machine translation system, we observe that the pivot language-based transfer learning technique gives a higher BLEU score.

1 Introduction

The aim of this work is to improve the quality of Machine Translation (MT) for low-resource, distant and non-English language pairs. One of the major requirements for the good performance of the Neural Machine Translation (NMT) systems is the availability of a large parallel corpus. Such large parallel corpus of good quality is not available for low-resource, distant and non-English language pairs but mostly available for language pairs containing English. This poses a major challenge in developing good quality Machine Translation systems for non-English and distant language pairs. As a result there is a need to come up with additional resources by augmenting parallel corpora or by using knowledge from other tasks using transfer learning for translation of non-English language pairs. In this paper, we focus on leveraging the knowledge from other tasks using transfer learning to improve the performance of NMT systems for low resource language pairs.

In our pivot based transfer learning experiments we try to utilize the resources of English language, that is English-Chinese and English-Russian parallel corpora to improve the quality of Russian-Chinese translation. We implement techniques which efficiently use the resources of the English language for the task of Russian-Chinese translation.

2 Related Work

Recurrent Neural Network (RNN) based encoder decoder architectures (Bahdanau et al., 2014; Cho et al., 2014; Sutskever et al., 2014) were initially used in NMT systems. Transformer (Vaswani et al., 2017) architecture improved the performance of NMT systems. In order to enable translation between distant and non-English language pairs for which a large amount of parallel corpus is not available, a cascade method can be used. In the cascade method, two models are trained, a source language to English and a English to target language model. Then to translate a source sentence to target sentence, the source sentence is passed through the two models. (Zoph et al., 2016) introduced a transfer learning technique in which a parent model is trained on high resource language pairs, which is then used to initialize the the parameters of a child model which is then trained on low resource language pair data. (Kim et al., 2019) introduced pivot language-based transfer learning techniques in which the encoder and decoder of the model for low resource language pair is initialized using the encoder and decoder of different models trained on high resource language pairs, and this model is then finetuned on low resource language

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 336–340

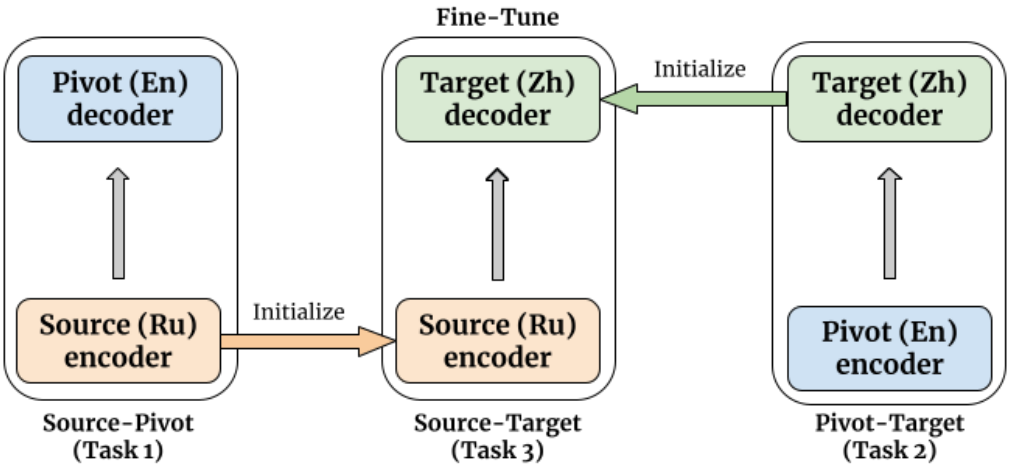

Figure 1: Direct Pivoting (En:English, Ru:Russian, Zh:Chinese)

pair data. Multi-lingual NMT systems (Zoph and Knight, 2016; Firat et al., 2016; Johnson et al., 2017) can also be used to improve the performance of low resource language pair translation as knowledge is transferred from various languages which helps the task of low resource language pair translation.

3 Approaches

In this section, we discuss the various approaches we used to build a Russian-Chinese MT system. We mainly focus on pivot-based transfer learning techniques, in which we use the resources of English to improve the quality of Russian-Chinese translation.

3.1 Baseline

The baseline Russian-Chinese model is a NMT model based on Transformer architecture. The model is trained on Russian-Chinese parallel data.

3.2 Cascade Model

The cascade model makes use of the resources of English language to train a Russian-Chinese MT system. In this approach, we train two NMT models, a source to pivot (Russian-English) model and a pivot to target (English-Chinese) model. The source Russian sentence is first translated into English using the Russian-English model. Then this English sentence is translated into Chinese using the English-Chinese model. In this way, the cascade model translates the Russian sentence to Chinese by passing it through the two NMT models. There are a few disadvantages in this cascade model based approach,

1. The source sentence is passed through two different NMT models to produce the target sentence. This doubles the decoding time for the generation of the output sentence which is very inefficient.

2. The errors in translation are propagated from first (source-pivot) model to the second (pivot-target) model.

These disadvantages of the cascade model approach make it an undesirable approach to utilize the resources of the pivot language. In order to overcome these disadvantages, we need to train a single source-target model which utilizes the resources of the pivot language. In the following pivot language-based transfer learning technique, direct pivoting, we overcome these disadvantages. In this technique, we train a single source-target model while utilizing the resources of the pivot language.

3.3 Direct Pivoting

In this technique, we first train two separate NMT models, a source-pivot model and a pivot-target model. As demonstrated in Figure 1, we first separately train a Russian-English (source-pivot) model (task 1) and a English-Chinese (pivot-target) model (task 2) on their respective parallel corpus. Then we use the encoder of the Russian-English (source-pivot) model and the decoder of

the English-Chinese (pivot-target) model to initialize the encoder and decoder of the Russian-Chinese (source-target) model respectively. Finally, we fine-tune the Russian-Chinese (source-target) model on the Russian-Chinese parallel corpus.

As in this technique we are training a single source-target (Russian-Chinese) model, there is no problem of double decoding time. The parameters of the encoder and decoder of the source-target (Russian-Chinese) model are not randomly initialized, they are trained on the source-pivot and pivot-target translation task respectively. The initialized encoder and decoder of the source-target (Russian-Chinese) model have already learned some representation or knowledge from the previous tasks. This knowledge helps in the source-target (Russian-Chinese) translation task. In this way this approach utilizes the resources of the pivot (English) language which assists in the translation task from source to target (Russian-to-Chinese).

4 Experiments

In this section, we discuss the details of all the experiments that we carried out to implement the Russian-Chinese MT system.

4.1 Dataset

The NMT systems were trained on the parallel corpora provided by the WMT 2021 organizers. We used the Russian-Chinese, Russian-English, and the Chinese-English parallel corpus. We used a subset of the provided parallel corpora for training the models. Byte Pair Encoding (BPE) (Sennrich et al., 2015) is used as a segmentation technique. The words in the data are broken down into sub-words using the BPE technique. For the baseline model the number of BPE merge operations used were 16000 for the source and target data. For the direct pivoting model, the source and target vocabulary are combined English-Russian and English-Chinese vocabulary, respectively. So, the BPE codes are computed by combining the source side Russian and English data for source and the target side English and Chinese data for target. The number of BPE merge operations used were 32000 for the source and target data. The detailed corpora statistics are mentioned in Table 1.

Language pair	Number of sentences
Russian-Chinese	10M
Russian-English	10M
English-Chinese	10M

Table 1: Corpora statistics of all the language pairs

4.2 Models

For all the experiments, Transformer architecture was used. The encoder of the Transformer consisted of 6 encoder layers and 8 encoder attention heads. The encoder used embeddings of dimension 512. The decoder of the Transformer consisted of 6 decoder layers and 8 decoder attention heads. For the implementation of all models, fairseq (Ott et al., 2019) library was used.

4.3 Training Setup

For all experiments, the transformer model from fairseq library was used. The optimizer used was adam with betas (0.9, 0.98). The inverse square root learning rate scheduler was used with an initial learning rate of 5e-4 and 4000 warm-up updates. The criterion used was label smoothed cross entropy with label smoothing of 0.1. The dropout probability value used was 0.3 for all layers. For the baseline model, the size of source (Russian) and target (Chinese) vocabulary is 16876 and 29500, respectively. For the direct pivoting model, the size of source (combined Russian-English) and target (combined English-Chinese) vocabulary is 34020 and 47052, respectively. The best model for all the techniques was chosen by calculating the BLEU (Papineni et al., 2002) scores on the development set provided by the WMT 2021 organizers and the choosing the model with best BLEU score.

4.4 Baseline

The baseline model is a transformer model trained on Russian-Chinese (source-target) parallel corpus.

4.5 Cascade Model

The cascade model consists of two NMT models trained separately. The first model is a Russian-English model trained on Russian-English parallel corpus. The second model is a English-Chinese model trained on English-Chinese parallel corpus. For translating a Russian sentence to Chinese, the sentence is passed through two models.

4.6 Direct Pivoting

The direct pivoting model uses a shared vocabulary of Russian-English (source-pivot) on the encoder side and English-Chinese (pivot-target) on the decoder side. This is done to ensure that the

Model	BLEU score
Baseline	18.2
Cascade	17.2
Direct Pivoting	18.8

Table 2: BLEU scores of Russian-Chinese NMT system using different techniques

encoder and decoder parameters are transferable as transformers are fixed vocabulary models. The Russian-English (source-pivot) model is trained on Russian-English parallel data and the English-Chinese (pivot-target) model is trained on English-Chinese parallel data. Then the encoder of Russian-English model and decoder of English-Chinese model is used to initialize the encoder and decoder of Russian-Chinese (source-target) model. Finally, we fine-tune the Russian-Chinese model on the Russian-Chinese parallel data.

5 Results and Analysis

The evaluation of the models were performed on the basis of the BLEU scores. These BLEU scores were calculated and provided by the WMT 2021 organizers. The BLEU scores were calculated on a test set provided by WMT 2021 organizers, which consisted of 1751 sentences. Table 2 shows the BLEU scores of all the models. The baseline Russian-Chinese model produced a BLEU score of 18.2. The cascade model in which the Russian sentence is first translated to English using Russian-English model and then the English sentence is translated to Chinese using the English-Chinese model, produced a BLEU score of 17.2. The possible reason for this decrease in BLEU score is that the errors made by the Russian-English model are propagated to the English-Chinese model, which further introduced its own errors. As the source sentence is passed through the two model each model introduces its own errors, which decreases the BLEU score.

The direct pivoting model produced a BLEU score of 18.8 which improved the BLEU score by 0.6 points over the baseline model. This increase in BLEU score is because the encoder and decoder of the Russian-Chinese model are not randomly initialized; but they are initialized from the encoder and decoder of Russian-English and English-Chinese model respectively. Then the model is fine-tuned on Russian-Chinese parallel corpus. The encoder and decoder have already learnt some representations which helps in the task of Russian-Chinese translation. Also as this is a single NMT model, there is no problem of propagation of errors or double decoding time.

6 Conclusion and Future Work

In this work, we implement and compared pivot language-based transfer learning technique to improve the task of translation between non-English language pair, that is Russian-Chinese. We observe that pivot language-based transfer learning technique improves the BLEU score over the baseline model and is an efficient way to use the resources of the pivot language. We also observe that the pivot language-based transfer learning technique mitigates the problems of double decoding time and error propagation present in simple cascade-based models.

In future, we plan to explore various data augmentation techniques that can make use of the resources of the English language to augment data for the task of translation of non-English language pair translation. We also plan to use various language model pretraining techniques like Masked Sequence to Sequence Pre-training (MASS) to pretrain the encoder and decoder before using them for the downstream task of translation.

Abstract

This paper describes Naver Papago's submission to the WMT21 shared triangular MT task to enhance the non-English MT system with tri-language parallel data. The provided parallel data are Russian-Chinese (direct), Russian-English (indirect), and English-Chinese (indirect) data. This task aims to improve the quality of the Russian-to-Chinese MT system by exploiting the direct and indirect parallel resources. The direct parallel data is noisy data crawled from the web. To alleviate the issue, we conduct extensive experiments to find effective data filtering methods. With the empirical knowledge that the performance of bilingual MT is better than multi-lingual MT and related experiment results, we approach this task as bilingual MT, where the two indirect data are transformed to direct data. In addition, we use the Transformer, a robust translation model, as our baseline and integrate several techniques, averaging checkpoints, model ensemble, and re-ranking. Our final system provides a 12.7 BLEU points improvement over a baseline system on the WMT21 triangular MT development set. In the official evaluation of the test set, ours is ranked 2nd in terms of BLEU scores.

1 Introduction

We participate in the WMT21 triangular machine translation task, using the direct and indirect parallel data to improve Russian-to-Chinese machine translation. The provided data consists of one noisy web corpus (Russian-Chinese, direct translation) and two combined bitexts from several public resources (English-Chinese/Russian, indirect). Such cases frequently occur in both actual translation services and research. In particular, this task is crucial in scenarios where we need to improve the performance of non-English translations or low-resource languages with high-resource parallel data.

Previous works deal with the triangular MT using several methods such as pivot-translation (Cheng et al., 2017), transfer learning (Kim et al., 2019), pre-trained multi-lingual MT (Liu et al., 2020; Tang et al., 2020) and so on.

In this paper, we explore existing novel techniques to integrate them for the triangular MT tasks. The original direct parallel degrades the translation quality of the model due to the noisy parts containing not well-aligned sentence pairs, erroneous characters, or the wrong language ID. To discard the noise parts of the noisy web corpus, we filter out data with sequence length, length ratio, language ID, de-duplication, and the sentence similarity computed with pre-trained multi-lingual language model (LaBSE, Feng et al., 2020). In preliminary experiments, we approached this task in three main ways: bilingual MT, multi-lingual MT, and fine-tuning the pre-trained multi-lingual translation model (i.e., mBART). As shown in Section 4, we found that the bilingual MT outperforms the others. Thus, to augment the Russian-to-Chinese corpus, we conduct two types of data augmentation: (1) back-translation on the discarded monolingual Chinese data from noise-refining steps and (2) translation using English as pivot language on two indirect bilingual data (e.g., feed English of English-Chinese data to English-to-Russian translation model to augment Russian-Chinese data). In detail, we generate the synthetic data by using different decoding methods such as beam search, sampling, and adding noise to beam search outputs. Our submission systems use 12-layer Transformer architecture. Furthermore, we exploit ensemble, averaging checkpoints, and noisy-channel re-ranking techniques to mitigate the over-fitting problem or improve the generalization capability in the test set.

To find suitable methods for triangular MT, we conduct extensive experiments, where all neural machine translation (NMT) systems are evaluated against the development set released in the WMT21

triangular MT shared task. Our final submission improves about 12.7 and 8.9 BLEU points compared to the organizer's baseline system on the development set and test set, respectively.

2 Approaches

2.1 Data Pre-processing

On all three corpora, we apply data normalization such as unifying punctuation marks and parentheses. For Chinese, we convert the traditional Chinese to Simplified Chinese using the open-source toolkit HanziConv[1] For all languages, we apply a language-specific tokenizer as a pre-tokenization step. We use NLTK[2] for English and Russian, jieba[3] for Chinese. And then, we apply joint multilingual Byte-Pair Encoding (BPE, Sennrich et al. 2016) to the pre-tokenized corpus with 75K merge-operations and 10K character limitation using the open-source toolkit Transformers[4].

2.2 Data Filtering

The provided parallel corpus contains a certain amount of noisy parts, which affects the translation quality. Thus, we eliminate noisy parts with the following heuristics rules:

- *Filtering out sentence pairs containing more than 256 tokens.
- *Filtering out sentence pairs consisting of characters of other languages than a predefined threshold. For this sake, we use an in-house language detector. We determine the threshold experimentally.
- *Filtering out sentence pairs with source/target length ratio exceeding 1.5 (Ott et al., 2019).
- Filtering out duplication in corpora (Khayrallah and Koehn, 2018; Ott et al., 2019). There are 4 options as follows: filtering out (1) duplicate sentence pairs (It is called Pair-dedup. in Table 3); (2) duplicate source sentences (Src-only-dedup.); (3) duplicate target sentences (Tgt-only-dedup.); (4) duplicate source and duplicate target sentences (Src&Tgt-dedup.).

+ Basic Filter	22M	19M	50M
+ De-duplicate	18M	15M	42M
+ LaBSE Filter	13M	12.7M	39.3M

Table 1: The amount of the sentence pairs

- Filtering out sentence pairs according to the cosine similarity of the sentence pair. To this end, we feed the sentence pair to LaBSE (Feng et al., 2020) and calculate the cosine similarity score of the sentence pair. Then, we discard sentence pairs whose cosine similarity score falls below a certain threshold. From here on, it is called LaBSE filtering,

where the filtering methods marked with * are basic filtering methods.

We conducted experiments on the de-duplication and LaBSE filtering to find an optimal combination of them in subsection 4.1. Based on the results, we remove the duplicate sentence pairs and set the threshold of LaBSE filtering to 0.5 in our experiment. Table 1 shows the amount of the sentence pairs after filtering.

2.3 Data Augmentation

To augment the direct bilingual data (Russian-to-Chinese), we generate synthetic bilingual sentence pairs on three data: one monolingual data (Chinese), two indirect parallel data (English-Chinese, and Russian-English). The Chinese monolingual corpora filtered out in the filtering step are translated back to Russian by the Chinese-to-Russian translation model (back-translation). To utilize indirect parallel data, we first train English-to-Chinese and English-to-Russian translation systems using provided corpora. Then we acquire synthetic Russian-Chinese pairs translating English sentences of English-Chinese data to Russian sentences using the trained English-to-Russian MT system (back-translated synthetic corpus). In the same way as before, we also acquire synthetic Russian-Chinese pairs translating English sentences of Russian-English data to Chinese using the English-to-Chinese MT system (forward-translated synthetic corpus). In this paper, we use the Transformer-Big model to augment the direct bilingual. In the future, we would thoroughly ex-

plore several methods to improve further the quality of augmented data, such as using a bigger model and iterative back-translation Hoang et al. (2018).

Following Edunov et al. (2018), we use various decoding strategies , including maximum a-posteriori (MAP) and non-MAP methods for effective data augmentation. In detail, there are five decoding methods: (1) beam search; (2) sampling; (3) sampling top 10; (4) noising beam outputs; (5) noising beam outputs only with sentences longer than 5. The sampling top 10 method is to restrict the sampling method to the k highest-scoring outputs at every decoding step. The noising beam outputs method denotes to add three types of noise such as random permutation over tokens, deleting some tokens, and masking some tokens. Edunov et al. (2018) demonstrated that the non-MAP decoding methods such as (2)-(5) outperform pure beam search.

In our experiments, we generate the five synthetic bilingual data using the different decoding methods. We train five models with each synthetic data embracing data variation. Performance of each way is described in Table 4 In the final submission, we choose a combination of (1) beam search, (2) sampling, and (3) restricted noising beam outputs experimentally. After generating the synthetic bilingual data, we apply the data filtering schemes described in section 2.2 to them. We upsample bitext data to maintain a 1-to-1 ratio of real to synthetic bitext during the training phase.

2.4 Model

In our experiments, we adopt three Transformer architectures.

- **Transformer-Base** with a 6-layers encoder-decoder and a model dimension of 512 as used in Vaswani et al. (2017).
- **Transformer-Big** with a 6-layers encoder-decoder and a model dimension of 1024 as used in Vaswani et al. (2017).
- **Transformer-Large** is similar to Transformer-Big model except that it uses a 12-layers encoder-decoder with pre-norm (Wang et al., 2019).

To boost the performance of the translation model, we average the parameters acquired from various epochs obtained in a training phase and then ensemble the averaged checkpoints involving various variations in terms of data. Moreover, we perform a grid search for decoding hyper-parameters such as length penalty and beam size to find the best performance. We conduct preliminary experiments using the Transformer-Big model to find (sub)optimal configurations in data filtering, data augmentation, hyper-parameters, and so on. Then, based on the observations, we apply the (sub)optimal configurations to the Transformer-Large model.

2.5 Noisy-Channel Re-ranking

The noisy channel re-ranking (Yee et al., 2019) applies Bayes' rule to decoding:

$$p(y|x) = \frac{p(x|y)p(y)}{p(x)}, \tag{1}$$

where x is source sequence and y is hypothesis sequence in translation task. Since $p(x)$ is constant for all y, re-ranking score for each hypothesis candidate can be reconstruct as follows:

$$\frac{\lambda_1 \log p(y|x) + \lambda_2 \log p(x|y) + \lambda_3 \log p(y)}{|y|^\alpha}, \tag{2}$$

where λ, α are tunable weights, $|y|$ is length of hypothesis sequence, and $p(y|x)$, $p(x|y)$, $p(y)$ denote score of forward model, backward model, and language model, respectively.

In a preliminary experiment, we used several publicly released Chinese language models [5] and found that they caused performance degradation. In addition, we used another scoring metric (inverse document frequency similar to BARTScore (Yuan et al., 2021)) when re-ranking, but this did not give any performance gain. Due to time and resource constraints, we could not fully explore our own Chinese language model.

3 Experiments and Results

3.1 Experiment Setup

Our base system is based on the Transformer-Large with an embedding size of 1024, 12 encoder and decoder layers, 12 attention heads, shared source and target embedding, the sinusoidal positional embedding, and pre-norm. We train with a batch size of 3584 tokens and optimize the model parameters using Adam optimizer with a learning rate 1e-3 β_1= 0.9 and β_2 = 0.98, learning rate warm-up

The others are described in section 2.2. The plus marks denote that the filtering method is applied additionally. For example, the "+ LaBSE filter" in fifth row means that both Pair-dedup and LaBSE filter are applied.

over the first 16k steps. Additionally, we apply label smoothing with a factor of 0.1. In the training phase, the dropout is set to 0.1, and the attention dropout is set to 0.3. We apply the early stopping technique using the WMT21 triangular MT development set, and all models are trained for a minimum of 30 and a maximum of 50 epochs. We trained all our models using FAIRSEQ [6] (Ott et al., 2019) on 8 NVIDIA Tesla V100 GPUs.

3.2 Experimental Results

As shown in Table 2, our final model outperforms about +12.7 BLEU compared to the organizer's systems. In detail, we got the most significant performance improvement in scaling up the Transformer model. Through the data filtering process, our model achieved an improvement of about 1 BLEU. By augmenting the Russian-to-Chinese corpus, our model obtained a gain of about 1.5 BLEU. When model-level methods such as averaging parameters, ensemble, and re-ranking were applied, the BLEU score could be raised again by 1.5.

4 Discussions

4.1 Analysis of Data Filtering

In order to verify the impact of various data filtering methods on translation performance, we conduct experiments on the direct parallel corpus (i.e., Russian-to-Chinese). As shown in Table 3, we can see that the performance improves even though we have removed more than half of the data, which means that the original data is quite noisy.

To find the best threshold value for the LaSBE filtering, we executed an additional experiment in which the threshold range is set from 0.0 to 0.9. The threshold 0.0 denotes that the filtering is not applied, and threshold 0.9 means filtering out the sentence pairs whose cosine similarity score falls below 0.9. As can be seen from the results in Figure 1a, we set the threshold value of LaBSE filtering to 0.5 in our final system. Figure 1b shows the distribution of cosine similarity scores on training data. In contrast to the distribution of the train data, that of the WMT21 triangular MT development set is clustered around 0.8. It means that the train data contain many noisy sentence pairs (nearby cosine similarity score 0.2) in terms of LaBSE sentence similarity.

4.2 Analysis of Data Augmentation

We evaluate the impact of the different decoding methods for data augmentation. Table 4 shows the experiment results, which are consistent with Edunov et al. (2018). We observed that sampling and noise beam search are more effective than vanilla beam search. In particular, it is more effective to limit adding noise only to sentences longer than 5 (Noising beam*). As shown in the Table 4, none of the decoding strategies demonstrates superior performance. Therefore we ensemble models

trained with the different decoding methods. As a result, the ensemble model performs better, as seen in the Table 2. In an additional experiment, we also find that the performance of the augmentation (back-translation) models has a significant impact on the performance of the forward model as suggested in Hoang et al. (2018)

4.3 Bilingual MT vs Multi-lingual MT

We experimented with two ways to fully utilize the triangular MT data: to transform the indirect parallel data into direct parallel data and use them for bilingual MT as described in subsection 2.3; the another is to use the all provided data for multi-lingual MT. From the experiment result, we observed that the bilingual MT outperforms the multi-lingual MT by 1 BLEU point, and the multi-lingual MT requires more training time due to upsampling specific direction data.

4.4 Pre-trained Multi-lingual Language Model

Recently, fine-tuning pre-trained multi-lingual MT models (Liu et al., 2020; Tang et al., 2020) showed remarkable performance in multi-lingual translation scenarios. To explore the effectiveness of fine-tuning a pre-trained multi-lingual translation model for triangular MT, in the Table 5, we conducted experiments using mBART50 (Tang et al., 2020) on several datasets: (1) the augmented RU2ZH with beam search; (2) the augmented RU2ZH with noising beam search; (3) the RU-ZH and EN-ZH data; (4) the RU-ZH, EN-ZH, and RU-EN data. We use the Transformer-Large equal to mBART50 in model size as a baseline model for a fair compar-

ison. For fine-tuning mBART, the WMT21 triangular MT development set is used to compute the stopping criterion, and the models are fine-tuned for a minimum of 10 and a maximum of 20 epochs. In general, mBART transfer learning is known to be effective in low-resource language data. Fine-tuning mBART does not work well when large enough data are available. As can be seen from the experimental results, it is more effective to train the model from scratch after data augmentation.

5 Conclusion

This paper depicts Papago's submissions to the WMT21 triangular MT shared task. We have conducted extensive experiments using various techniques such as data filtering, data augmentation, model ensembling, and re-ranking in the triangular MT scenario. Except for existing techniques, we also have tried to apply data filtering with LaBSE sentence score and data augmentation using pivot language and demonstrated their effectiveness in translation performance. As a result, our system achieves the second record according to the released official results.

Machine Translation of Low-Resource Indo-European Languages

Wei-Rui Chen **Muhammad Abdul-Mageed**
Natural Language Processing Lab
The University of British Columbia
{weirui.chen,muhammad.mageed}@ubc.ca

Abstract

In this work, we investigate methods for the challenging task of translating between low-resource language pairs that exhibit some level of similarity. In particular, we consider the utility of transfer learning for translating between several Indo-European low-resource languages from the Germanic and Romance language families. In particular, we build two main classes of transfer-based systems to study how relatedness can benefit the translation performance. The *primary* system fine-tunes a model pre-trained on a *related* language pair and the *contrastive* system fine-tunes one pre-trained on an *unrelated* language pair. Our experiments show that although relatedness is not necessary for transfer learning to work, it does benefit model performance.

1 Introduction

Machine translation (MT) is currently one of the hot application areas of deep learning, with neural machine translation (NMT) achieving outstanding performance where large amounts of parallel data are available (Koehn and Knowles, 2017; Ranathunga et al., 2021; Luong et al., 2015a; Nguyen and Chiang, 2017). In low-resource settings, transfer learning methods have proven useful for improving system performance (Zoph et al., 2016; Nguyen and Chiang, 2017; Kocmi and Bojar, 2018). In this work, we focus on studying NMT, including in the low-resource scenario. In particular, we focus our attention on investigating the effect of ***language relatedness*** on the transfer process. We define relatedness of a pair of languages based on belonging to the same language family. That is, by 'related' we mean 'within the *same* language family' whereas by 'unrelated' we mean 'belong to two *different* language families'. For example, we call English and Swedish related since they belong to the Germanic language family but English and French *not* related since the latter belongs to the Romance language family. As an analogy to human learning, we would like to ask: *if there are two translators (pre-trained models), for example one Catalan → Spanish translator and one Catalan → English translator, will they (after extra training, i.e., fine-tuning/transfer learning process) have different abilities to translate from Catalan into Occitan?* If the Catalan-Spanish translator proves to perform better Catalan → Occitan, we may attribute this to Spanish and Occitan being members of the Romance language family while English being a member of the, Germanic, different family.

Of particular interest to us are two sets of languages belonging to two different language families, one set to Romance and the other set to Germanic. For the former set, we take Catalan (ca), Italian (it), Occitan (oc), Romanian (ro), and Spanish (es); and we take English (en) for the latter set. We note that both Romance and Germanic are two branches of the larger Indo-European language family, and hence there are some level of relatedness between all the languages we study in this work. Nevertheless, languages in Romance and Germanic differ in some syntactic structures. For example, the position of attributive adjectives in Germanic languages is before the noun while it is after the noun for Romance languages (Van de Velde et al., 2014). Despite differences, the writing system of all languages in this work is the Latin script. This can be beneficial to transfer learning because these languages can potentially share common lexical items or morphemes, which may facilitate the transfer learning process.

As mentioned, we adopt transfer learning since it has been shown to improve translation quality for low-resource language pairs. For example, Zoph et al. (2016) sequentially build a *parent* model and a *child* model where each is trained, respectively, on high-resource and low-resource language pairs with the child model retaining parameters from

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 347–353

ca-oc	ca-es	ca-en
ca-ro	ca-es	ca-en

Table 1: Pre-trained model choices for our primary and contrastive NMT systems.

the parent model. In addition, Nguyen and Chiang (2017) successfully transfer knowledge from a parent model to a child model where both models are trained on low-resource but related language pairs. Kocmi and Bojar (2018) also adopt a similar approach to these previous works, but based their work on the Transformer architecture (Vaswani et al., 2017) instead of using a recurrent encoder-decoder network with attention (Bahdanau et al., 2015; Luong et al., 2015b).

Our work builds on these studies. Namely, we empirically apply transfer learning under different conditions to members of various language families. The outcomes of our work are similar to those of Zoph et al. (2016); Kocmi and Bojar (2018). That is, while we find relatedness to be beneficial, a positive transfer between an unrelated language pair can still be possible (although with a potentially diminished performance).

The rest of this paper is organized as follows: In Section 2, we overview related work. We introduce our datasets and experiments in Section 3. In Section 4, we present and analyze our results. We conclude in Section 5.

2 Background

2.1 Transfer learning

Transfer learning is a machine learning approach that aims at transferring the knowledge of one task to another. As an analogy to human learning, one who masters the skills to ride a bicycle may transfer the knowledge to riding a motorcycle because these two tasks share common abilities such as maintaining balance on a two-wheel moving vehicle (Pan and Yang, 2009; Weiss et al., 2016). We employ transfer learning to port knowledge from a model trained on one pair of languages to another. We now discuss transfer learning in NMT.

2.2 Transfer learning in Machine Translation

Zoph et al. (2016) design a framework where a parent model is trained on a high-resource language pair while retaining model parameters for the child model to start fine-tuning with. Using this method, Zoph et al. (2016) improve system performance by an average of 5.6 BLEU points. The improvement is realized by transferring what is learnt in the high-resource language pair to the low-resource language pair. The Uzbek-English model obtains 10.7 BLEU score without the parent model and improves to 15.0 with the French-English parent model. The Spanish-English model has 16.4 BLEU score without the parent model and 31.0 with the French-English parent model. These results show that applying transfer learning contributes 4.3 and 14.6 BLEU points gain. Based on results from Zoph et al. (2016), the closer the two source languages, the more performance gain acquired. Due to the relatedness between Spanish and French (both are members of the Roman language family), performance gain is higher for this pair.

Following previous work, Nguyen and Chiang (2017) design a paradigm similar to that of Zoph et al. (2016) but maintain one major difference. In particular, Nguyen and Chiang (2017) try to make use of relatedness between the parent and child models at the vocabulary level: instead of randomly mapping tokens in the parent and child vocabulary, they retain the parent tokens for the child model if these tokens exist in child language pair. This approach is based on two assumptions - (i) the lexicons of the parent and child language pair have at least some partial overlap and (ii) these identical tokens have similar meaning. Instead of the word-level tokenization in Zoph et al. (2016), Nguyen and Chiang (2017) use Byte Pair Encoding (BPE) (Gage, 1994; Sennrich et al., 2016) to obtain subword tokens which may increase the number of overlapped tokens between the parent and child models. Improvement of 0.8 and 4.3 in BLEU score were obtained for the Turkish-English and Uyghur-English child models as transferred from an Uzbek-English parent model.

Following the previous two works, Kocmi and Bojar (2018) take a similar approach but use the Transformer architecture. They obtain an improvement of 3.38 BLEU for an English-Estonian child model transferred from an English-Czech parent model. Similarly, Neubig and Hu (2018) add a second language related to the added low-resource language to avoid overfitting when fine-tuning. This mechanism has shown to be effective. Other works have investigated NMT approaches

to similar languages by pre-training new language models on the low-resource languages (Nagoudi et al., 2021) or without necessarily applying transfer learning (Przystupa and Abdul-Mageed, 2019; Adebara et al., 2020; Barrault et al., 2019, 2020), and there are several works on low resource languages (Adebara et al., 2021). We now introduce our experimental settings.

3 Experimental Settings

3.1 Languages & Settings

We carry out experiments on three language pairs: *ca-it*, *ca-oc*, and *ca-ro*. The number of parallel sentences of each dataset is shown in Table 4. Training data are from OPUS (Tiedemann, 2012), particularly version 1 of the WikiMatrix datasets (Schwenk et al., 2021). They are data of child language pair and are used to fine-tune pre-trained model. Development and test data are provided by organizers of the Multilingual Low-Resource Translation for Indo-European Languages shared task. The shared task is hosted in EMNLP 2021 Sixth Conference on Machine Translation (WMT21).

We build two systems: a ***Primary system*** and a ***Contrastive system***. The primary system fine-tunes pre-trained *ca-es* and *ca-it* models, while the contrastive system fine-tunes a pre-trained *ca-en* model as shown in Table 1. The primary and contrastive systems serve as context for studying the role of language ***relatedness*** in transfer learning in NMT. We submitted predictions of the two systems to the WMT2021 shared task, and evaluation was based on blind test sets with a number of metrics as run by shared task organizers. An exception is the *ca-it* language pair fine-tuned on top of the *ca-es* pre-trained model–we train the model of this pair post shared task formal evaluation.

3.2 Model Architecture

We leverage publicly accessible pre-trained models on Huggingface (Wolf et al., 2020) from Helsinki-NLP (Tiedemann and Thottingal, 2020). The pre-trained MT models released by Helsinki-NLP are trained on OPUS. These models are Transformer-based implemented in the Marian-NMT framework (Junczys-Dowmunt et al., 2018). Each model has six self-attention layers in both the encoder and decoder sides, and each layer has eight attention heads. The tokenization method is SentencePiece (Kudo and Richardson, 2018) which produces vocabulary of size $49,621$, $21,528$ and $55,255$ for *ca-es, ca-it*, and *ca-en* models, respectively.

3.3 Approach

The pre-trained models are chosen based on the degree of *relatedness* of the original target language on which the model is trained and the new target language on which the model is fine-tuned. *Primary system* takes related languages while contrastive system takes unrelated languages. Since Catalan, Italian, Occitan, Romanian, and Spanish are all members of the Roman language family, we take **ca-es** as our pre-trained MT model for transfer learning. As English is a member of the Germanic language family, we use a **ca-en** pre-trained model for our transfer learning. Our model choices are summarized in Table 1.

Without modifying the architecture of the MT pre-trained models, all architecture-related hyperparameters are identical to the original edition. As for hyperparameters related to fine-tuning, the number of beams for beam search is modified from four for pre-training to six for fine-tuning. The batch size is set to be 25. Pre-trained models are further fine-tuned for $30,000$ steps on OPUS bitext. The checkpoint with the lowest validation loss is then selected as our best model for prediction.

Similar to Zoph et al. (2016); Nguyen and Chiang (2017); Kocmi and Bojar (2018), to achieve transfer learning, we retain the parameters of the parent model when fine-tuning the child model. Besides, parent and child models share a common vocabulary. That is, we do not build distinct vocabularies for the parent model and child models. A shared vocabulary can contribute to better transfer learning since all our language pairs employ the same Latin writing system. We suspect a shared vocabulary is more influential when the two languages are related to each other since the languages may have common morphemes, lexical items, or syntactical structure. For unrelated languages, a shared vocabulary may not hurt since the token embeddings are not frozen throughout the fine-tuning process. That is, token embeddings can still be updated to attain better representations during training.

3.4 Baseline Models

To demonstrate the effectiveness of our transfer learning approach, we provide a baseline model for each language pair that is simply a parent model (a

		Baseline		Our models				
Pre-trained Model	**Lang. Pairs**	**BLEU**	**chrF**	**BLEU**	**chrF**	**TER**	**COMET**	**BertScore**
ca-it	ca-it	29.31	0.583	**35.06**	**0.622**	0.477	0.391	0.886
ca-es	ca-it	7.07	0.370	**33.13**	**0.602**	0.499	-	-
ca-es	ca-oc	12.56	0.472	**59.93**	**0.787**	0.254	0.538	0.928

ca-ro	490,064	1269	1743

Table 4: Distribution of dataset

pre-trained model) without any fine-tuning on data of the child language pair.

3.5 Evaluation

The adopted metrics are BLEU (Papineni et al., 2002), chrF (Popović, 2015), TER (Olive, 2005), COMET (Rei et al., 2020), and BERTScore (Zhang et al., 2019). BLEU, chrF and TER are measured with the implementation of *Sacrebleu* (Post, 2018)[1].

4 Results and Analysis

4.1 Primary and Contrastive Systems

As can be seen in the rightmost five columns in Table 2 and Table 3, primary system outperforms contrastive system across all metrics. We believe that **ca-es** pre-trained MT model performs better transfer learning because Spanish is closer to Italian, Occitan, and Romanian than English is to these languages. These results, as such, indicate that transfer learning between related language pairs can produce better performance than between unrelated language pairs.

4.2 Baseline and Fine-tuned Models

Our results in Table 2 and Table 3 show the effectiveness of transfer learning for both related and *unrelated* language pairs. This is the case since both systems experience a performance gain after fine-tuning.

As an interesting observation, it seems counter-intuitive to have the unrelated language pairs experience slightly higher performance gain. For example, regarding **ca-oc** language pair, the transfer learning provides 47.37 BLEU score improvement transferring from **ca-es** parent model but 49.3 BLEU score improvement transferring from **ca-en** parent model. We suspect this is because in our work, when fine-tuning, we fix source language and alter the target language.

Unlike multilingual MT models which requires target language label to be prepended at the beginning of a source sentence (Johnson et al., 2017) or notifying the model what target language is for this forward propagation (Liu et al., 2020), the pre-trained models we use in this work are bilingual models which lack a mechanism to provide the model any information about current target language. Therefore, the **ca-en** pre-trained model does not know it should now be translating Catalan to Occitan instead of English. Due to producing pre-

[1] https://github.com/mjpost/sacrebleu

diction in an incorrect target language, the metrics will be very poor. After fine-tuning the parent models on data of the child language pairs, the models are likely abler to produce prediction in the correct target language. Due to baseline metrics being too low, the difference in metric values between non-fine-tuned (baseline) and fine-tuned models are large and that is why the performance gain can be higher in contrastive system than in primary system.

5 Conclusion

In this work, we confirm previous works showing that transfer learning benefits NMT. Besides, an empirical comparison between transferring from related and unrelated languages shows that relatedness is not strictly required for knowledge transfer, but it does result in higher performance than transferring with unrelated languages.

Charles University
{jon,mnovak,aires,varis,bojar}@ufal.mff.cuni.cz

Abstract

This paper describes Charles University submission for Multilingual Low-Resource Translation for Indo-European Languages shared task at WMT21. We competed in translation from Catalan into Romanian, Italian and Occitan. Our systems are based on shared multilingual model. We show that using joint model for multiple similar language pairs improves upon translation quality in each pair. We also demonstrate that chararacter-level bilingual models are competitive for very similar language pairs (Catalan-Occitan) but less so for more distant pairs. We also describe our experiments with multi-task learning, where aside from a textual translation, the models are also trained to perform grapheme-to-phoneme conversion.

1 Introduction

The goal of the task was to translate text from Catalan into Occitan, Italian and Romanian. Additionally, use of parallel corpora which combine the evaluated languages with English, French, Portuguese and Spanish was permitted. The choice of the languages from the same family invites to explore how to take advantage of similarities between the languages.

One way to exploit similarities between the languages translated by an NMT model is to train a single joint model for multiple languages. This way, parameters representing rules and features which are common for multiple languages can be shared and better estimated due to a larger amount of training examples related to them.

Another approach which can be effective when source and target languages are very similar is character-level processing of the text. Since most of the differences between Catalan and Occitan are straightforward orthographic variations, we hypothesize that the translation model would benefit from being able to manipulate the text at character level instead of larger subwords.

We also explore making use of language similarity in spoken form, aside from written form. Languages from the same language group may be more mutually intelligible in their spoken form rather than in the written form. For instance, based on our anecdotal observations, native speakers of Czech report better understanding of spoken rather than written Polish. This is mainly due to Polish orthography, which is regular but uses various digraphs, making Polish texts less comprehensible for common Czech speakers. Phonemic representations may be even more helpful for languages with irregular spelling.

Instead of using automatically acquired phonemic representation as one of the inputs, we rather focus on strengthening robustness of our translation models by teaching them to produce this representation as an additional task. Some of our models are thus trained to provide machine translation as well as grapheme-to-phoneme conversion (G2P) of the source.

2 Main features of our approach

The core of our approach lies in leveraging multilingual training data, various subword granularity and phonemic representation of texts by multi-task learning.

All our models are instances of the Transformer architecture (Vaswani et al., 2017) as implemented in the MarianNMT (Junczys-Dowmunt et al., 2018). For the final submissions, we trained several models in multiple stages and tuned the decoding hyperparameters. Moreover, we applied character-level rescoring for the Catalan-Occitan submissions.

2.1 Data preparation

In this section we describe our preprocessing steps, the relevant code is available at https://github.com/ufal/bergamot.git/wmt21-multi-low-res

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 354–361
November 10–11, 2021.

Mulilinguality. It has been shown (e.g. by Zhang et al. (2020); Fan et al. (2020); Firat et al. (2016); Tan et al. (2019); Arivazhagan et al. (2019); Lakew et al. (2018)) that combining multiple translation directions into one model may be beneficial for the translation quality (especially for related languages) in the low-resource scenarios due to knowledge transfer between the translation directions, as it allows the model to get better estimates of the parameters that represent principles which are shared between the languages.

For our multilingual systems, we use the vanilla Transformer (single encoder, single decoder), concatenate the training data and insert a special token at the start of each source sentence to mark the desired target language, e.g. for translation from Catalan into Occitan: `<oc> Tres dels seus costats tenen porxada.`

Subwords granularity and character-level translation. It has been shown (Sennrich and Zhang, 2019) that granularity of subword segmentation and thus the resulting vocabulary size has a large effect on translation quality in low-resource scenarios. For mid- and high-resource language pairs, vocabulary size of around 32k subwords is the usual choice. However, for smaller corpora, this size causes sparsity problems, since the vocabulary contains many subwords that were seen too few times to estimate sufficiently good embeddings for them. The solution is to split the words into smaller subwords or even into single characters. Moreover, we suspected that for similar languages, like Catalan and Occitan, small subword or character level translation may be beneficial because large part of the differences between the translations are merely orthographic variations and the ability to work on character level will allow the model to learn to perform these variations more easily.

Grapheme-to-phoneme conversion as an extra task. We hypothesize that teaching the model both to translate and to perform G2P may increase the model's robustness and consequently its performance. Multi-task learning (Caruana, 1997) has been successfully shown in NMT to either incorporate linguistic knowledge (Luong et al., 2016; Eriguchi et al., 2017; Kiperwasser and Ballesteros, 2018) or to exploit monolingual data (Wang et al., 2020). Although it has been also used in G2P (Prabhu and Kann, 2020), the two tasks has not been to the best of our knowledge modelled jointly so far.

Using a G2P tool, we prepare phonemic representation of the source side of the training data and combine it with the text data in two possible ways.

Vertical combination is an analogy of how multiple translation directions are combined. We concatenate the bitext with the data that consist of the same source side and its phonemic representation as the target side. Furthermore, we use a special token at the start of each source sentence to indicate the G2P task, e.g. `<ca_p>` for Catalan phonemization.

In *horizontal combination*, we attempt to mimic multi-output learning (Xu et al., 2019), i.e. producing outputs for multiple tasks at the same time. We thus enrich each target sentence with the phonemic representation of the source sentence. The two are separated by a special symbol `<sep>`. To evaluate the MT output, we need to strip off the phonemic part first.

2.2 Model training and decoding

Learning stages. Some of the models submitted to the shared task are a result of learning in two consecutive stages, each utilizing a different dataset. In the pre-training stage, we build a general multilingual model, leveraging most of the available data sources. In the fine-tuning stage, we continue training only on selected languages, possibly in conjunction with learning to convert graphemes to phonemes.

Decoding. During the beam search, we normalize the scores of each hypothesis by its length (the score is divided by $length^n$). We performed grid search over the n coefficient and beams size for our primary submission and we obtained values $n = 1.0$ and $b = 8$. We used these values for all the systems.

Character-level rescoring. For Catalan-Occitan, we found character-level models to be competitive with subword models, but after manual inspection, we see some of the translations produced by these models included superfluous repetitions of groups of characters. For this reason, we decided to use the character-level model only for rescoring hypotheses produced by the subword-level models.

Table 1: Number of lines (in thousands) in corpora for each language pair used in our systems.

3 Datasets

Apart from the Catalan, Occitan, Romanian and Italian data, we take advantage of the data in other languages allowed by the Shared Task organizers: Spanish, French and English (we did not use Portuguese corpora). We used datasets specified by the task organizers, namely ParaCrawl, GlobalVoices, EuroParl, JW300, WikiMatrix, MultiCCaligned, Opus100, Books and Bible. Table 1 shows number of lines for each language pairs used in our experiments.

4 Results

In this section, we report BLEU (Papineni et al., 2002) and ChrF2 citepopovic-2015-chrf scores on development and test sets provided by the organizers. We did not rerun test set evaluations for all the models, so for a small number of configurations we only show scores on the development sets.

4.1 Tools

We break the input text into subwords using SentencePiece (Kudo and Richardson, 2018). We use MarianNMT (Junczys-Dowmunt et al., 2018) to train the models and the BLEU and ChrF scores are computed using SacreBLEU (Post, 2018). For experiments involving G2P conversion, we used `phonemizer` wrapper script[1] around Espeak-ng speech synthesizer[2] to produce phonemic representation of the texts.

4.2 Baselines

We used publicly available services and models as external baselines, and traditional bilingual Transformer models trained on provided corpora as our own baselines. We use SentencePiece preprocessing with 8k subword models for our bilingual baselines. We also trained models to translate from Catalan to English and from English to the target languages to be able to do pivoted translation. The external baselines include Google Translate (for Romanian and Italian), Romance multilingual model[3] from Opus-MT project (Tiedemann and Thottingal, 2020) and Apertium rule-based machine translation system (Forcada et al., 2011), which was chosen since we suspected that the rule-based approach might work better than NMT for very low resource, but very similar language pairs, like Catalan-Occitan (and also Apertium is especially focused on languages of that region). Results on dev and test sets are presented in Tables 2 and 3, respectively.

System	BLEU			ChrF		
	it	ro	oc	it	ro	oc
Opus-MT	32.4	-	16.7	0.608	-	0.545

Table 3: Results of the baseline system evaluation, test set.

We see that even our bilingual baselines outperform all other baselines aside from Apertium on Catalan-Occitan. We were unable to train functional English-Occitan model on the provided data (only 37k noisy sentence pairs), so the pivoted approach was not feasible in this direction.

4.3 Improving bilingual models

Before working on multilingual models, we focused on improving the bilingual systems to be sure our baselines are sufficiently strong.

First, we add backtranslated data. We trained a joint multilingual model for translation from the target languages into Catalan. For Romanian and Italian, we used this model to translate Wikipedia,[4]

for Occitan, we utilized Apertium and aside from Wikipedia, we also translated Occitan sides of all the other provided parallel corpora. The results are presented in Tables 4 and 5. We see that backtranslation improves results for all the language pairs, and that for Occitan, wiki translation (rows marked as *w*) works better than general corpora backtranslation obtained from Occitan sides of other parallel corpora (En-Oc, Fr-Oc and Es-Oc). We also observe that the performance is better when training with parallel and BT data from the beginning (*scr.*), opposed to finetuning parallel-only trained model on parallel-BT mix (*finet.*).

We also tried to improve the results by choosing a correct subword granularity. We compared baseline models, which use SentencePiece vocabulary with 8k tokens, with 2k tokens and character level translation (see Tables 6 and 7). Based on observations by Libovický and Fraser (2020), we trained character level models both from scratch (row *char*) and by finetuning the subword models (row *char-f*). We see that the character-level training works best for Catalan to Occitan translation. We suppose it partially stems from the lack of resources for the language pair and partially from the relative similarity of the two languages.

We combined the backtranslation and character level processing for Occitan to see if the improvements are orthogonal (Tables 4 and 5). We also trained transformer-big models on the same data for comparison with larger models introduced in the next section.

4.4 Multilingual models

Our final submission is based on multilingual models. We combined the datasets allowed for the task and included a special language tag at the beginning of the source sentence to indicate the target language. The results on dev and test sets are presented in Tables 8 and 9. We use 32k vocabulary for the multilingual models.

Firstly, we trained a model only on the languages that were evaluated (system 1). We see that just by using the joint model, we obtained improved results for all language pairs. We also trained transformer-big model on the same data, as increasing model capacity usually improves performance especially for multilingual settings (system 2), but we observed same or worse results than with a base model.

Next, we added corpora with the other allowed translation directions which contain the evaluated

Table 9: Multilingual models, test set. [1] marks our primary submissions, [2] is our secondary submission.

languages on their target side, i.e. French, Spanish and English into Occitan, Romanian and Italian (system 3). At the first glance, including additional related languages did not improve the performance (and even hurts the performance for Catalan-Occitan), but we suspected that this might be a model capacity and data balancing problem. After oversampling the smaller training corpora to have the same number of sentences as the largest one, we see that performance of the model for this pair (4) reaches the levels of the previous model. Interestingly, adding backtranslated Wikipedia results in worse scores, even though backtranslation helped in bilingual models (5). To see whether increasing the model capacity while using larger amount and more diverse training data is beneficial, we trained transformer-big (6) and transformer-big with 12-layer encoder instead of 6-layers, which we call transformer-bigger (7). For transformer-bigger, we used depth-scaled initialization proposed by Zhang et al. (2019). We see that in fact, after adding more data, larger model capacity helps, but the 12-layered encoder transformer-big performs worse than the 6-layered one. We believe this is caused by instability of the training for the deeper models as in the next paragraph, we see improvements with the deeper model.

Until now, our goal was to mainly improve the target language generation by including other corpora with evaluated languages at the target side. We also tried to improve source-side Catalan encoding by adding corpora with Catalan on the source side, namely Catalan to French, English and Spanish (8). Resulting model shows improvements compared to the other language combinations, and again, increasing the model size ((9), (10) and (11[5])) has even larger effect than for the previous models due to the amount and diversity of the training data. We hypothesize that increasing depth of the encoder helps in this case compared to the previous model because we added more data with Catalan source side and the increased encoder capacity could be used to learn more Catalan-specific features and rules.

Our primary submissions for Romanian and Italian are simply translations produced by the largest multilingual model (10). The training has not fully converged at the time of the submission and further training brought improvements in the range of 1-3 BLEU. Our secondary submissions for these two languages were the same models, however, we also included the backtranslated Wikipedia (12) in the training dataset. Surprisingly, this approach lead to decrease in performance in terms of BLEU and ChrF2. On the other hand, BERT and COMET scores in the official evaluation are same or slightly better for the models trained with backtranslation.

Table 10: Results of human evaluation performed by the organizers.

Due to the data imbalance, even the largest model underperforms in Catalan-Occitan. Because of the time constraints, we did not try oversampling Occitan corpora and training with balanced data, instead we fine-tuned the multilingual model for specific language pairs (13[6]). Finally, we produced 20 best hypotheses for each sentence and rescored them by the character level Catalan-Occitan transformer-big introduced earlier (Table 4), leading to a 1.5 BLEU increase on the dev set. This is our primary system for Catalan-Occitan.

Our submissions were ranked first in all directions with respect to all metrics except for the Catalan-Romanian BLEU score, where the M2M model was 0.2 points better (but after finishing the training, our model outperforms it by 0.8 BLEU).

For translation into Occitan and Italian, the organizers also performed human direct assessment evaluation. Translations produced by different systems were scored from 1 to 5 (on sentence-level, but document-level context was provided to the annotators). The results are shown in Table 10.

4.5 Multi-task models

In our experiments with multi-task learning, we trained the models to be able to both translate and perform G2P conversion of the source. Using the `phonemizer` script, we automatically acquired phonemic representations of the Catalan sides in the Catalan-Italian, Catalan-Romanian and Catalan-Occitan data. We then combined them with the

Table 11: Results of multi-task models on dev set. The source side always consists of Catalan texts. The top part shows bilingual models, while the models in the bottom part are multilingual.

original bitexts as proposed in Section 2.1.

As shown in Table 11, we started with training multi-task transformer-base models from scratch using vocabularies of 32k tokens.[7] Apart from translation to Italian, multilingual models (in the bottom part) outperform the bilingual models (in the bottom). In addition, vertical combination of texts and phonemes appears to perform better than the horizontal one.

Comparison of Tables 11 and 8 suggests that even though trained from scratch multi-task learning seems to achieve competitive results for Catalan-Occitan. We thus focus on this language pair in the following steps. Interestingly, best scores for Occitan are achieved with a multilingual model that excludes Romanian. We suppose Occitan is too distant from Romanian to benefit from it. Therefore, we took the best-performing multilingual model at the time (system 9 in Tables 8 and 9) and fine-tuned it with the Catalan-Italian and Catalan-Occitan training sets vertically combined with Catalan phonemes for these datasets (15). As data balancing in multilingual models proved to be beneficial for Occitan, we also applied it before the fine-tuning, which results to even better performance for Occitan (16[8]). Finally, we rescored 20 best hypotheses by char-level Catalan-Occitan model as in the system 14, resulting in our contrastive submission for Catalan-Occitan (17). Within all submitted Catalan-Occitan systems, our submission was ranked first in all metrics.

5 Conclusion

We described our submission to the shared task, which ranked first according to the majority of the used metrics for all languages. We used multilingual transformer models and we present results showing that combining all the languages into single model improves upon bilingual baseline by a large margin. We also present our findings about using multi-task learning, where aside from translation of the source, the model also learns to convert the source sentence from graphemes to its phonemic form.

[7] Except for Occitan bilingual model, which uses a vocabulary of 8k tokens.

Abstract

This paper describes the participation of the BSC team in the WMT2021's Multilingual Low-Resource Translation for Indo-European Languages Shared Task. The system aims to solve the Subtask 2: Wikipedia cultural heritage articles, which involves translation in four Romance languages: Catalan, Italian, Occitan and Romanian.

The submitted system is a multilingual semi-supervised machine translation model. It is based on a pre-trained language model, namely XLM-RoBERTa, that is later fine-tuned with parallel data obtained mostly from OPUS. Unlike other works, we only use XLM to initialize the encoder and randomly initialize a shallow decoder. The reported results are robust and perform well for all tested languages.

1 Introduction

We present the work carried out by the BSC Team in the context of WMT2021's first edition of the Multilingual Low-Resource Translation Shared Task. The tasks addresses the issue of multilinguality in machine translation (MT) for low-resource languages, focusing on two language families: North Germanic and Romance. We take part in the Subtask 2, which involves translation in four Romance languages: Catalan, Italian, Occitan and Romanian.

2 Background

Machine translation for low-resource languages is characterised by the lack of sufficient parallel data of a given language pair, either because the combination is infrequent or because the languages involved are themselves low-resource. Several works have attempted to overcome this pitfall, using different techniques. A common solution is to employ back-translation (Sennrich et al., 2016), while other research focuses on using other languages as pivots to compensate for the lack of data (Firat et al., 2016; Zoph et al., 2016). Artetxe et al. (2018); Lample et al. (2018) make use of monolingual data only.

Our approach is based on multilinguality. Previous works such as Vergés Boncompte and Ruiz Costa-Jussà (2020); Tubay and Costa-Jussa (2018) have shown that the use of multilingual MT is beneficial, as it generalizes better by sharing parameters among all the languages involved, especially if the languages belong to the same linguistic family. At the same time, training of multilingual MT models from scratch usually requires large parallel corpora and may not be feasible in a low-resource and zero-resource translation scenarios.

Pre-training of large language models from scratch on monolingual data and then fine-tuning them for the specific downstream tasks, has proved to be an extremely successful approach for many natural language processing problems. Cross-lingual language models such as XLM and XLM-RoBERTa (Conneau and Lample, 2019; Conneau et al., 2020), that combine unsupervised (monolingual data) and supervised (parallel data) training objectives, perform especially well both on cross-lingual NLU tasks and in machine translation. The idea of combining the power of pre-trained cross-lingual language models with a multilingual machine translation setting naturally follows from there.

This idea was explored in (Liu et al., 2020) where a denoising seq2seq auto-encoder (mBART) based on BART (Lewis et al., 2020) was pre-trained on extensive monolingual corpora in many languages. A similar approach is implemented in (Lin et al., 2020) where alignment information is used to pre-train a multilingual MT transformer on existing public parallel datasets. Both approaches require either a computationally intensive pre-training on monolingual data or access to extensive large-scale

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 362–367

parallel data.

Initializing an encoder and decoder of a bilingual MT seq2seq transformer with a pre-trained cross-lingual language model was famously proposed in (Conneau and Lample, 2019). A natural next step is to initialize a multilingual MT seq2seq transformer with a shared encoder and a shared decoder by the XLM-like language encoder which was first performed in (Ma et al., 2020).

We reuse this idea by initializing the encoder with a pre-trained XLM-Roberta (Conneau et al., 2020), as in (Ma et al., 2020). However, unlike (Ma et al., 2020), we only initialize the encoder, with the motivation of being able to instantiate a shallower decoder, following previous works that for a given compute budget suggest that it is more efficient to use deeper encoders and shallower decoders (Kasai et al., 2020). The encoder-only initialization was already implemented in Fairseq (Ott et al., 2019).[1]

3 Experimental Framework

3.1 Fine-Tuning Data

To train our MT system, we use all parallel data available in OPUS[2] for the targeted language pairs, namely ca-it, ca-oc, ca-ro.

We further include a small dataset ca-oc, the Catalan - Occitan Gencat Crawling, specifically obtained for the occasion, by leveraging parallel data from a crawling of the Catalan Government Internet domains and subdomains. We use the CorpusCleaner[3] pipeline to process the WARC files obtained from the crawling. This allows us to maintain the metadata and retrieve the original url per each document. We then extract the content of the same URLs in both languages and align them at document level using vecalign[4]. The final dataset of 503 sentences was obtained by manually reviewing 1,237 automatically aligned sentences. Although smaller than expected, one motivation to crawl this brand new dataset is to contribute to the development of MT resources for Occitan, which is a severely under-resourced language. We are publicly releasing this new dataset with an open license.[5]

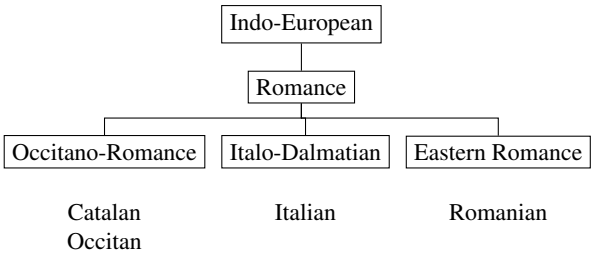

Figure 1: Family tree of Romance languages showing only the languages targeted by the Shared Task.

The resulting statistics of the corpora used to train our system can be seen in Table 1. As expected, the number of aligned sentences is much larger for Italian and Romanian as target languages, since Occitan is such a low-resource language. Nonetheless, we must bear in mind that Catalan and Occitan belong to the same sub-branch in the family tree of the Romance languages, as shown in Figure 1. Thus, their considerable typological closeness makes up for the reduced amount of aligned sentences available for this language pair.

3.2 Preprocessing

We start by preprocessing our data with a filtering and a tokenization step.

To ensure that there is no train-test overlap, we filter all of our training data by removing all sentences from the validation and test sets present in our train set.

To build our system, we use SentencePiece BPE tokenization with the original shared vocabulary of 250,000 tokens of XLM-R model (Conneau et al., 2020; Kudo and Richardson, 2018), and we only keep sentences with a maximum size of 512 tokens.

The final number of parallel sentences used for training is shown in Table 1.

3.3 System Description

We base our system on XLM-RoBERTa (Conneau et al., 2020) and then fine-tune it with the collected parallel data. As described earlier, the seq2seq multilingual transformer with shared encoders, shared decoders and shared embedding tables is initialized by XLM-R BASE pretrained language model on the encoder side, whereas a shallow decoder of 3 layers is initialized randomly. Sharing of embedding tables for all directions (ca-it, it-ca, ca-ro, ro-ca, ca-oc, oc-ca) was initially implemented due

to memory constraints but eventually turned out to work well.

The token indicating the required target language is prepended to the target sentences, thus the model is aware to what language it has to translate to, as in (Wu et al., 2016).

It is important to note that the data used to train XLM-RoBERTa does not contain any Occitan text, as can be seen in Table 2. Thus the only knowledge that the multilingual transformer has about the language directions including Occitan comes from the XLM-R language model being pre-trained on text in related languages, such as Catalan.

We use default Fairseq parameters for fine-tuning, first of all, the Adam optimizer (Kingma and Ba, 2017) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. The polynomial decay learning rate schedule starts from $5\mathrm{e}{-04}$, warmed up to over 1000 updates and gradually decays to 0 over around 60k updates. The model was fine-tuned for 2 days on 4 NVIDIA V100 GPUs. The final learning rate was around $3\mathrm{e}{-04}$ with a batch size of $3,072$ sentences.

During inference we use the beam search generation algorithm with a beam size of 5. Since the languages between which we are translating are typologically close, we do not assign any length penalty, and we use the best checkpoint for generating.

4 Results

Here we report the official evaluation.[6] We submitted our results a bit later than the deadline due to some bottlenecks in our in-house computational resources. Table 3 reports the results obtained by our system on the evaluation test set, together with the two official baselines provided by the organisers (M2M-100 and mt5-devFinetuned).

Out of 7 competing systems and 2 baselines, our system was ranked 5th in Average, 3rd in the Catalan-to-Occitan direction, 4th in the Catalan-to-Romanian direction and 6th in the Catalan-to-Italian direction.

4.1 Human Evaluation

The organizers of the workshop have recently released the results of a human evaluation for the

mT5-dev-ft.	30.38	40.14	17.33	29.28

Table 3: Official BLEU scores for the evaluation of the final test set

language pairs ca-it and ca-oc.[7] A sentence level evaluation has been performed taking into account the document as context. Each sentence is evaluated in a Likert-like scale [1,5] answering the question of direct assessments. A second human evaluation is performed where 60 selected terms (mostly named entities, dates and locations) are annotated as being either well translated, not translated or mistranslated, by majority voting among the annotators. The results can be found in Tables 4 and 5, respectively.

5 Discussion

5.1 Little sisters over big cousins

As seen in Table 3 the average results of our system are above both baselines, although it is the results for Catalan-Occitan that give the greater leverage, because in the other two scenarios M2M has a higher BLEU. Actually, the score for Catalan-Occitan is substantially higher than the score obtained for the other two pairs, although the fine-tuning data used in this model is, at least, ten times smaller than the data used in the other two models. These results are replicated in most of the other competing systems[8]. The reason for this apparent anomaly is clearly due to the linguistic similarity between the Catalan and Occitan, which in medieval times were practically one and the same language. This result confirms the intuition that when two languages are similar enough, less data is needed.

That said, we also hypothesize a positive impact of the curated dataset (Catalan - Occitan Gencat Crawling) added to the rest of parallel data obtained in the OPUS repository, but there is no definitive proof of it. Furthermore, we can also hypothesize that the presence of Spanish in the multilingual corpus, being a high-resource language and also linguistically close to Catalan and Occitan (more so than to the other two Romance languages involved in the task), has a beneficial impact on the results. Indeed, low-resource languages can greatly benefit from their similarity to other languages present in the multilingual training. In such scenarios, less data can lead to satisfactory results, and with a smaller carbon print, since the models use less computational power for training.

5.2 Human Evaluation results

The human evaluation on two of the test sets shown in in table 4 validates the relative position of our system in the global ranking. Interestingly, human scores correlate well with BLEU for Catalan-Italian, and less well for Catalan-Occitan. In the latter case, human scores tend to be lower than the corresponding BLEU. The reason for this may again have to do with linguistic similarity between Catalan and Occitan: "Catalanish" Occitan may be deemed acceptable by subword-based BLEU, but not by human evaluators. The performance of our system as evaluated for term translation, shown in in table 5 is consistent with the other evaluations regarding the position of the system in the overall ranking.

5.3 Vocabulary

One of the shortcomings of our approach is the big vocabulary size (250k tokens), inherited from XLM. This big vocabulary size was required by XLM to cover a very diverse set of languages. However, this makes it sometimes challenging to fit the embedding tables in memory, which is especially inefficient taking into account that a large proportion of tokens are not used (since we focus on a tiny subset of languages). Thus, either pruning the vocabulary, or using pre-trained models specifically trained for the Romance languages family (with a reduced vocabulary size) would be better alternatives.

5.4 Shallow decoders and transfer learning

While recent works have suggested that allocating more computation to (deeper) encoders (Kasai et al., 2020) at the expense of allocating less computation to (shallower) decoders is more efficient, this approach is not yet standard in the machine translation literature, especially when applying transfer learning. This method has the advantage of not reusing pre-trained weights for the decoder, although a middle ground is perhaps worth exploring.

Namely, use just some of the pre-trained weights to initialize the decoder layers. For example reuse the first N layers of XLM in the decoder, even if there is no 1-to-1 mapping between layers because there are less in the fine-tuned model.

6 Conclusions

We have showed that our approach is a simple, yet effective method for multilingual machine translation between linguistically similar languages. The encoder-only initialization allows for having a shallow decoder, which is computationally wise. As future work, we plan to further explore transfer learning techniques in the context of shallow decoders as well as applying different vocabulary pruning techniques.

Code availability

We release[9] with an open license the scripts used for this work for the sake of reproducibility.

Abstract

We describe the EdinSaar submission to the shared task of Multilingual Low-Resource Translation for North Germanic Languages at the Sixth Conference on Machine Translation (WMT2021). We submit multilingual translation models for translations to/from Icelandic (is), Norwegian-Bokmål (nb), and Swedish (sv). We employ various experimental approaches, including multilingual pre-training, back-translation, fine-tuning, and ensembling. In most translation directions, our models outperform other submitted systems.

1 Introduction

This paper presents the neural machine translation (NMT) systems jointly submitted by The University of Edinburgh and Saarland University to the WMT2021 Multilingual Low-Resource Translation for Indo-European Languages task, describing both primary and contrastive systems which translate to/from the three North Germanic languages, Icelandic (is), Norwegian-Bokmål (nb), and Swedish (sv). Our contrastive system, submitted as "edinsaarContrastive" outperforms the other submissions across all evaluation metrics except for BLEU, for which our "edinsaarPrimary" system performs best.

Although low-resource MT has recently gained much attention, there is little prior work on North Germanic languages. We contribute to this space by experimenting with both training a multilingual system from scratch and exploiting model adaptation from a large pre-trained language model. We fine-tune our initial translation models to the target languages, and then experiment with further in-domain fine-tuning. Data is sourced from openly available data sets in accordance with the corpora allowed in the shared task. We use parallel data sets pairing our target languages with each other and with the allowed high-resource languages, and monolingual data from Wikipedia.

The rest of the paper is structured as follows: we review related work in Section 2, we introduce the methods and experimental settings including data and model architecture in Section 3, we evaluate model performance in Section 4, and, finally, we draw conclusions and suggest avenues for future work in Section 5.

2 Related Work

Recent work in NMT for North Germanic languages is limited; however, OPUS-MT (Tiedemann and Thottingal, 2020), which contains over 1,000 pre-trained, ready-to-use neural MT models including models for Danish, Norwegian, and Swedish, is a notable exception.

Due to the scarcity of parallel data for low-resource languages, recent work leverages monolingual data, including pivoting from high-resource languages (Currey and Heafield, 2019; Kim et al., 2019), and using back-translation (Sennrich et al., 2016a; Edunov et al., 2018) to generate pseudo-parallel data with synthetic sources from monolingual data. Since the little parallel data that is available often comes from noisy web crawls, parallel corpus filtering is used to develop better translation models (Koehn et al., 2020). Additional methods for boosting the performance of low-resource pairs include transfer learning from models trained on higher-resource pairs (Zoph et al., 2016; Kocmi and Bojar, 2018), and developing multilingual systems to allow models to take advantage of linguistic relatedness. Multilingual systems can employ either separate encoders or decoders for each language (Dong et al., 2015; Firat et al., 2016), or shared encoders/decoders, and can additionally make zero-shot MT possible (Johnson et al., 2017; Ha et al., 2016), while scaling to hundreds of language pairs (Aharoni et al., 2019; Fan et al., 2020). Sampling language pairs in proportion to their prevalence in the training data can ensure that all directions get enough coverage by the model (Arivazhagan et al.,

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 368–375
November 10–11, 2021.

2019; Fan et al., 2020). Further fine-tuning multilingual systems on target language directions can improve performance of low-resource pairs (Neubig and Hu, 2018; Lakew et al., 2019). Adapting a multilingual pre-trained language model to the translation task has led to improvements in translation quality (Clinchant et al., 2019; Chen et al., 2020). Finally, combining multiple MT system checkpoints together by ensembling improves performance of the final system (Sennrich et al., 2017).

3 Method

Given a set of primary languages L_p and secondary languages L_s, we train a multilingual MT system on the parallel data between all the language combinations $\{L_p, L_s\} \leftrightarrow \{L_p, L_s\}$. This is our **baseline**. We extend this approach with a combination of the following methods:

Pre-training: We initialize a base model using a highly multilingual pre-trained model, in order to transfer the learned parameters to the translation task. This is our **primary** system.
Back-translation: We use the baseline model to back-translate monolingual corpora in L_p into all other languages in L_p to obtain a training data set of back-translations D_{BT}.
Fine-tuning: We fine-tune the baseline model on the subset of languages $\{L_p, L_s\} \leftrightarrow L_p$, on both parallel and back-translated data D_{BT}. Our **contrastive** system is an ensemble of the last four checkpoints of this model.

3.1 Data

For training our models, we include data from the target primary low-resource languages, Icelandic (`is`), Norwegian-Bokmål (`nb`), and Swedish (`sv`), and the related secondary languages Danish (`da`), German (`de`), English (`en`).

We use data for all translation directions involving `da`, `de`, `en`, `is`, `nb`, `sv` from the following **parallel** corpora from Opus: Bible (Christodouloupoulos and Steedman, 2014), Books (Tiedemann, 2012), Europarl (Koehn, 2005), GlobalVoices (Tiedemann, 2012), JW300 (Agić and Vulić, 2019), MultiCCAligned (El-Kishky et al., 2020), Paracrawl (Esplà et al., 2019), TED2020 (Reimers and Gurevych, 2020), and WikiMatrix (Schwenk et al., 2019). We also use all corpora from ELRC[1] that include these directions (a total of 159 corpora, retrieved in May 2021). These corpora include all corpora allowed by the shared task, with the exception of the Opus-100 data set, which we avoided as it had many duplicate sentences with the above corpora.

We use **monolingual** data from Wikipedia for `is` and `nb` to augment our data set with back-translations (Sennrich et al., 2016a). Because the Wikipedia data for `sv` was created in large part by a bot[2] and consisted of many stub articles and tables, we use the `sv` portion of our training data as monolingual data for back-translation instead.

Our final data includes 30 language directions:

(a) $L_p \leftrightarrow L_p$: {`is`,`nb`,`sv`} $\leftrightarrow$ {`is`,`nb`,`sv`}
(b) $L_p \leftrightarrow L_s$: {`is`,`nb`,`sv`} $\leftrightarrow$ {`da`,`de`,`en`}
(c) $L_s \leftrightarrow L_s$: {`da`,`de`,`en`} $\leftrightarrow$ {`da`,`de`,`en`}
(d) $L_{p\_bt} \rightarrow L_p$: {`is`,`nb`,`sv`} $\rightarrow$ {`is`,`nb`,`sv`}

where L_{p_bt} is created from the monolingual target side back-translated data D_{BT}.

Parallel Data Filtering We filter the parallel data using rule-based heuristics borrowed from the Bifixer/Bicleaner tools (Sánchez-Cartagena et al., 2018; Ramírez-Sánchez et al., 2020) and language identification using FastText (Joulin et al., 2016, 2017). This repairs common orthographic errors, including fixing failed renderings of glyphs due to encoding errors, replacing characters from the wrong alphabet with correct ones, and un-escaping html. It also removes any translation pairs where: the pair is a duplicate, the source and target are identical, the source or target language is not the intended language, one side is more than 2x the length of the other, one side is empty, one side is longer than 5000 characters, one side is shorter than 3 words, or one side contains primarily URLs and symbols rather than text.

Filtering reduces our parallel data to 77% of its original total size. This data is then reversed in order to train our multilingual model in all translation directions, resulting in a total of 421,656,410 parallel sentence pairs in all 30 language directions. Table 1 lists the filtered data counts and the percentage of the original data that these counts represent.

Monolingual In-Domain Data Filtering The validation set provided by the shared task organizers, containing thesis abstracts and descriptions, is dissimilar to our available parallel corpora. Therefore, we filter the Wikipedia monolingual `is` and

Table 1: Number of sentences after filtering (with % of total raw data remaining after filtering) in each language direction from source (left) to target (top) from all corpora and for additional monolingual data from Wikipedia. The parallel data was mirrored in the reverse directions to create 30 total language directions for training.

nb data for similarity to this validation set to create in-domain monolingual data for use in back-translation. We identify in-domain monolingual instances in our data by calculating the cosine similarity between each sentence in a given language in the monolingual data to each of the sentences in the shared task validation data for that language. When a training instance has a similarity of $>= \theta$ with at least one validation instance, it is added to the in-domain fine-tuning corpus. We set $\theta = 0.9$ and use LASER (Artetxe and Schwenk, 2019) to extract vector representations of sentences for calculating similarity.

Validation and Test Data We split off 2000 sentence pairs from each language pair in our parallel data to use as an **internal test set**. For is-nb directions, we use the few parallel sentences available for this, meaning that no parallel data is left for the training or validation corpus. Therefore, translating between these directions is a zero-shot task for our models.

We also split off 2000 sentence pairs from each language pair in our parallel data for **internal validation**. For validation of our primary model, we use the entire collection of 2000 validation sentence pairs in each language direction. For the baseline system, we cut this down to a total of $\sim$ 2000 sentences, because performing validation is quicker on smaller data. Therefore, we use a subset of 72 validation sentences in each $\{L_p, L_s\} \leftrightarrow \{L_p, L_s\}$, except is-nb, resulting in 2016 sentences. For the contrastive model, we use the same sentences in only $\{L_p, L_s\} \leftrightarrow \{L_p\}$, to which we add 72 sentences from the back-translated data in the is-nb directions, resulting in a total of 1728 sentences.

We use the **shared task validation** set, to compare performance between our systems, and do not use it during model training or fine-tuning. We additionally report results Section 4 on the **shared task test set**, which was provided to the teams after the completion of the shared task. These test sets contain approximately 500 sentences in each language direction.

	is	nb	sv
is		2564234 (87)	10123 (99)
nb	279818 (80)		344583 (78)
sv	299277 (85)	2521823 (86)	

Table 2: Number of back-translated filtered sentences (with % of total data remaining after filtering) between synthetic source (left) to original target (top).

Back-translation We use the baseline system (Section 3.3) to create back-translations of our monolingual in-domain filtered Wikipedia data. This generates synthetic sources from is to {nb, sv} and from nb to {is, sv}. We additionally back-translate the sv side of our parallel nb-sv corpus into is and our is-sv corpus into nb. After creating the back-translations, we filter the new synthetic parallel data sets again using the parallel data filtering steps (Section 3.1), in order to remove sentences that consisted primarily of model errors or hallucinations. The final counts of filtered back-translated data are in Table 2, as well as the percentage of the original total in-domain data that these counts represent.

3.2 Byte-pair Encoding

To create a vocabulary for our baseline and contrastive systems, we train a shared byte-pair encoding (BPE) (Sennrich et al., 2016b) model using SentencePiece (Kudo and Richardson, 2018). We sample 10 million monolingual sentences from our parallel training data, based on the amount of monolingual data available for each language. Following the idea of Arivazhagan et al. (2019), we use temperature sampling, where the probability of sampling any particular data set D in language ℓ out of the n total data sets is defined as $p_\ell = (\frac{D_\ell}{\sum_i^n D_i})^{\frac{1}{T}}$, where we set $T = 5$. The goal of sampling in this way is to provide a compromise that allows the BPE model to view a larger portion of lower resource

language tokens (unlike sampling according to the original distribution would), while still providing extra space in the model for the larger variety of tokens coming from high-resource corpora (unlike sampling uniformly would). We use a vocabulary of $32,000$ tokens. When BPE-ing our training data, we use BPE-dropout (Provilkov et al., 2020) with a probability of 0.1.

3.3 Models

Baseline Our baseline system is trained on a concatenation of data sets (a), (b), and (c) (see Section 3.1). The data is pre-processed using byte-pair encoding as described in Section 3.2. Following the method of Johnson et al. (2017), we jointly train the model to translate in all our language directions, pre-pending a token `<2xx>` to the source side to inform the model which target language to translate into. The system is comprised of a transformer base model trained using Marian (Junczys-Dowmunt et al., 2018) with cross-entropy loss, following the method of (Vaswani et al., 2017) and the default Marian `transformer` configuration.

We differ from the default configuration in the following ways. We fit our mini-batch to a workspace of 6144 MB, set the learning rate to 0.0003 with a warm-up increasing linearly for 16000 batches and decaying by $\frac{16000}{\sqrt{no.\ batches}}$ afterwards. We train on multiple GPUs using Adam (Kingma and Ba, 2014) with synchronous updates for optimization, setting $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 1e-09$. We set transformer dropout between layers to 0.01. We use a maximum sentence length of 200 tokens, a maximum target length as source length factor of 2, and a label smoothing of 0.01. During validation, we use a beam size of 6 and normalize the translation score by $translation\_length^{0.6}$. We check translation quality on our internal validation set (Section 3.1) every 5000 model updates and stop training when performance doesn't improve for 15 checkpoints. The model was trained for approximately 66 hours on four NVIDIA GeForce RTX 3090 GPUs.

Contrastive Our contrastive model fine-tunes the baseline model directly, using a concatenation of all data sets that incorporate our target languages, including parallel and back-translated data (the data sets (a), (b), and (d) described in Section 3.1). The fine-tuned model uses the same architecture, training settings, and stopping criterion as the original baseline model, essentially allowing us to continue training further from the original baseline. The final submitted system is an ensemble of the last four checkpoints of this model. The model was trained for approximately 54 hours on two NVIDIA GeForce RTX 2080 TI GPUs.

Primary For the primary system, we adapt mT5 (Xue et al., 2020), a multilingual pre-trained transformer language model, to the translation task. We use mt5 because of its state-of-the-art performance and its coverage of all of our target North Germanic languages. We use the SimpleTransformers[3] framework which extends HuggingFace (Wolf et al., 2019), with the default parameters. Since our model is initialized from the parameters of the `mt5-base` system, including the embedding layers, we use the same byte-pair encoded vocabulary as the original model. Due to resource constraints, we sample a total of 100k parallel sentences from data sets (a) and (b) (described in Section 3.1). We pre-pend a string to the source side to indicate to the model which target language to translate into, and adapt the model for 5 epochs. We further fine-tune this model on data that includes our target languages (sets (a) and (b) from Section 3.1) to create our Primary system. The model was trained for approximately 46 hours on a single NVIDIA A100 SXM4 GPU.

4 Evaluation

Table 3 reports results on detokenized SacreBLEU on each of our internal test set, the shared task validation set, and the shared task test set[4]. Comparing results on the internal test set and shared task validation sets show that our models fail to generalize well to the shared task domain. The `mt5_base_ada_ft` performance drops by an average of -4.2 BLEU points between the internal test set and the shared task validation set, while the `marian_ft_esmb` model performance drops by an average of -1.0 BLEU points. Performance on the shared task test set suffers the most on the least represented languages (in particular on `is`) causing the `marian_ft_esmb` to lose an additional -1.7 average BLEU points and the `mt5_base_ada_ft` model to lose an additional -1.8 average BLEU points. In future work, we would like to experiment with different sampling

Table 3: SacreBLEU (detokenized) results on the internal test set and the shared task validation and test sets.

methods to boost the performance of the least represented directions.

Comparing results between models, our primary `mt5_base_ada` system outperforms the `marian` model trained from scratch by an average of +10.7 and +8.6 BLEU points on the internal and shared task validation sets, respectively. The further fine-tuned variant `mt5_base_ada_ft` leads to an additional average improvement of just under +1 BLEU point on both sets, showing that the mt5 model already learned a good amount about our target task and languages from our initial adaptation step. The `marian` model is also outperformed by the fine-tuned variant `marian_ft`, resulting in an average improvement of +7.7 BLEU points on the internal test set and +8.5 BLEU points on the shared task validation set.

Both the `mt5_base_ada_ft` and `marian_ft` models are exposed to similar language data; however, the mt5 language model we adapted from (`mt5-base`) is much larger than our `marian` model (580 million vs 44 million parameters), and was trained on more language data (750 GB vs 46 GB), so it had a much stronger base to start from. Ensembling the last 4 checkpoints of the fine-tuned marian model for `marian_ft_esmb` boosts performance by +0.3 and +0.6 average BLEU on the internal and shared task validation sets over `marian_ft`; however, the `mt5_base_ada_ft` model still outperforms the `marian_ft_esmb` model by +3.7 and +0.5 average BLEU on the internal test set and the shared task validation set, respectively. Therefore, we submitted the `mt5_base_ada_ft` model as our primary system to the shared task; however, our contrastive system, the `marian_ft_esmb` model, won in the shared task rankings.

In the global automated evaluations of the shared task, our contrastive system is the best-performing submitted system[5], outperforming the official mT5 baseline by approximately +8.5 BLEU. We hypothesize that the mt5 baseline, while being pre-trained on massive amounts of partially noisy monolingual data, has learned the translation task via training on the development set only, so it has less informative parallel data available than our models. The M2M-100 (Fan et al., 2020) baseline outperforms all submitted systems, despite having been trained on noisy parallel data only. We hypothesize that the highly-multilingual nature of the M2M-100 model allows the target languages to benefit from the supervisory signals between related language combinations.

5 Conclusion and Future Work

We contribute to the growing space of NMT for North Germanic languages. We explore multilingualism by training a transformer with a shared encoder and decoder for all language pairs from scratch, as well as adapting a pre-trained multilingual language model. Fine-tuning these models to our low-resource language pairs was a key component in our success in the task, and we additionally confirm that employing popular techniques in machine translation, such as data filtering, back-translation, and model ensembling are beneficial for improving performance on low-resource directions. In future work, we would like to experiment with fine-tuning additional pre-trained models such as the M2M-100, incorporating iterative back-translation, and trying different sampling methods during training to boost lower performing low-resource language pairs.

[5]Only our primary model was submitted for manual evaluation, where it outranked the other submissions. Official rankings are available at: http://statmt.org/wmt21/multilingualHeritage-translation-task.html

Abstract

This paper describes TenTrans' submission to WMT21 Multilingual Low-Resource Translation shared task for the Romance language pairs. This task focuses on improving translation quality from Catalan to Occitan, Romanian and Italian, with the assistance of related high-resource languages. We mainly utilize back-translation, pivot-based methods, multilingual models, pre-trained model fine-tuning, and in-domain knowledge transfer to improve the translation quality. On the test set, our best-submitted system achieves an average of 43.45 case-sensitive BLEU scores across all low-resource pairs. Our data, code, and pre-trained models used in this work are available in TenTrans evaluation examples[1].

1 Introduction

We participate in the WMT21 Multilingual Low-Resource Translation shared task. This task focuses on the multilinguality in the cultural heritage domain for two Indo-European language families: North-Germanic and Romance. We devote the research into translations among Romance languages, including Catalan→Occitan, Catalan→Romanian, Catalan→Italian. Additionally, this task explicitly encourages the use of data of four related high-resource languages (Spanish, French, Portuguese and English) in the same linguistic family.

For the model architecture, we adopt a universal encoder-decoder architecture that shares parameters across all languages (Johnson et al., 2017). And almost all of the subsequent experiments are based on Transformer *base* model (Vaswani et al., 2017).

To effectively exploit low and high resource data in the multilingual low-resource scenario, we explore several approaches, and each approach shows effectiveness. We employ back-translation (Sennrich et al., 2016a) and pivot-based methods to augment the training corpus. In terms of knowledge transfer, we explore the pre-trained model and the multilingual model that trained with both low and high resource language pairs. Moreover, we extract in-domain corpus by a domain classifier and adapt the model to the target domain by in-domain fine-tuning.

This paper is structured as follows: Section 2 introduces used datasets, data statistic and pre-processing pipeline. Section 3 describes the details of different approaches. In Section 4 we present experimental settings and results. Section 5 draws a brief conclusion of our work in the WMT21.

2 Data

2.1 Datasets

The training datasets are majorly provided by the publicly available OPUS (Tiedemann, 2012) repository. We use almost all available datasets provided in the task, including Europarl, JW300, WikiMatrix, MultiCCAligned, OPUS-100, Bible, ELRC, and 167.2K It-Ro pairs in TED talks as well as 15M/360K sentence pairs of En-It/En-Ro extracted from Wikipedia dumps. For datasets that can be found through the resources search form on the top-level website of OPUS, we use opus-tools[2] to extract low-resource language pairs. As for rest of the data, we download them in the usual way. Statistics of different datasets are showed in Table 1.

2.2 Data Pre-processing

Cleaning datasets is necessary when the datasets are noisy and of low quality. We partially refer to

Table 2: Number of sentences in low-resource bilingual data.

M2M-100[3] (Fan et al., 2020) data pre-processing procedures to filter bilingual sentences. We remove sentences with more than 50% punctuation, deduplicate training data and remove all instances of evaluation data from the bilingual training data.

We tokenize all data and normalize punctuation with the Moses tokenizer (Koehn et al., 2007). To enable open-vocabulary and share information among languages, we use joint Byte-Pair-Encoding (BPE) with 32K split operations for subword segmentation (Sennrich et al., 2016b). We also remove sentences longer than 512 as well as sentence pairs with a source/target length ratio exceeding 3.

For monolingual data, we still employ those rules except the length ratio filter. See Table 2 for the statistics of low-resource bilingual data, Table 3 for the statistics of high-low resource bilingual data and Table 4 for the statistics of low-resource monolingual data.

3 System Overview

3.1 Base Systems

In multilingual translation scenarios, one can employ multi-task learning framework using multiple encoders or multiple decoders (Luong et al., 2016; Dong et al., 2015; Firat et al., 2016). Either, one can employ a unified model consisting of a shared encoder and a shared decoder for all the language pairs (Johnson et al., 2017). We experiment with these two models and conduct the conclusion that a universal encoder-decoder model outperforms the model with multiple decoders. The unified architecture is adopt in subsequent experiments in this work. Parameters and vocabulary are shared among all language pairs and this helps the generalization across languages improving the translation for the low-resource language pairs (Aharoni et al., 2019). We also train three separate bilingual models to be regarded as contrastive model with multilingual model. Furthermore, we jointly train on Catalan, Occitan, Romanian, Italian four low-resource languages simultaneously to obtain a many-to-many multilingual model. Detailed results of base systems are shown in Table 6.

We use the Transformer (Vaswani et al., 2017) as our model architecture for all of our systems. We experiment with increasing network capacity but we find that deep and wide model architectures bring training hurdles. So almost all subsequent models are based on the Transformer *base* architecture (Vaswani et al., 2017) as implemented in TenTrans[4], expect for pre-trained model M2M-100 trained using FAIRSEQ[5] (Ott et al., 2019).

3.2 Back-translation

Back-translation (briefly, BT) (Sennrich et al., 2016a) is an effective and commonly used data augmentation technique to incorporate monolingual data into a translation system.

In this work, for translation direction with more than 5 million bilingual data such as Catalan→Italian, we train a dedicated bilingual BT

model Italian→Catalan to translate Italian monolingual data into Catalan. For other translation directions with less than 5 million bilingual data, we use the jointly pre-trained many-to-many multilingual model with four low-resource languages as its source and target side (see Section 3.1) to back translate Occitan and Romanian monolingual data into Catalan. Beam search with beam size 5 is used when generating the synthetic sentences. Detailed results of reverse models are shown in Table 5.

3.3 Multilingual Model

Arivazhagan et al. (2019) shows that multilingual models can improve the translation performance of medium and low resource languages, as multilingual models are often trained on greater quantities of data compared to individual models. So we utilize high-low resource paired data such as English→Occitan in addition to low-resource bilingual data during training. Training on high-resource and low-resource language pairs together may bring knowledge transfer (Zoph et al., 2016), especially when languages are from the same linguistic family.

In the experiment, we train on four high-resource languages (Spanish, French, Portuguese and English) combined with four target-task low-resource languages together, resulting in an **8-to-4 multilingual** model with Ca, Oc, Ro, It as the target side. We randomly extract 2K sentence pairs from training data as the validation set for each high-low resource languages pairs. BPE codes and multilingual vocabulary are shared among all languages, but a shared multilingual vocabulary runs the risk of favoring high-resource languages over others, due to the imbalance of the dataset size the vocabulary is extracted. To reduce the effect of imbalanced dataset size, we apply a temperature sampling strategy named Vocabulary Sampling to construct a joined vocabulary. Following Arivazhagan et al. (2019), we set sampling temperature $\underline{T} = 5$.

Table 6 shows results on validation set of our baseline systems. Obviously, the universal encoder-decoder model outperforms the model with separate decoders for each target language by 7 BLEU on average. Compared to the bilingual baseline system, our universal multilingual 1-to-3 baseline system performs great improvement on low-resource languages, at the cost of sacrificing performance on relatively rich language Italian. However, the jointly trained multilingual 4-to-4 system shows performance degradation. We ascribe this phenomenon to multilingual model capacity is split for more translation directions, from 3 directions to 12 translation directions in this case.

3.4 Pivot-based Method

Pivot-based approaches are prevalent when addressing the data scarcity problem in machine translation, nonetheless, they suffer from cascaded translation errors: the mistakes made in the source-to-pivot translation will be propagated to the pivot-to-target translation (Dabre et al., 2020). Another pivot-based approach used in zero-resource transla-

Base System	Ca-Oc	Ca-Ro	Ca-It	Average BLEU

Multilingual 4-to-4	41.44	22.81	31.01	31.75

Table 6: BLEU scores (%) for baseline systems evaluated in the validation data. And the numbers represent languages used in models, e.g. 1-to-3 means source side of model is Ca but target side consists of Oc, Ro, It, and 4-to-4 means both the source and target side of model consist of four languages Ca, Oc, Ro and It.

tion scenario is that the pivot side of the pivot-target parallel corpus is back-translated to the source language, creating a synthetic source-target parallel corpus (Lakew et al., 2018; Gu et al., 2019). In this work, we adopt the latter pivot-based method.

In practice, we consider four high-resource languages En, Es, Fr, Pt as pivot languages, thus we train a pivot-to-source multilingual model to back translate four pivot languages in pivot-to-target parallel data into source language. Owing to relatively rich data of Catalan-Italian, we only perform experiments on low-resource languages of Occitan and Romanian. To balance distribution between genuine parallel data and synthetic parallel data, we oversample genuine data to be of the same magnitude as synthetic data.

We can combine all synthetic parallel data generated from back-translation and pivot-based method with genuine parallel data to jointly train a multilingual model from scratch, which is named **Combine-All**. Source side of this model is comprised of four rich-resource and four low-resource languages, and target side of this model is comprised of four low-resource languages.

3.5 Pre-trained Model Fine-tuning

Because of the recent popularity of using large scale pre-training models to fine-tune specific languages and tasks, we employ the M2M-100, a true Many-to-Many multilingual translation model (Fan et al., 2020) that can translate between 100 languages which cover four task languages. Our experiments are based on the M2M-100 1.2B model due to its better performance than the 418M model. In the subsequent fine-tuning procedure, we follow the parameters setting in fine-tuning mBART (Liu et al., 2020). In three task directions, we try fine-tuning M2M-100 model with genuine bilingual data (Bilingual FT) and fine-tuning with genuine multilingual data (Multilingual FT). Moreover, we try fine-tuning the M2M-100 1.2B model using **Combine-All** data with four high-resource plus low-resource languages as the source side and four low-resource languages as the target side.

Unfortunately, M2M-100 model trains on SentencePiece(Kudo and Richardson, 2018) rather than Byte-Pair-Encoding so that the fine-tuned model can not be directly combined with the models that listed above for ensembling. We utilize synthetic Catalan-Occitan, Catalan-Romanian data generated through sentence-level knowledge distillation (Kim and Rush, 2016) to train a 'student' model so as to incorporate knowledge of 'teacher' model M2M-100 1.2B into 'student' model. Concretely, in Catalan→Occitan direction, we employ multilingual fine-tuning on M2M-100 1.2B model using Combine-All data for 200K updates (1.1M updates for each epoch), after that, we continue with bilingual fine-tuning using genuine Catalan-Occitan parallel data. As for Catalan→Romanian direction, we directly use the pre-trained model without fine-tuning. We continue to train on **8-to-4 multilingual** model (See Section 3.3) in three task translation directions with data obtained through knowledge distillation and finally get a new model named **M2M-KD**. We do not implement knowledge distillation in Catalan→Italian direction since we find other systems perform equivalently to the pre-trained model. If time permitted, we believe that more improvements will be observed.

3.6 Domain Adaptation

Domains of training data are various, whereas validation and hidden test data belong to the cultural

System	Ca-Oc	Ca-Ro	Ca-It	Average BLEU

*In-domain-FT + M2M-KD + Combine-All	64.02	32.63	**40.04**	45.56

Table 7: BLEU scores (%) for different systems on the validation data. The number 8 means source side of model consists of both four high-resource languages and four low-resource languages, 4 means target side of model consists of four low-resource languages Ca, Oc, Ro and It. '†' is the submitted primary system. '*' is the submitted contrastive system.

heritage domain. Owing to the domain discrepancy, adapting models to the cultural heritage domain (Luong et al., 2015) is required.

Due to the scarcity of in-domain data, we utilize pre-trained language model multilingual Bert [6] (Devlin et al., 2019) to train a domain classifier for extracting in-domain sentences from genuine bilingual data. To train the domain classifier, we consider validation data of three languages Ca, Ro, It as positive samples, and randomly sample the low-resource side of high-low resource bilingual data as negative samples. Then classifier is exploited to score the source sentences (Ca/Ro/It). We select sentence pairs whose source is predicted to be positive with a probability greater than threshold 0.7 to construct in-domain corpus. In the end, we pick out 60K Catalan-Occitan, 297K Catalan-Romanian and 815K Catalan-Italian data respectively as in-domain corpus. We fine-tune **8-to-4 multilingual** model on the in-domain corpus in three task translation directions and then get the **In-domain-FT** model. For the purpose of preventing overfitting, we set the max-tokens to be 2K with a learning rate of 3e-5 and we force fine-tuning to stop when finishing the first epoch. Note that we do not perform fine-tuning on the validation set.

4 Experiments

4.1 Settings

Except that the pre-training experiments are trained on 4 NVIDIA V100 GPUs, the rest of our experiments are carried out with 8 NVIDIA P40 GPUs. Except for the pre-training experiments, the rest of our experiments use the following settings. Our models apply Adam (Kingma and Ba, 2015) as optimizer to update the parameters with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. We set the label smoothing and dropout rate to 0.1. The initial learning rate is set to 5e-4

varied under a warm-up strategy with 4000 steps. In the training stage, batch size is 8K tokens per GPU.

We use uncased BLEU scores calculated with Moses multi-bleu.pl[7] toolkit as the evaluation metric. And we choose model checkpoints based on the BLEU score on average of the validation set.

4.2 Main Results

Table 7 shows that the translation quality is largely improved with different systems. Although minority systems encounter the problem of average performance degradation on the validation set, they contribute to at least one translation direction. Back-translation gives a solid improvement by nearly 0.8 BLEU on average. Pivot-based method offers 1∼2 BLEU in Catalan→Romanian, Catalan→Italian directions, however, pivot degrades in Catalan→Occitan direction. When we train an 8-to-4 multilingual model jointly with both the high and low resource languages, the model shows an absolute improvement in three task directions of 6 BLEU on average score. It can be explained by that a larger quantity of genuine data leads to robust encoder/decoder or knowledge can be transferred from high-resource into low-resource languages. As for the pre-trained model, we notice that M2M-100 1.2B model performs very well in Catalan→Romanian, Catalan→Italian directions without fine-tuning. And we find that average bilingual fine-tuning outperforms multilingual fine-tuning by about 2.6 BLEU. We also observe some systems hold a comparable performance with M2M-100 1.2B model in Catalan→Romanian and Catalan→Italian directions when training data is abundant.

Further experiments include the in-domain fine-tuning and M2M-KD based on the **multilingual 8-to-4** system. In-domain fine-tuning is restricted to in-domain data size, but we also obtain a solid improvement of 1.5 BLEU on average, especially in Catalan→Occitan direction. M2M-KD model yields a greater improvement that we get the best BLEU in Catalan→Occitan, Catalan→Romanian directions with 65.18, 32.85 respectively. Ultimately, to take advantages of multiple single models, two or three top performing models are ensembled to be the submitted systems.

[7] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

5 Conclusions

In this paper, we present the system TenTrans submitted for the WMT21 Multilingual Low-Resource Translation for Indo-European Languages shared task. We focus on Romance languages, translating from Catalan to Occitan, Romanian and Italian. Back-translation, pivot-based method, multilingual model, knowledge distillation using pre-trained model, domain adaptation and ensembles are employed and proven effective in the experiments. Our best submitted system achieves an average of 43.45 case-sensitive BLEU score across all low-resource languages pairs.

Abstract

This paper describes the system submitted to Large-Scale Multilingual Shared Task (Small Task #2) at WMT 2021. It is based on the massively multilingual open-source model FLORES101_MM100 model, with selective fine-tuning. Our best-performing system reported a 15.72 average BLEU score for the task.

1 Introduction

Massively multilingual models such as Facebook's M2M-100 (Fan et al., 2020) model provide an attractive approach to scaling Machine Translation to many language pairs by sharing encoder-decoder parameters across languages. By not centering English in its training process, M2M-100 improves translation quality substantially (by over 10 BLEU points) compared to the best single systems of WMT before 2020 on the "large-scale Many-to-Many dataset for 100 languages" (Fan et al., 2020). However, translation quality for low-resource languages still leaves much room for improvement.

We address the Large-Scale Multilingual Machine Translation Shared Task (Small Track #2) at WMT 2021, by fine-tuning the FLORES101_MM100 model for the languages in the Shared task. We consider different fine-tuning configurations, with a goal to minimize the computational and data resources required. First, we consider the impact of finetuning on datasets of different sizes, and surprisingly show that finetuning with the smaller dataset gives better performance for some language pairs. Second, we consider selectively dropping layers during fine-tuning to reduce the computational cost of working with a Transformer model with millions of parameters. We adopt a structure dropout technique, *LayerDrop*, which has been shown to have a regularization effect and to effectively reduce model size for inference (Fan et al., 2019), as well as to reduce training time while preserving decoding quality (Zhang and He, 2020). We have used *LayerDrop* so that our model can run on large datasets for low resource language pairs.

Our best performing system is fine-tuned on the large MultiCCAligned training data and yields a sentence-piece BLEU score (the official Shared task metric) of 15.72 on the Shared task test set. However, a model fine-tuned on smaller amounts of data (bible-uedin) approaches that result, with a BLEU score of 15.10. This paper describes the submitted models, as well as experiments with *LayerDrop* configuration, which show that dropping the top layers does not help BLEU.

2 Shared Task Data

Training Our training data is provided by the Shared task organizers and is drawn from the publicly available open-source multilingual parallel corpus (OPUS) data repository for the languages of the Shared task (Tiedemann, 2012). It consists of the MultiCCAligned large dataset which supports 112 languages (El-Kishky et al., 2020) with English as the pivot language. The bible-uedin dataset (Christodouloupoulos and Steedman, 2015) is comparatively smaller than the MultiCCAligned dataset and is supported by 102 languages based on translations from the Bible. Table 1 reflects the statistics for the datasets from 23 different language pairs (3 from bible-uedin with a size of 125 MB and 15 from MultiCCAligned with a size of 16 GB) considering only the 6 languages in the Shared task which are Indonesian, Javanese, Tamil, Tagalog, Malay, and English. MultiCCAligned takes up more than 50% of the dataset while bible-uedin takes less than 0.2%.

We preprocess the data using the "SentencePiece" module (Kudo and Richardson, 2018) for tokenization and byte-pair encoding, and remove duplicate samples.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 383–386

Evaluation Sets The Shared task evaluates models on three distinct datasets: *dev*, *devtest* and *test*. They are all drawn the FLORES-101 benchmark for Many-to-Many multilingual translation (Goyal et al., 2021). It consists of 3001 sentences extracted from English Wikipedia and covering a variety of different topics and domains. These sentences have been translated into 101 languages by professional translators through a carefully controlled process. The Shared task uses a subset of six languages including English from FLORES-101. The languages are: Javanese (jav), Indonesian (ind), Malay(msa), Tagalog (tgl), Tamil (tam), and English (eng). The *dev* and *devtest* sets are both 2.8MB in size. These datasets were evaluation test set and were therefore held out from our fine-tuning experiments. The *test* set were inaccessible to the Shared Task participants.

3 Model Configurations

This section describes our base model and the various fine-tuning configurations considered.

3.1 Base Model

Figure 1 shows a FLORES101_MM100 model with the original encoder and decoder.

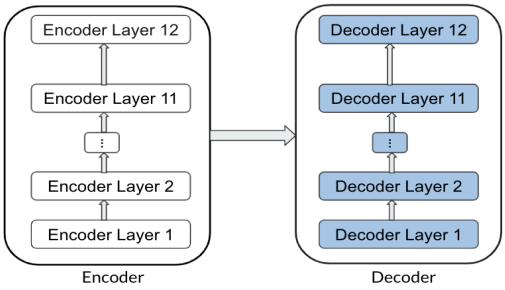

Figure 1: Baseline FLORES101_MM100 architecture

3.2 Finetuning Strategies

Hyper-parameters Table 2 gives the list of the hyper-parameter settings we use for all finetuning in our experiments. Since batch size and learning rate affect finetuning, we experimented with two different learning rates, $3e^{-5}$ and $3e^{-7}$, on the smaller dataset (bible-uedin). Changing the learning rate from $3e^{-5}$ to $3e^{-7}$ boosts the BLEU score of bible-uedin fine-tuned model to 15.10.

Batch Size	4
Loss Function	Label Smoothed Cross Entropy
Label Smoothing	0.2
Optimizer	Adagrad
Learning Rate	$3e^{-5}$ / $3e^{-7}$
LR Scheduler	Inverse Square Root
Warmup updates	2500
Dropout	0.3
Attention Dropout	0.1

Table 2: Hyperparameter setup

Data We compare the impact of using each of the datasets decribed in Section 2 to fine-tune the models: bible-uedin and MultiCCAligned.

Activation function In addition to using the standard ReLu activation function, we experiment with the GELU nonlinearity, which weighs inputs by their percentile, rather than gates inputs by their sign as in ReLUs. Compared to ReLU or leaky ReLU, GELU has the theoretical advantage of being differentiable for all values of x.

LayerDrop Fan et al. (2019) introduced a *LayerDrop* technique to generate shallow models from larger ones by dropping entire layers at inference time. These dropped layers have a regularization effect and reduce training time. Inspired by these results, we fine-tune our model with *LayerDrop*

Dataset	Dev	DevTest	Test
Baseline	12.39	11.78	12.11
Fine-tuned Models			
Bible-uedin	15.50	14.89	15.10
MultiCCAligned	**16.05**	**15.45**	**15.72**

Table 3: Impact of fine-tuning data on spBLEU: MultiCCAligned data yields the best scores, but Bible-uedin achieves close results despite being much smaller.

		Dev	DevTest	Test
Baseline		12.39	11.78	12.11
GeLu	no LD	15.19	14.61	14.83
ReLu	LD	7.35	6.94	7.34
ReLu	no LD	**16.05**	**15.45**	**15.72**

Table 4: Impact of activation function and LayerDrop (LD) on spBLEU: the standard settings with ReLu and without LD yield the best translation quality.

by selectively dropping the last three layers (9, 10, 11) in the encoder and the decoder. We compare this approach to fine-tuning all layers in our model without *LayerDrop*.

4 Results

Aggregate Results The Shared task evaluates the performance of models using a sentence-piece BLEU (spBLEU) score, aggregated across all language pairs tested. We report results using this metric and to it as BLEU in this section.

Table 3 reports the BLEU score of our models finetuned with the different datasets on the three Shared task evaluation sets. From Table 3, we can see that the model finetuned with MultiCCAligned obtains higher BLEU scores across the board compared to the model finetuned with bible-uedin. On the *test* set, it obtains a BLEU score of 15.72. However, the model fine-tuned on bible-uedin, is only about .6 BLEU point behind (15.10 BLEU), despite being only about $\frac{1}{340}$ in size comparing to the MultiCCAligned. These results suggest that amount of data is not the most important factor when selecting a dataset for fine-tuning.

Table 4 shows the BLEU scores obtained with fine-tuning configurations which vary in the activation function used and in the use of the *LayerDrop* technique for reducing model size. The best results are obtained with the standard settings: fine-tuning with the ReLU activation and no *LayerDrop*. *LayerDrop* degrades translation quality substantially, which suggests that it is not a promising strategy to reduce the computational cost of neural MT.

Per Language Results In addition to aggregate results, we report BLEU scores per language pair in Figure 2 for each of the main experimental conditions considered. Since our main motivation is to improve the performance of the model for low-resource languages, we would like to fill the gap between the languages with a higher score and the languages with a lower score, i.e. to see more dark blue squares in the Figure. Comparing the score break down of the MultiCCAligned model and the bible-uedin model, the latter one performs better on almost all translations to Tamil and Tagalog; for example, there is a 2.33 improvement on eng-tam and a 6.49 improvement on eng-tgl. Some translations from Tamil also show improvements, 1.3 on tam-eng, while the only improvement from Tagalog is 1.31 on tgl-tam. However, bible-uedin model performs worse on 19 out of all 30 language pairs and has a lower average.

5 Submitted System Configuration

The submitted system is fine-tuned with the MultiCCAligned dataset for all the language pairs mentioned in Table 1. The hyper-parameters are set as described in Table 2 with learning rate $3e^{-05}$. This system uses ReLu as the activation function and keeps all the original layers in the encoder and decoder. The fine-tuning is done for 10 epochs.

6 Conclusion

We described the University of Maryland submission to the Large-Scale Multilingual Shared Task (Small Task #2) at WMT 2021. We considered several fine-tuning configurations on top of the massively multilingual FLORES101_MM100, and find that using MultiCCAligned data and a standard model configuration give the best result. We also show that finetuning on the much smaller Bible-uedin dataset approaches our best result, with a BLEU score of 15.10. Selecting appropriate fine-tuning data thus plays a significant role in the quality of the final model, and the amount of data alone is a suboptimal selection criterion. Dropping the last three layers of the encoder and decoder decreased the translation quality. Future work is needed to determine how to reduce the computational needs of large-scale multilingual MT.

Abstract

We describe TelU-KU models of large-scale multilingual machine translation for five Southeast Asian languages: Javanese, Indonesian, Malay, Tagalog, Tamil, and English. We explore a variation of hyperparameters of flores101_mm100_175M model using random search with 10% of datasets to improve BLEU scores of all thirty language pairs. We submitted two models, TelU-KU-175M and TelU-KU-175M_HPO, with average BLEU scores of 12.46 and 13.19, respectively. Our models show improvement in most language pairs after optimizing the hyperparameters. We also identified three language pairs that obtained a BLEU score of more than 15 while using less than 70 sentences of the training dataset: Indonesian-Tagalog, Tagalog-Indonesian, and Malay-Tagalog.

1 Introduction

This paper describes our participation in the WMT21 shared task of large-scale multilingual machine translation. Specifically, we chose small track #2, which involves thirty language pairs, and used the neural machine translation (NMT) method. We call our models TelU-KU (Telkom University - Kumamoto University) as we use our university name in our submissions.

*These authors contributed equally. Everyone contributed to writing this paper.

NMT has been widely used in machine translation research for many languages. Currently NMT has become the state of the art of machine translation with a large number of parallel corpus (Bojar et al., 2017; Nakazawa et al., 2017; Chu and Wang, 2018; Sutskever et al., 2014). Meanwhile, for low resources cases, the NMT tends to give poor translation results (Duh et al., 2013; Sennrich and Zhang, 2019; Zoph et al., 2016; Koehn and Knowles, 2017). In order to get better translation results of NMT for low resources languages, some approaches are applied, such as using a large number of monolingual corpora (Artetxe et al., 2018a,b; Lample et al., 2018b,a), applying transfer learning approach to share lexical and sentence level representation (Gu et al., 2018), using sub-word representation (Durrani et al., 2019), and hyperparameter optimization (HPO) (Sennrich and Zhang, 2019; Rubino et al., 2020).

HPO is an important part of building an NMT system in many real-world applications. In other words, selecting effective hyperparameters is critical to building a strong NMT system. However, in many cases, hyperparameters are often set manually based on intuition and heuristics mechanisms, tedious and error-prone processes that can lead to unreliable experimental results and poor performance of shared tasks or production systems.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 387–397
November 10–11, 2021.

This is because HPO requires rigorous testing and resources, which makes it a high-cost process. To deal with this problem, table-lookup has been proposed as a benchmark procedure (Zhang and Duh, 2020). Their study provides evaluation protocols and a benchmark dataset for comparing the HPO methods. Moreover, like other NMT models, transformers require setting various hyperparameters, but researchers often use default parameters, even when their data conditions differ substantially from the data conditions previously used to determine those default values.

In low-resource languages cases, the performance of the transformer is highly dependent on the hyperparameter settings (Araabi and Monz, 2020). The experimental results show that the best-suited combination of hyperparameters and regularization methods can produce substantial improvement for low-resource languages data. On the other side, grid search and manual search are the most frequently used strategies for HPO. However, according to the experiment, random search is actually better than grid search in several conditions (Bergstra and Bengio, 2012). Random searches are actually better suited to running on a cluster of computers than grid searches when a group of computers fails. Random search also allows the experimenter to change the "resolution" on the fly. In addition, they have advantages in high-dimensional searching spaces.

In this work, we experimented with two models, that is, TelU-KU-175M and TelU-KU-175M_HPO. Both models are based on a pre-trained model of flores101_mm100_175M. The TelU-KU-175M is our model that manually fine-tuning the hyperparameters, whereas the TelU-KU-175M_HPO is based on hyperparameter optimization. We used a random search method while using 10% of datasets to find the best hyperparameter optimization. In addition, we also included the M2M-100 175M model to compare with our results. This model uses the same pre-trained model as ours but without fine-tuning. Fine-tuning is a common practice in NLP to train a pre-trained model for several epochs on a downstream dataset and has proven to improve performance.

Our experimental results show improvement in most language pairs after optimizing the hyperparameters. The TelU-KU-175M is able to improves the average BLEU scores by 0.35-0.59 over M2M-100 175M. Meanwhile, the TelU-KU-175M_HPO improve the scores by 1.08-1.41 over the baseline. We also identified three language pairs that obtained a BLEU score of more than 15 while using less than 70 sentences of the training dataset: Id-Tl, Tl-Id, and Ms-Tl.

This paper is organized as follows. Section 2 explains the experiment. Section 3 shows the obtained results. Section 4 discusses the effect of HPO and the multilingual model. Section 5 provides the conclusion and future direction of this work.

2 Experiments

In this section, we first describe languages overview of the Southeast Asian language. Then, we discuss data and preprocessing. Finally, we discuss the model and architecture of our model submission.

2.1 Languages overview

We chose small track #2, which involves six languages from Southeast Asia, namely, Javanese (Jv), Indonesian (Id), Malay (Ms), Tagalog (Tl), Tamil (Ta), and English (En).

Indonesian and Malay are considered closely related languages due to being mutually intelligible in morphology, and both languages belong to the Malayo-Polynesian language family (Susanto et al., 2012). The base of formal Indonesian is from Malayo-Riau (Abas, 1987). The main difference is the influence of the vocabulary. Indonesian is largely influenced by Dutch, whereas English influences Malay. The Tagalog language has the same language family as Indonesian and Malay. However, it has different morphology characteristics, and the vocabulary is influenced by several countries, such as Spain, America, and Malay. Javanese is one of the Indonesian ethnic languages used by more than 42% of Indonesia's population, mostly from the central and eastern parts of Java (Novitasari et al., 2020). Javanese is also used in Suriname and New Caledonia. Currently, the Javanese is influenced by Indonesian. This is because Indonesian is used in

Language	Family	Alphabet
Indonesian	Malayo-Polynesian	Latin
Malay	Malayo-Polynesian	Latin
Tagalog	Malayo-Polynesian	Latin
Tamil	Dravidian	Tamil
English	Germanic	Latin
Javanese	Malayo-Polynesian	Latin

Table 1: Language family and writing system.

formal documents and as a daily conversation. Last, Tamil belongs to Dravidian, a unique family where the language is mostly spoken in a southern state (Tamil Nadu) of India (Kumar and Singh, 2019). Table 1 shows the general characteristic of the selected languages.

2.2 Data and preprocessing

We used a dataset provided by the WMT21 organizers. Thus, our system was considered a constrained system. We used three types of datasets, that is, training, evaluation, and hidden test datasets. The training dataset is a parallel corpus from Opus monolingual and Wikipedia, as shown in Table 2. The evaluation dataset is a parallel corpus from Flores101 (Goyal et al., 2021). The evaluation dataset consists of two evaluations, that is, *dev* and *devtest*, as much as, 997 and 1,012 sentences, respectively. Last, the hidden test dataset is an unknown parallel corpus provided by the organizer through the Dynabench leaderboard.[1]

We tokenized all the training and evaluation datasets by SentencePiece tokenizer (Sennrich et al., 2016). This tokenizer is an unsupervised text tokenizer and detokenizer, where the vocabulary size is predetermined prior to the neural model training. We preprocessed dataset according to the guideline,[2] that is, encode and binarize.

2.3 Models & Architectures

We use an NMT system with big Transformer architecture (Ng et al., 2019; Vaswani et al., 2017), i.e., *transformer_wmt_en_de_big*, as implemented in the Fairseq toolkit (Ott et al., 2019). We run experiments on Standard NC24 of Microsoft Azure virtual machine consisting of 4 NVidia Tesla K80 with 12 GB GPU memory.[3] We experimented with the following two models:

Language pairs	Sentences
En - Id	1,019,169
En - Jv	13,049
En - Ms	120,016
En - Ta	95,162
En - Tl	75,447
Id - Jv	42
Id - Ms	1,167
Id - Ta	24,648
Id - Tl	56
Jv - Ms	18
Jv - Ta	1,296
Jv - Tl	2,251
Ms - Ta	3,920
Ms - Tl	5
Ta - Tl	1,478

Table 2: Training datasets of each language pair.

- **TelU-KU-175M** is a pre-trained flores101_mm100_175M with fine-tuning. We manually tune the hyperparameters, as shown in Table 3, column 4.
- **TelU-KU-175M_HPO** is a pre-trained flores101_mm100_175M with HPO. The hyperparameters and their ranges are shown in Table 3. Some of these hyperparameters are based on (Ravikumar, 2020). Figure 1 shows the logical flow of our approach. We run 30 iterations of random searches for two epochs. Due to costly training, we only run the optimization using only 10% *training*, *dev*, and *devtest*. From those 30 models, we select the best model based on the results from the *devtest*. Then, we use the hyperparameter from the best models to fine-tune the flores101_mm100_175M model. The hyperparameter optimization results are shown in Table 3, column 5.

3 Results

We evaluate the generated texts of our models using the sentence-piece BLEU (spBLEU). The spBLEU uses a SentencePiece tokenizer with 256k tokens, and then the BLEU score is computed on the SentencePiece tokenized text. The results are shown in Table 4.

Table 3: Hyperparameter range for each hyperparameter and the values for each model.

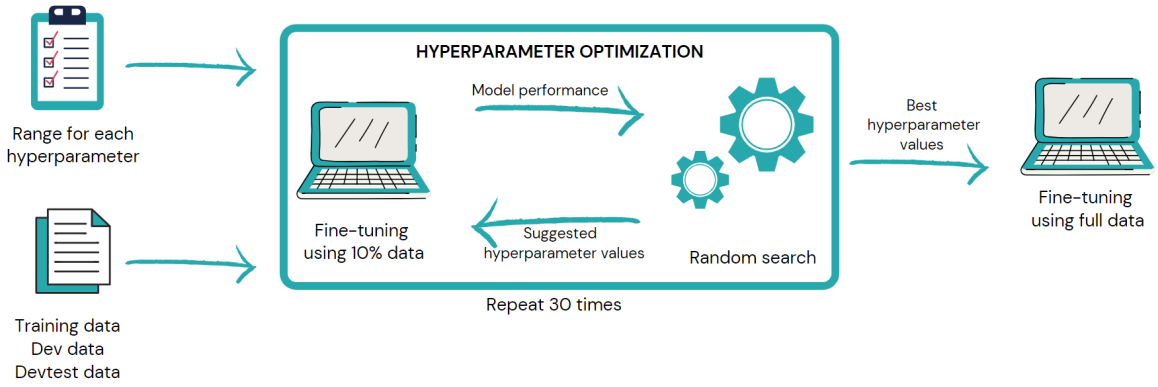

Figure 1: Logical flow of hyperparameter optimization.

We also compare our results with the pretrained model without fine-tuning (M2M-100 175M) as the baseline. Our models: the TelU-KU-175M and TelU-KU-175M_HPO, improved the BLEU scores on 16-17 language pairs over the M2M-100 175M model. In terms of the improvement in each language pair, TelU-KU-175M and TelU-KU-175M_HPO improved BLEU scores by 0.04-5.39 and 0.01-12.22, respectively. The BLEU scores also decreased on several language pairs between 0.1 to 3.25 and 0.02 to 6.5 for TelU-KU-175M and TelU-KU-175M_HPO, respectively.

4 Discussion

This section discusses the effect of HPO and NMT of the multilingual model against our models' evaluation results.

4.1 Effect of HPO

The main objective of HPO in this task is to explore a high-dimensional search space in NMT. As we mentioned in Section 2.3, we run HPO using random search for 30 iterations using 10% of the dataset. The best hyperparameter values were determined based on *devtest*. The best configurations based on the average BLEU scores for each iteration were saved for running the pretrained model, M2M-100 175M, using full datasets (TelU-KU-175M_HPO). The detail of the best configurations is shown in Table 3. The evaluation results were conducted by translating the *dev*, *devtest*, and *test* datasets. We show our detailed evaluation results in Table 4, while Table 5 is our average evaluation among other participants.

We found that fine-tuning of 10% dataset does not lead to the best results for all language pairs translation compared to the manual hyperparameter tuning (TelU-KU-175M) and fine-tuning using 100% dataset (TelU-KU-175M_HPO). The best HPO using 10% of datasets resulted in an average BLEU of 12.75 for dev, 12.33 for devtest, and 12.39 for test datasets. Nevertheless, these values are higher compared to the baseline (M2M-100 175M) in Table 5. This means that fine-tuning with only 10% dataset using a basic method, random search (Bergstra and Bengio, 2012), indeed increases the BLEU scores.

Table 4: Summary of results for all language pairs based on BLEU scores. Blue font means that there is an improvement over the M2M-100 175M model, while red font means a decline over the M2M-100 175M model.

The BLEU scores improved even more after using the full dataset with the same hyperparameter values (TelU-KU-175M_HPO). This means that the number of datasets influences the performance. We left for future work discussing the effect of the number of datasets in HPO for NMT.

We also study the hyperparameter importance of all optimized hyperparameters using Hyanova[4], a python implementation of a functional analysis of variance (fANOVA) algorithm (Hutter et al., 2014). The algorithm partitions the observed variation of a response value into components against its inputs (Klein and Hutter, 2019). In this study, the response value is the BLEU score, while hyperparameters are the inputs. The higher the fANOVA values, the more important the hyperparameter. Table 6 shows that LR is the most important hyperparameter, while BS is the least important. This means that the LR influence the achieved BLEU scores. From our observation, within our selected range in Table 3, the higher the learning rate, the higher the average BLEU score. Therefore, it is important to tune the LR within a higher range.

Furthermore, we investigate the statistical significance across language pairs from Table 4 using Wilcoxon signed-rank test with $\alpha = 0.05$. We show the p-values of all models in Table 7. Unfortunately, all the results demonstrate statistically non-significant as all of the p-values were more than 0.05. Although the average BLEU can be increased by optimizing the hyperparameter values, this finding shows that HPO might not contribute much to the performance.

One of the possible causes is the utilization of random search, which is categorized as an uninformed search. This category does not learn from previous results, and therefore, each solution is independent of the other. Moreover, uninformed search is proven to be inferior to the informed search, i.e.,

bayesian optimization or evolutionary algorithm (Fatyanosa and Aritsugi, 2020, 2021).

This work only calculates the statistical significance across language pairs and leaves the calculation per language pair for future studies.

4.2 Effect of multilingual model

The TelU-KU-175M and TelU-KU-175M_HPO models produced 16-17 language pairs that have higher BLEU scores compared to M2M-100 175M, as shown in Table 4 with blue colors. Among them, we identified seven language pairs that obtained a BLEU score below 10: Id-Ta, Ta-Id, Ta-Jv, Ms-Ta, Ta-Ms, Ta-Tl, and Jv-Tl. Most of these language pairs were related to the Tamil language. We found that most of the Tamil translation results had an English sentence as unknown words (see Tables 8 and 9 in appendix). The translation results leading to not the same as a reference file. As a result, these language pairs had a lower BLEU score.

Surprisingly, we identified three language pairs that obtained a BLEU score of more than 15: Id-Tl, Tl-Id, and Ms-Tl, while using less than 70 sentences of the training dataset. This could be because of the attention mechanism in NMT of multilingual models. The attention mechanism, which was initially called a soft-alignment model in (Bahdanau et al., 2015), aligns a source phrase to a target word. Training this attention-based model is done by maximizing the conditional log-likelihood. After training, the model can do translation from any of the source languages to any of the target languages included in the parallel training corpora (Firat et al., 2016).

The Id-Tl, for example, obtained a BLEU score of 17.94 using only 56 sentences of training datasets. The NMT system that trained with fewer training datasets, e.g., below 1M, usually obtained lower BLEU scores. However, the Id-Tl results indicated that this language pair obtained an advantage from the attention mechanism of the multilingual model using 30 language pairs. In this study, these 30 language pairs are considered as low-resource languages and mostly have the same language family. Table 2 shows that our models used a small number of training datasets, e.g., below 1M, in all language pairs. Whereas, Table 1 shows that most languages have the same language family: Malayo-Polynesian. Therefore, we argue that low-resource language with the same language family should be considered in the NMT of the multilingual model. For example, if we want to improve the Tamil language performance, we should considered to add other languages with the same (or closely) language family as Tamil, e.g., Kannada, Bengali, Hindi.

Model	Dev			Devtest			Test		
	M2M-100 175M	TelU-KU-175M	TelU-KU-175M_HPO	M2M-100 175M	TelU-KU-175M	TelU-KU-175M_HPO	M2M-100 175M	TelU-KU-175M	TelU-KU-175M_HPO
M2M-100 175M	x	0.567	0.399	x	0.360	0.289	x	0.734	0.572
TelU-KU-175M		x	0.229		x	0.329		x	0.360
TelU-KU-175M_HPO			x			x			x

Table 7: Results of Wilcoxon signed-rank test.

5 Conclusion

We described our team submission for WMT21. Our results show improvement in most language pairs after optimizing the hyperparameters.

Furthermore, we also found three language pairs that obtained a BLEU score of more than 15 while using less than 70 sentences of the training dataset. In this study, we used 30 language pairs that are considered as low-resource language and mostly have the same language family. This result indicated that low-resource language with the same language family should be considered in the NMT of the multilingual model.

As future work, we plan to use a more sophisticated optimization algorithm, specifically informed searches such as bayesian optimization or evolutionary algorithm. Additionally, we want to try other percentages of the optimized dataset to see the effect of the number of training data on the performance. We also plan to use a specific tokenizer for Tamil, e.g., Indic NLP library (Kunchukuttan, 2020), iNLTK (Arora, 2020). The Tamil language needs a particular pre-processing due to its writing system that differs from other languages. Last, we plan to clean the dataset in pre-processing steps, considering that the dataset used in this work is noisy. We expect this will maximize the attention mechanism in the NMT of a multilingual model. Therefore, our model could produce better translation results.

Abstract

In this paper, we focus on the task of multilingual machine translation for African languages and describe our contribution in the 2021 WMT Shared Task: Large-Scale Multilingual Machine Translation. We introduce MMTAfrica, the first many-to-many multilingual translation system for six African languages: Fon (fon), Igbo (ibo), Kinyarwanda (kin), Swahili/Kiswahili (swa), Xhosa (xho), and Yoruba (yor) and two non-African languages: English (eng) and French (fra). For multilingual translation concerning African languages, we introduce a novel backtranslation and reconstruction objective, BT&REC, inspired by the random online back translation and T5 modelling framework respectively, to effectively leverage monolingual data. Additionally, we report improvements from MMTAfrica over the FLORES 101 benchmarks (spBLEU gains ranging from $+0.58$ in Swahili to French to $+19.46$ in French to Xhosa).

In this paper, we make use of the following notations:

- $\circledast$ refers to any language in the set $\{eng, fra, ibo, fon, swa, kin, xho, yor\}$.
- $\diamond$ refers to any language in the set $\{eng, fra, ibo, fon\}$.
- AL(s) refers to African language(s).
- X$\longrightarrow$ Y refers to neural machine translation from language X to language Y.

1 Introduction

Despite the progress of multilingual machine translation (MMT) and the many efforts towards improving its performance for low-resource languages, African languages suffer from under-representation. For example, of the 2000 known African languages (Eberhard et al., 2020) only 17 of them are available in the FLORES 101 Large-scale Multilingual Translation Task as at the time of this research. Furthermore, most research that look into transfer learning of multlilingual models from high-resource to low-resource languages rarely work with ALs in the low-resource scenario. While the consensus is that the outcome of the research made using the low-resource non-African languages should be scalable to African languages, this cross-lingual generalization is not guaranteed(Orife et al., 2020) and the extent to which it actually works remains largely understudied. Transfer learning from African languages to African languages sharing the same language sub-class has been shown to give better translation quality than from high-resource Anglo-centric languages (Nyoni and Bassett, 2021) calling for the need to investigate AL$\longleftrightarrow$AL multilingual translation.

This low representation of African languages goes beyond machine translation (Martinus and Abbott, 2019; Joshi et al., 2020; $\forall$ et al., 2020). The analysis conducted by $\forall$ et al. (2020) revealed that low-resourcedness of African languages can be traced to the poor incorporation of African languages in the NLP research community (Joshi et al., 2020). All these call for the inclusion of more African languages in multilingual NLP research and experiments.

With the high linguistic diversity in Africa, multilingual machine translation systems are very important for inter-cultural communication, which is in turn necessary for peace and progress. For example, one widely growing initiative to curb the large gap in scientific research in Africa is to translate educational content and scientific papers to various African languages in order to reach far more African native speakers (Abbott and Mart-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 398–411
November 10–11, 2021.

inus, 2018; Nordling, 2018; Wild, 2021).

We take a step towards addressing the under-representation of African languages in MMT and improving experiments by participating in the 2021 WMT Shared Task: Large-Scale Multilingual Machine Translation with a major target of ALs⟷ALs. In this paper, we focused on 6 African languages and 2 non-African languages (English and French). Table 1 gives an overview of our focus African languages in terms of their language family, number of speakers and the regions in Africa where they are spoken (Adelani et al., 2021b). We chose these languages in an effort to create some language diversity: the 6 African languages span the most widely and least spoken languages in Africa. Additionally, they have some similar, as well as contrasting, characteristics which offer interesting insights for future work in ALs:

- Igbo, Yorùbá and Fon use diacritics in their language structure while Kinyarwanda, Swahili and Xhosa do not. Various forms of code-mixing are prevalent in Igbo (Dossou and Emezue, 2021b).
- Fon was particularly chosen because there is only a minuscule amount of online (parallel or monolingual) corpora compared to the other 5 languages. We wanted to investigate and provide valuable insights on improving translation quality of very low-resourced African languages.
- Kinyarwanda and Fon are the only African languages in our work not covered in the FLORES Large-Scale Multilingual Machine Translation Task and also not included in the pretraining of the original model framework used for MMTAfrica. Based on this, we were able to understand the performance of multilingual translation finetuning involving languages not used in the original pretraining objective. We also offered a method to improve the translation quality of such languages.

Our main contributions are summarized below:

1. MMTAfrica – a many-to-many AL⟷AL multilingual model for 6 African languages.
2. Our novel reconstruction objective (described in section 4.2) and the `BT&REC` finetuning setting, together with our proposals in section 5.1 offer a comprehensive strategy for effectively exploiting monolingual data of African languages in AL⟷AL multilingual machine translation,
3. Evaluation of MMTAfrica on the `FLORES Test Set` reports significant gains in spBLEU over the M2M MMT (Fan et al., 2020) benchmark model provided by Goyal et al. (2021),
4. We further created a unique highly representative test set – `MMTAfrica Test Set` – and reported benchmark results and insights using MMTAfrica.

Language	Lang ID (ISO 639-3)	Family	Speakers	Region
Igbo	ibo	Niger-Congo-Volta-Niger	27M	West
Fon (Fongbe)	fon	Niger-Congo-Volta-Congo-Gbe	1.7M	West
Kinyarwanda	kin	Niger-Congo-Bantu	12M	East
Swahili	swa	Niger-Congo-Bantu	98M	Southern, Central & East
Xhosa	xho	Niger-Congo-Nguni Bantu	19.2M	Southern
Yorùbá	yor	Niger-Congo-Volta-Niger	42M	West

2 Related Work

2.1 Multilingual Machine Translation (MMT)

The great success of the encoder-decoder (Sutskever et al., 2014; Cho et al., 2014) NMT on bilingual datasets (Bahdanau et al., 2015; Vaswani et al., 2017; Barrault et al., 2019, 2020) inspired the extension of the original bilingual framework to handle more languages pairs simultaneously – leading to multilingual neural machine translation.

Works on multilingual NMT have progressed from sharing the encoder for one-to-many translation (Dong et al., 2015), many-to-one translation (Lee et al., 2017), sharing the attention mechanism across multiple language pairs (Firat et al., 2016a; Dong et al., 2015) to optimizing a single NMT model (with a universal encoder and decoder) for the translation of multiple language pairs (Ha et al., 2016; Johnson et al., 2017). The universal encoder-decoder approach constructs a shared vocabulary for all languages in the training set, and uses just one encoder and decoder for multilingual translation between language pairs. Johnson et al. (2017) proposed to use a single model and prepend

special symbols to the source text to indicate the target language. We adopt their model approach in this paper.

The current state of multilingual NMT, where a single NMT model is optimized for the translation of multiple language pairs (Firat et al., 2016a; Johnson et al., 2017; Lu et al., 2018; Aharoni et al., 2019; Arivazhagan et al., 2019b), has become very appealing for a number of reasons. It is scalable and easy to deploy or maintan (the ability of a single model to effectively handle all translation directions from N languages, if properly trained and designed, surpasses the scalability of $O(N^2)$ individually trained models using the traditional bilingual framework). Multilingual NMT can encourage knowledge transfer among related language pairs (Lakew et al., 2018; Tan et al., 2019) as well as positive transfer from higher-resource languages (Zoph et al., 2016; Neubig and Hu, 2018; Arivazhagan et al., 2019a; Aharoni et al., 2019; Johnson et al., 2017) due to its shared representation, improve low-resource translation (Ha et al., 2016; Johnson et al., 2017; Arivazhagan et al., 2019b; Xue et al., 2021) and enable zero-shot translation (i.e. direct translation between a language pair never seen during training) (Firat et al., 2016b; Johnson et al., 2017).

Despite the many advantages of multilingual NMT it suffers from certain disadvantages. Firstly, the output vocabulary size is typically fixed regardless of the number of languages in the corpus and increasing the vocabulary size is costly in terms of computational resources because the training and inference time scales linearly with the size of the decoder's output layer. For example, the training dataset for all the languages in our work gave a total vocabulary size of $1,683,884$ tokens ($1,519,918$ with every sentence lowercased) but we were constrained to a decoder vocabulary size of $250,000$.

Another pitfall of massively multilingual NMT is its poor zero-shot performance (Firat et al., 2016b; Arivazhagan et al., 2019a; Johnson et al., 2017; Aharoni et al., 2019), particularly compared to pivot-based models (two bilingual models that translate from source to target language through an intermediate language). Neural machine translation is heavily reliant on parallel data and so without access to parallel training data for zero-shot language pairs, multilingual models face the spurious correlation issue (Gu et al., 2019) and *off-target translation* (Johnson et al., 2017) where the model ignores the given target information and translates into a wrong language.

Some approaches to improve the performance (including zero-shot translation) of multilingual models have relied on leveraging the plentiful source and target side monolingual data that are available. For example, generating artificial parallel data with various forms of backtranslation (Sennrich et al., 2015) has been shown to greatly improve the overall (and zero-shot) performance of multilingual models (Firat et al., 2016b; Gu et al., 2019; Lakew et al., 2018; Zhang et al., 2020) as well as bilingual models (Edunov et al., 2018). Zhang et al. (2020) proposed random online backtranslation to enhance multilingual translation of unseen training language pairs.

Additionally, leveraging monolingual data by jointly learning to reconstruct the input while translating has been shown to improve neural machine translation quality (Févry and Phang, 2018; Lample et al., 2017; Cheng et al., 2016; Zhang and Zong, 2016). Siddhant et al. (2020) leveraged monolingual data in a semi-supervised fashion and reported three major results:

1. Using monolingual data significantly boosts the translation quality of low resource languages in multilingual models.

2. Self-supervision improves zero-shot translation quality in multilingual models.

3. Leveraging monolingual data with self-supervision provides a viable path towards adding new languages to multilingual models.

3 Data Methodology

Table 2 presents the size of the gathered and cleaned parallel sentences for each language direction. We devised preprocessing guidelines for each of our focus languages taking their linguistic properties into consideration. We used a maximum sequence length of 50 (due to computational resources) and a minimum of 2. In the following sections we will describe the data sources for the the parallel and monolingual corpora.

Parallel Corpora: As NMT models are very reliant on parallel data, we sought to gather more parallel sentences for each language direction in an effort to increase the size and domain of each language direction. To this end, our first source was JW300 (Agić and Vulić, 2019), a parallel corpus of

	Target Language							
	ibo	**fon**	**kin**	**xho**	**yor**	**swa**	**eng**	**fra**
ibo	-	3,179	52,685	58,802	134,219	67,785	85,358	57,458
fon	3,148	-	3,060	3,364	5,440	3,434	5,575	2,400
kin	53,955	3,122	-	70,307	85,824	83,898	77,271	62,236
xho	60,557	3,439	70,506	-	64,179	125,604	138,111	113,453
yor	133,353	5,485	83,866	62,471	-	117,875	122,554	97,000
swa	69,633	3,507	84,025	125,307	121,233	-	186,622	128,428
eng	87,716	5,692	77,148	137,240	125,927	186,122	-	-
fra	58,521	2,444	61,986	112,549	98,986	127,718	-	-

Table 2: Number of parallel samples for each language direction. We highlight the largest and smallest parallel samples. We see for example that much more research on machine translation and data collation has been carried out on swa⟷eng than fon⟷fra, attesting to the under-representation of some African languages.

over 300 languages with around 100 thousand biblical domain parallel sentences per language pair on average. Using OpusTools (Aulamo et al., 2020) we were able to get only very trustworthy translations by setting $t = 1.5$ (t is a threshold which indicates the confidence of the translations). We collected more parallel sentences from Tatoeba[1], kde4[2] (Tiedemann, 2012), and some English-based bilingual samples from MultiParaCrawl[3].

Finally, following pointers from the native speakers of these focus languages in the Masakhane community (∀ et al., 2020) to existing research on machine translation for African languages which open-sourced their parallel data, we assembled more parallel sentences mostly in the $\{en, fr\}$⟷AL direction.

From all this we created `MMTAfrica Test Set` (explained in more details in section 3.1), got $5,424,578$ total training samples for all languages directions (a breakdown of data size for each language direction is provided in Table 2) and $4,000$ for dev.

Monolingual Corpora: Despite our efforts to gather several parallel data from various domains, we were faced with some problems: 1) there was a huge imbalance in parallel samples across the language directions. In Table 2 we see that the ⊛ ⟷fon direction has the least amount of parallel sentences while ⊛ ⟷swa or ⊛ ⟷yor is made up of relatively larger parallel sentences. 2) the parallel sentences particularly for AL⟷AL span a very small domain (mostly biblical, internet)

We therefore set out to gather monolingual data from diverse sources. As our focus is on African languages, we collated monolingual data in only these languages. The monolingual sources and volume are summarized in Table 3.

Language(ID)	**Monolingual source**	**Size**
Xhosa (xho)	The CC100-Xhosa Dataset created by Conneau et al. (2019), and OpenSLR (van Niekerk et al., 2017)	158,660

Igbo (ibo)	(Ezeani et al., 2020)	7,817

Table 3: Monolingual data sources and sizes (number of samples).

3.1 Data Set Types in our Work

Here we elaborate on the different categories of data set that we (generated and) used in our work for training and evaluation.

- `FLORES Test Set`: This refers to the dev test set of 1012 parallel sentences in all 101 language directions provided by Goyal

[1] https://opus.nlpl.eu/Tatoeba.php
[2] https://huggingface.co/datasets/kde4
[3] https://www.paracrawl.eu/

et al. (2021)[4]. We performed evaluation on this test set for all language directions except ⊛ ⟷fon and ⊛ ⟷kin.

- `MMTAfrica Test Set`: This is a *substantial* test set we created by taking out a small but equal number of sentences from each parallel source domain. As a result, we have a set from a wide range of domains, while encompassing samples from many existing test sets from previous research. Although this set is small to be fully considered as a test set, we open-source it because it contains sentences from many domains (making it useful for evaluation) and we hope that it can be built upon, by perhaps merging it with other benchmark test sets (Abate et al., 2018; Abbott and Martinus, 2019; Reid et al., 2021).

- `Baseline Train/Test Set`: We first conducted baseline experiments with Fon, Igbo, English and French as explained in section 4.4.1. For this we created a special data set by carefully selecting a small subset of the FFR Dataset (which already contained parallel sentences in French and Fon), first automatically translating the sentences to English and Igbo, using the Google Translate API[5], and finally re-translating with the help of Igbo (7) and English (7) native speakers (we recognized that it was easier for native speakers to edit/tweak an existing translation rather than writing the whole translation from scratch). In so doing, we created a data set of $13,878$ translations in all 4 language directions.

  We split the data set into $12,554$ for training `Baseline Train Set`, 662 for dev and 662 for test `Baseline Test Set`.

4 Model and Experiments

4.1 Model

For all our experiments, we used the mT5 model (Xue et al., 2021), a multilingual variant of the encoder-decoder, transformer-based (Vaswani et al., 2017) "Text-to-Text Transfer Transformer" (T5) model (Raffel et al., 2019). In T5 pre-training, the NLP tasks (including machine translation) were cast into a "text-to-text" format – that is, a task where the model is fed some text prefix for context or conditioning and is then asked to produce some output text. This framework makes it straightforward to design a number of NLP tasks like machine translation, summarization, text classification, etc. Also, it provides a consistent training objective both for pre-training and finetuning. The mT5 model was pre-trained with a maximum likelihood objective using "teacher forcing" (Williams and Zipser, 1989). The mT5 model was also pretrained with a modification of the masked language modelling objective (Devlin et al., 2018).

We finetuned the `mt5-base` model on our many-to-many machine translation task. While Xue et al. (2021) suggest that higher versions of the mT5 model (*Large*, *XL* or *XXL*) give better performance on downstream multilingual translation tasks, we were constrained by computational resources to `mt5-base`, which has $580M$ parameters.

4.2 Setup

For each language direction $X \rightarrow Y$ we have its set of n parallel sentences $\mathcal{D} = \{(x_i, y_i)\}_{i=1}^{n}$ where x_i is the ith source sentence of language X and y_i is its translation in the target language Y.

Following the approach of Johnson et al. (2017) and Xue et al. (2021), we model translation in a text-to-text format. More specifically, we create the input for the model by prepending the target language tag to the source sentence. Therefore for each source sentence x_i the input to the model is $<Y_{tag}>\ x_i$ and the target is y_i. Taking a real example, let's say we wish to translate the Igbo sentence *Daalụ maka ikwu eziokwu nke Chineke* to English. The input to the model becomes *<eng> Daalụ maka ikwu eziokwu nke Chineke*.

4.3 Training

We have a set of language tags L for the languages we are working with in our multilingual many-to-many translation. In our baseline setup (section 4.4.1) $L = \{eng, fra, ibo, fon\}$ and in our final experiment (section 4.4.2) $L = \{eng, fra, ibo, fon, swa, kin, xho, yor\}$. We carried out many-to-many translation using all the possible directions from L except $eng \longleftrightarrow fra$. We skipped $eng \longleftrightarrow fra$ for this fundamental reason:

- our main focus is on African⟷African or $\{eng, fra\}$ ⟷African. Due to the high-

[4] https://dl.fbaipublicfiles.com/flores101/dataset/flores101_dataset.tar.gz

[5] https://cloud.google.com/translate

resource nature of English and French, adding the training set for $eng \longleftrightarrow fra$ would overshadow the learning of the other language directions and greatly impede our analyses. Our intuition draws from the observation of Xue et al. (2021) as the reason for *off-target* translation in the mT5 model: as English-based finetuning proceeds, the model's assigned likelihood of non-English tokens presumably decreases. Therefore since the `mt5-base` training set contained predominantly English (and after other European languages) tokens and our research is about AL$\longleftrightarrow$AL translation, removing the $eng \longleftrightarrow fra$ direction was our way of ensuring the model designated more likelihood to AL tokens.

4.3.1 Our Contributions

In addition to the parallel data between the African languages, we leveraged monolingual data to improve translation quality in two ways:

1. **our backtranslation (BT):** We designed a modified form of the random online backtranslation (Zhang et al., 2020) where instead of randomly selecting a subset of languages to backtranslate, we selected for each language num_bt sentences at random from the monolingual data set. This means that the model gets to backtranslate different (monolingual) sentences every backtranslation time and in so doing, we believe, improve the model's domain adaptation because it gets to learn from various samples from the whole monolingual data set. We initially tested different values of num_bt to find a compromise between backtranslation computation time and translation quality.

   Following research works which have shown the effectiveness of random beam-search over greedy decoding while generating backtranslations (Lample et al., 2017; Edunov et al., 2018; Hoang et al., 2018; Zhang et al., 2020), we generated num_sample prediction sentences from the model and randomly selected (with equal probability) one for our backtranslated sentence. Naturally the value of num_sample further affects the computation time (because the model has to produce num_sample different output sentences for each input sentence) and so we finally settled with $num\_sample = 2$.

2. **our reconstruction:** Given a monolingual sentence x^m from language m, we applied random swapping (2 times) and deletion (with a probability of 0.2) to get a noisy version $\hat{x}$. Taking inspiration from Raffel et al. (2019) we integrated the reconstruction objective into our model finetuning by prepending the language tag <m> to $\hat{x}$ and setting its target output to x^m.

4.4 Experiments

In all our experiments we initialized the pretrained `mT5-base` model using Hugging Face's AutoModelForSeq2SeqLM[6] and tracked the training process with Weights&Biases (Biewald, 2020). We used the AdamW optimizer (Loshchilov and Hutter, 2017) with a learning rate (lr) of $3e^{-6}$ and transformer's $get\_linear\_schedule\_with\_warmup$[7] scheduler (where the learning rate decreases linearly from the initial lr set in the optimizer to 0, after a warmup period and then increases linearly from 0 to the initial lr set in the optimizer.)

4.4.1 Baseline

The goal of our baseline was to understand the effect of jointly finetuning with backtranslation and reconstruction on the African$\longleftrightarrow$African language translation quality in two scenarios: when the AL was initially pretrained on the multilingual model and contrariwise. Using Fon (which was not initially included in the pretraining) and Igbo (which was initially included in the pretraining) as the African languages for our baseline training, we finetuned our model on a many-to-many translation in all directions of $\{eng, fra, ibo, fon\}/eng \longleftrightarrow fra$ amounting to 10 directions. We used the `Baseline Train Set` for training and the `Baseline Test Set` for evaluation. We trained the model for only 3 epochs in three settings:

1. `BASE` : in this setup we finetune the model on only the many-to-many translation task: no backtranslation nor reconstruction.

2. `BT` : refers to finetuning with our backtranslation objective described in section 4.2. For our

[6] https://huggingface.co/transformers/model_doc/auto.html#transformers.AutoModelForSeq2SeqLM

[7] https://huggingface.co/transformers/main_classes/optimizer_schedules.html#transformers.get_linear_schedule_with_warmup

baseline, where we backtranslate using monolingual data in $\{ibo, fon\}$, we set $num\_bt = 500$. For our final experiments, we first tried with 500 but finally reduced to 100 due to the great deal of computation required.

For our baseline experiment, we ran one epoch normally and the remaining two with backtranslation. For our final experiments, we first finetuned the model on 3 epochs before continuing with backtranslation.

3. `BT&REC`: refers to joint backtranslation and reconstruction (explained in section 4.2) while finetuning. Two important questions were addressed – 1) the ratio, backtranslation : reconstruction, of monolingual sentences to use and 2) whether to use the same or different sentences for backtranslation and reconstruction. Bearing computation time in mind, we resolved to go with $500 : 50$ for our baseline and $100 : 50$ for our final experiments. We leave ablation studies on the effect of the ratio on translation quality to future work. For the second question we decided to randomly sample (with replacement) different sentences each for our backtranslation and reconstruction.

For our baseline, we used a learning rate of $5e^{-4}$, a batch size of 32 sentences, with gradient accumulation up to a batch of 256 sentences and an early stopping patience of 100 evaluation steps. To further analyse the performance of our baseline setups we ran `comparemt` [8] (Neubig et al., 2019) on the model's predictions.

4.4.2 MMTAfrica

MMTAfrica refers to our final experimental setup where we finetuned our model on all language directions involving all eight languages $L = \{eng, fra, ibo, fon, swa, kin, xho, yor\}$ except eng⟷fra. Taking inspiration from our baseline results we ran our experiment with our proposed `BT&REC` setting and made some adjustments along the way.

The long computation time for backtranslating (with just 100 sentences per language the model was required to generate around $3,000$ translations every backtranslation time) was a drawback. To mitigate the issue we parallelized the process using the multiprocessing package in Python[9]. We further slowly reduced the number of sentences for backtranslation (to 50, and finally 10).

Gradient descent in large multilingual models has been shown to be more stable when updates are performed over large batch sizes are used (Xue et al., 2021). To cope with our computational resources, we used gradient accumulation to increase updates from an initial batch size of 64 sentences, up to a batch gradient computation size of 4096 sentences. We further utilized PyTorch's DataParallel package[10] to parallelize the training across the GPUs. We used a learning rate (lr) of $3e^{-6}$

5 Results and Insights

All evaluations were made using spBLEU (sentencepiece (Kudo and Richardson, 2018) + sacreBLEU (Post, 2018)) as described in (Goyal et al., 2021). We further evaluated on the chrF (Popović, 2015) and TER metrics.

5.1 Baseline Results and Insights

Figure 1 compares the spBLEU scores for the three setups used in our baseline experiments. As a reminder, we make use of the symbol ⋄ to refer to any language in the set $\{eng, fra, ibo, fon\}$.

`BT` gives strong improvement over `BASE` (except in eng⟶ibo where it's relatively the same, and fra⟶ibo where it performs worse).

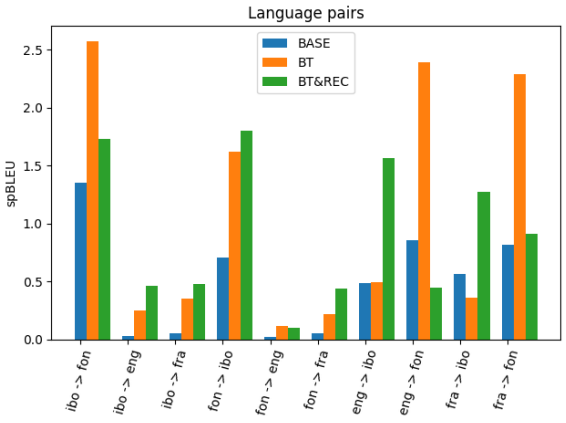

Figure 1: spBLEU scores of the 3 setups explained in section 4.4.1

When the target language is ***fon***, we observe a considerable boost in the spBLEU of the `BT` setting, which also significantly outperformed `BASE`

[8] https://github.com/neulab/compare-mt

[9] https://docs.python.org/3/library/multiprocessing.html

[10] https://pytorch.org/docs/stable/generated/torch.nn.DataParallel.html

and BT&REC. BT&REC contributed very little when compared with BT and sometimes even performed poorly (in eng⟶fon). We attribute this poor performance from the reconstruction objective to the fact that the mt5-base model was not originally pretrained on Fon. Therefore, with only 3 epochs of finetuning (and 1 epoch before introducing the reconstruction and backtranslation objectives) the model was not able to meaningfully utilize both objectives.

Conversely, when the target language is ***ibo*** BT&REC gives best results – even in scenarios where BT underperforms BASE (as is the case of fra⟶ibo and eng⟶ibo). We believe that the decoder of the model, being originally pretrained on corpora containing Igbo, was able to better use our reconstruction to improve translation quaity in ⋄ ⟶***ibo*** direction.

Drawing insights from fon⟷ibo **we offer the following propositions concerning AL⟷AL multilingual translation**:

- our backtranslation (section 4.2) from monolingual data improves the cross-lingual mapping of the model for low-resource African languages. While it is computationally expensive, our parallelization and decay of number of backtranslated sentences are some potential solutions towards effectively adopting backtranslation using monolingual data.

- Denoising objectives typically have been known to improve machine translation quality (Zhang and Zong, 2016; Cheng et al., 2016; Gu et al., 2019; Zhang et al., 2020; Xue et al., 2021) because they imbue the model with more generalizable knowledge (about that language) which is used by the decoder to predict better token likelihoods for that language during translation. This is a reasonable explanation for the improved quality with the BT&REC over BT in the ⋄ ⟶***ibo***. As we learned from ⋄ ⟶***fon***, using reconstruction could perform unsatisfactorily if not handled well. Some methods we propose are:

  1. For African languages that were included in the original model pretraining (as was the case of Igbo, Swahili, Xhosa, and Yorùbá in the mT5 model), using the BT&REC setting for finetuning produces best results. While we did not perform ablation studies on the data size ratio for backtranslation and reconstruction, we believe that our ratio of $2:1$ (in our final experiments) gives the best compromise on both computation time and translation quality.
  2. For African languages that were not originally included in the original model pretraining (as was the case of Kinyarwanda and Fon in the mT5 model), reconstruction together with backtranslation (especially at an early stage) only introduces more noise which could harm the cross-lingual learning. For these languages we propose:
     (a) first finetuning the model on only our reconstruction (described in section 4.2) for fairly long training steps before using BT&REC. This way, the initial reconstruction will help the model learn that language representation space and increase its the likelihood of tokens.

5.2 MMTAfrica Results and Insights

In Table 4, we compared MMTAfrica with the M2M MMT(Fan et al., 2020) benchmark results of Goyal et al. (2021) using the same test set they used – FLORES Test Set. On all language pairs except swa→eng (which has a comparable -2.76 spBLEU difference), we report an improvement from MMTAfrica (spBLEU gains ranging from $+0.58$ in swa⟶fra to $+19.46$ in fra⟶xho). The lower score of swa→eng presents an intriguing anomaly, especially given the large availability of parallel corpora in our training set for this pair. We plan to investigate this in further work.

In Table 5 we introduce benchmark results of MMTAfrica on MMTAfrica Test Set. We also put the test size of each language pair.

Interesting analysis about Fon (fon) and Yorùbá (yor): For each language, the lowest spBLEU scores in both tables come from the ⟶yor direction, except fon⟷yor (from Table 5) which interestingly has the highest spBLEU score compared to the other fon⟶ ⊛ directions. We do not know the reason for the very low performance in the ⊛ ⟶yor direction, but we offer below a plausible explanation about fon⟷yor.

The oral linguistic history of Fon ties it to the ancient Yorùbá kingdom (Barnes, 1997). Furthermore, in present day Benin, where Fon is largely

spoken as a native language, Yoruba is one of the indigenuous languages commonly spoken. [11] Therefore Fon and Yorùbá share some linguistic characteristics and we believe this is one logic behind the fon⟷yor surpassing other fon⟶ ⊛ directions.

This explanation could inspire transfer learning from Yorùbá, which has received comparably more research and has more resources for machine translation, to Fon. We leave this for future work.

6 Conclusion and Future Work

In this paper, we introduced MMTAfrica, a multilingual machine translation model on 6 African Languages, which outperformed the M2M MMT model Fan et al. (2020). Our results and analyses, including a new reconstruction objective, give insights on MMT for African languages for future research. Moreover, we plan to launch the model on Masakhane MT and FFRTranslate in order to get human evaluation feedback from the actual speakers of the languages in the Masakhane community (Orife et al., 2020) and beyond.

In order to fully test the advantage of MMTAfrica, we plan to finish comparing it on direct and pivot translations with the Masakhane benchmark models (∀ et al., 2020). We also plan to perform human evaluation. All test sets, results, code and checkpoints will be released at https://github.com/edaiofficial/mmtafrica

7 Acknowledgments

The computational resources for running all experiments were provided by the FLORES compute grants[12] as well as additonal computational resources provided by Paco Guzman (Facebook AI) and Mila Quebec AI Institute. We express our profound gratitude to all who contributed in one way or the other towards the development of MMTAfrica including (in no order):

Mathias Müller (University of Zurich) for giving immense technical assistance in finetuning the model and advising us on best hyperparameter tuning practises.

Graham Neubig (Carnegie Mellon University) for explaining and setting up `comparemt` for us to better understand and evaluate the performance of our baseline models.

Angela Fan (FacebookAI) for guiding us during the shared task and taking the time to answer all our questions.

Julia Kreutzer (GoogleAI) for advising us on useful model comparison and evaluation techniques.

Colin Leong (University of Dayton) for painstakingly proof-reading the paper and helping us make it more reader-friendly.

Daria Yasafova (Technical University of Munich) and Yeno Gbenou (Drexel University) for additionally proof-reading the paper.

Finally the entire Masakhane community[13] for, among many other things, 1) guiding us to existing parallel and monolingual data set for the focus African languages, 2) explaining their (the focus African languages) important linguistic charteristics which helped us work better with them (like in preprocessing) and 3) performing (in the future) human evaluation on MMTAfrica.

Indeed it took a village to raise MMTAfrica[14].

[11] https://en.wikipedia.org/wiki/Benin (Last Accessed : 30.08.2021).

The LMU Munich System for the WMT 2021 Large-Scale Multilingual Machine Translation Shared Task

Wen Lai and **Jindřich Libovický** and **Alexander Fraser**
Center for Information and Language Processing, LMU Munich, Germany
{lavine, libovicky, fraser}@cis.lmu.de

Abstract

This paper describes the submission of LMU Munich to the WMT 2021 multilingual machine translation task for small track #1, which studies translation between 6 languages (Croatian, Hungarian, Estonian, Serbian, Macedonian, English) in 30 directions. We investigate the extent to which bilingual translation systems can influence multilingual translation systems. More specifically, we trained 30 bilingual translation systems, covering all language pairs, and used data augmentation techniques such as back-translation and knowledge distillation to improve the multilingual translation systems. Our best translation system scores 5 to 6 BLEU higher than a strong baseline system provided by the organizers (Goyal et al., 2021). As seen in the Dynalab leaderboard, our submission is the only fully constrained submission that uses only the corpus provided by the organizers and does not use any pre-trained models.

1 Introduction

Neural Machine Translation (NMT) (Vaswani et al., 2017) has been shown to be effective with rich and in-domain bilingual parallel corpora. Although the NMT model obtained promising performances for high resource language pairs, it is hardly feasible to train translation models for all directions of the language pairs since the training progress is time- and resource-consuming. Recent work has shown the effectiveness of multilingual neural machine translation (MNMT), which aims to handle the translation from multiple source languages into multiple target languages with a single unified model (Johnson et al., 2017; Aharoni et al., 2019; Arivazhagan et al., 2019; Zhang et al., 2020; Fan et al., 2021; Goyal et al., 2021).

The MNMT model dramatically reduces training and serving costs. It is faster to train a MNMT model than to train bilingual models for all language pairs in both directions, and MNMT significantly simplifies deployment in production systems (Johnson et al., 2017; Arivazhagan et al., 2019). Further, parameter sharing across different languages encourages knowledge transfer, which improves low-resource translation directions and potentially enables zero-shot translation (i.e., direct translation of a language pair not seen during training) (Ha et al., 2017; Gu et al., 2019; Ji et al., 2020; Zhang et al., 2020).

We participate in the WMT 2021 multilingual machine translation task for small track #1. The task aims to train a multilingual model to translate 5 Central/East European languages (Croatian, Hungarian, Estonian, Serbian, Macedonian) and English in 30 directions. The multilingual systems presented in this paper are based on the standard paradigm of MNMT proposed by Johnson et al. (2017), which prefixes the source sentence with a special token to indicate the desired target language and does not change the target sentence at all. Language tags are typically used in MNMT to identify the language to translate to. A language code, in the form of a two- or three-character identification such as `en` for English, is the main constituent of a language tag and is provided by the ISO 639 standard[1] (International Organization for Standardization, nd). Following ISO 639 standard, `en` indicates English, `mk` indicates Macedonian, `sr` indicates Serbian, `et` indicates Estonian, `hr` indicates Croatian and `hu` indicates Hungarian in this paper.

Compared with the other three submissions to the task, our submissions have the following advantages:

- Our submissions are fully constrained, which means we using the data only provided by the organizer, and do not use models pre-trained on extra data.
- Our model only has 313M parameters, which

+ deduplicated filter	304M	44M
+ `langid` filter	302M	43M
+ length filter	274M	42M

Table 1: Number of sentences in bitext datasets (total in 15 directions) for different filtering schemes. **Whole** denotes the use of all data provided by the organizers, **Select** denotes the use of data selection.

is smaller than the other submissions.

2 Data

The training data provided by the organizers come from the public available Opus repository (Tiedemann, 2012), which contains data of mixed quality from a variety of domains (WMT-News, TED, QED, OpenSubtitles, etc.). In addition to the bilingual parallel corpora, in-domain Wikipedia monolingual data for each language is provided. The validation and test sets are obtained from the Flores 101 evaluation benchmark (Goyal et al., 2021), which consists of 3001 sentences extracted from English Wikipedia covering a variety of different topics and domains. See Table 1 for details on data used for training our systems.

2.1 Data Preprocessing

To prepare the data for training, we used the following steps to process all of the corpora:

1. The datasets were truecased and the punctuation was normalized with standard scripts from the Moses toolkit[2](Koehn et al., 2007).

2. Sentences containing 50% punctuation are removed.

3. Duplicate sentences are removed.

4. We used a language detection tool[3] (`langid`) to filter out sentences with mixed language.

5. SentencePiece[4] (Kudo and Richardson, 2018) was used to produce subword units. We trained a model with 0.9995 character coverage to have sufficient coverage of character-based languages.

6. The length filtering removes sentences that are too long (more than 250 subwords after segmentation with Sentencepiece), sentences with a mismatched length ratio (more than 3.0) between source and target language are removed.

2.2 Data Selection

Data selection (Moore and Lewis, 2010; Axelrod et al., 2011; Gascó et al., 2012), aims to select the most relevant sentences from the out-of-domain corpora, which improved the in-domain translation performance. The training data provided by the organizers is large scale and contains multiple domains. Therefore, the data selection becomes a key factor affecting the performance of MNMT. Preliminary experiments (see in Table 1 model #3 and model #4) showed that the performance of using all corpora provided by the organizer was poor. Following the original paper (Goyal et al., 2021), we selected three data sources (CCAligned, MultiCCAligned, WikiMatrix) for further experimentation.

3 Method Description

We first trained bilingual translation models with 30 directions for all language pairs. Next, we trained a single multilingual model that can translate all language pairs. Finally, we use back-translation and knowledge distillation technologies to further improve the performance of the multilingual translation system. The details of these components are outlined next.

3.1 Bilingual NMT Model

We use Transformer (Vaswani et al., 2017) architecture for all bilingual models. To achieve the best BLEU score on the validation dataset, random search was used to select the hyperparameters since the datasets are in different sizes. We segment the data into subword units using SentencePiece jointly learned for all languages. The details of selected hyper-parameters are listed in Section 4.1.

3.2 Multilingual NMT Model

The multilingual model architecture is identical to the bilingual NMT model. To train multilingual models, we used a simple modification to the

[2] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer

[3] https://fasttext.cc/docs/en/language-identification.html

[4] https://github.com/google/sentencepiece

source sentence proposed by Johnson et al. (2017) which introduce an artificial token at the beginning of the source sentence indicating the target language (Johnson et al., 2017). For instance, for the English-Macedonian (en→mk) translation direction, we insert a token like <2mk> at the beginning of all English sentences and do not change the Macedonian sentences.

3.3 Back Translation

Back-translation (BT) (Sennrich et al., 2016) is a simple and effective data augmentation technique, which makes use of monolingual corpora and has proven to be effective. Back-translation first trains a target-to-source system that is used to translate monolingual target data into source sentences, resulting in a pseudo-parallel corpus. Then we mix the pseudo-parallel corpus with the authentic parallel data and train the the desired source-to-target translation system. Zhang et al. (2020) has shown how BT can be useful for multilingual MT.

After generating the pseudo parallel corpus, we tag our BT data by adding an artificial token <BT> at the beginning of the source sentence (Caswell et al., 2019), which indicates that the data is generated by back-translation.

3.4 Knowledge Distillation

Knowledge Distillation (KD) is a commonly used technique to improve model performance. The standard KD training (Kim and Rush, 2016) derives a student model from a teacher model by training the student model to mimic the outputs of the teacher. We follow a recent approach to KD proposed by Wang et al. (2021), which uses selection at the batch level and at the global level to choose suitable samples for distillation.

4 Experiments

4.1 Training Details

We use the Transformer architecture (Vaswani et al., 2017) as implemented in fairseq[5] (Ott et al., 2019). For training NMT and MNMT systems, we use the `Transformer-Big` architecture (hidden state 1024, feed-forward layer 4096, 16 attention heads, 6 encoder layers, 6 decoder layers). For optimization, we follow the default settings from the original paper (Vaswani et al., 2017) and used the Adam optimizer with a learning rate of 0.0003. To prevent overfitting, we applied a dropout of 0.3 on all layers. At the time of inference, a beam search of size 5 is used to balance the decoding time and accuracy of the search. The number of warm-up steps was set to 4000 and the vocabulary size is 133k. In addition, we set a length penalty factor of 1.7 to maintain a balance between long and short sentences. The batch size is set to 128 during decoding. We trained our models for approximately 3 weeks on one machine with 8 NVIDIA GTX 2080 Ti 11GB GPUs.

Because of the problems of the international tokenization in the standard BLEU score, the organizers used sentence-piece BLEU (spBLEU)[6] (Goyal et al., 2021) as the official evaluation metric which operates on strings segmented using a SentencePiece model. Recently, the BLEU score was criticized as an unreliable automatic metric (Mathur et al., 2020; Kocmi et al., 2021). Therefore, we also evaluate our models using chrF (Popović, 2015) and BERTScore (Zhang et al., 2019).

4.2 Systems

All of our systems described in Section 3.2 are listed as follows:

Flores. As a baseline system, we use the pretrained models public available by Flores teams. We use `flores101_mm100_615M` tested on the devtest datasets as our baseline.

Bilingual. We trained the bilingual models using standard `Transformer-Big` architecture for 6 languages in 30 directions. The hyperparameters used are discussed in Section 4.1.

Multilingual. We trained the multilingual translation model using standard `Transformer-Big` architecture and a specific language token to indicate the desired translation target language.

Tagged BT. We augment the training data by exploring the monolingual corpus using back-translation proposed by Caswell et al. (2019), with tagged back-translated source sentences with an extra token <BT>.

Selective KD. We focused on selective knowledge distillation proposed by Wang et al. (2021), which uses batch-level and global-level selections to pick suitable samples for distillation.

4.3 Results

The results of our systems on the devtest dataset are presented in Table 2. For models 1–4, we observed

Table 2: The automatic evaluation metrics on devtest data. **spBLEU**, **chrF**, **BERTScore** denotes the average scores of spBLEU, chrF and BERTScore respectively, **BEST BLEU** denotes the language pair with the best BLEU score. Systems with subscript *whole* denote the use of all data provided by the organizers, and systems with subscript *select* denote the use of data selection. Model #6 is our primary system submitted to the Dynalab leaderboard. Systems 7* and 8* were trained after the shared task and were not used for the final submission.

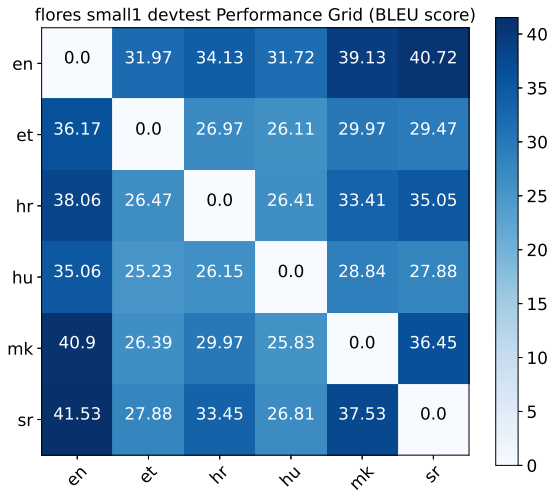

Figure 1: spBLEU scores on devtest data in 30 directions

that the amount of training data is not proportional to the performance of the model for the bilingual or multilingual translation model. The training data provided by the organizers contains multiple domains and does not match the dev/devtext/test data domain. Therefore, we apply the data selection methods to select data-relevant data from the training dataset to do the following experiments. Our multilingual model (#4) performs competitively with the Flores strong baseline (Model #0).

After these initial experiments, we explored how the bilingual models can be used to improve the multilingual model. More specifically, we use the Bilingual$_{select}$ model (#2) and Multilingual$_{select}$ model (#4) to back-translate the relevant monolingual corpora, and then we use the back-translations to train a new multilingual model. Although the overall performance of the Multilingual model (#4) is better than the Bilingual model (#2), back-translation using the Bilingual model (model #6) is better than back-translation using the Multilingual model (model #5). The possible reason is that the multilingual BT is in fact a form of self-training, but bilingual BT uses separate models, which means the knowledge obtained from bilingual BT models is more independent of the knowledge already learned by the baseline multilingual BT model.

Knowledge Distillation further improves performance slightly (Model # 7* and Model # 8*). Based on Model # 6, selective KD (Wang et al., 2021) is added to further improve the performance of the multilingual system.

Our best systems were outperformed by two other shared task submissions, which however used models pre-trained on additional data sources.

The performance grid of our best system (Model # 8*) is presented in Figure 1. We see from the results that the `sr-en` language pair produced the best results in terms of spBLEU score while the `hu-hr` language pair scored the lowest.

5 Conclusions

In this paper, we presented the LMU Munich system for the WMT 2021 Large-scale Multilingual Translation shared task for small track #1. The task evaluates translation between five central/eastern European languages and English, in total 30 translation directions. The system we submitted was fully constrained, using only the data provided by the organizers and not using any pre-trained model. The experiments show that back-translation and knowledge distillation techniques are effective for training multilingual machine translation systems.

6 Acknowledgments

We would like to thank the Flores team for the organization and for the grant of computer credits that we used in our experiments. This work was supported by funding to Wen Lai from LMU-CSC (China Scholarship Council) Scholarship Program (CSC, 202006390016). This work has received funding from the European Research Council under the European Union's Horizon 2020 research and innovation program (grant agreement #640550). This work was also supported by the DFG (grant FR 2829/4-1). We thank the other members of the machine translation group at CIS, LMU Munich, for their ideas and feedback.

Back-translation for Large-Scale Multilingual Machine Translation

Abstract

This paper illustrates our approach to the shared task on large-scale multilingual machine translation in the sixth conference on machine translation (WMT-21). In this work, we aim to build a single multilingual translation system with a hypothesis that a universal cross-language representation leads to better multilingual translation performance. We extend the exploration of different back-translation methods from bilingual translation to multilingual translation. Better performance is obtained by the constrained sampling method, which is different from the finding of the bilingual translation. Besides, we also explore the effect of vocabularies and the amount of synthetic data. Surprisingly, the smaller size of vocabularies perform better, and the extensive monolingual English data offers a modest improvement. We submitted to both the small tasks and achieve the second place. The code and trained models are available at https://github.com/BaohaoLiao/multiback.

1 Introduction

Bilingual neural machine translation (NMT) systems have achieved decent performance with the help of Transformer (Vaswani et al., 2017). One of the most exciting recent trends in NMT is training a single system on multiple languages at once (Johnson et al., 2017b; Aharoni et al., 2019a; Zhang et al., 2020; Fan et al., 2020). This is a powerful paradigm for two reasons: simplifying system development and deployment, and improving the translation quality on low-resource language pairs by transferring similar knowledge from high-resource languages.

This paper describes our experiments on the task of large-scale multilingual machine translation in WMT-21. We primarily focus on the small tasks, especially on Small Task 2 which has a small amount of training data. Small Task 1 contains five Central/East European languages and English, having 30 translation directions. Similarly, Small Task 2 contains five South East Asian languages and English, also having 30 translation directions.

In this work, we mainly concentrate on different back-translation methods (Sennrich et al., 2016a; Edunov et al., 2018; Graça et al., 2019) for multilingual machine translation, including beam search and other sampling methods. Along with it, we also explore the effect of different sizes of vocabularies and the effect of various amounts of synthetic data. On this large-scale multilingual machine translation task, we achieved the second place for both small tasks, obtaining 34.96 and 33.34 average sp-BLEU scores (Goyal et al., 2021) on the hidden test set for the Small Task 1 and 2, respectively.

2 Related Work

Multilingual Neural Machine Translation has received increasing attention recently. Since Dong et al. (2015) extended the traditional bilingual NMT to one-to-many translation, there has been a massive increase in work on MT systems that involve more than two languages (Dabre et al., 2017; Choi et al., 2018; Chu and Dabre, 2019). The recent research on multilingual NMT can be split into two directions: developing language specific components (Kim et al., 2019; Escolano et al., 2020) and training a single model with extensive training data, including parallel and monolingual data (Fan et al., 2020). Here, we continue to explore the second research direction, trying to built a single multilingual NMT model for simple industrial deployment.

Back-translation (Sennrich et al., 2016a) has been proven as a powerful technique to leverage monolingual data for improving low-resource language pairs. Edunov et al. (2018) and Graça et al. (2019) explore different sampling methods for bilingual back-translation, including beam search, constrained and unconstrained sampling. Constrained sampling randomly predicts the next word

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 418–424

within some candidates that have higher prediction probability. And unconstrained sampling randomly predicts the next words from the whole vocabulary without caring for the output distribution. In this paper, we extend their exploration to the realm of multilingualism, where similar languages affect the results.

3 Experimental Setup

3.1 Data

The organizer offers parallel and monolingual data for Small Task 1 and 2. Table 1 shows the size of the data in terms of the number of sentences for each language. There are five extra sets for evaluation, i.e. dev, devtest, hidden dev, hidden devtest and test sets. The dev set with 997 parallel sentences among all language pairs and the devtest set with 1,012 parallel sentences are public. Whereas, the hidden dev and hidden devtest sets are invisible to the participants and used for the first submission period. The hidden test set is also invisible and used for the final ranking.

Pre-processing is done by a regular Moses toolkit (Koehn et al., 2007) pipeline that involves tokenization, byte pair encoding and removing long sentences. We borrow the 256K vocabularies from the organizer's pretrained model and the 128K vocabularies from M2M_100 (Fan et al., 2021), one shared vocabularies among all languages. Our submissions only use the 256K vocabularies, and the 128K vocabularies is used for ablation experiments.

We also perform back-translation on the monolingual data, and only accept the synthetic sentence pair whose length is less than 250 words, and whose length ratio between the source and target sentence length is less than 1.8. In order to balance the volume across different languages, we apply temperature sampling $\tilde{D}_i = (D_i / \sum_j D_j)^{1/T}$ with $T = 5$ over the dataset, where D_i is the number of sentences in the i_{th} language.

3.2 Model

All our models are built using the fairseq implementation (Ott et al., 2019) of the Transformer architecture (Vaswani et al., 2017). Multilingual models are built using the same technique as Johnson et al. (2017a) and Aharoni et al. (2019b), namely adding a language label to the target sentence.

We apply three types of architectures, i.e. *Trans_small*, *Trans_base* and *Trans_big*. The detailed settings of these architectures are shown in Table 2. The parameters of all architectures are in the half-precision floating-point format.

Small Task 1		**Small Task 2**

Table 1: Number of sentences of the parallel and monolingual data used for two small tasks. The monolingual English data for the two small tasks are the same.

All our submissions on the shared task leaderboard are *Trans_base*, due to the memory and time limit of the evaluation system. *Trans_small* is mainly used for the ablation experiments. And the pretrained *Trans_big* from M2M_100 (Fan et al., 2021) is finetuned on the parallel corpus to generate high-quality synthetic sentences.

3.3 Optimization and Evaluation

The following hyper-parameter configuration is used: Adam optimizer with $\beta_1 = 0.90$, $\beta_2 = 0.98$, a weight-decay of 0.0001, the label smoothed cross-entropy criterion with a label smoothing of 0.1, an initial learning rate of 0.0003 with the inverse square root lr-scheduler and warmup updates of 2,500 steps. The batch size (the number of tokens) is 4096×32 for *Trans_small*, and 2048×64 for *Trans_base* and *Trans_big*.

For ablation experiments, we continue to train the pretrained *Trans_small* offered by the organizer

Model	Trans_small	Trans_base	Trans_big
#vocabularies	256K	256K	128K
Word representation size	512	1,024	1,024
Feed-forward layer dimension	2,048	4,096	8,192
#prenormed encoder/ decoder layer	6	12	24
#attention head	16	16	16
Dropout rate	0.1	0.1	0.1
Layer dropout rate	0.05	0.05	0.05
#parameters	175M	615M	1.2B

Table 2: Settings of different pretrained models. Pretrained *Trans_small* and *Trans_base* are provided by the organizer. And pretrained *Trans_big* is from Fan et al. (2021).

on the given parallel dataset for one epoch. When combining both parallel and synthetic data, we further train the model finetuned on the parallel data for another one epoch. For the final submissions, we train a pretrained *Trans_base* for two epochs instead of one epoch. Pretrained *Trans_big* from M2M_100 is only further trained on parallel data for two epochs to generate high-quality synthetic data. Even though we only train these models for a few epochs, they seems converged quite well according to the spBLEU curve during validation.

The model is validated every 3,000 steps on the dev set and saved. We use the beam search with a beam size of five, and stop translation when $l_{tgt} = 1.5 * l_{src} + 20$, where l_{src} and l_{tgt} are the source and target sentence length, respectively. The evaluation metric is BLEU based on sentence piece tokenization (spBLEU) (Goyal et al., 2021). We submit the average checkpoint of the last 15 checkpoints to the evaluation system. While for the ablation experiment, we use the best performed model on the dev set.

4 Results

4.1 The Role of Vocabularies

There are two pretrained vocabularies, the one with the size of 256K from the organizer and the one with the size of 128K from M2M_100 (Fan et al., 2021). To evaluate which vocabulary is the better one, we train two *Trans_smalls* with these two vocabularies from scratch on the parallel data of Small Task 2 for five epochs. To make the parameter sizes of these two models comparable, we set the following hyper-parameter for the model with the 128K vocabularies: 5 pre-normed encoder and decoder layers with a word representation size of 768 and a feed-forward layer dimension of 3072, resulting to 181M parameters. The other settings stay the same with *Trans_small* (with 256K vocabularies).

Model	Ave. spBLEU
128K *Trans_small* (scratch)	23.14
256K *Trans_small* (scratch)	21.65
256K *Trans_small* (pretrained)	23.72

Table 3: Average spBLEU on the devtest set of Small Task 2 for the models with different vocabularies.

Model	Ave. spBLEU
1st finetuned on parallel data	28.27
2nd finetuned on synthetic data	32.16
3rd finetuned on synthetic data	33.01

Table 4: Average spBLEU on the devtest set of Small Task 2 for *Trans_base* on different finetuning steps. These three models are iteratively trained. *Trans_base* is first finetuned on the parallel data, and then finetuned on the combination of the parallel data and the synthetic data generated by *Trans_big*, and finally finetuned on the combination of the parallel data and the synthetic data generated by the 2nd step *Trans_base*.

Table 3 shows the performance with different vocabularies. It is obvious that the 128K vocabulary outperforms the 256K vocabulary, 23.14 vs 21.65 spBLEU. However, if we finetune the pretrained *Trans_small* with the 256K vocabulary, 0.58 score improvement is achieved compared to the 128K *Trans_small*. In a word, 128K vocabulary is a better choice for training from scratch, while pretrained model offers us more gain.

Model	Ave. spBLEU
1st finetuned on parallel data	32.46
2nd finetuned on synthetic data	34.73

Table 5: Average spBLEU on the devtest set of Small Task 1 for *Trans_base* on different steps. These two models are iteratively trained. *Trans_base* is first finetuned on the parallel data, and then finetuned on the combination of the parallel data and the synthetic data generated by the previous step *Trans_base*.

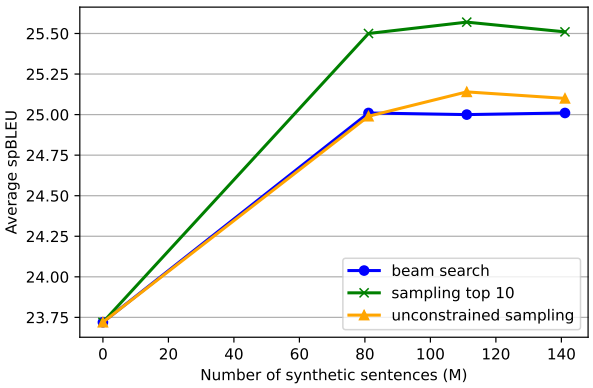

Figure 1: Average spBLEU on the devtest set of Small Task 2 for different back-translation methods with various amount of synthetic data. 80M synthetic data covers only 6M monolingual English data and all other monolingual data. We increase the amount of monolingual English data with a interval of 6M for the last two experiments.

4.2 Different Back-translation Methods

Similar to Edunov et al. (2018), we explore three types of back-translation methods, i.e. beam search with the beam size of five (Sennrich et al., 2016a), unconstrained sampling (Edunov et al., 2018) and sampling constrained to the most 10 likely words (Graves, 2013; Ott et al., 2018; Fan et al., 2018). Unconstrained sampling predicts the next word from the whole vocabulary without caring for the model distribution. Whereas constrained sampling predicts the next words within some candidates that have the highest prediction probabilities. Both constrained and unconstrained sampling can be considered as adding uncertainty to the greedy search.

Figure 1 shows the back-translation results on the devtest set of Small Task 2. We combine three different amount of synthetic data and parallel data to further train our *Trans_small*s after finetuned on parallel data. 80M synthetic sentences cover only 6M monolingual English data and all other monolingual data. In addition to the 80M synthetic sentences, we further increase the amount of monolingual English data to verify the model performance with respect to the amount of synthetic English data on the target side. The reason for this implementation is there are too many monolingual English sentences compared to other languages. We try to check whether it is necessary to use all monolingual English sentences.

As seen in Figure 1, little improvement is obtained with increasing the number of monolingual English sentences after 6M. Besides, in contrast to the results in Edunov et al. (2018) where the unconstrained sampling offers the best performance among these three methods, the constrained sampling method gives us the best score.

Beam search is the worst among these three methods. We hypothesize this is because beam search focuses only on the high probability words, while both constrained sampling and unconstrained sampling methods offer rich translations on the source side. With the diverse synthetic data generated from the sampling methods, model can be trained with more generalization.

In contrast to the bilingual translation (English-German) in Edunov et al. (2018) where unconstrained sampling outperforms constrained sampling, multilingual translation of Small Task 2 contains similar languages. We argue that unconstrained sampling might result in generating synthetic sentences with a mix of similar languages, which damages the quality of synthetic data, while constrained sampling gives us some restriction, to some extent avoiding the mix of different languages.

The reason for the slight effect of the synthetic English (on the source side) data after 6M might be that English is dissimilar to the other five South East Asian languages. Less similar knowledge could be transferred from this synthetic English (on the source side) data to other languages.

4.3 Final Submissions

Section 4.1 suggests us to employ a pretrained model with the 128K vocabulary. M2M_100 (Fan et al., 2021) offers multiple pretrained models with the 128K vocabularies [1]. Their sizes are 418M, 1.2B and 12B, respectively. Considering our limited GPU budget, we finetune the 1.2B model, i.e.

[1] https://github.com/pytorch/fairseq/tree/master/examples/m2m_100

Small Task	devtest	hidden dev	hidden devtest	hidden test
#1	34.73	35.12	35.39	34.96
#2	33.01	33.74	33.51	33.34

Table 6: Average spBLEU on different test sets for both small tasks. The hidden sets are invisible to the participants. The final ranking is based on the model performance on the hidden test set.

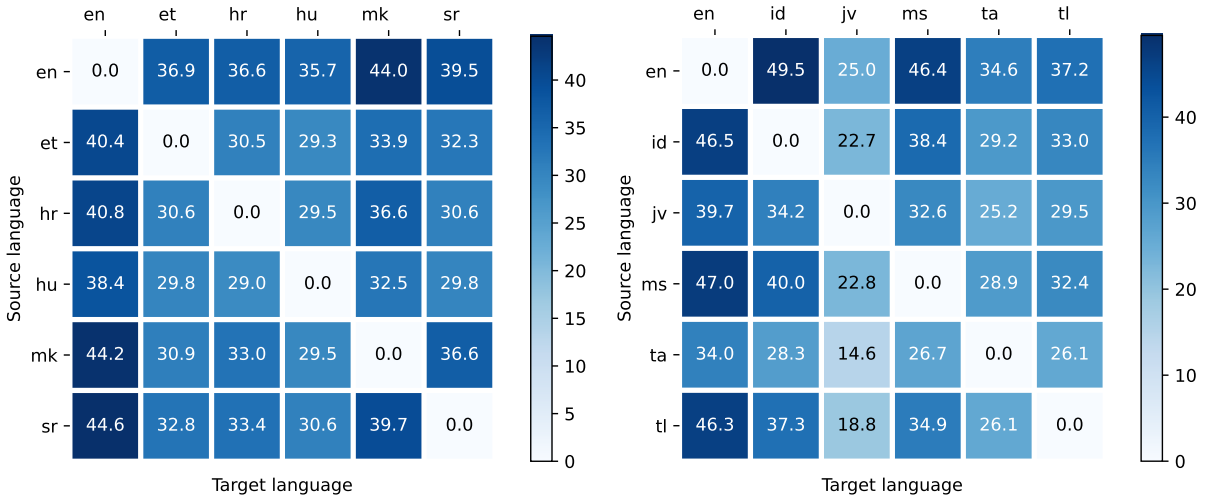

Figure 2: The spBLEU scores of different language pairs for both small tasks on the devtest set from our final submissions.

Trans_big, on parallel data of Small Task 2, obtaining 28.78 spBLEU on the devtest set. Whereas, training a *Trans_base* on the same data only provides 28.23 spBLEU. Even though *Trans_big* outperforms *Trans_base*, we only train it for generating high-quality synthetic data, since it is too large for the evaluation system.

Section 4.2 advises us to use the constrained sampling method on partial monolingual English data. With the constrained sampling method, we generate synthetic sentences with *Trans_big* that is first finetuned on the parallel data. Instead of using all monolingual English data, we synthesize en-id, en-jv, en-ms, en-ta and en-tl with all, 15M, 60M, 10M and 60M monolingual English sentences, respectively, a ratio of about $5:1$ between the number of parallel sentences and synthetic sentences if there are enough monolingual data.

Table 4 shows the results for iterative finetuning. Except for finetuing *Trans_base* on the combination of the parallel data and the synthetic data generated by *Trans_big*, we use the finetuned *Trans_base* to generate the synthetic data secondly and finetune it again. Finally, it offers us 33.01 spBLEU on the devtest set for Small Task 2.

Due to time and resource limit, we only conduct one trial on Small Task 1. We first finetune the pretrained *Trans_base* on parallel data. Then we use this *Trans_base* to generate synthetic data with only 20M monolingual English sentences and all other monolingual sentences. Table 5 shows the corresponding results. Different with Small Task 2, large amount of monolingual English data might be helpful for Small Task 1, since Central/East European languages are more similar to English than Asian languages. Finally, We leave this exploration to the future work.

Table 6 summarizes the results of our submissions on different evaluation sets for both small tasks. And Figure 2 lists the spBLEU scores for all language pairs of both small tasks on the devtest set. Finally, our submissions achieve the second place for both small tasks.

5 Conclusion

We demonstrate that a pretrained model with the smaller size of vocabularies is a better choice. Because of the memory and time limit of the evaluation system, we can only apply a 1.2B model with the smaller vocabularies to generate high-quality synthetic data. Besides, we have a different obser-

vation than previous research for bilingual back-translation: the constrained sampling method performs the best among all three back-translation methods, including the beam search and the unconstrained sampling. Finally, we also show that extensive monolingual English data offers a modest improvement. Combining these three findings, we iteratively train our models on partial high-quality synthetic data, achieving the second place for both small tasks.

Maastricht University's Large-Scale Multilingual Machine Translation System for WMT 2021

Danni Liu, Jan Niehues
Department of Data Science and Knowledge Engineering, Maastricht University
{danni.liu,jan.niehues}@maastrichtuniversity.nl

Abstract

We present our development of the multilingual machine translation system for the large-scale multilingual machine translation task at WMT 2021. Starting form the provided baseline system, we investigated several techniques to improve the translation quality on the target subset of languages.

We were able to significantly improve the translation quality by adapting the system towards the target subset of languages and by generating synthetic data using the initial model. Techniques successfully applied in zero-shot multilingual machine translation (e.g. similarity regularizer) only had a minor effect on the final translation performance.

1 Introduction

This paper describes Maastricht University's participation in the large-scale multilingual machine translation task of WMT 2021. We participate in Small Track #2. In this track, the task is to build a translation system between English and 5 Southeast Asian languages. The evaluation is performed on all 30 possible translation directions between these languages. We are provided with parallel data extracted from Wikipedia and other sources for all language pairs, as well as a large-scale multilingual machine translation model pretrained on 124 languages (Goyal et al., 2021) including the languages in this task.

Starting from the provided baseline models, we investigate several directions in order to improve the performance on the 30 target language directions. As the first step, we focus on methods to adapt the model to these language directions. Specifically, we investigate different strategies to fine-tune the model on the proposed parallel training data.

Since the provided parallel data is extremely limited for several translation directions, we investigate the use of synthetic parallel data. We focus on using pivot languages in order to use well performing language direction to generate training data for worse performing language directions.

Finally, we investigate the usefulness of techniques to promote the similarity of representation between different languages. While these techniques were shown essential for models to perform zero-shot machine translation (Arivazhagan et al., 2019a; Pham et al., 2019; Liu et al., 2021), in our experiments the impact of these methods is only limited.

ta						1,864

Table 1: Number of sentences for each languages pair after preprocessing (in thousand sentences).

2 Data

We start by introducing the training data and preprocessing steps.

2.1 Languages

As required for the small tracks, we only use the data provided by the organizers. The covered languages are: Javanese (jv), Indonesian (id), Malay (ms), Tagalog (tl), Tamil (ta), English (en). Although Sundanese (su) is later excluded from the evaluations, we still include it in the training data because of its high relatedness to Javanese (jv), one of the lowest-resource languages in this track.

2.2 Preprocessing

After de-duplicating, we remove sentences with more than 50% punctuation marks or digits, and

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 425–430
November 10–11, 2021.

sentence pairs of length ratios beyond 1:5 in character count. We also apply frequency cleaning following M2M-100 (Fan et al., 2021). An overview of the training data amount after preprocessing is shown in Table 1.

3 Techniques

Our efforts to improve upon the provided baselines can be categorized into three directions: finetuning (subsection 3.1), utilizing synthetic data (subsection 3.2), encouraging similarities between languages (subsection 3.3).

3.1 Language Adaptation

While the provided baseline systems are trained on over 100 languages, our target track focuses on 6 specific languages. Therefore, we investigate different fine-tuning methods to adapt the model to the target languages. In this framework, we initialize from the pretrained baseline model and continue training on different subsets of the given training data. First (§3.1.1), we finetune on each of the language pairs. Then (§3.1.2), we apply finetuning on all the languages jointly. Finally (§3.1.3), in an attempt to preserve model performance on all other directions, we use adapter layers dedicated to the languages of interest.

3.1.1 Language-Specific Adaptation

First, we adapt the model to each translation direction individually, resulting in 30 different translation systems. Each of the models is trained on a single language pair from the provided translation directions.

While this approach achieves good performance, the main disadvantage is that we will have 30 individual systems. Since all of the individual models are fine-tuned from the same baseline model, we hypothesize that the resulting models are relatively similar. Therefore, we investigate the possibility of checkpoint-averaging on all the models adapted to individual language pairs, as successfully done in previous evaluations of multilingual translation (Pham et al., 2017).

3.1.2 Language-Independent Adaptation

Similar to the motivation for the checkpoint-averaging described above, in order to preserve one single model, we adapt the baseline system to all the target language pairs jointly by continue training on all the provided training data.

3.1.3 Adapter Layers

The approaches above update all parameters of the pretrained baseline model during the fine-tuning stage. As a result, the models would lose performance on translation directions other than those in the training data. To avoid this catastrophic forgetting, we take inspiration from the adapters (Bapna and Firat, 2019) and insert feedfoward layers after each encoder/decoder layer. When finetuning, we only train these parameters while keeping the rest of the model frozen. At test time, the model keeps the adapter layers for the languages seen in training. When handling languages unseen in training, the model drops the adapters and falls back to the pretrained baseline.

A main difference to the multilingual adapters (Bapna and Firat, 2019) is that our adapter layers are not language-pair-specific. Instead, they are shared among all the directions. A main reason for sharing the adapters is that, when scaling to more languages, a quadratic set of adapters would be needed.

Due to resource constraints, in this work we only train one set of adapter layers for the translation directions in Small Track #2. Nevertheless, we believe this approach could remain applicable when scaling to more languages like in Large Track. This could, for instance, be achieved by multiple sets of adapter layers dedicated to different language families.

3.2 Synthetic Data

Motivated by the strong improvements from synthetic data in multilingual speech translation evaluation (Anastasopoulos et al., 2021), we investigate the creation of synthetic parallel data for all language direction with limited available parallel data. Based on the corpus statistics (Table 1), we select all languages pairs with less than n parallel sentences as low-resource directions. In the initial experiments, we choose a threshold of $n = 500$K sentences pairs. Following successful initial experiments, we increase n to 2M sentences. For all the language with $k < n$ parallel sentences, we generated $n - k$ synthetic sentences. Consequently, the final system is trained on at least n sentences for each language pair.

While monolingual data was provided, as the initial translation system performed poorly on low-resource directions, we chose not to directly generate synthetic data from the monolingual data. In-

stead, we create synthetic data based on parallel data between the source and a pivot language. Synthetic target-side data is created by translating out of the pivot language. When selecting the pivot language, we choose the source-pivot pair with the highest BLEU scores.[1]

In this above-described scenario, as the source sentences are human-generated and the synthetic target sentences are automatically generated, we hypothesize that the mistakes are concentrated on the target side. This is normally addressed by using back-translation and generating the translation in the inverse directions. Since we aim to use the generated languages for both direction (source to target and target to source) for the sake of efficiency, we generate half of the sentences in the one direction and the other half in the inverse direction.

3.3 Encouraging Similar Representations

As shown in the statistics in Table 1, our training data is highly unbalanced. Extreme low-resource pairs such as ta↔jv could be considered as few-shot directions. We therefore explore several techniques shown useful for zero-shot conditions, and investigate their usefulness in this current scenario.

3.3.1 Similarity Regularization

First shown in (Arivazhagan et al., 2019a; Pham et al., 2019), an auxiliary loss promoting similarities between source and target languages facilitate zero-shot translation. Given source sentence X and target sentence Y, besides the translation loss, we minimize the following auxiliary loss:

$$\mathcal{L}_{similarity} = \lambda \cdot \texttt{dist}(X, Y), \qquad (1)$$

where $\texttt{dist}(\cdot)$ is the Euclidean distance between two meanpooled sentence embeddings, and λ is the weight for this auxiliary loss.

3.3.2 Residual Removal

The residual removal approach was shown helpful to zero-shot translation by reducing the positional information from source sentences (Liu et al., 2021). Specifically, the residual connections of a middle encoder layer is removed to relax the strong positional correspondence between input tokens and encoder outputs.

[1] In the later experiments, the best-performing source-pivot direction is always source-English.

4 Experimental Setup

4.1 Training Details

The provided M2M-100 models (Fan et al., 2021; Goyal et al., 2021) cover over 100 languages and have a vocabulary size of 256K. To accelerate training and reduce GPU memory usage, we trim away the word embedding of those tokens that do not occur in our training data. After vocabulary trimming, our vocabulary size is 165K. An exception where we do not trim the vocabulary is when training with adapters, since the goal is to preserve performance on all languages.

To counteract the data imbalance among the language pairs, following previous works (Arivazhagan et al., 2019b; Tang et al., 2020), we use a sampling temperature of 5.0 which upsamples the low-resource pairs.

For the model with similarity regularizer, we use weight of 0.1 on the auxiliary loss. For the model with residual removal, the residual layer is skipped after the third encoder layer. For the adapters, we use a bottleneck dimension of 256.

4.2 Decoding and Evaluation

When decoding we use a beam size of 5, and limit the maximum output length to 1.3 * source length + 5. We report translation performance on the FloRes-101 (Goyal et al., 2021) devtest set. The BLEU reported scores are the spBLEU (Goyal et al., 2021) variant based on sentencepiece (Kudo and Richardson, 2018) tokenization. The systems are also submitted to Dynabench (Kiela et al., 2021)[2] for evaluation on a blind test set.

5 Results

In this section, we report the results of the three directions we explored: finetuning on the focus languages (subsection 5.1), utilizing synthetic data (subsection 5.2), and encouraging similarities between languages (subsection 5.3).

5.1 Language Adaptation

The results of adapting the model towards different language pairs are shown in Table 2.

5.1.1 Language-Dependent and -Independent Adaptation

We start with the small baseline model for faster experiment iterations, with results summarized in

[2] https://dynabench.org/flores

System	BLEU
baseline small	11.5
+ lang. dep. fine-tune	20.6
+ averaging	5.7
+ lang. indep. fine-tune	19.6
baseline big	15.4
+ lang. indep. fine-tune	27.4
+ shared adapter layers (rest frozen)	23.0

Table 2: Results of different fine-tuning approaches from the baseline models. Language-dependent fine-tuning achieves the strongest performance, but creates individual models for each translation direction. Averaging the models from the individual directions performs poorly. Fine-tuning on all directions falls slightly behind language-specific fine-tuning but preserves one single model.

the upper section of Table 2. When adapting to each language pair individually (lang. dep. fine-tune), we see large gains with average BLEU score increasing from 11.5 to 20.6. In contrast to previous work (Pham et al., 2017), we are not able to preserve this gain by averaging all the individual models into one single models. Instead, averaging the models results in a low average BLEU score of 5.7. This suggests the adapted individual models are relatively dissimilar and cannot be simply averaged.

Nevertheless, by fine-tuning on all 30 language directions together (lang. indep. fine-tune), we achieve a comparable gain in performance, results in a BLEU score of 19.6. Since this is achieved by a single model instead of 30 individual models, we continue with jointly training on all directions in the upcoming experiments on the big baseline model. Similar to findings on the small model, by fine-tuning on all the languages, we were able to improve the average BLEU score of the big baseline model from 15.4 to 27.4.

5.1.2 Adapters

As shown in the lower section of Table 2, by inserting adapters into the large baseline model and only training these modules, we achieve 23.0 BLEU on average. While the gain is less compared to full parameter tuning, the model preserves performance on the remaining tens of thousands directions.

As motivated previously (§3.1.3), the adapter layers are shared across the language directions rather than language-pair-specific. This could explain the performance gap to full parameter tuning.

System	jv-ta	ta-jv
baseline big	3.8	3.1
+ parallel data	8.5	7.9
+ syn. jv-ta data	10.0	8.2
+ syn. ta-jv data	15.0	10.7
+ both syn. data	15.9	9.7
+ both syn. data big	16.0	11.7

Table 3: Impact of synthetic data on jv↔ta, the lowest-resource language pair in this task.

5.2 Synthetic data

In the first set of experiments, we evaluate the influence of synthetic data only on the translations between Javanese (jv) and Tamil (ta), since this was the language pair with the least data (44K sentences). The synthetic data was always produced by the system fine-tuned on all the target language directions. The results are summarized Table 3. First, although the available parallel data is limited, we see a clear improvement of the baseline model when trained on the provided training data.

Adding the synthetic data (225K sentences for jv-ta and ta-jv each) does improve the performance compared to only using the parallel data. For both directions, the data generated from ta-jv was performing better than the other data. Since the combination of both directions performed the best for the jv-ta direction and reasonable good for the other direction and it is not clear how we should select the direction without perfoming test for each langauge pair, we continued the experiments by always using synthetic data generated by both directions.

By increasing the amount of synthetic data, so that the model is not trained on around 500k sentences by 2M sentence, we see additional gains to the best performance of 16.0 and 11.7 BLEU points for both directions. This is an improvement nearly by a factor of 3 compared to the baseline system.

Given the best system so far with 27.4 average BLEU, we continue fine-tuning with the additional synthetic data. This leads to an improvement to 27.9 BLEU on average. This improvement is significantly lower than expected, considering the general positive role of utilizing synthetic data. This has two potential reasons. First, as all other language directions have more data, the gains from the additional data could be reduced. Furthermore, the initial model is fine-tuned on the parallel data

Directions	# Sent.	Δ BLEU
jv↔ta	46K	+0.6
ms↔ta	297K	+0.1
jv↔ms	340K	+0.1
Overall	89M	+0.0

Table 4: The average change in BLEU after fine-tuning with residual removal. There is no gain in overall average BLEU, and limited gain in the top 3 lowest-resource directions.

of all the language pairs and therefore performing better.

5.3 Encouraging Similar Representations

Next we report the results of the approaches that promote language similarity as motivated in subsection 3.3.

5.3.1 Similarity Regularizer

Based on the best system trained with synthetic data (with 27.9 BLEU on average), we continue fine-tuning with the similarity regularizer described in §3.3.1. While we observe consistent increase in the similarity scores on the dev set, fine-tuning with the similarity regularizer alone does not improve the system further, achieving 27.7 BLEU on average. Nevertheless, we see gains when combining the similarity regularizer and the adapters described in §3.1.3. As adding the adapter layers expands the capacity of the existing model, we hypothesize the similarity regularizer could help combat overfitting. With this combination, we achieve an average of 28.1 BLEU.

5.3.2 Residual Removal

Based on the baseline big + fine-tune model (with 27.4 BLEU on average), we fine-tune once again using the residual-removal architecture described in §3.3.2. In Table 4, we summarize the average change in BLEU after this additional fine-tuning step. While there was no improvement in the overall average BLEU score, we observe some gain in the lowest-resource direction of jv↔ta which has 46K parallel data. However, the gain falls largely for the second and third lowest-resource directions.

5.4 Final System

The final system submitted to the evaluation is presented in Table 5. In a first step, we fine-tuned on the provided parallel data. Using this model, we created additional synthetic data. Fine-tuning the previous model on the parallel data and the synthetic data gave an additional improvement of 0.5 BLEU.

System	BLEU
baseline big	15.4
+ fine-tune	27.4
+ synthetic data	27.9
+ sim. regularizer + adapter	28.1

Table 5: Average BLEU scores on FLoRes-101 devtest set on 30 directions of the final system.

Finally, on top of the previous improvements, our best system uses the additional similarity regularization and adapters during training and further improves the average BLEU by 0.2 points to 28.1. The submitted system achieves 28.6 BLEU on average on the blind test set[3].

6 Conclusion

This paper summarizes our participation in the WMT 2021 large-scale multilingual translation task. We focus on Small Track #2 for English and 5 Southeast Asian languages. Building upon the provided baseline models, we achieved the largest gain from fine-tuning on the parallel data of all directions in this task. By further utilizing synthetic data and a combination of similarity regularization and adapters, we were able to further improve the system.

Abstract

In this paper, we describe the submission of the joint Samsung Research Philippines-Konvergen AI team for the WMT'21 Large Scale Multilingual Translation Task - Small Track 2. We submit a standard Seq2Seq Transformer model to the shared task without any training or architecture tricks, relying mainly on the strength of our data preprocessing techniques to boost performance. Our final submission model scored 22.92 average BLEU on the FLORES-101 devtest set, and scored 22.97 average BLEU on the contest's hidden test set, ranking us sixth overall. Despite using only a standard Transformer, our model ranked first in Indonesian → Javanese, showing that data preprocessing matters equally, if not more, than cutting edge model architectures and training techniques.

1 Introduction

This paper describes the machine translation system submitted by the joint team of Samsung Research Philippines and Konvergen AI for the WMT'21 Large Scale Multilingual Translation Task. Our team participated in **Small Track #2**, where the task is to produce a multilingual machine translation system for five Southeast-Asian languages: Javanese, Indonesian, Malay, Tagalog, and Tamil[1], plus English, in all 30 directions.

We will first describe the filtering heuristics that we used to preprocess the data, and then outline the steps we took to train and evaluate our models. Specific hyperparameters, preprocessing decisions, and other training parameters will be listed in their corresponding sections. Finally, we report our results on the FLORES-101 (Goyal et al., 2021) devtest set, as well as on the competition's hidden test set.

*Equal contribution. Order determined via coinflip.

[1]Tamil is considered an official language in Singapore, a Southeast Asian country

2 Parallel Text Preprocessing Heuristics

The contest dataset comprises of various bitext sources, including: bible-uedin (Christodouloupoulos and Steedman, 2015), CCAligned (El-Kishky et al., 2020), ELRC 2922[2], MultiCCAligned (El-Kishky et al., 2020), ParaCrawl [3], TED2020 (Reimers and Gurevych, 2020), WikiMatrix (Schwenk et al., 2019), tico-19, Ubuntu, OpenSubtitles, QED, Tanzil, Tatoeba, GlobalVoices, GNOME, KDE4, and WikiMedia (Tiedemann, 2012).

We preprocess the datasets before training in order to minimize spurious relations that originate from incorrect text pairs. Our preprocessing removes samples based on a few heuristics that we developed based on our observation on the datasets. Each bitext file is applied a different set of preprocessing based on observation. For example we filter by number content for datasets such as CCAAligned while TED2020 is not applied that same filter.

In this section, we will cover the decisions made during preprocessing. We observe a score increase of 1.91 BLEU on our submission model when the preprocessing is applied. We report the total number of lines filtered from the bitext for all language pairs on Table 1.

2.1 Filter by Duplicate

Duplication is present throughout the dataset. Table 2 outlines samples of duplication based on three distinct types:

- **Duplicates within the same language** Within a subset file of a designated language, multiple lines have the same string while the its counterpart may feature different translations.

jv-ta	Javanese - Tamil	65,997	48,806	26.05%

Table 1: Number of parallel text lines per language pair before and after applying preprocessing

- **Partial duplication** The whole string of text in one language is present in its counterpart translation.
- **Duplication among parallel text** Both source and target text line feature exactly the same string. While this may be correct for named entities, most of these duplication are short and can be non-informative.

2.2 Filtering by Language and Letters

In algorithmically-aligned datasets such as CCAligned, some training examples are not in the list of contest languages. We find full text lines that are in Azerbaijani, Turkish, Arabic, and Japanese. To identify these languages, we use langdetect[4]. This filter works for sentences that are fully foreign. It is also the case that foreign letters that may refer to named-entity can be found in the dataset. We consider this to be allowable so long as the the foreign character string is present in both source and target text line. To filter this, we use AlphabetDetector[5] and check if detected foreign letters are present in both text line.

2.3 Filter by Specific Keywords and Symbols

There are a number of cases where the translations are generally correct but also feature extra keywords that have no relation to the parallel text. These keywords are generally in English and are consistently present in a number of bitext datasets such as KDE4, GNOME, and Ubuntu.

Bitexts such as OpenSubtitles feature secondary information that relates to a particular scene (for example "*(loud music playing)*"). These secondary information may be in parentheses to denote an action being done or to signify a song being played. These secondary information are not always available for each language. We opt to remove all lines that have these specific symbols.

2.4 Filtering Number Content

We apply a filter to remove incorrect text lines in the bitext by checking if both source and target text lines feature the same numeric values such as date and quantities. Table 4 shows that filtering by number can remove text lines that do not relate to one another as numeric values tend to translate the same. Due to the limited time allotted for the shared task, we opt to remove entirely parallel sentences that do not have matching numbers. We filter this by using regular expressions.

2.5 Filtering by Length

Text lines with very long lengths are generally not informative, we find most of these text lines consists of a list of names that would normally be found in a bibliography. We set an arbitrary max length of 500 characters for both source and target sentences.

Kept	(Terakhir diperbarui saat: 24/03/2020) Harga / $: 1,2835	(Huling nai-update Sa: 24/03/2020) presyo / $: 1.2835

Table 4: Incorrect translations can be easily identified by checking whether numeric values in both strings match. In the first example, the sentence pair was removed due to differing date and time. In the second example, the sentence pair was kept as we do not check punctuation for numerical values.

3 Experiments

3.1 Model Architecture

For our submission, we wish to measure how much performance can be boosted by heuristics-based data preprocessing alone. Given that we anticipate most, if not all, submissions to the shared task will be transformer-based models, we opt to use the standard "vanilla" Sequence-to-Sequence Transformer (Vaswani et al., 2017) model with little-to-no changes. This lets us more clearly compare the performance boost of our filtering heuristics against the boost provided by a number of architecture augmentations and training tricks that other submissions might have.

In addition to using a standard Transformer model, we only train the model directly on our filtered bitext and do not make use of Backtranslation (Sennrich et al., 2015a) for data augmentation. We also start from-scratch with models initialized using Glorot Uniform (Glorot and Bengio, 2010), opting not to use massively-pretrained translation models such as M2M-100 (Fan et al., 2021) as our starting checkpoint.

Following Vaswani et al. (2017), we produce two models: a base model and a large model. For the sake of simplicity, for the rest of the paper, we will refer to our models trained with our filtered data as $\textbf{Base}_{\textbf{Heuristics}}$ and $\textbf{Large}_{\textbf{Heuristics}}$.

The hyperparameters used for our models are presented in Table 5.

	Base	Large
Vocab Size	37,000	37,000
Encoder Layers	6	6
Decoder Layers	6	6

Attention Dropout	0.1	0.3
Pos. Embeddings	Sinusoid	Sinusoid
Parameters	63M	214M

Table 5: Model hyperparameter choices for the base and large Transformer variants.

3.2 Data Preformatting and Tokenization

Our models employ one single shared vocabulary for all languages and directions. We train our tokenizer using the SentencePiece[6] library, limiting our vocabulary to 37,000 BPE (Sennrich et al., 2015b) tokens, and training with a character coverage of 0.995.

Before training the tokenizer, we first preformat the dataset into the format to be used for training later on. We append the source and target language's ISO-639-1 code enclosed in square brackets at the beginning of each sentence. For example:

`[en] [tl]` Today is a sunny day.

is the preformatted version of "Today is a sunny day." when translating from English to Tagalog.

This preformatting is only done for the source sentences in the training dataset, while the target sentences are untouched.

For the purpose of training the tokenizer, the six language tokens (`[en]`, `[id]`, `[jv]`, `[ms]`, `[ta]`, and `[tl]`) are treated as special tokens to ensure that they will not be segmented later on.

3.3 Training Setup

We then compile our filtered, preformatted bitext and train our base and large models. During training, we limit all source and target sentences to a maximum sequence length of 150 subword tokens. All sentences that are much longer are truncated.

Our models are trained using the Adam (Kingma and Ba, 2014) optimizer. Following Vaswani et al. (2017), we also use the "Noam" learning rate scheduler, linearly increasing the learning rate from 0 for the first 8000 steps, then decaying afterward. We also set Adam's $\beta_2 = 0.998$ and use a label smoothing factor of 0.1.

For batching, we accumulate tokens until we reach a maximum size of approximately 32,000 tokens per batch, an increase over the 25,000 tokens used in Vaswani et al. (2017). We then train the base model and the large model for 100,000 steps and 300,000 steps, respectively. All our models are trained on 8 NVIDIA Tesla P100 GPUs in parallel using the OpenNMT-py (Klein et al., 2017) toolkit.

3.4 Translation

To generate translations using the model, we use Beam Search with beam size 5 and apply an average length penalty of 0.6. During generation, we limit all outputs to a maximum sequence length of 100, preemptively terminating generation if it begins to exceed this maximum length. We do not use sampling during translation, nor increase the temperature parameter as this induces randomness (Lopez et al., 2020).

We test our experimental models on the FLORES-101 devtest set. We report our BLEU scores using the SPM-BLEU variant of SacreBLEU[7] (Post, 2018).

4 Results

After training our models and producing sample translations from the FLORES-101 devtest set, we compare the results of our two models with a number of baselines:

- Transformers with No Heuristics – These models are essentially identical with our Transformer models in terms of architecture, hyperparameters, and training setups, except the bitext they are training on are the raw training corpus given in the competition (i.e. the filtering heuristics were not applied on them). We train these models as an ablation experiment to be able to identify how much of the final performance is attributable to the filtering heuristics.

- M2M-100 615M – This is the baseline given for the WMT'21 Large-scale Multilingual Translation Task Small Track 2 competition. This M2M-100 (Fan et al., 2021) model was

[6] https://github.com/google/sentencepiece

[7] BLEU+case.mixed+numrefs.1+smooth.exp+tok.spm +version.1.5.0

trained on CCMatrix and CCaligned with no further finetuning on the contest dataset.

- DeltaLM+ZCode – This is the best performing model for the Small Track 2. The model is a finetuned version of the DeltaLM (Ma et al., 2021) encoder-decoder pretrained model.

All analyses and results within this section are based on the *public devtest set* and not the contest's hidden test set, unless specified. A summary of the BLEU scores for all models and baselines are available on Table 6.

4.1 Transformer + Heuristics vs. Baselines

We report the results of our $\text{Base}_{\text{Heuristics}}$ and $\text{Large}_{\text{Heuristics}}$ models against the M2M-100 615M model baseline as well as the best performing model for the shared task.

$\text{Base}_{\text{Heuristics}}$ scored an average BLEU of 20.78 on all 30 directions. On the other hand, $\text{Large}_{\text{Heuristics}}$ scored 22.92 average BLEU on all 30 directions, which is 2.14 BLEU points higher than the base model. Both models outperformed the M2M-100 615M baseline, with the base model giving a 5.32 BLEU improvement, and the large model giving a 7.46 BLEU improvement.

It is worth noting that, while the $\text{Base}_{\text{Heuristics}}$ outperforms the baseline on average, it fails to outperform it on four specific translation directions: en↔id and en↔ms. Note that it is these two language pairs that have the most number of training sentences in the training corpus.

The language pairs that benefit significantly from training on the contest dataset are language pairs that are of less volume than en↔id and en↔ms. This is likely due to these pairs being less-sampled in M2M100's training dataset, and thus were not as learned by the model compared to pairs with a higher volume of training data.

The same observations can be found when comparing the performance of $\text{Large}_{\text{Heuristics}}$ against the baseline model. $\text{Large}_{\text{Heuristics}}$ only marginally outperformed the baseline in one direction (id→en, +0.07 BLEU), and marginally underperformed against the baseline in one direction (ms→en, -0.47 BLEU). This higher performance for M2M-100 is likely due to the training method used in the model in addition to the size of the training corpora used. While M2M-100 is advantageous in these translation directions, the difference is only marginal, most likely owing to $\text{Large}_{\text{Heuristics}}$'s size which gives it higher capacity.

Both our transformer models and the baseline model are significantly outperformed by the DeltaLM+ZCode model, which is the best performing model in the competition. The best model outperforms our best model ($\text{Large}_{\text{Heuristics}}$) by a significant 11.02 average BLEU, and the baseline model by 18.48 average BLEU.

While DeltaLM+ZCode outperforms our model in terms of average performance, it is worth noting that our model – a standard Transformer without any augmentations and training tricks – managed to outperform DeltaLM+ZCode in one translation direction: id→jv.

$\text{Large}_{\text{Heuristics}}$ scored 23.91 BLEU while DeltaLM+ZCode scored 23.35 BLEU. While the difference is marginal (+0.56 BLEU), our model still outperforms the best model in this direction, which we attribute to the quality of our data preprocessing and filtering heuristics.

4.2 Heuristics vs. No Heuristics

To quantify how much our filtering heuristics contributed to the final performance of our models, we trained two additional models: both identical to our base and large transformer variants, except the training corpus used was not processed using our filtering heuristics. For these ablation experiments, we use the same BPE tokenizer that is used for our main transformer models (trained on the filtered data). This is to ensure full model equivalency. To prevent confusion, we will refer to these ablation models simply as **Base** and **Large** to differentiate them from our contest models $\textbf{Base}_{\textbf{Heuristics}}$ and $\textbf{Large}_{\textbf{Heuristics}}$.

On average, both sizes of models performed worse when trained without the filtering heuristics. Base scored 19.28 average BLEU on the devtest set, 1.5 points lower than $\text{Base}_{\text{Heuristics}}$. On the other hand, Large scored average 21.01 BLEU, which is 1.91 points lower than $\text{Large}_{\text{Heuristics}}$.

It is interesting, however, that Base outperformed $\text{Base}_{\text{Heuristics}}$ in two translation directions: en→ms and ms→id. This may indicate that the filtering heuristics work better for a certain subset of languages. We look towards exploring how filtering methods such as ours affect multilingual translation datasets in terms of balance and informativeness in the future.

On the other hand, Large performed worse than $\text{Large}_{\text{Heuristics}}$ in all 30 directions. This may be due to the increase in total trainable parameters, as

	Base$_{\text{Heuristics}}$	**Large$_{\text{Heuristics}}$**	**Base**	**Large**	**M2M100 Baseline**	**DeltaLM +ZCode**

Table 6: Summary of BLEU scores on the FLORES-101 devtest set. The first two columns show the performance of our Transformer models trained with the data filtering heuristics. The next two columns show the same Transformer models, but trained on an unpreprocessed version of the training dataset. We also show the scores of the M2M-100 615M baseline model, as well as the best performing model (DeltaLM+ZCode) for the Small Track 2. Large$_{\text{Heuristics}}$ (column 2) is our final submission model for the contest.

larger models need more data with higher quality to be effectively trained.

4.3 The Case of Tamil

We observe that our models, including the other models on the shared task leaderboard, struggled with Tamil. X↔ta translation is on average much worse in terms of BLEU score compared to the other translation directions that do not involve it.

We hypothesize that this is due to two things.

First, Tamil is the most underrepresented language in the shared task dataset, with X↔ta having the least amount of parallel text for every language X in the training set. This causes the model, to a certain extent, to underfit on directions that translate to or from Tamil.

Second, Tamil is the only language in the shared task dataset that does not use the latin alphabet. Combined with the fact that it is the most underrepresented language in the dataset, there is a possibility that the model may have treated Tamil as noise during training. The observation that X→ta performs worse on average compared to its inverse direction ta→X lends more credence to this hypothesis. The model is not trained well to represent sentences in Tamil, and thus, struggles when generating Tamil translations.

Part of our planned future work includes identifying methods to improve translation in multilingual datasets where the alphabets used may be more than one. This is to improve translation to non-latin alphabet languages in future methods.

4.4 Hidden Test Set Performance

We also report the performance of our models on the shared task's hidden test set. We once more compare our results against the baseline M2M-100 model as well as the best performing DeltaLM+ZCode model.

Our final submission for the shared task was our $\text{Large}_{\text{Heuristics}}$ model, which performed with an average BLEU of 22.97 on the shared task's hidden test set. This is a marginal difference from it's devtest set score (+0.05 average BLEU).

$\text{Large}_{\text{Heuristics}}$, unsurprisingly, still outperformed $\text{Base}_{\text{Heuristics}}$ (20.73 average BLEU, +2.24 improvement) and the baseline M2M-100 model (14.02 average BLEU, +8.95 improvement) in the hidden test set. The shared task's best performing model, DeltaLM+ZCode, still outperforms all other models in the hidden test set, scoring 33.89 average BLEU, a 10.92 improvement over our best model.

	Public Test	**Hidden Test**	**Rank**
M2M-100 615M	15.46	14.02	8
DeltaLM+ZCode	33.94	33.89	1
$\text{Base}_{\text{Heuristics}}$	20.78	20.73	-
$\text{Large}_{\text{Heuristics}}$	22.92	22.97	6

Table 7: Average BLEU scores on the contest's hidden test set. The $\text{Base}_{\text{Heuristics}}$ model is unranked as it was not submitted as our final model.

On the hidden test set, $\text{Large}_{\text{Heuristics}}$ still ranked first in the id→jv translation direction, scoring 24.05 BLEU. This outperforms DeltaLM+ZCode's 23.79 BLEU (+0.26) and M2M-100's 15.33 BLEU (+8.72).

A summary of our model's performance on the hidden test set, as well as the baseline and best performing model, can be found on Table 7

5 Conclusion

In this paper, we described the translation systems submitted by the joint Samsung Research Philippines-Konvergen AI team for the WMT'21 Large Scale Multilingual Translation Small Track 2 shared task. We outline the filtering heuristics that we took to preprocess our data. We then train two models with a bitext preprocessed using our filtering heuristics, with our best model reaching an average BLEU score of 22.92 on the devtest set, and outperforming the baseline model by 7.46 BLEU points. In addition, we rank sixth in the contest leaderboard overall, scoring 22.97 BLEU on the hidden test set.

We also reached first place for the id→jv translation direction, beating all other more complex models, despite only using a standard transformer without any special augmentations and training tricks. This provides empirical evidence that data quality and preprocessing decisions weigh just as much, if not even more, than cutting edge model architectures and training techniques do.

Abstract

This paper describes TenTrans large-scale multilingual machine translation system for WMT 2021. We participate in the Small Track 2 in five South East Asian languages, thirty directions: Javanese, Indonesian, Malay, Tagalog, Tamil, English. We mainly utilized forward/back-translation, in-domain data selection, knowledge distillation, and gradual fine-tuning from the pre-trained model FLORES-101. We find that forward/back-translation significantly improves the translation results, data selection and gradual fine-tuning are particularly effective during adapting domain, while knowledge distillation brings slight performance improvement. Also, model averaging is used to further improve the translation performance based on these systems. Our final system achieves an average BLEU score of 28.89 across thirty directions on the test set.

1 Introduction

We participate in the WMT 2021 large-scale multilingual machine translation task small track 2 in 6 languages: English, Indonesian, Javanese, Malay, Tamil, Tagalog (briefly, En, Id, Jv, Ms, Ta, Tl). Any two of these languages translated into each other produces a total of 30 directions, including English↔Indonesian, English↔Javanese, English↔Malay, English↔Tamil, English↔ Tagalog, Indonesian↔Javanese, Indonesian↔Malay, Indonesian↔Tamil, Indonesian↔Tagalog, Javanese ↔Malay, Javanese↔Tamil, Javanese↔ Tagalog, Malay↔Tamil, Malay↔Tagalog and Tamil↔Tagalog. To meet the requirements for data restrictions, our systems are all built with constrained data sets. For all systems, we adopt a universal encoder-decoder architecture that shares parameters across all languages (Johnson et al., 2017).

Our systems are based on several techniques and approaches. We experiment with base and deeper Transformer (Vaswani et al., 2017) architectures to get reliable baselines, fine-tune the pre-training model FLORES-101 (Goyal et al., 2021) to further improve the baseline system. Moreover, we generate pseudo bilingual sentences from the large-scale monolingual data, apply sequence level knowledge distillation (Kim and Rush, 2016) on partial language pairs, and try a more effectively fine-tuning strategy to domain adaptation (Gu et al., 2021). Particularly in the language pairs with inferior translations, we specifically improve their performance. All of these technologies have improved our systems, particularly data selection and gradual fine-tuning. We carefully rethought this strategy and found the main gain may come from in-domain knowledge adaptation.

This paper was structured as follows: Section 2 describes the data set. Then, we present a detailed overview of our systems in Section 3. The experiment settings and main results are shown in Section 4. Finally, we conclude our work in Section 5.

2 Data Prepration

We use FLORES-101 SentencePiece (SPM) [1] tokenizer model with 256K tokens to tokenize bitext and monolingual sentences [2]. Since it is important to clean data strictly (Wang et al., 2018), we follow m2m-100 data preprocessing procedures [3] to filter bitext data. The rules are as follows:

- Remove sentences with more than 50% punctuation.

- Deduplicate training data.
- Remove all instances of evaluation data from the training data.
- Filter sentences that are longer than 250 tokens or length ratio upper than 3.

For monolingual data, we still employ those rules except the length ratio filter. See Table 1 for the statistics of bitext data sets and Table 2 for monolingual data sets.

3 System Overview

3.1 Base Systems

Our systems are based on the Transformer architecture (Vaswani et al., 2017) as implemented in TenTrans [4], a unified end-to-end multilingual and multi-task training platform. We first train a model following the Transformer *base* setup to jointly training all language pairs as our base system. Then, inspired by Wang et al. (2019), we experiment with raising network capacity by increasing encoder/decoder layers and feed-forward networks. We found that using a deeper encode layer (24) and a larger feed-forward network size (4096) can provide reasonable performance improvements while maintaining manageable network size and not increasing inference time.

Because of the recent popularity of using large-scale pre-training models to fine-tune specific languages and tasks (Fan et al., 2020; Liu et al., 2020), we use the pre-trained model FLORES-101 released by the organizer to fine-tune on the bitext data. This system has further improved our translation performance in all thirty translation directions. Note that to fine-tune FLORES-101 we train our models using FAIRSEQ (Ott et al., 2019).

3.2 Forward-Translation and Back-Translation

Back-translation is an effective and common way to boost translation quality by using monolingual data to produce pseudo training parallel data. As opposed to back-translation, forward translation use source-side monolingual data to translate into the target language, and can be quite effective in some cases (Bogoychev and Sennrich, 2019). Wu et al. (2019) has shown that when monolingual data from source and target languages are used together to produce pseudo data, the translation quality is best, and the experimental performance will be improved with the increase of data.

In this work, considering the excellent performance of forward-translation and back-translation, we use both methods together. For translation directions with more than 5 million bitext data, such as En↔Id, En↔Ms, En↔Tl, we separately train an individual model for each direction and use it for the pseudo-corpus generation. For other translation directions with less than 5 million bitext data, we use the baseline system of all language pairs jointly training for translating pseudo sentences. Due to a large amount of English monolingual data, English monolingual sentence was randomly divided into 13.36M, 25M, 25M, 25M, and 25M for En→Id, En→Jv, En→Ms, En→Ta, and En→Tl translation respectively. All monolingual data of Id, Jv, Ms, Ta, and Tl are used in translation to all other directions.

3.3 In-domain Data Selection

The training data is provided by the publicly available Opus repository, which contains data of various quality from a variety of domains, while the hidden test set is the same domain as the provided dev and devtest datasets. After fine-tuning on a

Table 3: Data filtered at different thresholds for all language pairs.

mixture of authentic bitext and pseudo-data, we select domain-specific data from the bitext and continue to fine-tune to further improve translation quality.

Due to the scarcity of in-domain data, we utilize pre-trained language model multilingual BERT (Devlin et al., 2019) to train a domain classifier for extracting in-domain sentences from authentic bilingual sentences. To train the domain classifier, we consider all available dev data as positive data, and randomly sample bilingual data as negative samples. At the same domain test set, the domain classifier recognition accuracy is achieved at 93.97%. We select sentences predicted to be positive with a probability greater than threshold 0.7 to form an in-domain corpus.

3.4 Knowledge Distillation

Knowledge distillation (Hinton et al., 2015) is a way to train a smaller network of students to perform better by learning from a larger teacher model. On this basis, sequence-level knowledge distillation trains the student model on the new data generated by the teacher model to further improve the performance of the student (Kim and Rush, 2016).

A multilingual translation model that trains too many languages at the same time may degrade performance (Xie et al., 2021), especially involving 30 translation directions in this work. It makes it harder for the model to accommodate all language pairs. Based on this, we fine-tune the FLORES-101 model on five language pairs with En→Ta, Id→Ta, Jv→Ta, Ms→Ta, Tl→Ta to produce an Any-to-Ta specific translation model (Tan et al., 2019). These five language pairs are chosen because they do not perform very well and have more room for improvement. We used this model as the teacher model to translate the training data of the five language pairs. The new data was then combined with data of other language pairs to train the student model.

3.5 Gradual Fine-tuning

Fine-tuning can improve the machine translation model by adapting the initial model trained on abundant but less domain-specific examples to the data in the target domain. This domain adaptation is usually accomplished with a phase of fine-tuning. While Xu et al. (2021) prove that gradual fine-tuning over a multi-stage process can yield substantial further gains. Intuitively, the model is iteratively trained to convergence on data whose distribution progressively approaches that of the in-domain data, similar to the curriculum learning strategy (Bengio et al., 2009; Kocmi and Bojar, 2017).

In this work, we use gradual fine-tuning combined with in-domain data selection. After training the domain classifier, authentic bilingual sentences with positive predictions and probabilities greater than the thresholds of 0.7, 0.8, 0.9, and 0.99 are selected to form in-domain corpora with different similarity degrees. Data statistics with different thresholds are shown in the Table 3. The higher the threshold, the more the selected data fits into the domain of the dev set and test set. We started with a gradual fine-tuning on the domain-specific data selected at the 0.7 thresholds, followed by the 0.8 thresholds, and so on.

+ F&B	25.05
+ deep (24)	25.43
FLORES-101	15.38
+ Fine-tuning	24.23
+ F&B	26.50
+ Data Selection	27.24
+ Gradual FT	28.03
+ KD	28.15
+ Recover 12	28.32
Averaging	**28.94**

Table 4: Average BLEU (%) scores of all systems. The '+' means the approach added to the system over the previous line.

To further improve performance, we selected 12 language pairs that are significantly better than the baseline system. We consider them BLEU-sensitive and performance-friendly language pairs, which include En→Ta, Id→Ta, Jv→En, Jv→Ta, Jv→Tl, Ms→Ta, Ta→En, Ta→Id, Ta→Jv, Ta→Ms, Ta→Tl and Tl→Ta. After the gradual fine-tuning, we recover all the authentic bilingual sentences of these 12 language pairs, while the training sentences of other language pairs are still the training data when the threshold is 0.99. We continue to fine-tune the multilingual translation model. We find that the results still improve on these 12 language pairs and the performance of other language pairs is almost unchanged.

3.6 Model Averaging

Model averaging is typically used between 5 or 10 adjacent checkpoints on the same system. It is almost impossible to average different systems because neurons or parameters at the same location in different systems may be responsible for completely different knowledge or responsibilities. Our systems kept the random seeds consistent, and the training data did not differ too much, so we tried a variety of model averaging methods to see whether the performance was improved. We finally chose average multiple checkpoints in a single system, and then averaged on different systems. In this way, the translation result can be further improved.

4 Experiments

4.1 Experiment Settings

Except for the FLORES-101 fine-tuning experiments training on 48 NVIDIA P40 GPUs, the rest of our experiments are carried out with 16 NVIDIA P40 GPUs. Our model apply Adam (Kingma and Ba, 2015) as optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 10^{-9}$. We set the label smoothing to 0.2 and the dropout rate to 0.3. The initial learning rate is set to 5e-4 varied under a warm-up strategy with 4000 steps. For training, the batch size is 4096 tokens per GPU. For fine-tuning FLORES-101, we apply a temperature sampling strategy with sampling temperature T = 1.5 (Arivazhagan et al., 2019). During inference, we decode with beam search and set beam size to 4 for all language pairs. The translation results we reported is detokenized and then the quality is evaluated using the 4-gram case-sensitive BLEU (Papineni et al., 2002) with the *SacreBLEU* tool (Post, 2018).[5]

4.2 Main Results

Results for all of our systems are shown in Table 4. For convenience, we only report the average BLEU for 30 language pairs. The detailed BLEU scores for each language pair of systems implemented by TenTrans tool are shown in Table 5, and the relevant systems for fine-tuning FLORES-101 are shown in Table 6.

As shown in Table 4, we found that the baseline system with fine-tuning FLORES-101 performed better than the baseline system with no pre-training model (24.23 vs. 22.25). Forward-translation and back-translation (F&B) greatly improved the translation performance in both TenTrans (25.05 vs. 22.25) and FLORES-101 (26.50 vs. 24.23) frameworks. The results of individual models for forward-translation and back-translation are shown in Table 7. Deep Transformer with 24 encoder layers further improves translation results, but still not as high as fine-tuning FLORES-101 systems. Given the excellent performance of the pre-trained model, our subsequent series of approaches are based on fine-tuning FLORES-101.

In-domain data selection is restricted to in-domain data size (threshold 0.7), but we also obtain a solid improvement of 0.74 BLEU on average. Gradual fine-tuning (Gradual FT) is also effective, which enables the model to potentially better fit

flores101-small2-devtest	28.94

Table 9: Flores MT Evaluation (Small task 2) results: https://dynabench.org/models/460

the distribution of the target domain. The knowledge distillation, however, has not brought much improvement (28.15 vs. 28.03). The translation performance of the teacher model is shown in Table 8. We guess that it may be because the translation quality of the teacher model is not excellent enough, which leads to the improvement of the student model is not satisfactory. We then recovered bilingual sentences for 12 BLEU-sensitive language pairs. As shown in Table 6, the performance of these 12 language pairs improved significantly, while the results of the other language pairs barely changed, so our average BLEU improved further. For model averaging, we tried different combinations and finally found that averaging the three best checkpoints in "+ Gradual FT" and "+ Recover 12" will produce the best performance (28.94).

4.3 Submitted Results

As shown in Table 9, we ultimately chose the best-performing model on devtest to submit to Dynabench [6] and achieve 28.89 in the hidden test set.

5 Conclusion

This paper introduced our TenTrans submissions on WMT21 large-scale multilingual machine translation small task 2. Our main exploration is using more diversified architectures and fine-tuning strategy, utilizing forward-translation and back translation and approaches including in-domain data selection, knowledge distillation, and gradual fine-tuning. We experimented with these methods and continuously improve our system performance. On the whole, all of our systems performed competitively and ranked 3rd on the leaderboard.

Abstract

This report describes Microsoft's machine translation systems for the WMT21 shared task on large-scale multilingual machine translation. We participated in all three evaluation tracks including Large Track and two Small Tracks where the former one is unconstrained and the latter two are fully constrained. Our model submissions to the shared task were initialized with DeltaLM[1], a generic pre-trained multilingual encoder-decoder model, and fine-tuned correspondingly with the vast collected parallel data and allowed data sources according to track settings, together with applying progressive learning and iterative back-translation approaches to further improve the performance. Our final submissions ranked first on three tracks in terms of the automatic evaluation metric.

1 Introduction

Recently, multilingual neural machine translation has attracted lots of attention because it enables one model to translate between multiple languages (Dong et al., 2015; Johnson et al., 2017; Arivazhagan et al., 2019; Dabre et al., 2020; Philip et al., 2020; Lin et al., 2021). To improve the performance of the multilingual translation models, there are various approaches on the training methods (Aharoni et al., 2019; Wang et al., 2020a,c), the model structures (Wang et al., 2018; Gong et al., 2021; Zhang et al., 2021a), and the data augmentation (Tan et al., 2019; Pan et al., 2021). M2M (Fan et al., 2020) leverages the large-scale data mined from the web data and explore the strategies to scale the model size and train the model effectively. Meanwhile, the multilingual pre-trained language models have proven beneficial for the multilingual machine translation models. mBART (Liu et al., 2020) pre-trains a multilingual model with the multilingual denoising objective to improve the multilingual machine translation.

[1] https://aka.ms/deltalm

In this work, we explore the effects of different advanced approaches for multilingual machine translation models, especially on the large-scale dataset. We first explore the way to leverage the pre-trained language models that have been trained with large-scale monolingual data. We use the public available DeltaLM-Large checkpoint to initialize the model. DeltaLM (Ma et al., 2021) is a multilingual pre-trained encoder-decoder model, which has been proven useful for multilingual machine translation.

We further explore the training methods and the data augmentation to improve the model. For efficient training, we apply progressive learning (Li et al., 2020; Zhou et al., 2021; Zhang et al., 2021b) to our model that continue-trains a shallow model into a deep model. Specifically, we first train a model with 24 encoder layers, and then continue-train it by adding 12 layers on the top of the encoder. As for the data augmentation, we implement iterative back-translation (Hoang et al., 2018; Dou et al., 2020) that back-translates the data for multiple rounds. Due to the limits of time and GPU memories of the shared task, we do not explore other approaches like mixture-of-experts (MOE) and model ensemble.

We participated in all three tracks including Large Track, Small Track #1, and Small Track #2. Our final submissions are fine-tuned from DeltaLM with the allowed data sources according to the track settings, followed by progressive learning and iterative back-translation. The submissions on three tracks all rank first in terms of the automatic evaluation metric.

2 Data

Large Track The monolingual and bilingual data are collected from multiple sources, including CCAligned (El-Kishky et al., 2020), CCMatrix (Schwenk et al., 2021), OPUS-100 (Zhang et al., 2020), JW300 (Agic and Vulic, 2019), Tatoeba

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 446–455
November 10–11, 2021.

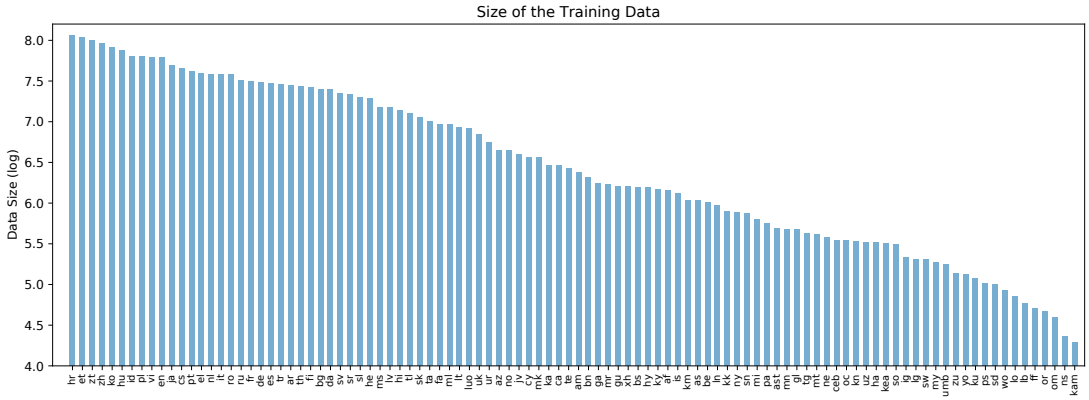

Figure 1: Dataset statistics of the bilingual data of the 102 languages. For better visualization, we apply the logarithmic function (base 10 logarithm) to the size of the training data. Each column denotes the data size of a language that was paired with the remaining 101 languages. For example, the first column denotes the number of bilingual sentence pairs that contain sentences from language hr.

(Tiedemann, 2012), WMT2021 news track[2], multilingual track data[3], and our in-house data. To improve the translation quality of non-English languages, we construct dual-pseudo parallel data (or dual-pseudo data briefly) in which the source and target sides per each sentence pair are translated from the same monolingual English sentence respectively. The Wikipedia English monolingual sentences are translated to other 70 languages by leveraging various machine translation models including in-house MT models, M2M (Fan et al., 2020), the multilingual model of small tracks, and our intermediate multilingual MT model.

Finally, the training data was split into three parts: the bitext data (1.7B parallel sentences from 394 language pairs), the back-translation (1.4B parallel sentences from 45 language pairs), and the dual-pseudo data (8.7B parallel sentences of 70 languages from 4830 language pairs). Figure 1 lists the statistics of the bilingual training data size of 102 languages.

Small Track #1 We use the constrained monolingual and bilingual data of 6 languages (Croatian, Hungarian, Estonian, Serbian, Macedonian, and English) provided by the shared task. According to the statistics, the bitext data contains 273M sentence pairs of all translation directions. Inspired by the previous work, we leverage the multilingual iterative back-translation method with one single multilingual model to generate parallel pseudo data. For En→X and X→En directions, we generate the back-translation data of 390M sentence pairs. As for X→Y directions, we generate the dual-pseudo data of 1.18B sentence pairs, where X and Y stand for any two non-English languages.

Small Track #2 The monolingual and bilingual corpora of 6 languages (Javanese, Indonesian, Malay, Tagalog, Tamil, and English) provided by the shared task are used for the multilingual model training, containing 98M bilingual data, 256M generated back-translation data, and 860M generated dual-pseudo data.

3 Large-scale Data Augmentation

In this section, we introduce details about how to perform the iterative back-translation method (Hoang et al., 2018) to augment data. We use different models for data augmentation according to different tracks. For the small tracks, the multilingual models were trained over the constrained data sets to generate data. For the large track, we leverage the M2M model (Fan et al., 2020), the intermediate multilingual MT models, and in-house MT models to generate different language pairs' data respectively, so as to play their respective advantages to enhance the data generation quality.

In practice, both the monolingual and bilingual corpora are effectively utilized in three ways: 1) For the back-translation data of X→En and En→X directions, we used the best model to generated X data accordingly by back-translating monolingual English Wikipedia data; 2) For the dual-pseudo data of X→Y directions, they are generated by back-translating the same English text to X and Y

[2] http://statmt.org/wmt21/translation-task.html

[3] http://data.statmt.org/wmt21/multilingual-task/

respectively. Alternatively, when the monolingual data of either X or Y is enough, we also directly perform back-translation between X and Y to obtain pseudo parallel data; 3) We try to augment existing bilingual corpora with the third language. Given the bilingual corpus (X_1, Y_1), we generate pseudo parallel corpus of (X_1, Y_2) and (X_2, Y_1) by back-translating X_1 to X_2 and Y_1 to Y_2, where X_2 and Y_2 are non-English languages.

4 Preprocessing

Filtering To enhance the model performance, we remove the noisy sentence pairs with the incorrect language identification or character encoding. More specifically, we remove the sentences longer than 1024 words and truncate the sentence to 512 tokens. We also construct three corpora after tokenization with different length ratio limitations, i.e. $\{1.5, 2.0, 2.5, 3.0\}$, between the source and the target sentence. Our multilingual model is first trained on the entire noisy data set and then continually tuned on cleaner data with descending length ratio, where the number of training directions is also gradually reduced by removing noisy language pairs. Therefore, we can progressively fine-tune the multilingual model in an efficient way (noisy corpora $\rightarrow$ clean corpora $\wedge$ numerous directions $\rightarrow$ selected directions $\wedge$ shallow encoder layers $\rightarrow$ deep encoder layers). Besides, to clean the back-translation corpora, we remove the sentences containing unknown tokens (`[UNK]`). Regarding the language Sr (Serbian), those sentences comprised of Latin characters in training data were also discarded since we found that the validation sets use Cyrillic script for this language instead.

Tokenization After data filtering, we use the SentencePiece (Kudo and Richardson, 2018) to tokenize all raw training, validation, and test data sets, where the SentencePiece model is consistent with the one used for DeltaLM (Ma et al., 2021). We shuffled the whole training dataset before launching the training of multilingual models. The input sentence is prefixed with the language tag to indicate the translation direction.

5 Model and Training

5.1 DeltaLM

We adopt the `DeltaLM_large` architecture as the backbone model for all our experiments, which has 24 Transformer encoder layers and 12 interleaved decoder layers with an embedding size of 1024, a dropout of 0.1, the feed-forward network size of 4096, and 16 attention heads. We directly initialize our model with the public available DeltaLM large checkpoint[4].

5.2 Multilingual Fine-tuning

The training data was split into the bitext corpora $D_b = \{D_b^1, \ldots, D_b^u\}$, the back-translation corpora $D_{bt} = \{D_{bt}^1, \ldots, D_{bt}^v\}$, and the dual-pseudo corpora $D_{dp} = \{D_{dp}^1, \ldots, D_{dp}^w\}$, where u, v, w represent the number of the corpora of different translation directions. The multilingual model with parameters Θ is jointly trained over the corpora to optimize the combined objective as below:

$$\begin{aligned}\mathcal{L}_{MT} = &-\lambda_1 \sum_{i=1}^{u} \mathbb{E}_{x,y \in D_b^i} \left[-\log P(y|x;\Theta)\right] \\ &-\lambda_2 \sum_{i=1}^{v} \mathbb{E}_{x,y \in D_{bt}^i} \left[-\log P(y|x;\Theta)\right] \\ &-\lambda_3 \sum_{i=1}^{w} \mathbb{E}_{x,y \in D_{dp}^i} \left[-\log P(y|x;\Theta)\right]\end{aligned} \tag{1}$$

where x, y denote the sentence pair in the bilingual corpus. $\mathcal{L}_{MT}$ is the combined translation objective of the multilingual model. $\lambda_1, \lambda_2, \lambda_3$ ($\lambda_1 + \lambda_2 + \lambda_3 = 1.0$) are used to balance the training objectives of the bitext corpora, the back-translation corpora, and the dual-pseudo corpora. In this work, we first set $\lambda_1 = 0.33, \lambda_2 = 0.33, \lambda_3 = 0.33$ and then reset $\lambda_1 = 0.6, \lambda_2 = 0.2, \lambda_3 = 0.2$ to focus more on the bitext corpora avoiding the noise introduced by pseudo data.

We follow the dynamic temperature-based data-sampling strategy (Fan et al., 2020; Wang et al., 2020b) to ease the underrepresentation of low-resource languages. The probability of picking a language is proportional to its number of sentences D_l, i.e., $p_l = \frac{D_l}{\sum_i D_i}$. We set the temperature $T = 5$ to rescale and control the distribution $p_l^{\frac{1}{T}}$. It can balance the samples between the high-resource languages and the low-resource languages.

5.3 Progressive Learning

We implement the progressive training method to train the model from shallow to deep (Li et al., 2020). The training process can be divided into two stages. In the first stage, the pre-trained DeltaLM model with 24 encoder layers and 12 decoder layers is directly adopted to initialize the multilingual

[4] https://aka.ms/deltalm

translation model with the same architecture. The shallow translation model with 24 encoder layers and 12 decoder layers is fine-tuned on all available multilingual corpora. In the second stage, we increase the depth of the encoder from 24 layers to 36 layers, where the bottom 24 layers of the encoder are initialized with the shallow model's encoder and the top 12 layers are randomly initialized. Then we perform continue training. The deeper encoders enlarge the model's capacity, but no much extra decoding cost is introduced.

5.4 Training Details

We train multilingual models with the Adam optimizer (Kingma and Ba, 2014) ($\beta_1 = 0.9$, $\beta_2 = 0.98$). The learning rate is set as 1e-4 with a warm-up step of $4,000$. The models are trained with the label smoothing with a ratio of 0.1. All experiments are conducted on 64 NVIDIA V100 or 32 A100 GPUs. The batch size is 1536 or 2048 tokens per GPU and the model is updated every 32 (for 64 V100 GPUs) or 64 (for 32 A100 GPUs) steps to simulate the large batch size.

5.5 Decoding

To enhance the performance of low-resource language pairs for X→Y directions, we adopt the pivot-based translation method (Kim et al., 2019). We use English as the pivot language and employ a unified model to perform the pivot-based translation. When the performance of X→Y directions on the validation set is better than the pivot-based translation X→En ∧ En→Y, we directly translate the language X into Y. Otherwise, we translate them in the pivot way. This approach is used for the submission to Large Track and Small Track #2. As for Small Track #1, we do not use the pivot-based translation.

6 Evaluation Results

Following the previous work (Goyal et al., 2021), we use the dev and the devtest of the FLORES-101 benchmark as our validation set and test set respectively. During the inference, the beam search strategy is performed with a beam size of 4 for the target sentence generation. We set the length penalty as 1.0 by default. The last N checkpoints ($N = \{1, 5, 10, 15, 20\}$) are averaged for evaluation and we select the best checkpoint based on the performance on the validation set. We report the SentencePiece-based BLEU using spBLEU[5].

6.1 Large Track

Given the unbalanced large-scale multilingual corpora, we use the hybrid strategy for the translation for Large Track. The pivot-based translation is more suitable for the low-resource translation direction between non-English languages since the corpora of X→Y are commonly scarce. Our model with the 36 encoder layers significantly outperforms the shallow counterpart with the 24 encoder layers, which indicates that using a deep encoder and shallow decoder is a good trade-off between the translation quality and the decoding speed. Table 1 shows that our model with the hybrid strategy gets the best performance with less inference cost than the pivot-based translation which costs double inference time compared to the direct translation. We build a massively multilingual neural machine model, which translates between any pair of 102 languages. In Figure 2 and Figure 3, we reported the spBLEU scores of the shallow model with 24 encoder layers and 6 decoder layers and our best multilingual model with 36 encoder layers and 12 decoder layers in all translation directions, where the languages are ordered alphabetically by the language code. Nearly 30% translation directions adopt the pivot-based translation, where the zero-resource and low-resource translation directions lack of supervised training data tend to be chosen for pivot-based translation.

6.2 Small Track #1

In Table 2, we compare the performance of M2M with our method in different architectures on any to English (X→En), English to any (En→X), and the translation between any non-English languages (X→Y). Both En→X and X→En contain 5 directions, while X→Y have 20 directions. Given the enormous bilingual and back-translation data of Small Track #1, we are able to perform the direct translation for all X→Y directions. Furthermore, we explore the deep encoder (36 encoder layers) and shallow decoder (12 decoder layers) considering the limited inference time. From Table 2, we can observe that the largest model (36 encoder layers and 12 decoder layers) has a significant improvement of +9.41 BLEU points over the strong M2M baseline.

Avg_{all} denotes the average result of all translation directions.

	#Languages	#Params	#Layers	$\text{Avg}_{X\rightarrow En}$	$\text{Avg}_{En\rightarrow Y}$	$\text{Avg}_{X\rightarrow Y}$	Avg_{all}
M2M (Fan et al., 2020)	102	175M	6/6	24.60	20.83	20.80	21.44
	102	615M	12/12	31.58	29.62	26.66	27.98
DeltaLM + Zcode (Direct)	6	862M	24/12	43.78	41.02	34.38	37.06
	6	1013M	36/12	**44.34**	**41.32**	**34.68**	**37.39**

Table 2: Evaluation results of Small Track #1 for M2M and our method of 6 languages (Croatian, Hungarian, Estonian, Serbian, Macedonian, English) on the devtest of the FLORES-101 benchmark. **DeltaLM + Zcode (Direct)** denotes the strategy that we choose the direct translation for all translation directions, where the target language symbol is prefixed to the input sentence to indicate the translation direction. Our mutilingual translation model is only trained on the constrained corpora of 6 languages provided by the shared task.

6.3 Small Track #2

Compared to Small Track #1 (273M bilingual pairs), Small Track #2 contains smaller while more unbalanced training data (93M bilingual pairs). Therefore, we consider the hybrid strategy for the X→Y translation directions. We separately calculate the BLEU scores of the direct and the pivot-based translation on the validation set. For those directions satisfying $\text{BLEU}_{direct}(X, Y) \geq \text{BLEU}_{pivot}(X, Y)$, we employ the direct translation. Otherwise, we use the pivot-based translation direction by first translating the source language to English and then to the target language. According to Table 3, **DeltaLM + Zcode (Hybrid)** outperforms both the direct and pivot-based translation by about +0.5 BLEU points. It confirms that the hybrid strategy is essential since the training data of the X→En and En→Y is easy to obtain while the X→Y is hard to obtain. The deep model with the 36 encoder layers and 12 decoder layers has comparable performance with the shallow model with the 24 encoder layers and 12 decoder layers, which may be caused by the overfitting problem on the low-resource directions.

6.4 Discussion on Progressive Learning

Given the pre-trained model and large-scale parallel data, we adopt progressive learning as an alternative to fine-tune the multilingual model on the multilingual translation task. Our multilingual model is first trained on the large-scale noisy data and then continues to be tuned on the clean data (Noisy Data → Clean Data), where the model is denoted as ③. Since the training data of K languages in the dual-pseudo parallel data is generated by the same English monolingual data, we are able to adopt all possible $K \times (K-1)$ training directions on the clean data. The performance of many translation directions is improved by the additional dual-pseudo data while the performance of other directions has been degraded compared to the initial model ④, due to the poor quality of some languages in the dual-pseudo data. Therefore, only the part of $K \times (K-1)$ training directions is selected to continue training the multilingual model (Numerous Directions → Selected Directions), which we denoted as ②. To further enlarge the model's capacity, we extend the shallow model with 24 encoder layers to the deep model with 36

	#Languages	#Params	#Layers	$\text{Avg}_{X\rightarrow En}$	$\text{Avg}_{En\rightarrow Y}$	$\text{Avg}_{X\rightarrow Y}$	Avg_{all}
M2M (Fan et al., 2020)	102	175M	6/6	18.95	15.16	9.49	12.01
	102	615M	12/12	24.67	19.14	12.11	15.38
DeltaLM + Zcode (Direct)	6	862M	24/12	43.12	39.78	28.69	32.94
	6	1013M	36/12	43.56	39.04	28.60	32.83
DeltaLM + Zcode (Pivot)	6	862M	24/12	43.12	39.78	29.02	33.17
	6	1013M	36/12	43.56	39.04	28.63	32.85
DeltaLM + Zcode (Hybrid)	6	862M	24/12	**43.12**	**39.78**	**29.38**	**33.40**
	6	1013M	36/12	43.56	39.04	28.99	33.09

Table 3: Evaluation results of Small Track #2 for M2M and our method of 6 languages (Javanese, Indonesian, Malay, Tagalog, Tamil, English) on the devtest of the FLORES-101 benchmark. **DeltaLM + Zcode (Hybrid)** denotes the strategy that we choose the pivot-based translation (X→En, En→X) for low-resource X→Y directions and direct translation for high-resource X→Y directions.

ID	Large Track	Avg_{all}
①	DeltaLM + Zcode	14.65
②	① - Shallow Model → Deep Model	13.89
③	② - Numerous Directions → Selected Directions	13.09
④	③ - Noisy Data → Clean Data	12.24

Table 4: Ablation study of the large track on devtest. DeltaLM + Zcode is fine-tuned on the multilingual translation task via progressive learning.

Track	Submission Name	Avg_{all}
Large	DeltaLM + Zcode (Microsoft)	16.63
Small #1	DeltaLM + Zcode (Microsoft-Small)	37.59
Small #2	DeltaLM + Zcode (Microsoft-Small)	33.89

Table 5: Submission results based on the hidden test sets of our method on three tracks, including Large Track, Small Track #1, and Small Track #2.

encoder layers, where the top 12 encoder layers are initialized by random parameters (Shallow Model → Deep Model). Putting them all together, we obtain the final model ① **DeltaLM + Zcode**. Table 4 summarizes the results of the ablation study of these approaches. It shows that each approach has a significant contribution to the final model. This proves the effectiveness of progressive learning that can gradually improve performance in different aspects.

7 Submissions

Considering the trade-off between the decoding time and the performance, we submit the model (24 encoder layers and 12 decoder layers) with the hybrid strategy to both the Large Track and Small Track #2, while the deep model (36 encoder layers and 12 decoder layers) with the direct translation is submitted to Small Track #1. Table 5 summarizes the evaluation results of our model on the hidden test sets. According to the final results on the leaderboard, **DeltaLM + Zcode** ranks first across three tracks.

8 Conclusion

This paper describes Microsoft's submission to the large-scale multilingual machine translation of the WMT21 shared task. Our multilingual translation model achieves substantial improvement over the baseline systems by fine-tuning the pre-trained language model DeltaLM. We further enhance the model performance with the progressive learning and the iterative back-translation methods. As a result, our submitted systems get the top evaluation results on three tracks, including Large Track, Small Track #1, and Small Track #2.

Abstract

This paper presents the submission of Huawei Translation Services Center (HW-TSC) to the WMT 2021 Large-Scale Multilingual Translation Task. We participate in Small Track #2, including 6 languages: Javanese (Jv), Indonesian (Id), Malay (Ms), Tagalog (Tl), Tamil (Ta) and English (En) with 30 directions under the constrained condition. We use Transformer architecture and obtain the best performance via multiple variants with larger parameter sizes. We train a single multilingual model to translate all the 30 directions. We perform detailed pre-processing and filtering on the provided large-scale bilingual and monolingual datasets. Several commonly used strategies are used to train our models, such as Back Translation, Forward Translation, Ensemble Knowledge Distillation, Adapter Fine-tuning. Our model obtains competitive results in the end.

1 Introduction

This paper introduces our submission to the WMT 2021 Large-Scale Multilingual Translation Task. We participate in Small Track #2, including 6 languages: Javanese (Jv), Indonesian (Id), Malay (Ms), Tagalog (Tl), Tamil (Ta) and English (En) with 30 directions. We consider that the officially provided dataset has the acceptable size and quality and therefore only participate in the constrained evaluation. Our method is mainly based on previous works but with fine-grained data cleaning techniques and a multi-step multilingual training strategy.

For each language pair, we perform multi-step data cleaning on the provided dataset and only keep a high-quality subset for training. At the same time, several training strategies are tested in a pipeline, including Backward (Edunov et al., 2018) and Forward (Wu et al., 2019a) Translation, Multilingual Translation (Johnson et al., 2017), Iterative Joint Training (Zhang et al., 2018), Ensemble Knowledge Distillation (Freitag et al., 2017; Li et al., 2019), Adapter Fine-Tuning (Bapna et al., 2019), and Ensemble (Garmash and Monz, 2016).

Based on the task requirements, we train a single multilingual model that translates all 30 directions. We refer to (Johnson et al., 2017) and employ language tags (Wu et al., 2021). By combining multiple strategies, our model achieves considerable quality improvements in all directions.

Section 2 focuses on our data processing strategies while section 3 describes our training techniques, including model architecture and the iterative training strategy, etc. Section 4 explains our experiment settings and training processes and section 5 presents our experiment results.

2 Data

2.1 Data Source

For all language pairs, we follow the constrained data requirements and take full advantage of the bilingual and monolingual training data available. Table 1 lists the data sizes of each language pair before and after filtering.

2.2 Data Pre-processing

We conduct the following steps to pre-process the data:

- Filter out repeated sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Convert XML escape characters.
- Normalize punctuations using Moses (Koehn et al., 2007).
- Delete html tags, non-UTF-8 characters, unicode characters and invisible characters.
- Filter out sentences with mismatched parentheses and quotation marks; sentences of

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 456–463
November 10–11, 2021.

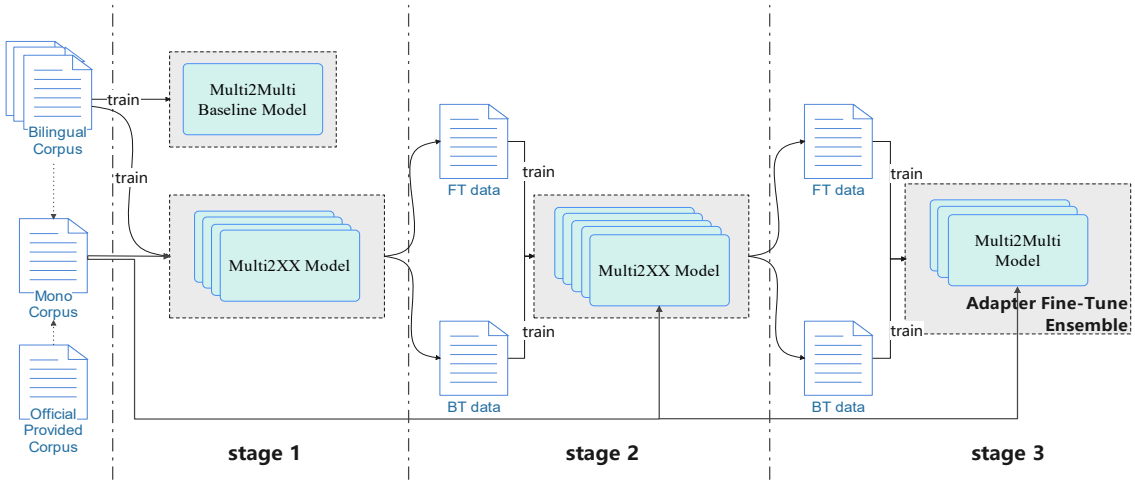

Figure 1: This figure shows the training process for the WMT 2021 Large-Scale Multilingual Translation Task, which consists of three stages. In stage 1, one Multi→Multi model as baseline and five Multi→XX models are trained. In stage 2, the synthetic data by forward and sampling back translation (FTST) is used to train the second round Multi→XX models. In stage 3, second round synthetic FTST data is used to train three Multi→Multi models. Finally, adapter fine-tune and model ensemble are used to enhance the performance.

which punctuation percentage exceeds 0.3; sentences with the character-to-word ratio greater than 12 or less than 1.5; sentences of which the source-to-target token ratio higher than 3 or lowers than 0.3; and sentences with more than 120 tokens. Based on our experience in the industry, this strategy can reduce the low-level errors in model inference and the problem of missing translations.

- Apply langid (Joulin et al., 2016b,a) to filter sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter sentence pairs with poor alignment.
- Use LaBSE (Feng et al., 2020) to rank and filter the monolingual data.

Data sizes before and after cleaning are listed in Table 1.

2.3 Data Selection

According to (Arivazhagan et al., 2019), high-resource language pairs may squeeze the living space of low-resource language pairs. In other words, different data sizes across languages may lead to uneven translation quality in a multilingual model. Since we incorporate all 30 directions in one multilingual model, this issues should be addressed. We use temperature sampling strategy (Zoph et al., 2016) with T=5 to over-sample the low-resource language pairs.

We train all 30 directions under the constrained condition. To improve the performance of back-translation, we combine officially provided monolingual data with the monolingual data extracted from corresponding bilingual corpora. Data sizes are listed in Table 1. The detailed bilingual data size after forward translation and sampling back translation (FTST) and over-sampling are listed in Table 3.

3 System Overview

3.1 Model

Transformer (Vaswani et al., 2017) has been widely used for machine translation in recent years, which has achieved good performance even with the most primitive architecture without much modifications. Therefore, we choose to start from Transformer-Deep (Sun et al., 2019) and consider it as a baseline. The detailed model parameters are as follow: 35-layer encoder, 3-layer decoder, 512 hidden units and a batch size of 4096. We used the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$, and the same warmup and decay strategy for learning rate as (Vaswani et al., 2017), with 4,000 warmup steps. During training, we employ label smoothing with a value of 0.1 (Szegedy et al., 2016). For evaluation, we use beam search with

Language pairs	Raw bi data	Filtered bi data	Mono data
En/Id	54M	16.5M	En: 80M
En/Jv	3M	2.2M	
En/Ms	13.4M	12.1M	
En/Ta	2.1M	1.9M	
En/Tl	13.6M	8.7M	
Id/Jv	0.78M	0.51M	Id: 58M
Id/Ms	4.8M	4.3M	
Id/Ta	0.5M	0.4M	
Id/Tl	2.7M	1.6M	
Jv/Ms	0.43M	0.26M	Jv: 3.8M
Jv/Ta	0.06M	0.037M	
Jv/Tl	0.8M	0.32M	
Ms/Ta	0.37M	0.32M	Ms: 19.7M
Ms/Tl	1.3M	0.8M	Tl: 12.2M
Ta/Tl	0.5M	0.3M	Ta: 5M

Table 1: Bilingual data sizes before and after filtering, and monolingual data used in the task. The monolingual data includes officially provided monolingual data and the mono data extracted from the bilingual corpus of corresponding languages.

a beam size of 4 and length penalty $\alpha = 0.6$ (Wu et al., 2016).

3.2 Data Augmentation

Back-translation (Edunov et al., 2018) is an effective way to enhance translation quality by using monolingual sentences to generate synthetic training parallel data. As described in (Wu et al., 2019b), similar to back translation, the monolingual corpus in source language can also be used to generate forward translation text with a trained MT model, and the generated forward and backward translation data can both be merged with the authentic bilingual data. This strategy can increase the data size to a large extent.

We take full advantage of the officially provided monolingual data for data augmentation. In terms of back translation, we adopt top-k sampling for high-resource languages, and adopt beam search for low-resource languages. With regard to forward translation, we translate monolingual data using beam search. Through sampling, we ensure that the sizes of data generated by forward and back translation are relatively equal. In this paper, we refer to the combination of forward and sampling back translation as FTST.

3.3 Multilingual Strategy

Johnson et al. (2017) propose a simple solution to use a single neural machine translation model to translate among multiple languages, and the model requires no change to the model architecture. Instead, the model introduces an artificial token at the beginning of the input sentence to specify the required target language. According to (Wu et al., 2021), we add "2XX" (XX indicates the target language, e.g. 2id) at the beginning of the source sentence. All languages use a shared vocabulary. We train the hybrid SentencePiece model (Kudo and Richardson, 2018) in conjunction with all 6 languages as the shared word segmentation system for all language pairs. We keep the vocabulary within 40k, including tokens of all 6 languages (En/Id/Jv/Ms/Ta/Tl).

Two mainstream methods about multilingual training are available: two models with XX→Multi and Multi→XX separately and a mono Multi→Multi model. According to (Johnson et al., 2017), Multi→XX performs better than Multi→Multi and XX→Multi in general. Multi→Multi model contains too many languages pairs (30 in this case), so conflicts and confusions may occur among language pairs in different directions. However, due to the requirements of the task, we need to provide a Multi→Multi model that includes all 30 directions. In our experiment, we divide 30 language pairs into five Multi→XX multilingual models as step 1. Than we use five Multi→XX multilingual models to conduct back-translation and train a Multi→Multi model as step 2 and step 3, as shown in Figure 1.

3.4 Iterative Joint Training

Zhang et al. (2018) propose a new iterative joint training method, that is, using monolingual data from both source and target sides to train a source-to-target (forward) model and a target-to-source (backward) model at the same time. The two models generate synthetic data for each other. The advantage of such method is that both of the two models gain improvement after each iteration with the synthetic data provided by the other, and then can generate synthetic data with higher quality. Such training procedure is repeated after the two models converge.

3.5 Language independence Adapter Fine-tuning

Previous works demonstrate that fine-tuning a model with in-domain data could effectively improve the model performance. However, due to limitations of a multilingual translation model, once the model is trained, when fine-tuning one of the language pairs, the performance of others will go worse. Thanks to the finding of Adapter (Bapna et al., 2019), we are able to fine-tune each language pair without impacting the performance of others. In the experiment, we set the adapter size to 512 and fine-tune the model on the bilingual data for each language pair in 30 directions with 3,000 tokens per batch for one epoch.

3.6 Ensemble Knowledge Distillation (EKD)

Ensemble Knowledge Distillation (Freitag et al., 2017; Li et al., 2019) improves the performance of a student model by distilling knowledge from a group of trained teacher models. Comparing with some soft label distillation methods, the EKD for NMT is relatively straightforward, which can be implemented by training the student models on the combination of the original training set and the translation from the ensembled teacher model on the training set. In our experiments, we ensemble models as the teacher model to translate the FLORES dev set, and use the translation results to further fine-tune models.

3.7 Ensemble

Model ensemble is a widely used technique in previous WMT workshops (Garmash and Monz, 2016), which can improve the performance by combining the predictions of several models at each decoding step. In our work, we ensemble models with different architectures to further improve system performances.

System	FLORES dev	FLORES devtest
baseline M2M	26.9	26.8
FTST1	28.2 (+1.3)	28.1 (+1.3)
FTST2	29.4 (+1.2)	29.6 (+1.5)
Adapter Fine-Tune	30.2 (+0.8)	30.1 (+0.5)
ensemble	30.7 (+0.5)	30.9 (+0.8)
wmt21 final submit	28.6	28.3

Table 2: The experimental results on FLORES dev/devtest, BLEU scores in table are the average of 30 directions.

4 Experiment Settings

4.1 Settings

We use the open-source fairseq (Ott et al., 2019) for training and SentencePieceBLEU to measure system performances. Each model is trained using 8 GPUs. The architectures and main parameters we used are described in section 3.1. Marian (Junczys-Dowmunt et al., 2018) is used for decoding during inference.

4.2 Training Process

We employ iterative training and phase-based data augmentation. Figure 1 shows our training process in details. The specific steps are as follows:

1) Process data using methods described in section 2.2. Train one Multi→Multi model as baseline and five Multi→XX models as forward models and backward models.

2) Generate back translation and forward translation data. Mix the data with parallel training data and train second round five Multi→XX models.

3) Generate back translation and forward translation data using models trained in step 2. Mix data with bilingual training data and train three Multi→Multi models.

4) Average the last eight checkpoints of each model and adapter fine-tune it with bilingual data. Ensemble models to produce the final system.

5 Results and analysis

We use methods described in Section 2.2 for data processing. Model architecture mentioned in Section 3.1 is employed to increase system diversity. On the basis of Multi→Multi baselines model, we use FTST data augmentation to further enhance model performance.

Table 2 lists the results of our experiment on FLORES dev set and devtest set (Goyal et al., 2021). Comparing with the baseline model, the first round FTST Multi→XX models leads to 1.3 BLEU increase on average for the 30 directions. Further, the second round FTST achieves 1.2 BLEU increase on average. We fine-tune the model using bilingual data with adapter and achieve 0.8 BLEU increase on average. Finally, ensemble further leads to 0.5 BLEU increase. When submitting the final results, because of time limits, we only finish round-two FTST. As for model inference, there is a problem with our fairseq architecture, resulting in poor model quality that seriously affects the FTST results. The final model we submitted achieves 28.64 BLEU on FLORES dev and 28.34 BLEU on FLORES devtest. After the submission, we fixed the problem and continued our experiments, eventually achieving 30.7 BLEU on on FLORES dev and 30.9 BLEU on FLORES devtest. The detailed experiment results are listed in Table 4.

In our experiment, due to the inference problem mentioned above, we have not seen much performance improvements. The low quality of model inference leads to poor FT results, which made no contributions to the model. And even worse, it offsets the gain brought by BT results to the model. We also found that the Multi→en model does surpass the Multi→Multi model in quality, which is the same as the results observed by the industry.

6 Conclusion

This paper presents the submissions of HW-TSC to the WMT 2021 Large-Scale Multilingual Translation Task. We perform experiments with a series of pre-processing and training strategies. The effectiveness of each strategy is demonstrated. We finally achieve competitive results.

On the Stability of System Rankings at WMT

Rebecca Knowles
National Research Council Canada
Rebecca.Knowles@nrc-cnrc.gc.ca

Abstract

The current approach to collecting human judgments of machine translation quality for the news translation task at WMT – segment rating with document context – is the most recent in a sequence of changes to WMT human annotation protocol. As these annotation protocols have changed over time, they have drifted away from some of the initial statistical assumptions underpinning them, with consequences that call the validity of WMT news task system rankings into question. In simulations based on real data, we show that the rankings can be influenced by the presence of outliers (high- or low-quality systems), resulting in different system rankings and clusterings. We also examine questions of annotation task composition and how ease or difficulty of translating different documents may influence system rankings. We provide discussion of ways to analyze these issues when considering future changes to annotation protocols.

1 Introduction

At the WMT (now Conference on Machine Translation) shared task on news translation, research groups build machine translation systems to accurately translate news data, as tested on test sets of recent news documents. The systems are clustered and ranked on their performance as judged by human annotators. The way that human judgments of translation quality have been collected has varied over the course of WMT's history.

In this work, we examine how changes in the collection of human judgments over the last three years have resulted in rankings that are now less robust to the effects of outliers (high- or low-performing systems) and overall annotation task composition. We replicate the human judgment rankings from 2018-2020, perform simulations for reranking, and examine issues of annotation task composition and translation difficulty. We find that sampling sentences for annotators to annotate by document – intended as a step towards evaluating sentences in context – reintroduces a known problem from the earlier era of relative rankings, namely that systems suffer or benefit in their rankings based on the quality of the other data being rated alongside them in the same annotation tasks.

We begin with a discussion of the progression of direct assessment (DA) styles employed in WMT evaluations (§2) and how scoring is performed (§3), before delving into theoretical and practical understandings of the z-scores used to rank systems (§4 and §5), including simulations and analysis of specific examples. We also discuss issues around document distribution and translation difficulty (§6), and close with considerations for downstream impacts (§7) and future study (§8).

2 Historical Context

In 2016, WMT added direct assessment (DA) scoring of system outputs as an investigatory ranking, with relative ranking (RR) remaining the official scoring mechanism (Bojar et al., 2016). In relative ranking, five system outputs for a given segment were ranked in comparison to one another, from which pairwise translation comparisons were generated; these were then used to produce overall system rankings by means of the TrueSkill algorithm (Herbrich et al., 2007; Sakaguchi et al., 2014). Relative ranking can be used to compare systems, but does not provide an absolute score, thus obscuring how close a good system is to a "perfect" translation or, at the other extreme, how poor a system is as compared to others.

The following year, 2017, WMT adopted DA as its main assessment format on the basis of high Pearson correlations between RR and DA in the previous year's investigations (Bojar et al., 2017). In DA (Graham et al., 2013, 2014, 2016), annotators provide an absolute numerical score (0-100) for MT output adequacy (at the sentence level or at the document level) using a sliding scale.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 464–477

The use of DA has changed since it was first introduced to WMT. In 2016, it was trialed for monolingual evaluations of translation fluency and monolingual evaluations of adequacy. Here we provide an overview of changes from the 2016 task to the present, based on Findings papers descriptions.

Bojar et al. (2016) noted that the 2016 version of DA assessments has the potential to avoid a known bias of the RR setup. In RR, each rating task consisted of ranking the outputs of five systems on the same input segment, and "a system may suffer more losses if often compared to the reference, and similarly it may benefit from being compared to a poor competitor" (Bojar et al., 2011). In the 2016 DA setup, translations were annotated in sets of 100, including quality assurance tasks, but each segment was annotated individually, rather than in direct comparison to other system output for the same segment.[1] Quality assurance tasks can include *references* (which should score highly), *"bad" references* (which should score poorly; these are produced by randomly replacing substrings in references to degrade quality), and *repeat assessments* of a segment (which should be scored consistently).

In 2017, DA was adopted as the main annotation style, with exact duplicate segment translations being able to be scored just once (rather than once per system that produced them) and with human assessment scores "standardized according to each individual human assessor's overall mean and standard deviation score" (Bojar et al., 2017).

Bojar et al. (2018) describes two setups for the 2018 DA tasks, a standard structure (with repeat pairs, "bad" references, and references, as quality assurance) and an alternate setup where an additional constraint was imposed, such that within each 100-translation task, for each input the task would include the corresponding output of *all* MT systems. This makes a tradeoff between the aim of DA (to make absolute score judgments rather than relative ones) and getting a single annotator to provide scores for all systems' output of the same source input (which risks reintroducing some form of relative judgement to the task). This is also the first year that the findings paper explicitly spells out the goal of the way tasks (referred to here using the Amazon Mechanical Turk nomenclature "Human Intelligence Task" or HIT) are built in the standard HIT structure:

> [...] within each 100-translation HIT, the same proportion of translations are included from each participating system for that language pair. This ensures the final dataset for a given language pair contains roughly equivalent numbers of assessments for each participating system. This serves three purposes for making the evaluation fair. Firstly, for the point estimates used to rank systems to be reliable, a sufficient sample size is needed and the most efficient way to reach a sufficient sample size for all systems is to keep total numbers of judgments roughly equal as more and more judgments are collected. Secondly, it helps to make the evaluation fair because each system will suffer or benefit equally from an overly lenient/harsh human judge. Thirdly, despite DA judgments being absolute, it is known that judges "calibrate" the way they use the scale depending on the general observed translation quality. With each HIT including all participating systems, this effect is averaged out.[2]

The 2018 shared task also introduced source-based DA, trialling a bilingual version of the task. Rather than scoring MT output against a reference, this version scores it against the source segment, which allows human references to be scored as a "human system" rather than solely as a QA task. They raise a number of potential cautions against drawing strong conclusions, namely that bilingual DA is not yet validated, the alternate task structure may introduce biases, the year's sample size for source-based DA was smaller than 1,500 judgments per system, and that there may be quality issues with some reference segments.

In 2019, WMT introduced additional versions of DA (Barrault et al., 2019). They used monolingual (reference-based) assessment for translation into English and for language pairs that did not include English at all. For translation out of English, they performed bilingual (source-based) DA. The style of DA used in previous years is renamed to SR–DC (Segment Rating without Document Context), as a new style, SR+DC (Segment Rating *with* Document Context) is introduced. In the new SR+DC style, the full translation of a single docu-

[1] It is still possible that there may be biases based on the segments observed in any given set of 100.

[2] Here we reproduce this quote from Barrault et al. (2019), though it appears consistent 2018-2020.

ment by a single MT system is shown to the annotator in order (but still scored segment-by-segment);[3] a task consists of multiple such documents. The generation of annotation tasks is described as follows: all documents translated by all systems are pooled, then sampled (without replacement) until up to 70 segments are selected, at which point quality control documents are added, and finally the order of documents in the task is shuffled. Barrault et al. (2020) uses both SR–DC and SR+DC styles.

3 Scoring

In order to experiment with questions surrounding human evaluation, it is necessary to understand and be able to replicate the official scores produced by WMT. For the human annotations of interest (segment-level evaluation, with or without document context), there are two main types of scores: raw scores and z-scores, with the latter used as the official ranking. These are presented in a table, ordered by z-score, and clusters of systems deemed statistically significantly different (according to a Wilcoxon rank-sum test $p < 0.05$) are separated by horizontal lines.[4]

Following the approach used at WMT, after removing any HITs deemed unacceptable due to quality issues, we calculate raw and z-scores for systems as follows. First, any worker ID whose scores have a standard deviation of 0 is removed. Given a raw score x generated by the worker with worker ID W, its corresponding z-score z is computed as

$$z = \frac{x - \text{mean}(y \in W)}{\text{std}(y \in W)} \quad (1)$$

where $\text{mean}(y \in W)$ is the mean of *all* raw scores generated by worker W, and $\text{std}(y \in W)$ is the standard deviation of *all* raw scores generated by that worker. When we say that the mean and standard deviation are computed from *all* raw scores from a given worker ID, this includes references (which are treated as systems in SR+DC but are treated as quality assurance in SR–DC), "bad references" (which are only ever used for quality assurance), and repeats.[5] However, after computing the mean and standard deviation, only a subset of scores are used to actually compute system averages: those with type "SYSTEM" or "REPEAT" (discarding "BAD_REF" and "REF" types).[6] To compute averages (raw or z-score), first an average is computed for any "SYSTEM" or "REPEAT" scores that share the same system ID, the same document ID, *and* the same sentence ID; that is, if a given sentence of a given document was annotated multiple times for a particular system, we first average those scores (so that more frequently annotated sentences do not receive more weight). Then, for each system, all of its "SYSTEM" or "REPEAT" type scores are averaged, resulting in a system-level score.

We note that the 2019 and 2020 document context (SR+DC) evaluations differ in their quality assurance (see Table 1). In both 2019 and 2020, references are treated as a "Human" system, to be ranked alongside the other systems; which may explain the lack of "REF" labeled segment types in the data. In 2019, the Appraise interface data used to generate the rankings did not include any segments labeled as "REPEAT", "REF", or "BAD_REF", though these are described as being included in the HITs (Barrault et al., 2019); perhaps they were removed before processing the data. In 2020, the Appraise data *did* include segments labeled as "BAD_REF", but none labeled as "REPEAT" or as "REF", while the 2020 Mechanical Turk document-level ones included all three. The 2019 data collected using the Turkle platform contains no human or reference data and we do not use it for any of our analysis in this work.

We reimplemented the scoring system using python and plan to release code for this paper. We were able to exactly replicate the raw scores and z-scores for most of the language pairs of interest from 2018-2020,[7] as well as the significance clusters.[8] See Appendix A for details. We use this reimplementation of the WMT scoring scripts in or-

[3] There is also a Document Rating with Document Context DR+DC, but we do not examine that in this work.

[4] A horizontal line is drawn below a system if and only if it is significantly better ($p < 0.05$) than *every* system with a lower z-score than it.

[5] We compute mean and standard deviation using `ad-latest.csv`, but use `ad-good-raw-redup.csv` to compute the individual z-scores and averages. The files are downloaded from 2018-2020 WMT websites: `http://www.statmt.org/wmt18/results.html`, `http://www.statmt.org/wmt19/results.html`, and `http://www.statmt.org/wmt20/results.html`.

[6] "SYSTEM" type are system outputs, while the remainder are quality assurance: "REPEAT" are repeated system outputs which are also valid for computing averages, "BAD_REF" are degraded references, and "REF" are references.

[7] In order to match the z-scores generated by the R packages used for WMT, we set `ddof` equal to 1 when using the `stats.zscore` function from scipy.

[8] We replicated the significance clusters using scipy's `stats.mannwhitneyu` function.

Table 1: Counts of sentence types in ad-good-raw-redup.csv files from 2018-2020. We omit the Turkle data from most of our analysis because it contains neither human systems nor reference data.

der to score authentic and modified WMT data, to examine underlying assumptions and hypothesize about how these may impact final system rankings.

For 21 language pairs annotated in SR–DC style and 25 in SR+DC style from 2018-2020, we were able to exactly replicate rankings, nearly replicate rankings (e.g., with rounding difference related changes to one significance line), or produce rankings whose differences could be explained by delays in data collection (2020 en-iu).[9] Appendix A provides more details on replication. We use our recalculated rankings and clusters as the starting point for all remaining analysis in this paper.

4 Understanding z-scores

While we've described how the z-score is calculated in the setting of the WMT human annotations, it's important to take a closer look at z-scores to understand how they behave in different scenarios. In this section, we explore z-scores and their underlying assumptions in hypothetical scenarios.

Given a raw score x, a mean μ, and a standard deviation σ, the **z-score** (or standard score) is the number of standard deviations above or below the mean that x falls. The z-score for a given raw score x can be computed as follows:

$$z = \frac{x - \mu}{\sigma} \tag{2}$$

This is a linear transformation; the shape of the distribution of z-scores is the same as that of the raw scores, but now with a mean of 0 and a standard deviation of 1. It is a unitless score.

Intuitively, the z-score provides a potential way of comparing scores from different annotators, but it requires a careful examination of underlying assumptions. If we think of the z-score as a unitless score, perhaps we can think of each annotator as having their own measurement units: we might have a lenient annotator and a harsh annotator, such that a raw score of 50 by the lenient annotator is quite *bad* while a raw score of 50 for the harsh annotator is actually quite *good*. In order to directly compare the two annotators' scores, we would like to map them to a shared scale, a unitless z-score. Under what assumptions is it appropriate to calculate z-scores to compare annotators' scores?

We start with perhaps the most obvious (but frequently unstated) assumption: there exists some latent "quality" of a given translation, which can be judged by a human annotator, such that annotators roughly agree about what constitutes a "good" or a "bad" translation. In practice, human annotators may disagree – for any number of reasons (Basile et al., 2021) – about which of two translations of "similar quality" is better, but we assume that the disagreement is not *extreme*; i.e., we hope that under a correlation coefficient like Pearson's r or Spearman's ρ, the correlation between annotators' scores would be much closer to 1 than to -1. For the sake of simplicity in the following examples, we will assume there exists a "true" and "objective" score for every translation.

Suppose that we have some translations with a true mean score of μ and a true standard deviation of σ. A lenient annotator scores all of the translations such that the distribution of their scores has a mean of $\mu + n$ and a standard deviation of σ, while a harsh annotator scores all of the translations such that the distribution of *their* scores has a mean of $\mu - m$ and a standard deviation of σ.[10] When we compute their z-scores, it is easier to directly compare sentence scores, since they are now on the same scale. This seems like a reasonable use of z-scores, but in this scenario annotators are scoring exactly the same data, which doesn't scale to WMT-style annotations; annotators simply don't

[9] Language codes: Chinese (zh), Czech (cs), German (de), English (en), Estonian (et), Finnish (fi), Gujarati (gu), Inuktitut (iu), Japanese (ja), Kazakh (kk), Khmer (km), Lithuanian (lt), Pashto (ps), Polish (pl), Russian (ru), Tamil (ta), Turkish (tr).

[10] We use the same standard deviation for simplicity, with arbitrary positive values of n and m.

have time to score all of the data.

Now suppose that we have two disjoint sets of sentences scored by two different annotators: the set S_X of sentences scored by annotator X and the set S_Y of sentences scored by annotator Y. From these raw scores, we can compute μ_X and μ_Y along with σ_X and σ_Y. If $\mu_X > \mu_Y$, can we conclude that annotator X is a more lenient annotator than annotator Y and resolve this by computing z-scores? Not without additional information! Imagine that we could see the "true" mean scores of S_X and S_Y, as annotated by a perfect omniscient annotator. It could be the case that the true means are identical and annotator X is indeed more lenient, but it could also be the case that the true mean of the scores in set S_X is actually higher. In the latter case, the annotators could be equally lenient, or it is even possible that annotator Y could be more lenient! In short, without a shared basis for comparison, we don't know whether computing z-scores is normalizing out annotator differences, differences in the data itself, or a combination.

5 z-scores in practice

This raises the question: what is happening in practice when we compute z-scores on WMT DAs? Are we really normalizing away inter-annotator differences, or is the normalization also doing something else, such as normalizing away real differences in HIT and system quality? If it is the latter, even z-scores for DAs may suffer the same bias from comparisons to better (or worse) systems.

We don't have access to an oracle, and we don't have a direct or reliable way to compute interannotator agreement, because in some collections it is rare that two annotators annotate the same text (and for the Appraise data, we only have HIT information, not annotator information). However, we can still examine this in the existing data and modifications thereof. Bojar et al. (2011) noted that systems might suffer from being compared to the reference too frequently under relative ranking, or might benefit from being compared to particularly poor systems. The same could hold true in DA. Consider the following toy example: a HIT contains 4 sentences, with raw scores of 25, 50, 50, 75, respectively. A sentence with a raw score of 50 in this HIT would have a z-score of 0. If, instead, the raw scores were 0, 25, 50, 75, a sentence with a raw score of 50 would have a z-score of 0.39, while for a HIT with raw scores of 25, 50, 75, 100, a sentence with a raw score of 50 would have a z-score of -0.39. While it is possible that such a set of scores could reflect differences in *annotator* behavior, we could also easily imagine that they might reflect differences in *HIT composition*, with one containing only system scores, one containing system scores and a bad reference, and one containing system scores and a (good) reference.

5.1 HIT Composition

Thus we examine HIT composition, or, more accurately, the composition of data annotated by any given worker/worker ID. In 2018, all systems were SR–DC, and 100% of workers annotated "BAD_REF" data.[11] However, an "Alternate DA HIT Structure" was employed for a subset of researcher HITs (run in Appraise), which used only "BAD_REF" segments for quality assurance, "omitting repeat pairs and good reference pairs" while also attempting to include "the output of all participating systems for each source input" (to have the same annotator produce annotations across systems). The percentage of (non-rejected) workers who annotated data containing "REF" in 2018 ranged from 4.9% (en-et) to 98.8% (zh-en); the former is an outlier, as the next two lowest are 25.8% (en-cs) and 47.4% (en-fi).

In 2019 annotations into English, 100% of workers annotated both "REF" and "BAD_REF" segments. In 2019 annotations out of English, the final output data does not include any "REF" or "BAD_REF" segments (though these *are* described as having been included for QA), but human references are treated as systems, and between 37.8% (en-de) and 61.5% (en-kk) of workers annotated at least some human reference data.

The 2020 Appraise annotations differed from prior years as well: 100% of the 2020 into English (Mechanical Turk) workers annotated both "REF" and "BAD_REF" segments. In 2020 annotations out of English (Appraise), between 95.8% (en-iu) and 100% (en-{ja, ta, zh}) of workers[12] annotated "BAD_REF" data. The percentage of Appraise "workers" that annotated data containing human references (treated as a system) ranged from 8.3% (en-iu) to 73.4% (en-zh).

[11] These values are calculated on ad-good-raw-redup.csv files, so only include annotators who successfully passed QA.

[12] The definition of "worker" is really a bit fuzzy here; the "WorkerID" produced by Appraise is really a HIT ID, so averages are *not* necessarily being computed across all of a given worker's annotations, but rather each HIT is being treated as a unique worker.

5.2 Analysis

In an ideal world where z-score normalization is only correcting for annotator variation, removing one system should not result in changes to the relative rankings of the remaining systems. That is to say, the z-scores themselves may be expected to change (shifting up if a very good system is removed, shifting down if a low-quality system is removed), but we wouldn't expect the relative ranking of two systems to change. After all, one stated motivation of the shift to DA was to avoid the known bias in RR of systems being unfairly penalized or benefiting unfairly from comparisons to stronger/weaker systems (Bojar et al., 2016). Similarly, replacing one system – for example with a much better or much worse system – should not result in other systems switching places in the rankings. We simulate these two scenarios using the existing data, and show that rankings produced in SR+DC settings are much more sensitive to removal or modification of systems than SR–DC.

Year/Type	Δ Rank	Δ Cluster	Δ Both
'18 (–DC)	1/13	0/13	0/13
'19 (–DC, MTurk)	2/5	1/5	0/5
'20 (–DC, MT.)	1/3	0/3	0/3
ALL SR–DC	**4/21**	**1/21**	**0/21**
'19 (+DC, MT.)	1/2	1/2	1/2
'19 (+DC, A.)	6/8	3/8	1/8
'20 (+DC, MT.)	7/7	3/7	3/7
'20 (+DC, A.)	4/8	5/8	3/8
ALL SR+DC	**18/25**	**12/25**	**8/25**

Table 2: Effect of removing human and "REF" scores from annotations and recalculating rankings by year, platform (MTurk or Appraise), and annotation style. Values indicate the fraction of language pairs that had changes in rank, clustering, or both rank and clustering.

We first examine removing human systems and "REF" – acting as though they had never been annotated at all, so all z-scores are calculated without "REF" or human system scores.[13] We then compute rankings and significance clusters. We compare these against the original rankings generated from all available data, with the significance clusters recomputed after removal of human systems.[14] For each pair of rankings, we check whether there is any change in the order of systems (ignoring significance clusters; we call this Δ *Rank*), whether there is any change in clusters (different number or composition of clusters; we call this Δ *Cluster*), and/or changes in both (Δ *Both*). Table 2 shows the results. Rank changes (ignoring significance clusters) are the most common, and many of these occur within significance clusters as we would expect. However, there are also a number of changes to the significance clusters (clusters merging, splitting, or rearranging), as well as pairs for which both rank and cluster changes occur. Most strikingly, all of these changes are *much* more common in the SR+DC settings than in the SR–DC. Removing human and "REF" data results in cluster changes to almost *half* (12/25) of the SR+DC rankings, but less than 5% (1/21) of the SR–DC rankings. No SR–DC rankings exhibit changes in both rank and clusters, but 32% of SR+DC rankings do. This is evidence that the SR+DC rankings are less stable, and consequently less reliable, than the SR–DC rankings. We replicate this result with removing the highest and lowest ranked systems, respectively, as shown in Table 3; the SR+DC rankings are much less robust than the SR–DC rankings to the removal of the best or worst single system.

Removed/Type	Δ Rank	Δ Cluster	Δ Both
Lowest (SR–DC)	4/21	3/21	1/21
Lowest (SR+DC)	18/25	10/25	7/25
Highest (SR–DC)	0/21	1/21	0/21
Highest (SR+DC)	17/25	10/25	5/25

Table 3: Effect of removing single lowest ranked or highest ranked system across all years, by data collection type (–/+DC). Values indicate the fraction of language pairs that had changes in rank, clustering, or both rank and clustering.

One might worry that some of this instability is due to the shrinking number of datapoints available when we remove "REF" and human systems, or the highest/lowest ranked systems. To account for this, we run the same experiment and measure the same changes, but instead of *removing* "REF" and human systems, we degrade their raw scores (dividing each score by 1.25, 1.5, 2, 4, and 10) before computing z-scores, rankings, and significance clusters. This could be viewed as a simulation of what would occur if the high-quality human system were replaced with mediocre (or, in the case of division by 10, very low-quality) systems.[15]

We visualize the result in Figure 1. Once again, the SR+DC evaluations are more brittle to these

[13] We observe similar results if we only remove "REF", but in that setting we cannot examine the 2019 and 2020 Appraise SR+DC rankings, as they do not make use of "REF" at all.

[14] Relevant to clusters containing or above human system(s).

[15] The reverse – inflating scores of low-performing systems – has a similar effect, but requires consideration of how to handle scores of zero.

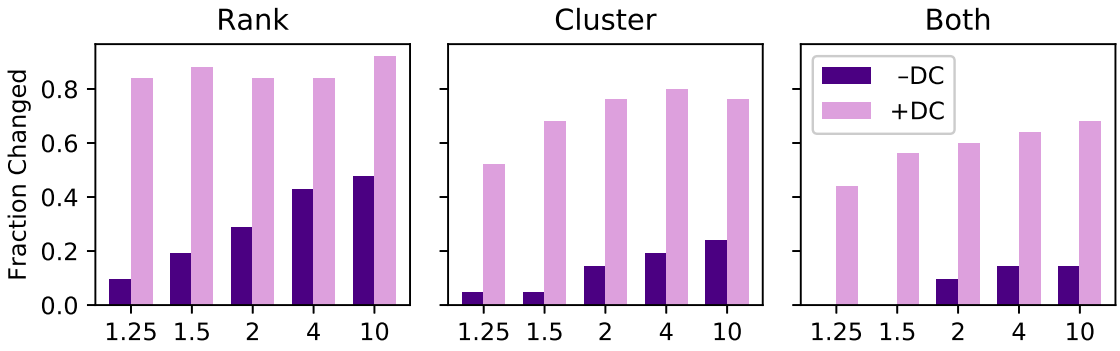

Figure 1: Effect of dividing raw human system and "REF" scores on overall (z-score) rankings for all SR–DC and SR+DC shown in Table 2. The x-axis shows the divisor (ranging from 1.25 to 10) and the y-axis shows the fraction of pairs for which the rankings, clusters, or both ranks and clusters changed.

changes. However, we see that even the SR–DC evaluations are not immune to the effects of extreme outliers on rankings and clusterings – as the divisor used increases, so does the fraction of pairs that have ranking and/or clustering changes. This makes sense intuitively: if most systems are of similar quality, a slight imbalance in which systems are compared to one another likely won't have dramatic effects, but if one system is much worse (or much better) than the rest, systems that are compared against it more or less frequently than others will see their z-scores benefit or suffer accordingly. We also examined monolingual vs. bilingual tasks in the SR+DC context (all SR–DC tasks were monolingual), but note similar rates of changes to ranks, clusters, and both across the two settings.

We have used a very coarse measurement here: counting whether the ranks or clusters changed *at all* rather than whether multiple clusters or large numbers of systems were reranked. Indeed, many of these changes are quite subtle, with just a single new significance line appearing or two clusters merging, or two close systems switching ranks (within or across clusters). If that is the case, why should we be concerned with this? The first reason is to better understand what it is that is actually being measured and whether the WMT annotation protocol is succeeding in its goals. If the inclusion of outliers or the degradation of system scores results in other systems shifting ranks, this indicates that the current approach does suffer from a similar comparison bias to RR. Thus we can't always be confident that what is being measured is a property of the system itself and not closely intertwined with HIT composition – this approach is doing something other than *only* normalizing away interannotator differences. The second reason is to highlight these goals and assumptions so that they can be considered when making future modifications to the annotation process. Many of these issues are currently resulting in small inconsistencies, but if future modifications are made to the annotation process without considering the underlying assumptions and goals, there is no reason to expect that the errors will cancel one another out rather than compound. If we are aware of the underlying assumptions when changes are introduced to the annotation process, we will be better positioned to consider potential problems in the hypothetical and then examine the real data to see if they appear in practice. There is also the question of effects on downstream tasks (§7). Finally, it also helps us to consider ways to mitigate these challenges before they grow, and we discuss some options for future consideration in §8.

5.3 Case Study

We manually select for examination a relatively dramatic case of rankings and clusters changing, from en-de 2020, pictured in Figure 2. This is an unusual case since it contained multiple human-based systems.[16]Nevertheless, it incorporates several issues we raised in hypotheticals, so we discuss it here.

Figure 2 shows the rankings for the original data (human systems were dropped only for the purpose of computing clusters, but *were* used for calculating z-scores), and each of the rankings computed by degrading raw scores by dividing them by 1.25 through 10 (denoted d-n where n is the divisor). We begin by focusing on PROMT_NMT, whose rank increases with increased degradation

[16]See Appendix A for details.

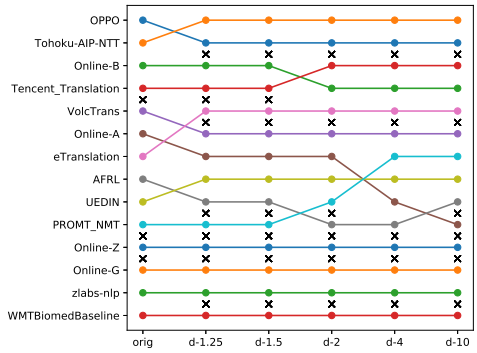

Figure 2: Plot showing z-score rankings (top is best) for 2020 en-de (SR+DC), from original rankings and five divisors for raw human scores. Significance lines are marked with black "x". Human systems were used in calculating z-scores but were removed prior to computing clusters for ease of visualization and comparison.

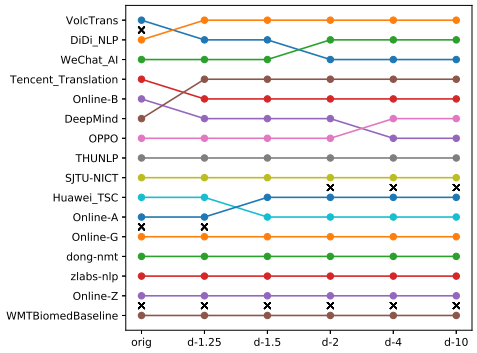

Figure 3: Rankings for 2020 zh-en (SR+DC), from original rankings and with divisors, as in Figure 2.

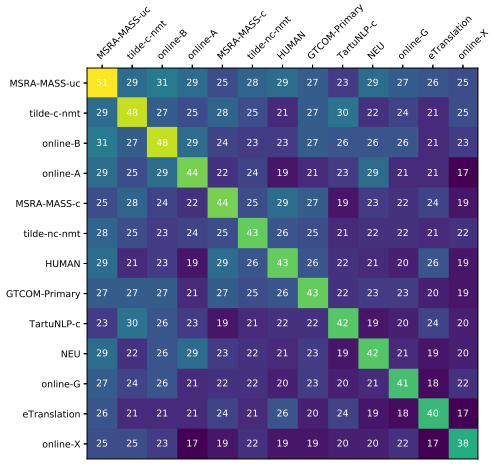

Figure 4: Co-occurrence matrix of systems for en-lt 2019 (SR+DC). Each cell shows the number of HITs that contained segments from the systems at those x and y values. The diagonal shows the total number of HITs that contained each system.

of the human systems. In the original ranking, AFRL and PROMT_NMT appear in the same cluster, with AFRL having a higher score than PROMT_NMT, but not statistically significantly so. When degrading the human raw scores by 1.25 or 1.5, AFRL is in a higher significance cluster than PROMT_NMT, but when dividing by 2, this is reversed: PROMT_NMT is now ranked as significantly *better* than AFRL, while with a divisor of 4 or 10, they return to the same cluster but with PROMT_NMT scoring higher. Thus we see, purely by degrading the raw scores of *other* systems, we observe the full range of possible relative rankings and clusterings for this pair of systems. The same holds true for PROMT_NMT compared with Online-A.

The en-de 2020 rankings may have suffered somewhat from having fewer annotations (1123.6 assessments per system), so we also show results for one of the most-assessed pairs that year: zh-en (2035.1 assessments per system). This is shown in Figure 3.[17] Here we focus on the top system: VolcTrans, which was ranked in Barrault et al. (2020) as significantly better than all systems. As we degrade the human systems, we see it begin to drop in rank, and this significance cluster merges with the one below it, raising the possibility that the initial finding was an artifact of the distribution of data across HITs rather than an inherent property of the MT quality of that particular system.

[17]Note that in the original rankings shown, the human system was omitted when computing significance clusters, and in this case a new significance line (separating Online-A and Online-G appears) where it had been, which was not there in the published rankings that do include human systems.

5.4 System Comparisons

There is a distinct difference in the way that systems are distributed across HITs in the SR–DC and SR+DC annotation styles. In SR–DC, almost all HITs contain segments from every single system (though there is no guarantee that they appear in exactly equal proportions to one another).

In SR+DC, this is not the case, owing to the fact that HITs are limited to 100 segments, there are often 10 or more systems, and documents are often longer than 10 segments. This means that it may be numerically impossible for a given HIT to cover all systems. We see this in Figure 4. A given system may be paired with any other system in less than half of the HITs in which it appears. These kinds

of imbalances mean that systems may be more frequently compared to better or worse systems, resulting in unfair effects on their rankings.

6 Documents

In both SR+DC and SR–DC styles, we don't have a guarantee that every segment-system pair is judged by an annotator, nor that at least one segment from every document-system pair is judged. If we assume approximately uniform translation difficulty across the test set, this isn't necessarily too much of a concern. However, is that really the case, or are some documents "easy" and others "hard"?

Figure 5 shows a matrix of document-system pairs, with each cell showing the average of all of the segment raw scores for that system-document pair.[18] The documents are ranked from highest average raw score to lowest average score (top to bottom), while the systems are ranked by highest average raw score to lowest average raw score (left to right). In the leftmost column, we see the "HUMAN" system, which has high scores across all documents. If all documents were equally difficult to translate, we would expect to see a gradient along the x-axis (i.e., across systems), with minimal variation along the y-axis (i.e., across documents). What we observe instead in this en-lt pair from 2019 (and across a number of other language pairs) is a rough gradient from the top left to the bottom right (with the exception of the "HUMAN" system, which remains strong throughout). This suggests that there are some documents that are "easy" for most systems to translate (top) and some that are "hard" (bottom). This raises a concern: when we attempt to compare two systems of very similar quality, they are not being measured on the same test set. An unlucky sample of documents might see one system judged on a "harder" set of documents, calling the resulting rankings into question.

7 Downstream Consequences

While researchers building MT systems for the shared task may view the human judgment rankings as the end result, the rankings are the *input* to the metrics tasks at WMT. Thus the reliability of the rankings has a direct impact on the reliability of the metrics task – which in the long term feeds into MT research as researchers decide

[18] We can also produce such a matrix using z-scores or automatic metric scores, and results are comparable.

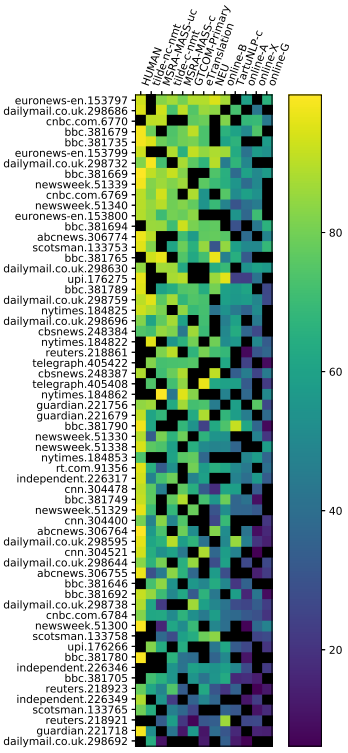

Figure 5: Average raw scores for document-system pairs from en-lt 2019 (SR+DC). Empty cells indicate pair was not judged. Documents are ranked by average raw score (highest: top) as are systems (highest: left).

which automatic metrics to use for evaluating their systems. In system-level metric evaluation at the WMT Metrics shared task, Pearson correlations are computed between metric scores and the z-score human rankings (Mathur et al., 2020b). Note that these correlations are directly between the system average z-scores and the metric scores, and as such do *not* treat all systems within a given cluster as tied. In practice, this means that even rank-only perturbations in the official ranking can be expected to cause changes to metrics task results.

Metrics scores are run on the *full* test set, not the various human-annotated subsets. Citing Graham et al. (2013), the Metrics task papers note that system-level DA scores are "consistent and have been found to be reproducible" even though different sets of segments are assessed for each system. However, that work predates the shift to sampling by document, and our analysis of instability and document difficulty suggest revisiting it.

Recent work has shown that outliers have a concerning impact on metric correlations (Mathur et al., 2020a), and organizers have worked to mitigate this (Mathur et al., 2020b). This paper is a step

towards answering questions raised in Mathur et al. (2020b) regarding outliers and unfair advantages. It may seem tempting to remove outliers from human judgment tasks, but this will not solve the other problems and could instead mask their presence.

8 Proposals for Future Work

The issues discussed in this paper raise concerns about changes to the human evaluation protocols used at WMT and their effects on the validity of WMT system rankings. A partial solution would be to return to SR–DC annotations, perhaps after validation of the 2018 alternate HIT structure that guarantees that for every segment in the HIT, the HIT contains *every* MT system's output for that sentence. But this may be an unsatisfactory conclusion, and fails to address the interest in pushing MT evaluation toward whole documents.

Document-level and context-inclusive evaluations are growing in popularity, but there is limited study on document-level assessment methodologies for MT. Castilho (2021) examines setups comparable to SR–DC, SR+DC, and document rating with document context (which we omitted from this work), and finds in a controlled experiment using Likert scale ratings that a methodology comparable to SR+DC produces higher levels of interannotator agreement and fewer misevaluations than either whole document scores or individual sentences without context. However, that experimental setup does not suffer from the same task composition issues we observe in WMT; in fact these may be orthogonal issues.

If the choice is made to use SR+DC style annotations, there are some improvements to consider, but as noted in Castilho (2020), it remains "essential to test which methodologies will be best suited for different tasks and domains" prior to adopting them. One option would be to create 2018-alternate-structure style HITs with document context, where a HIT contains all systems' output for one or more documents. The downside to this is that it would likely require longer HITs or HITs that only contain a small number of documents; if systems are of similar quality, we might be concerned about annotator fatigue from repetition. The amount of context needed to adequately assess translations is still a question under consideration (Castilho et al., 2020; Castilho, 2021), which ties into issues of document and HIT length.

Another possibility to consider would be to always normalize over annotators (rather than over HITs), but this isn't a solution on its own – it is still necessary to make sure that annotators see comparable distributions of systems and documents, or the same problems will be reintroduced. Having annotators do calibration HITs, i.e., a set of annotations that *all* annotators complete, could also be considered. The calibration HITs would provide a consistent basis for computing the parameters of an annotator-specific z-score transformation, which could then be applied to the remainder of the annotator's judgments. This could untangle the issue of annotator strictness/leniency, but would still merit study before implementation (as annotator behavior may depend on HIT composition, so the z-scores learned in calibration may not be as applicable as one might hope if there is a mismatch between calibration HITs and the remainder of the HITs). One could also consider additional ways of modeling annotator behavior beyond z-score normalization (Paun et al., 2018).

A simpler starting point to deal with the issue of different systems being annotated over different documents would be to guarantee that all systems are scored over the same subset of documents.

All of these are (partially) orthogonal to the questions of what type of annotation tasks result in the most reliable ratings – whether it be direct assessment, ranking, or detailed error annotation – or questions of annotator skills and knowledge (Freitag et al., 2021).

9 Conclusions

We have shown that the current judgment collection methodology at the WMT news translation task results in SR+DC judgments that are more prone to variation on the basis of outliers than SR–DC judgments, and that HIT composition issues have helped reintroduce the relative ranking problem of unfair comparisons to the WMT rankings. We examined issues of document difficulty and how this interacts with the decision to sample documents (rather than sentences) for judgment. These issues risk undermining the validity of WMT rankings, with real consequences for MT research and downstream tasks on automatic metrics. In examining these issues, we've also presented several approaches to diving into the WMT ranking data that may be helpful to consider when planning future changes to WMT human judgment collection procedures.

Acknowledgments

Thank you to the anonymous reviewers for their suggestions and comments. Thank you to Chi-kiu Lo, Nitika Mathur, Gabriel Bernier-Colborne, Roland Kuhn, Huda Khayrallah, Adam Poliak, and George Foster for feedback on various drafts of this work. Thank you to Yvette Graham and task organizers for the 2020 data release and pointers to DA-related code. Thank you also to those listed above and a number of other current and former colleagues – including Rachel Rudinger, Eric Joanis, Darlene Stewart, Samuel Larkin, Michel Simard, Serge Léger, Patrick Littell, and Cyril Goutte – for discussions on related topics.

A Notes on Replication

As shown in Table 4, we are able to duplicate the following rankings exactly (or with minor differences, as noted). Code to replicate this work will be available at https://github.com/nrc-cnrc/WMT-Stability/. Language codes are as follows: Chinese (zh), Czech (cs), German (de), English (en), Estonian (et), Finnish (fi), Gujarati (gu), Inuktitut (iu), Japanese (ja), Kazakh (kk), Khmer (km), Lithuanian (lt), Pashto (ps), Polish (pl), Russian (ru), Tamil (ta), Turkish (tr).

- 2018, Mechanical Turk, SR–DC: en-{cs, de, et, fi, ru, tr, zh} and {cs, de, et, fi, ru, zh}-en, but we do not successfully replicate the scores for tr-en (we omit tr-en 2018 from future experiments).
- 2019, Appraise, SR+DC: en-{cs, de, fi, gu, kk, lt, ru, zh}, though we note that en-kk contains a duplicate system that is omitted from the published table.
- 2019, Mechanical Turk, SR–DC: {gu, kk, lt, ru}-en, and fi-en is nearly replicated, but our replication of it is missing a significance line between two clusters due to a rounding difference when computing the significance value.
- 2019, Mechanical Turk, SR+DC: {de, zh}-en are successfully replicated.
- 2019, Turkle, SR–DC: de-cs, de-fr, fr-de, zh-en, are all successfully replicated but are not included in the analyses.
- 2020, Appraise, SR+DC: en-{cs, ja, ru, ta, zh}, are successfully replicated, while en-pl is missing one significance line due to rounding differences. The ranking for en-de has identical scores *except* for Human-A and Human-paraphrase. The original en-de ranking in Barrault et al. (2020) included Human-A, Human-B, and Human-paraphrase. The released en-de data only contained Human-A and Human-B, though Human-A was about twice as large as Human-B, suggesting that it may have incorporated the Human-paraphrase data. Finally, the ranking for en-iu is quite different, though we expect this is because of delays in data collection resulting in a mismatch between the reported scores in the findings paper and the released scores. The en-iu scores also contain an additional low-scoring system that was omitted from the published table.
- 2020, Mechanical Turk, SR+DC: {cs, de, ja, pl, ru, ta, zh}-en were all replicated exactly.
- 2020, Mechanical Turk, SR–DC: {iu, km, ps}-en were all replicated exactly.
- 2020 en-{km, ps} appear to be missing from the released data.

Abstract

Automatic metrics are commonly used as the exclusive tool for declaring the superiority of one machine translation system's quality over another. The community choice of automatic metric guides research directions and industrial developments by deciding which models are deemed better. Evaluating metrics correlations with sets of human judgements has been limited by the size of these sets. In this paper, we corroborate how reliable metrics are in contrast to human judgements on – to the best of our knowledge – the largest collection of judgements reported in the literature. Arguably, pairwise rankings of two systems are the most common evaluation tasks in research or deployment scenarios. Taking human judgement as a gold standard, we investigate which metrics have the highest accuracy in predicting translation quality rankings for such system pairs. Furthermore, we evaluate the performance of various metrics across different language pairs and domains. Lastly, we show that the sole use of BLEU impeded the development of improved models leading to bad deployment decisions. We release the collection of 2.3 M sentence-level human judgements for 4380 systems for further analysis and replication of our work.

1 Introduction

Automatic evaluation metrics are commonly used as the main tool for comparing the translation quality of a pair of machine translation (MT) systems (Marie et al., 2021). The decision of which of the two systems is better is often done without the help of human quality evaluation which can be expensive and time-consuming. However, as we confirm in this paper, metrics badly approximate human judgement (Mathur et al., 2020b), can be affected by specific phenomena (Zhang and Toral, 2019; Graham et al., 2020; Mathur et al., 2020a; Freitag et al., 2021) or ignore the severity of translation errors (Freitag et al., 2021), and thus may mislead system development by incorrect judgements. Therefore, it is important to study the reliability of automatic metrics and follow best practices for the automatic evaluation of systems.

Significant research effort has been applied to evaluate automatic metrics in the past decade, including annual metrics evaluation at the WMT conference and other studies (Callison-Burch et al., 2007; Przybocki et al., 2009; Stanojević et al., 2015; Mathur et al., 2020b). Most research has focused on comparing sentence-level (also known as segment-level) correlations between metric scores and human judgements; or system-level (e.g., scoring an entire test set) correlations of individual system scores with human judgement. Mathur et al. (2020a) emphasize that this scenario is not identical to the common use of metrics, where instead, researchers and practitioners use automatic scores to compare a pair of systems, for example when claiming a new state-of-the-art, evaluating different model architectures, deciding whether to publish results or to deploy new production systems.

The main objective of this study is to find an automatic metric that is best suited for making a *pairwise ranking of systems* and measure how much we can rely on the metric's binary verdicts that one MT system is better than the other. We design a new methodology for pairwise system-level evaluation of metrics and use it on – to the best of our knowledge – the largest collection of human judgement of machine translation outputs which we release publicly with this research. We investigate the reliability of metrics across different language pairs, text domains and how statistical tests over automatic metrics can help to increase decision confidence. We examine how the common use of BLEU over the past years has possibly negatively affected research decisions. Lastly, we re-evaluate past findings and put them in perspective with our work. This research evaluates not

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 478–494
November 10–11, 2021.

only the utility of MT metrics in making pairwise comparisons specifically – it also contributes to the general assessment of MT metrics.

Based on our findings, we suggest the following best practices for the use of automatic metrics:

1. Use a pretrained metric as the main automatic metric; we recommend COMET. Use a string-based metric for unsupported languages and as a secondary metric, for instance ChrF. Do not use BLEU, it is inferior to other metrics, and it has been overused.
2. Run a paired significance test to reduce metric misjudgement by random sampling variation.
3. Publish your system outputs on public test sets to allow comparison and recalculation of different metric scores.

2 Data

In this section, we describe test sets, the process for collecting human assessments, and MT systems used in our analysis. We publish all human judgements, metadata, calculated metrics scores, and the code with replication of our findings and promoting further research. We cannot release the proprietary test sets and so system outputs for legal reasons. The collection is available at https://github.com/MicrosoftTranslator/ToShipOrNotToShip. Moreover, we plan to evaluate new metrics emerging in the future.

2.1 Test sets

When evaluating our models, we use internal test sets where references are translated by professional translators from monolingual data. Freitag et al. (2020) have demonstrated that the quality of test set references plays an important role in automatic metric quality and correlation with human judgement. To maintain a high quality of our test sets, we create them by a two-step translation process: the first professional translator translates the text manually without post-editing followed by a second independent translator confirming the quality of the translations. The human translators are asked to translate sentences in isolation; however, they see context from other sentences.

The test sets are created from authentic source sentences, mostly drawn from news articles (news domain) or cleaned transcripts of parliamentary discussions (discussion domain). The news domain test sets are used in both directions, where the authentic side is mostly English, Chinese, French, or German. The discussion domain test sets are used in the direction from authentic source to translationese reference, e.g., we have two distinct test sets, one for English to Polish and second for Polish to English. Furthermore, some systems are evaluated using various other test sets.

We evaluate 101 different languages within 232 translation directions.[1] The size of the test sets can vary, and more than one test set or its subsets can be used for a single language direction. The average size of our test sets is 1017 sentences. The distribution of evaluated systems is not uniform, some language pairs are evaluated only a few times and while others repeatedly with different systems. The majority of the language pairs are English-centric, however, we evaluate a small set of French, German, and Chinese-centric systems (together only 90 system pairs). Details about the system counts of evaluated language pairs and average test set sizes can be found in the Appendix in Table 7.

2.2 Manual quality assessment

Our human evaluation is run periodically to confirm translation quality improvements by human judgements. For this analysis, we use human annotations performed from the middle of 2018 until early 2021. All human judgements were collected with identical settings with the same pool of human annotators. Thus, the human annotations should have similar distributions and characteristics.

The base unit of our human evaluation is called *a campaign*, in which we commonly compare two to four systems in equal conditions: We randomly draw around 500 sentences from a test set, translate them with each system and send them to human assessment. Each human annotator on average annotates 200 sentences, thus a system pair is evaluated by five different annotators (each annotating distinct set of sentences translated by both systems).

We use source-based Direct Assessment (*DA*, Graham et al., 2013) for collecting human judgements, where bilingual annotators are asked to rate all translated sentences on a continuous scale between 0 to 100 against source sentence without access to reference translations. This eliminates reference bias from human judgement by design.

We use the implementation of DA in the Appraise evaluation framework (Federmann, 2018),

[1] We compare metrics only over the intersection of languages supported by all evaluated metrics, which means that we use only 39 different target languages when Prism is part of the evaluation.

the same as is used in WMT since 2016 for out-of-English human evaluation (Bojar et al., 2016a).

We do not use crowd workers as human annotators. Instead, we use paid bi-lingual speakers that are familiar with the topic and well-qualified in the annotation process. Moreover, we track their performance, and those who fail quality control (Graham et al., 2013) are permanently removed from the pool of annotators, so are their latest annotations. This increases the overall quality of our human quality assessment.

We have two additional constraints in contrast to the original DA. Firstly, each system is compared on the same set of sentences which removes the problem of a system potentially benefitting from an easier set of randomly selected sentences. Moreover, it allows us to use a stronger paired test that compares differences in scoring of equal sentences instead of an unpaired one that evaluates scores of both systems in isolation. We use the Wilcoxon signed-rank test (Wilcoxon, 1946) in contrast to the Mann-Whitney U-test (Mann and Whitney, 1947) originally suggested for DA (Graham et al., 2017). Secondly, each annotator is assigned the same number of sentences for each evaluated system which mitigates bias from different rating strategies as each system is affected evenly by each annotator.

When calculating the system score, we take the average of human judgements.[2] We analyze human judgements for 4380 systems and 2.3 M annotated sentences. This data is one and a half orders of magnitude larger than the data used at WMT Metric Shared Tasks, which evaluate around 170 systems each year (see Section 6).

2.3 Systems

We evaluate competing systems against human judgement. The system pairs could be separated into three groups: (1) model improvements, (2) state-of-the-art evaluation, and (3) comparisons with third-party models. The first group contains system pairs where one system is a strong baseline (usually our highest quality system so far) and the second system is an improved candidate model; this group evaluates stand-alone models without additional pre- and post-processing steps (e.g., rule-based named entity matching). The second group contains pairs of the candidate for the new best performing system and the current best performing system. The third group compares our best-performing model at the time with a publicly available third-party MT system.

Analyzing the variety of systems, hyperparameters, training data, and even architectures is out of the scope of this paper. However, all models are based on neural architectures.

	Metric	Sentence-level	Use human data	Need reference	Multiple refer.	Languages

Table 1: Comparison of selected string-based and pretrained automatic evaluation metrics. We mark metrics designed to work at sentence-level, fine-tuned on human judgements, requiring reference(s), or supporting multiple references, and report the number of supported languages. *BLEURT is built on top of English-only BERT (Devlin et al., 2019) in contrast to BERTScore and ESIM that use multilingual BERT.

3 Automatic metrics

In this study, we investigate metrics that were shown to provide promising performance in recent studies (see Section 6) and currently most widely used metrics in the MT field.[3] We focus on language-agnostic metrics, therefore we do not include metrics supporting only a small set of languages. The full list of evaluated metrics and their main features is presented in Table 1.

Two categories of automatic machine translation metrics can be distinguished: (1) string-based metrics and (2) metrics using pretrained models. The former compares the coverage of various substrings between the human reference and MT output texts. String-based methods largely depend on the quality of reference translations. However, their advantage is that their performance is predictable as it can be

[2] We do not assume a normal distribution of annotator's annotations; therefore, we do not use z-score transformation.

[3] The YiSi – high correlating metric (Ma et al., 2019) – was not publicly available at the time of our evaluation.

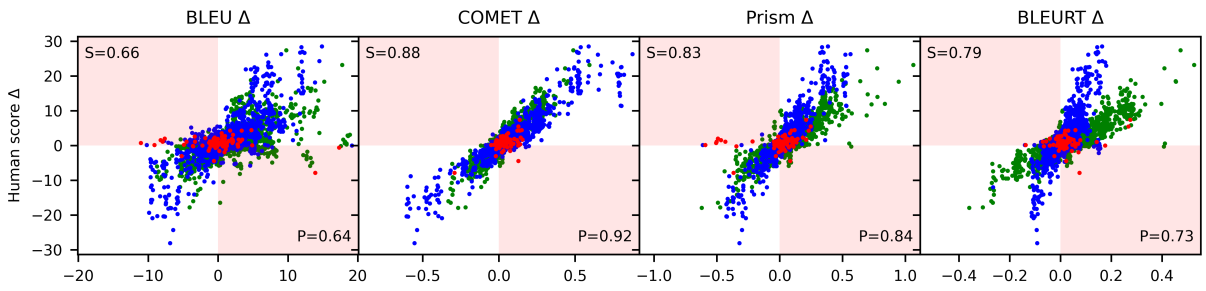

Figure 1: Each point represents a difference in average human judgement (y-axis) and a difference in automatic metric (x-axis) over a pair of systems. Blue points are system pairs translating from English; green points into English; red points are non-English system pairs (a few French, German, or Chinese-centric system pairs). We report Spearman's ρ correlation in the top left corner and Pearson's r in the bottom right corner. Metrics disagree with human ranking for system pairs in pink quadrants. Other metrics are in Figure 2 in the Appendix.

easily diagnosed which substrings affect the score the most. The latter category of pretrained methods consists of metrics that use pretrained neural models to evaluate the quality of MT output texts given the source sentence, the human reference, or both. They are not strictly dependent on the translation quality of the human reference (for example, they can better evaluate synonyms or paraphrases). However, their performance is influenced by the data on which they have been trained. Moreover, the pretrained models introduce a black-box problem where it is difficult to diagnose potential unexpected behavior of the metric, such as various biases learned from training data.

For all metrics, we use the recommended implementation. See Appendix A for implementation details. Most metrics aim to achieve a positive correlation with human assessments, but some error metrics, such as TER, aim for a negative correlation. We simply negate scores of metrics with anticipated negative correlations. Pretrained metrics usually do not support all languages, therefore to ensure comparability, we evaluate metrics on a set of language pairs supported by all metrics.

4 Evaluation

4.1 Pairwise score differences

Most previous works studied the system-level evaluation of MT metrics in an isolated scenario correlating individual systems with human judgements (Callison-Burch et al., 2007; Mathur et al., 2020b). They have mostly employed Pearson's correlation (see Section 6) as suggested by Macháček and Bojar (2014) and evaluated each language direction separately. However, Mathur et al. (2020a) suggest using a pairwise comparison as a more accurate scenario for the general use of metrics.

As the primary unit, we use the difference in metric (or human) scores between system A and B:

$$\Delta = \text{score}(\text{System A}) - \text{score}(\text{System B})$$

We gather all system pairs from each campaign separately as only systems within a campaign are evaluated under equal conditions. All campaigns compare two, three, or four systems, which results in one, three, or six system pairs, respectively.

To understand the relationship between metrics and absolute human differences, we plot these differences and calculate Pearson's and Spearman's correlations in Figure 1. All metrics exhibit a positive correlation with human judgements but differ in behavior. For example, COMET has the smallest deviation which results in the highest correlation with human judgements. However, when we evaluate into-English and from-English language directions separately, we observe that COMET, Prism, and mainly BLEURT have inconsistent value ranges for different language pairs.[4]

Hence, we cannot assume equal scales for one metric and different language pairs, so we can not use Pearson's nor Spearman's correlation in pairwise metrics evaluation. Nonetheless, we provide both correlations in Appendix Table 8 for the complete picture.

4.2 Pairwise system-level metric quality

As standard correlation cannot be used, we investigate a different approach to evaluation. We advocate that the most important aspect of a metric

[4] A possible explanation for BLEURT is that it is trained on English-only. But this does not explain other metrics.

is to make reliable binary pairwise decisions (i.e., which of two systems provides a higher translation quality) without the focus on the magnitude of difference.[5] Therefore, given the size of our data set, we propose to use accuracy on binary comparisons: which system is better when human rankings are considered gold labels.

We define the accuracy as follows. For each system pair, we calculate the difference of the metric scores (metricΔ) and the difference in average human judgements (humanΔ). We calculate accuracy for a given metric as the number of rank agreements between metric and human deltas divided by the total number of comparisons:

$$\text{Accuracy} = \frac{|\text{sign}(\text{metric}\Delta) = \text{sign}(\text{human}\Delta)|}{|\text{all system pairs}|}$$

Assuming human judgements as a gold labels, accuracy gets an intrinsic meaning of how „reliable" a given metric is when making pairwise comparisons. On the other hand, accuracy does not take into account that two systems can have comparable quality, and thus the accuracy of a metric can be over-estimated by chance if a small human score difference has the same sign as the difference in a metric score. To overcome this issue, we also calculate accuracy over a subset of system pairs, where we remove system pairs that are deemed to not be different based on Wilcoxon's signed-rank test over human judgements.

In order to estimate the confidence interval for accuracy, we use the bootstrap method (Efron and Tibshirani, 1994), for more details see Appendix B. We consider all metrics that fall into the 95% confidence interval of the best performing metric to be comparable. We visualize the clusters of best-performing metrics in our analysis with a grey background of table cells.

5 Results

5.1 Which metric is best suited for pairwise comparison?

In this section, we examine all available system pairs and investigate which metric is best suited for making a pairwise comparison.

The results presented in Table 2 show that pre-trained methods (except for Prism-src) generally have higher accuracy than string-based methods,

[5]The value of score difference (e.g., a difference of 2 BLEU) is important mainly to measure the confidence of a ranking decision.

	All	0.05	0.01	0.001	Within
n	3344	1717	1420	1176	541
COMET	**83.4**	**96.5**	**98.7**	**99.2**	**90.6**
COMET-src	83.2	95.3	97.4	98.1	89.1
Prism	80.6	94.5	97.0	98.3	86.3
BLEURT	80.0	93.8	95.6	98.2	84.1

CharacTER	74.9	88.6	91.9	95.2	74.1
BLEU	74.6	88.2	91.7	94.6	74.3
Prism-src	73.4	85.3	87.6	88.9	77.4
EED	68.8	79.4	82.4	84.6	68.2

Table 2: Accuracies for binary comparisons for ranking system pairs. Column "All" shows the results for system pairs. Each following column evaluates accuracy over a subset of systems that are deemed different based on human judgement and a given alpha level in Wilcoxon's test. Column "Within" represents a subset of systems where the human judgement p-value is between 0.05 and 0.001. "n" represents the number of system pairs used to calculate accuracies in a given column. Only the scores in each column are comparable. Results with a grey background are considered to be tied with the best metric.

which confirms findings from other studies (Ma et al., 2018, 2019; Mathur et al., 2020b). COMET reaches the highest accuracy and therefore is the most suited for ranking system pairs. The runner-up is *COMET-src*, which is a surprising result because, as a quality estimation metric, it does not use a human reference. This opens possibilities to use monolingual data in machine translation systems evaluation in an effective way. On the other hand, the second reference-less method *Prism-src* does not reach high accuracy, struggling mainly with into-English translation directions (see Figure 2 in the Appendix). In terms of string-based metrics, the highest accuracy is achieved by ChrF, which makes it a better choice for comparing system pairs than the widely used BLEU.

To minimize the risk of being affected by random flips due to a small human score delta, we also explore the accuracy after removing systems with comparable performance with respect to Wilcoxon's test over human judgements. We incrementally remove system pairs not significantly different with alpha levels of 0.05, 0.01, and 0.001. As expected, removing pairs of most likely equal-quality systems increases the accuracy, however, no metric reaches 100% accuracy even for a set of

n	Everything 1717 ↓	Into EN 922	From EN 768	Non Latin 131	Logograms 44	Non WMT 484	Discussion 78

Table 3: Accuracies for ranking system pairs. Each column represents a different subset of significantly different system pairs with alpha level 0.05. Results with a grey background are considered to be tied with the best metric. Accuracies across columns are not comparable as they compare different sets of systems.

strongly different systems with an alpha level of 0.001. This implies that either current metrics cannot fully replace human evaluation or remaining systems are incorrectly assessed by human annotators.[6] Moreover, we observe that the ordering of metrics by accuracy remains the same even after removing system pairs with comparable performance, which implies that accuracy is not negatively affected by non-significantly different system pairs. Due to that where we analyze only subsets of the data, we use systems that are statistically different by human judgement with an alpha level of 0.05.

Ma et al. (2019) have observed that system outliers, i.e., systems easily differentiated from other systems, can inflate Pearson's correlation values. Moreso, Mathur et al. (2020a) demonstrated that after removing outliers some metrics would actually have negative correlation with humans. To analyze if outliers might affect our accuracy measurements and the ordering of metrics, we analyze a subset of systems with human judgement p-values between 0.05 and 0.001, i.e. removing system pairs that have equal quality and outlier system pairs that are easily distinguished. From column "Within" in Table 2, we see that the ordering of metrics remains unchanged. This shows that accuracy is not affected by outliers making it more suitable for metrics evaluation than Pearson's ρ.

[6]An alpha level of 0.001 could (mis)lead to the conclusion that 0.1% of human judgements are incorrect. However, the alpha level only determines if two systems are different enough and cannot be used to conclude that a human pairwise rank decision is incorrect.

5.2 Are metrics reliable for non-English languages and other scenarios?

The superior performance of pretrained metrics raises the question if unbalanced annotation data might be responsible; around half of the systems translate into English. Moreover, COMET and BLEURT are fine-tuned on human annotations from WMT on the news domain. This could lead to an unfair advantage when being evaluated w.r.t. human judgements.[7] To shed more light on metrics behavior and robustness, we analyze various subsets, including into and from English translation directions, languages with non-Latin scripts, and non-news domain.

We showed in Section 4.1 that some metrics perform differently for systems translating from and into English. Analyzing this scenario in Table 3 reveals that BLEURT does better (the second best metric) for "into English" translation compared to other metrics. It is surprising that BLEURT has a high accuracy for unseen "from English" pairs which suggests that BLEURT might have learned some kind of string-matching. We also observe in Table 3 gains for Prism for the "from English" directions. The overall ranking of metrics, however, remains similar which confirms that the high accuracy of pretrained methods compared to the string-based ones cannot be attributed to the abundance of system pairs with English as the target.

[7]We double-checked and removed all campaigns containing test sets from WMT 2015 to 2020 from our work and analysis.

When investigating language pairs with non-Latin (Arabic, Russian, Chinese, ...) or logogram-based scripts (Chinese, Korean and Japanese) as the target languages, we observe a slight drop in metric ranks for some pretrained metric in contrast to higher score for ChrF. This indicates that non-Latin scripts might be a challenge for pretrained metrics but more analysis would be required here. For an summary on individual language pairs, refer to Table 9 in the Appendix.

We also investigate if some pretrained methods might have an unfair advantage due to being fine-tuned on human assessments in the news domain. For this, we analyze a subset of news test sets with target languages that were not part of WMT human evaluation (i.e., languages which those methods have not been fine-tuned on) and call this set "non-WMT", and also system pairs evaluated on a proprietary test sets in the EU parliamentary discussions domain covering ten languages. Neither results on non-WMT nor discussion domains in Table 3 show a change in the ranking of metrics, suggesting that COMET is not overfitted to the WMT news domain or WMT languages. Somewhat surprisingly, we actually see a drop in accuracy for the string-based metrics for the discussion domain. We speculate this might be due to their inability to forgivingly match disfluent utterances to expected fluent translations (Salesky et al., 2019).

Overall, the results for various subsets show a similar ordering of metrics based on their accuracy, confirming the general validity of our results.

5.3 Are statistical tests on automatic metric worth it?

Mathur et al. (2020a) studied the effects of statistical testing of automatic metrics and observed that even large metric score differences can disagree with human judgement. They have shown that even for a BLEU delta of 3 to 5 points, a quarter of these systems are judged by humans to differ insignificantly in quality or to contradict the verdict of the metric. In our analysis, we have 203 system pairs deemed statistically significant by humans (p-value smaller than 0.05) for which using BLEU results in a flipped ranking compared to humans. The median BLEU difference for these system pairs is 1.3 BLEU points. This is concerning as BLEU differences higher than one or two BLEU points are commonly and historically considered to be reliable by the field.

	No test	Boot. ↓	Type II Err.
COMET	**83.4**	**95.1**	204 (**17.3%**)
COMET-src	83.2	94.2	242 (19.4%)
BLEURT	80.0	92.0	349 (25.4%)
Prism	80.6	91.3	200 (18.3%)
BERTScore	78.3	87.9	244 (20.9%)
ChrF	75.6	85.4	350 (27.3%)
BLEU	74.6	83.4	378 (27.4%)
Prism-src	73.4	81.5	325 (29.4%)

Table 4: The first column shows accuracy for all system pairs and represent situation, where we would trust any small score difference. The second column shows accuracy, where we ignore systems considered to be tied with respect to the paired bootstrap resampling test. The third column represents the number of system pairs incorrectly decided to be non-significantly different by the paired bootstrap resampling and the percentage from all non-significant systems.

In this section, we corroborate that statistical significance testing can largely increase the confidence of the MT quality improvement and increase the accuracy of metrics. We compare how accurate a metric would be under two situations: either when not using statistical testing and solely trusting in the metric score difference; or when using statistical testing and throwing away systems that are not statistically different.

We evaluated the first situation in Section 5.1 and the results are equal with the first column of Table 2. For the second situation, we calculate accuracy only over the system pairs that are statistically different. We use paired bootstrap resampling (Koehn, 2004), a non-parametric test, to calculate the statistical significance for a pair of systems.[8]

Additionally, the second situation introduces type II errors which represent systems where the statistical significance test rejected a system pair as being non-significant, but humans would judge the given pair as significantly different. In other words, it shows how many system pairs are incorrectly rejected as non-significantly different. See Appendix C for a detailed explanation.

From the results in Table 4, we can see that if we apply paired bootstrap resampling on automatic metrics with an alpha level 0.05 the accuracy increases by around 10% for all metrics in con-

[8] Approximate randomization (Riezler and Maxwell III, 2005) can be used as an alternative test, and for metrics based on the average of sentence-level scores, we can use also tests such as the Student t-test.

trast to not using statistical testing. On the other hand, when using statistical testing, we introduce type II errors, where 17.3%, for COMET, of non-significantly different system pairs are deemed significantly different by humans.[9]

In conclusion, we corroborate that using statistical significance tests largely increases reliability in automatic metric decisions. We encourage the usage of statistical significance testing, especially in the light of Marie et al. (2021) who show that statistical significance tests are widely ignored.

5.4 Does BLEU sabotage progress in MT?

Freitag et al. (2020) have shown that reference translations with string-based metrics may systematically bias against modeling techniques known to improve human-judged quality and raised the question of whether previous research has incorrectly discarded approaches that improved the quality of MT due to the use of such references and BLEU. They argue that the use of BLEU might have mislead many researcher in their decisions.

In this section, we investigate the hypothesis if the usage of BLEU negatively affects model selection. To do so, we compare two groups of system pairs based on the premise if they could be directly affected by BLEU. The first group contains pairs of incremental improvements of our systems. We can assume that incremental models use similar architecture, data, and settings, although we do not study particular changes. We use BLEU as the main automatic metric to guide model development. If BLEU shows improvements, we evaluate models with human judgements to make a final deployment decision. Therefore, systems with degraded BLEU scores which would be deemed improved by humans are missing in this group as we reject them based on BLEU scores during development. The second group contains independent system pairs, which use different architectures, data, settings, and therefore BLEU has not been used to preselect them. In this group, we compare our systems with publicly available third-party MT systems.

We compare three models within the same campaign, two internal[10] and one external system. Thus, the same annotators annotated the same sentences from all three systems under the same conditions. We call system pairs comparisons between two internal models "incremental", and comparisons between the newer internal model and the external model as "independent".

n	Incremental 161 ↓	Independent 246
BLEU	**99.4**	90.7
BERTScore	98.8	91.5
ESIM	98.8	92.3
Prism	98.1	94.3
ChrF	98.1	91.5
COMET	98.1	**98.4**
COMET-src	97.5	98.8
CharacTER	97.5	89.8
Prism-src	96.9	92.7
BLEURT	96.9	93.5
TER	95.7	91.5
EED	78.9	78.0

Table 5: Evaluation of incremental and independent system pairs. We use a subset of 333 system pairs significantly different based on Wilcoxon's test and alpha level of 0.05 over human judgement. Results with grey background are considered tied with the best metric.

Over the past three years we carried out 333 campaigns across 17 language pairs (each campaign comparing three models), resulting in almost 530000 human annotations.

The results in Table 5 show that for independent systems, the ranking of the metrics is comparable with results in Table 3. Pretrained metrics generally outperform string-based ones and COMET is in the lead. However, when inspecting the incremental systems, BLEU wins. This indicates that BLEU influenced our model development and we rejected models that would have been preferred by humans.

Another possible explanation is that systems preselected by BLEU are easy to differentiate by all metrics. This could explain why all metrics have high accuracy in contrast to the "Independent" column and most of them are in a single cluster.

In conclusion, results showing BLEU as the metric with the highest accuracy where we would expect pretrained metrics to dominate, suggests that BLEU affected system development and we rejected improved models due to the erroneous degradation seen in the BLEU score. However, this is indirect evidence as for sound conclusions we would need to evaluate those rejected systems with other metrics and human judgement as well.

[9] Wilcoxon's test on human judgement and alpha level 0.05.

[10] The pair of internal models contains the best model from the last year and our latest improved model.

Table 6: "n" is sum of systems in each study used to calculate aggregated correlation. The results in brackets are without systems on English into Chinese. Correlations are comparable only within columns.

6 Meta Analysis

We analyze findings from past research to put our results in the broader context. We focus on the results on the system-level evaluation, however, a large part of the research studied a sentence-level evaluation. The largest source of metrics evaluation is yearly WMT Metric Shared Task occurring over more than the past ten years (Callison-Burch et al., 2007), where various methods are evaluated with human judgement over the set of submitted systems and language pairs in WMT News Translation Shared Tasks. Recently, Freitag et al. (2021) reevaluated two translation directions from WMT 2020 with the multidimensional quality metric framework and raised a concern that general crowd-sourced annotators used in into-English evaluation in WMT prefer literal translations and have a lower quality than some automatic metrics.

Past studies evaluate system-level correlations with Pearson's correlation calculated for each translation direction separately. We are interested in how metrics correlate with human judgement in general across different language pairs. Thus, to generalize the past findings, we use the Hunter-Schmidt method (Hunter and Schmidt, 2004), which allows combining already calculated correlations with various sizes. We use it to generalize correlations within each study across all language pairs. For this purpose, Hunter-Schmidt is effectively a weighted mean of the raw correlation coefficients.

Although past studies evaluated a larger number of methods and their variants, we have selected a subset of metrics that are evaluated in more than one study or showed promising performance over other metrics in a given study. When a study evaluated several variants of a metric with various parameters, we selected the setting closest to either the recommended setting in the recent years, such as SacreBLEU, or a setting that is used in the later evaluation study, mainly in Mathur et al. (2020b).

Meta-analysis in Table 6 shows that pretrained methods outperform string-based methods as concluded by Mathur et al. (2020b); Ma et al. (2019, 2018). The second important observation is that there was not a single year where BLEU had a higher correlation than ChrF. This supports our conclusions and shows that the MT community had results supporting the deprecation of BLEU as a standard metric for several years. Comparing the pretrained methods, ESIM is the best performing method in general (Mathur et al., 2020b), while COMET is the best performing method when removing the suspicious system.

In the study by Mathur et al. (2020b), COMET under-performed other pretrained metrics. We found out that submitted COMET scores failed to score one English-Chinese system with tokenized output. However, we obtain valid COMET scores on that system output when replicating the results. Moreover, we have not seen any problems with COMET on Chinese. As this one system largely skews Pearson's correlation, we also present analysis without English-Chinese systems in Table 6.

7 Discussion

We corroborate results from past studies that pretrained methods are superior to string-based ones. However, pretrained methods are relatively new

techniques and we can potentially discover significant drawbacks, for example, they could resemble biases from training data, fail on particular domains, or prefer fluency over adequacy. Another problem could arise if an MT system would be trained on the same data as the metric was or if it incorporates the same pretrained model, for example, XLM-R (Conneau et al., 2020) used by COMET. Pretrained methods support only a selected set of languages and the quality can differ for each of them. Thus, we argue that the string-based method should be used as a secondary metric.

An interesting solution to dissipate potential drawbacks of any metric would be if different research groups preselect a different primary pretrained metric in advance to lead their research decisions and to discover improvements not apparent under other metrics. However, we fear that it could lead to "metric-hacking", i.e., picking a metric that confirms results. Therefore, we recommend using COMET as the primary metric. And to use ChrF, the best performing string-based method, as a secondary metric and for unsupported languages.

A surprising results is the high accuracy of COMET-src, a reference-free metric. It allows automatic evaluation over monolingual domain-specific testsets as suggested by Agrawal et al. (2021).

Limitations of BLEU are well-known (Reiter, 2018; Mathur et al., 2020a). Callison-Burch et al. (2006) argued that MT community is overly reliant on it, which Marie et al. (2021) confirmed by showing that 98.8% of MT papers use BLEU. We present indirect evidence that the over-use of BLEU negatively affects MT development and support deprecation of BLEU as the evaluation standard.

We show that the reliability of metrics decisions can be increased with statistical significance tests. However, Dror et al. (2018) point out the assumption of statistical significance tests that data samples are independent and adequately distributed is rarely true. Also, statistical significance tests do not account for random seed variation across training runs. Thus, one should be cautious when making conclusions based on small metrics improvements. Wasserstein et al. (2019) give recommendations for a better use of statistical significance testing.

Marie et al. (2021) have shown that almost 40% of MT papers from 2020 copied score from different papers without recalculating them, which is a concerning trend. Also, new and better metrics will emerge and there is no need to permanently adhering to a single metric. Instead, the simplest and most effective solution to avoid the need to copy scores or stick to obsolete metric is to always publish translated outputs of test sets along with the paper. This allows anyone to recalculate scores with different tools and/or metrics and makes comparisons with past (and future) research easier.

There are some shortcomings in our analysis. We have only a handful of non-English systems, therefore we cannot conclude anything about the behaviour of the metrics for language pairs without English. Similarly, the majority of our language pairs are high-resource, therefore, we cannot conclude the reliability of metrics for low-resource languages. Lastly, many of our translation directions are from translationese into authentic, which as Zhang and Toral (2019) showed is the easier direction for systems to score high by human judgement. These are potential directions of future work.

Lastly, we assume that human judgement is the gold standard. However, we need to keep in mind that there can be potential drawbacks of the method used for human judgement or human annotators fail to capture true assessment as Freitag et al. (2021) observe. For example, humans cannot explicitly mark critical errors in DA and instead they usually assign low assessment scores.

8 Conclusion

We show that metrics can use a different scale for different languages, so Pearson's correlation cannot be used. We introduce accuracy as a novel evaluation of metrics in a pairwise system comparison.

We use and release a large collection of the human judgement confirming that pretrained metrics are superior to string-based. COMET is the best performing metric in our study, and ChrF is the best performing string-based method. The surprising effectiveness of COMET-src could allow the use of large monolingual test sets for quality estimation.

We do not see any drawbacks of the metrics when investigating various languages or domains, especially, for methods pretrained on human judgement. We present indirect evidence that the over-use of BLEU negatively affects MT development.

We show that statistical testing of automatic metrics largely increases the reliability of a pairwise decision based on automatic metric scores.

We endorse the recommendation for publishing translated outputs of research systems to allow comparisons and recalculation of scores in the future.

A Metrics Implementation Details

We use the most common implementation with default or recommended parameters to simulate standard metric usage.

For *BLEU* (Papineni et al., 2002), *ChrF* (Popović, 2015) and *TER* (Snover et al., 2006) metrics, we use SacreBLEU implementation `https://github.com/mjpost/sacrebleu/` version 1.5.0. We use "mteval-v13a" tokenizer for all language pairs except for Chinese and Japanese which use their own tokenizer, as is recommended.

For *CharacTER* (Wang et al., 2016), we use `https://github.com/rwth-i6/CharacTER` commit c4b25cb.

For *EED* (Stanchev et al., 2019), we use `https://github.com/rwth-i6/ExtendedEditDistance` commit f944adc.

For *BERTScore* (Zhang et al., 2020), we use `https://github.com/Tiiiger/bert_score` version 0.3.7.

For *BLEURT* (Sellam et al., 2020), we use the recommended model "bleurt-base-128" and implementation `https://github.com/google-research/bleurt` version 0.0.1. It is important to mention, that BLEURT is fine-tuned for English only. Additionally, we evaluated other variants and "bleurt-large-512" performed better than recommended variant. We add it in Table 8.

For *COMET* (Rei et al., 2020), we use recommended model "wmt-large-da-estimator-1719" and for *COMET-src* we use "wmt-large-qe-estimator-1719". The implementation is `https://github.com/Unbabel/COMET` in version 0.0.6. We evaluated all other COMET models, but neither performed better than recommended model.

For *Prism* and *Prism-src* (Thompson and Post, 2020), we use `https://github.com/thompsonb/prism` commit 06f10da.

For *ESIM* (Mathur et al., 2019), we use `https://github.com/nitikam/mteval-in-context`.

B Confidence Interval for Metric Accuracy

To estimate the confidence interval for the best performing metric, we use the bootstrap method (Efron and Tibshirani, 1994). It creates multiple resamples (with replacement) from a set of observations and calculates accuracy on each of these resamples. We employ modified paired bootstrap resampling (Koehn, 2004), a method which we also use for testing statistical significance of the metric difference in Section 5.3. However, the usage is different.

To calculate the bootstrap resampling. First, we note the best performing metric on all system pairs from the collection as metric α. We create 10 000 resamples by drawing system pairs with replacements from the collection of all. For each resample, we calculate accuracy for all metrics. We note

which metrics have equal or higher accuracy than metric α in a given resample.

If metric α outperforms metric X by less than 95% of the time, we draw the conclusion that metric X performs on par with 95% statistical significance to the winning metric α.

C Comparing Statistical Tests

The problem if two systems have the same MT quality is still an open question. Applying statistical tests over the metric scores allows us to confirm if the difference in score is significant or due to a random change based on the set of translated sentences and a given alpha level. To get the gold truth about system equivalence, we employ Wilcoxon's test on human judgement and alpha level 0.05. We use paired bootstrap resampling approach as the statistical test for automatic metrics. Unfortunately, we cannot directly compare the outputs of two statistical tests (for example, the Wilcoxon test on human judgements with the bootstrap resampling on metric scores) as even with the same alpha level, these tests have a different power. Therefore, we need to investigate it in isolation.

The null hypothesis in our setting is that both evaluated systems have the same translation quality. There are two possible outcomes of a statistical test: accept the null hypothesis (i.e. MT quality of systems is *not significantly* different) or reject the null hypothesis (i.e. MT quality of systems is *significantly* different). When observing outcomes of statistical tests over human judgement and over automatic metric, we get four possible outcomes:

		Statistical test on a metric	
		Signif.	Not signif.
Humans	Signif.	Truly differing system pair	Type II Error
	Not signif.	Type I. Error	Systems with the equal MT Quality

There are two outcomes for the statistical test over a metric that we investigate separately.

In the first scenario, the bootstrap resampling confirms the statistical difference between systems. However, even when both tests agree that systems have statistically different MT quality, it still may happen that humans and metrics disagree on which system is better than the other. The goal is to evaluate how accurate metric decisions are if we employ statistical testing. Therefore, we are interested in the accuracy of a metric over system pairs that are deemed statistically different according to the paired bootstrap resampling, in other words, accuracy for system pairs that are either truly different (top left quadrant) or fall into type I. error (bottom left quadrant).

In the second scenario, we want to find out how many system pairs are diagnosed as non-significant even though human judgements would deem them different. For this scenario, we investigate for how many system pairs bootstrap resampling fails to reject the null hypothesis. However, keep in mind that two statistical tests cannot be directly compared because different tests have different power and the type II error will differ based on that.

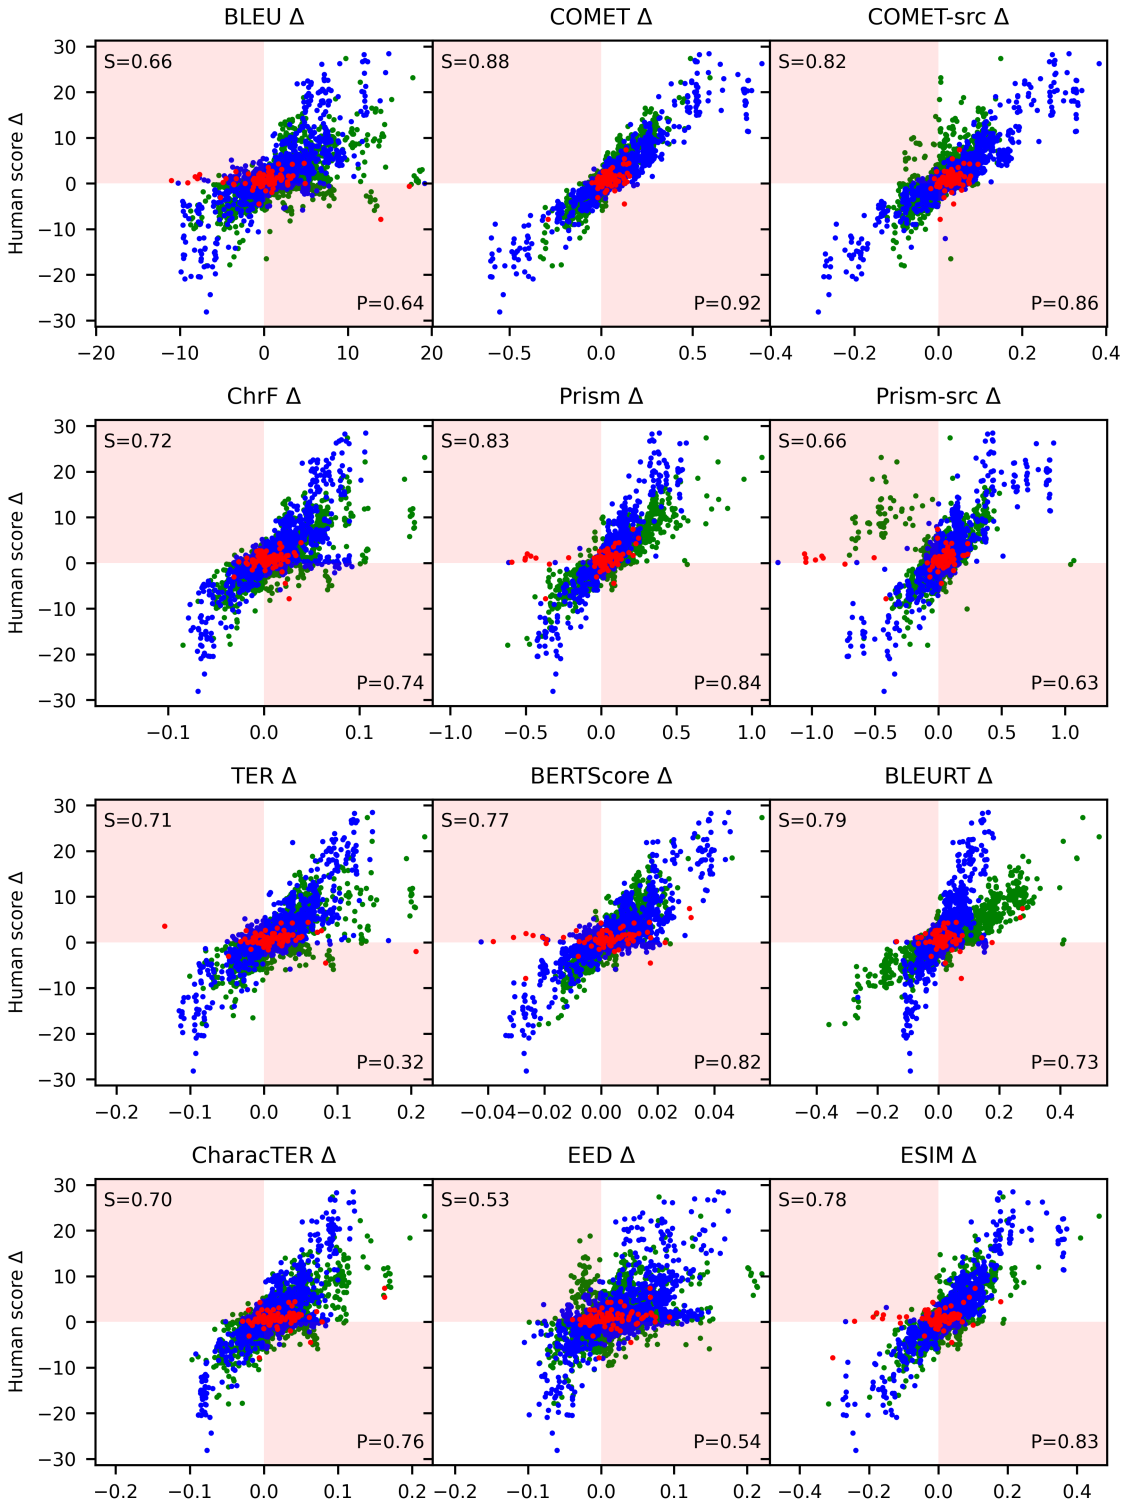

Figure 2: Each point represents a difference in average human judgement (y-axis) and a difference in automatic metric (x-axis) over a pair of systems. Blue points are system pairs translating from English; green points are into English; red points are non-English systems (French, German, and Chinese centric). Spearman's ρ correlation is in top left corner, while Pearson's r is in the bottom right corner. Metrics disagree with human ranking for system pairs in pink quadrants. For better visualization, we have clipped few outliers in BLEU, ChrF, and TER plots.

Language pair	Sys.	Size	Language pair	Sys.	Size	Language pair	Sys.	Size

Table 9: Each row represents accuracy of system pairs for given language pair. We list language pairs with at least 20 system pairs. Results are calculated over a set of significantly different system pairs with alpha level 0.05. Results with grey background are considered to be tied with the best metric. Interestingly, when we investigated Polish–English results, we found out the test set is likely post-edited MT output.

Just Ask!
Evaluating Machine Translation by Asking and Answering Questions

Abstract

In this paper, we show that automatically-generated questions and answers can be used to evaluate the quality of Machine Translation systems. Building on recent work on the evaluation of abstractive text summarization, we propose a new metric for system-level Machine Translation evaluation, compare it with other state-of-the-art solutions, and show its robustness by conducting experiments for various translation directions.

1 Introduction

The goal of automatic Machine Translation (MT) evaluation is to automatically evaluate the output quality produced by MT systems. Metrics used for this task assign a score by comparing the MT output to either a reference translation or to the source sentence (the latter is called Quality Estimation).

The main indicator that is used to assess the performance of a specific metric is the correlation with human judgement computed for outputs from several systems. It was recently shown that metrics based on contextualized embeddings, such as YiSi (Lo, 2019) or ESIM (Mathur et al., 2019), are able to achieve better performance than the most widely used BLEU (Papineni et al., 2002).

In this paper, we propose a new method for automatic evaluation of MT systems – MTEQA[1] (**M**achine **T**ranslation **E**valuation with **Q**uestion **A**nswering), building on previous works on evaluating abstractive summaries. We build upon the fact that state-of-the-art (neural) MT systems tend to produce a fluent output but sometimes fail in adequacy of the translation. We leverage the recent progress in Question Generation (QG) and Question Answering (QA) to formulate and answer human readable questions about the MT system output. Our experiments show that the effectiveness of the proposed metric is comparable to performance of other automatic metrics, while considering only a certain amount of information from the whole translation. We also examine the robustness of the metric by considering several translation directions and target languages.

The remainder of this paper is structured as follows. In Section 2, we introduce relevant research on question-based evaluation. In Section 3, we describe our metric in detail. In Section 4, we present and discuss the results of our experiments including s the influence of different human scoring methods. Section 5 presents conclusions.

2 Related Work

Metrics that are most widely used for automatic evaluation of MT outputs produce a score by comparing surface-level forms of hypothesis and reference translation. The most dominant one, BLEU (Papineni et al., 2002), is a version of n-gram precision calculated by averaging over different values of n with penalization for overly short translations (brevity penalty). Another one, CHRF (Popović, 2015), considers the character-level n-grams, making it possible to reward partial token matches. The standardised implementation provided in the sacreBLEU[2] package takes care of pre-processing and enables direct comparison between MT outputs.

Recently, various works (e.g., Lo, 2019; Mathur et al., 2019; Bawden et al., 2020) explored the usage of contextualized word-level or sentence-level embeddings to compare the numerical representations of reference and hypothesis. Such metrics enable explicit regression towards the desired human-produced labels.

2.1 Evaluation of Summarization

The task of automatic text summarization is to produce a concise summary of a given document that

[1]https://github.com/ufal/MTEQA

[2]https://github.com/mjpost/sacrebleu

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 495–506
November 10–11, 2021.

would preserve all the key information from the document. One of the most popular metrics used for evaluating summary quality is ROUGE (Lin, 2004), which compares overlapping n-grams between the model output and the reference summary.

To step beyond the n-grams comparison, Eyal et al. (2019) proposed the APES metric. They used the reference summary to produce fill-in-the-blank type of questions by finding all possible entities using a NER system. The APES score for a given summarization model is the percentage of questions that were answered correctly (using an Question Answering system), averaged over the whole test-set. The authors reported a higher correlation with the Pyramid method (Nenkova et al., 2007) for manual evaluation than the ROUGE metric. Scialom et al. (2019) extended their work into unsupervised settings by generating questions from the source document. Closest to our work are the metrics FEQA (Durmus et al., 2020) and QAGS (Wang et al., 2020), which automatically generate the natural language questions from the summary and/or document.

2.2 Question-based Evaluation of MT

Tomita et al. (1993) were the first to use the reading comprehension tests to measure the quality of MT systems. They translated several passages from TOEFL (Test of English as a Foreign Language) guide book into Japanese, using a selection of MT systems, while corresponding questions and answers were translated into Japanese by professional translators. The MT systems were evaluated by measuring the percentage of questions answered correctly by the Japanese speaking human annotators, using the MT output as a context.

Fuji et al. (2001) used the reading comprehension tests to examine the "usefulness" of machine-translated text. In their experiment, participants take the reading comprehension test in a foreign language (English), while also being presented with the text translated by the MT system into their mother language (Japanese). Authors claim that presenting the MT output yields a higher comprehension performance.

Castilho and Guerberof Arenas (2018) examine the user satisfaction when completing the comprehension type of test, using the context translated by the MT system. They collect the eye-tracking data to analyse the cognitive effort of the participants.

Scarton and Specia (2016) approached the problem of document-level Quality Estimation (QE) by extending the CREG corpus (Ott et al., 2012) of German documents designed for reading comprehension exercises. They use professional translators to translate the questions and answers to English. They examine the document-level translation quality by translating the documents by MT systems and asking the human annotators to complete the reading comprehension test using the MT output as a context. Forcada et al. (2018) used the same corpus to examine the usage of automatically generated gap-filling closure type of testing.

Berka et al. (2011) used the *yes/no* type of questions for manual evaluation of MT systems, examining the English-to-Czech direction. The authors prepared a set of English texts from various domains and used human annotators to come up with three content-based question-answer pairs in Czech for each of the texts. In the next step, the annotators were given the outputs from MT systems (in Czech) and were tasked to answer the questions using the corresponding translation as the context. For each system, the percentage of properly answered questions was measured.

We believe no prior work examines the usage of automatically generated questions and answers to assess the quality of MT systems.

2.3 Keyphrase Extraction

Keyphrases are representative and characteristic phrases from a text that express the key aspects of its content (Papagiannopoulou and Tsoumakas, 2020). In our work, keyphrases play the role of answers, i.e., the pieces of information which we test to be preserved in translation.

In recent years, a wide range of supervised and unsupervised keyphrase extraction methods have been proposed. Unsupervised methods normally perform two main steps to extract keyphrases: 1) select candidate phrases based on some heuristics such as matching with a specific part-of-speech pattern; 2) rank the candidates and select the top ones. Various approaches have been proposed to address this problem such as statistics-based (Won et al., 2019), graph-based (Mihalcea and Tarau, 2004), topic models-based (Liu et al., 2010), and language model-based (Tomokiyo and Hurst, 2003) methods.

On the other hand, supervised methods are relying on labeled data in which keyphrases are annotated in the documents. Supervised methods

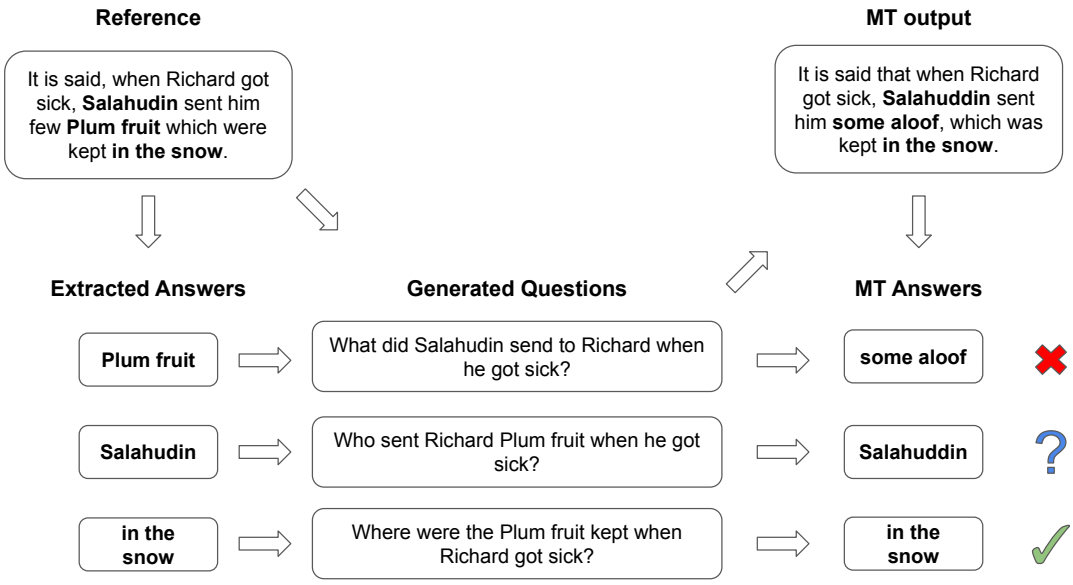

Figure 1: An illustration of the MTEQA pipeline. One of the MT answers is clearly wrong, one is correct but the other differs with just a single character, raising a question about the choice of the answer-comparison metric.

generally model the keyphrase extraction problem as binary classification to predict whether a candidate phrase is a keyphrase or not (Wang and Li, 2017), learning to rank to learn a ranking function that sorts the candidate phrases based on their score (Zhang et al., 2017), and sequence labeling problem (Zhang et al., 2016).

3 MTEQA

Our idea of evaluating MT quality by asking and answering questions is based on the assumption that a good translation should preserve all of the key information that one can extract from the reference. We propose to use a question answering framework as the proxy to measure this.

To check whether a piece of information is preserved, we automatically generate pairs of a question and its (gold-standard) answer from the reference translation and employ a question answering system to provide a new (test) answer given the question and the MT output (translation) used as the context. The generated (test) answer is then compared to the gold-standard answer.

We assume that if it was possible to answer a question looking only at the reference, it should also be possible to answer this question looking only at the MT output and that the two answers should be identical or very similar.

In principle, the proposed MTEQA metric requires solving the following tasks:

1) Answer extraction identifies the key information in a sentence (keyphrases) which should be also present in the MT output. This extraction can be treated in a hierarchical/nested manner. For instance, given the sentence *"Today for dinner I had an organic pasta with garlic."*, the question *"What did you have for dinner today?"* can be correctly answered by all the following phrases *pasta*, *organic pasta* and *organic pasta with garlic*. Thus, answer extraction is performed first and the questions are generated afterwards for each of the answers independently. The same question can be paired with multiple (nested) answers which allows capturing a partial correspondence.

2) Question generation, given a reference translation, produces a human readable question, for which a given keyphrase is the correct answer. For each of the extracted answers, each question is generated independently from the other answers.

3) Question answering generates an answer, given a natural language question and a sentence used as a context. Since we assume that the MT output should carry enough information to answer any question asked based on the reference, we do not consider the non-answerable questions.

4) Answer comparison assesses to what extent the generated answer is correct, given the gold-

standard answer extracted from the reference. Metrics based on exact match should be avoided because they are too strict. For example, given the gold-standard answer *"Tchaikovsky"*, both the *"Tchaikovski"* and *"Beethoven"* would get the same score.

3.1 Scoring Procedure

The entire procedure of MTEQA is illustrated in Figure 1. Formally, for a given segment s_i, reference translation r_i and MT system output t_i, it proceeds as follows:

1. Generate the gold-standard answers $a_{i1}, a_{i2}, \ldots, a_{ik}$ from the reference r_i
2. For each answer a_{ij} and reference r_i, generate a natural language question q_{ij}
3. Answer each question q_{ij} using the MT output t_i as a context, obtaining answer $\tilde{a}_{ij}$
4. The final score for a given translation of a segment s_i, is the average over all generated questions:

$$MTEQA(t_i) = \frac{\sum_1^k D(a_{ij}, \tilde{a}_{ij})}{k},$$

where $D(\cdot, \cdot)$ is a string-comparison metric used to compare the two answers and k is the number of gold-standard answers extracted from the reference.

For the task of comparing MT systems on the entire test-set (i.e. system-level comparison) or at the document-level, we simply report the average of the segment-level scores. When more than one reference $\hat{r}_i$ is available for a given segment, we can use it to generate additional questions and answers.

3.2 Baseline Implementation

Our implementation of the proposed MTEQA metric is based on the state-of-the-art system capable of solving the initial three tasks of the procedure: answer extraction, question generation, question answering. It is the T5 model (Raffel et al., 2020) fine-tuned on the SQuADv1 dataset (Rajpurkar et al., 2016) by Patil (2020) and available from GitHub[3]. Performance on the development set of SQuADv1 in Table 2. We report word-level F1 for question answering and BLEU and ROUGE-L for question generation.

The SQuAD dataset was created manually by tasking the crowd-workers to create up to five questions-answer pairs from a single paragraph from Wikipedia. While the crowd-workers were encouraged to formulate the questions in their own words, the answers were restricted to be continuous sub-sequences of words from the given paragraph. In MTEQA, the answers generated by this model are also continuous sub-sequences of words from the reference and test translations.

The same system is also used for question answering and question generation by prompting the model with a different initial token in the input – for Question Answering:

```
"question: {question_text}
 context: {context_text}"
```

for Question Generation:

```
"answer: {answer_text}
 context: {context_text}".
```

3.3 Generating Additional Answers

Since the QG system generates a single question for each sub-sequence of words marked as an extracted answer, the limit factor is the number of gold-standard answers we extract. To generate more questions, we need more keyphrases to formulate a question about.

Table 3: System-level Pearson correlation for selected metrics used for measuring MT quality with DA human assessment over MT systems using the *newstest2020* references. Average (avg) is computed over all to-English directions available. Number below the language pair indicates the number of systems considered. Figures without * are taken from Mathur et al. (2020a).

Considering the whole predictive power of our metric is based on questions, we propose two methods of generating additional questions.

1) We exploit the MT output as an additional source of question/answer pairs. After following the standard procedure, we swap the roles of MT output and reference – we generate gold-standard answers and questions from the MT output, and use reference as a context to answer it. As a final score we take the sum of the two scores.

2) We add keyphrases extracted by linguistic processing of the sentences based on Part-of-Speech (POS) pattern matching and Named Entity Recognition (NER). Given a sentence as the input, first, we parse the sentence using UDPipe (Straka et al., 2016) to extract part of speech (POS) tags. Then, we extract phrases that are matched with one of the patterns in our POS pattern bank. The POS pattern bank is created by parsing the sentences from XQuAD (Artetxe et al., 2020) dataset, extracting the POS patterns corresponding to the gold-standard answers, and taking the most frequent patterns. This dataset contains professional translations of the development set of SQuADv1, translated into various languages from different language families and using different scripts. Table 1 shows some examples of the extracted POS patterns. Second, we extract named entities mentioned in the input sentence using a combination of two multilingual NER models, POLYGLOT-NER (Al-Rfou et al., 2015), and Stanza (Qi et al., 2020). Finally, we output the union of the extracted phrases and named entities as the potential answers.

3.4 Choice of the $D(\cdot, \cdot)$ Metric

As already pointed, selection of the $D(\cdot, \cdot)$ might be crucial for optimal performance of the proposed metric and thus we consider several options. Motivated by QA evaluation, we employ the word-level F1 (Rajpurkar et al., 2016; Trischler et al., 2017; Chen et al., 2019; Durmus et al., 2020). Motivated by MT evaluation we also consider the BLEU (Papineni et al., 2002) metric and the CHRF (Popović, 2015) metric. Finally we also employ "exact match" (Rajpurkar et al., 2016) score, mainly for comparison. All of the metrics we use operate on a surface level and assign a similarity score for a pair of strings. In the future, it may be worth to explore e.g. cosine similarity between word embeddings.

4 Experiments

We evaluate the proposed MTEQA metric using the submissions to the WMT20 News translation task (Barrault et al., 2020) and their (direct) human assessments (DA). For each of the MT systems participating in the task, we compute a single score as the average of segment-level scores and report the system-level Pearson correlation with the human assessment. We report individual results for selected translation directions into English plus aggregated results (averages) for all to-English directions which were part of the WTM20 Metric Task (Mathur et al., 2020b) evaluation campaign[4].

4.1 Baseline

The baseline implementation is described in Section 3. It is based on the T5 model tuned on the SQuADv1 dataset and used to generate: 1) the gold-standard answers from the reference translations, 2) a question for each gold-standard answer, 3) a test answer for each question and MT output (context) pair. The test answers are compared by the word-level F1 score (Section 3.4).

The results of this system are shown in Table 3 labeled as MTEQA F1 together with other metrics for comparison. We experiment with the to-English direction, since the SQuADv1 dataset used for fine-tuning is in English. On average, the baseline

Table 4: System-level Pearson correlation for various variants of the proposed metric with DA human assessment over MT systems using the *newstest2020* references. Average is computed over all to-English directions available.

outperforms the traditional MT evaluation metrics (SENTBLEU, BLEU) as well as the recently proposed ones that performed very well in the WTM20 Metric Task (PRISM (Thompson and Post, 2020), YISI-2), though for some of the translation directions (e.g. Czech-English) MTEQA F1 is much worse (but for Czech-English, YISI-2 also does not beat BLEU).

4.2 Variants of the $D(\cdot, \cdot)$ metric

To assess the effect of choice of the $D(\cdot, \cdot)$ metric, we modified the baseline to exploit other options (see Section 3.4). The results are shown in the first section of Table 4. Unsurprisingly, the worst results are achieved by MTEQA EXACT which requires exact match of the test answer and the gold-standard one. But overall, the differences here are not large.

4.3 Generating Additional Answers

In general, the T5 model fine-tuned on the SQuADv1 dataset does not generate plentiful question/answer pairs. In fact, the average number of such pairs that are generated for an English sentence is only around two. Table 5 (row *baseline*) presents exact figures from our experiments, i.e., the average numbers of questions generated from a single segment of the *newstest2020* reference files for selected translation directions and the average computed for all directions into English.

To increase the number of question/answer pairs, we implemented the two methods described in Section 3.3 and present the results in Table 4. The systems denoted as OUT exploit question/answer pairs extracted from the references and MT outputs and the systems denoted as KEYPHRASE extract the pairs by POS pattern matching and NER.

The average correlation obtained using the MT output to generate questions (denoted as OUT) was very similar, but slightly worse than the one using just the questions from the reference. However, the method based on POS pattern matching and NER (denoted as KEYPHRASE) yielded improvements over various translation directions and answer comparison methods. The average numbers of question/answer pairs obtained by this method is shown in Table 5. It increased by the factor of 4 (approximately). Together with the CHRF metric used for answer comparison, it forms the best-performing configuration of the proposed metric. We also include its results in Table 3 . From now on, we will report our results using this variant. See Appendix A for examples of usage of different evaluation methods.

4.4 Non-English Reference

So far, all the experiments were conducted for the translations directions into English. This is given by the limitation of the T5 model which was trained on English data and most importantly by the SQuADv1 dataset which was used for fine-tuning and which is in English.

To overcome that, we used the multilingual mT5 model (Xue et al., 2021) and fine-tuned it on machine translation of SQuADv1 dataset into German by Lewis et al. (2020) and into Czech by (Macková and Straka, 2020). The results for English-Czech and English-German are included in both

	cs-en	de-en	ja-en	pl-en	zh-en	avg	en-cs	en-de
BASELINE	2.87	2.75	1.74	1.36	1.65	1.76	1.66	1.41
KEYPHRASE	13.36	12.01	6.66	5.10	8.79	6.98	9.45	8.71

Table 5: Average number of questions generated from a single segment in the *newstest2020* reference file by the baseline system (fine-tuned T5) and the keyphrase extraction method (POS pattern matching and NER). The average is computed over all to-English directions.

Tables 3 and 4. Overall, MTEQA still performs very well. It is better than the traditional metrics (SENTBLEU, BLEU) and also YISI-2 and comparable with PRISM for English-German. However, it is substantially worse than PRISM for English-Czech. Given the fact, that the system is multilingual and fine-tuned on machine-translated data, the results are encouraging and open doors for a cross-lingual setting which would not require reference translations.

4.5 Comparison with MQM Scores

Recently, Freitag et al. (2021) demonstrated that the WMT DA method traditionally used for human evaluations has actually lower correlation with expert-based labels than the Multidimensional Quality Metrics (MQM) scoring method developed in the EU QTLaunchPad and QT21 projects.

To provide a more complete picture of the performance of the proposed MTEQA metric, we also report correlation with the MQM assessments. Table 6 presents the system-level Pearson correlation of the proposed metric with both the MQM and DA labels for 8 systems that were re-annotated by Freitag et al. (2021) and are available from GitHub[5].

The results are surprising and to a large extent unintuitive. Metrics performing well in comparison with MQM are bad in comparison with DA. This issue was already discussed by Freitag et al. (2021) and we leave deeper analysis of the difference for the future when MQM labels will be available for more data and for more translation directions.

5 Conclusions

In this paper we introduced a new metric for automatic evaluation of Machine Translation systems. We showed that the degree to which the MT output can be used to answer questions about the reference can be used as a proxy to evaluate the translation quality. We proved that our metric is robust by conducting experiments over multiple translation directions.

We examined a linguistically motivated way of extracting key phrases from the sentence and showed that it boosts the final performance. We checked the influence of various word-level comparison metrics used to compare the test and gold-standard answers, and reported how it affects the correlation with human scores. In our work, we focused on translation directions into English. The only limiting factor in applying our metric to other translation directions is the availability of Question Generation and Question Answering systems in a given language. However, automatic translation of SQuAD can be an effective way to obtain data for training such systems.

Finally, we examined the performance against the MQM labels and compared the performance against the DA labels. While for the DA labels our metric performs close to state-of-the-art solutions, for the MQM labels there is a noticeable drop in performance.

In the future, we plan to examine the cross-lingual approach – instead of generating questions and answers from the reference, one may instead use the source directly.

A Appendix

A.1 Answer extraction

Below we show the difference in the answer extraction process using the baseline approach as opposed to the proposed method based on POS patterns and NER tags. In both cases the same system is used for question generation.

Answer	Question
Answers extracted using the method based on POS sequences and NER tags	
the stadium	Where did the cat fall from?
an American football match	At what event did spectators catch a cat?
upper deck	What part of the stadium did the cat fall from?
A cat	What animal was caught by spectators at an American football match in Miami Gardens?
Florida	Where is Miami Gardens located?
spectators	Who caught a cat at an American football match in Miami Gardens?
Miami Gardens	Where was a cat caught by spectators at an American football match?
Answers extracted using the baseline model	
cat	What animal was caught by spectators at a football match in Miami Gardens?
Miami Gardens	Where was a cat caught by spectators at an American football match?

Table 7: Extracted keyphrases and generated corresponding questions for the sentence: `A cat was caught by spectators at an American football match in Miami Gardens, Florida, after it fell from the stadium's upper deck.`

Answer	Question
Answers extracted using the method based on POS sequences and NER tags	
Liberal	What party did Ed Davey belong to?'
vaccine passports	What did Ed Davey call 'divisive, unworkable and expensive'?
opposition	What type of opposition was there on the Covid Recovery Group?
the Covid Recovery Group	What group did Tory MPs oppose?
Ed Davey	Which Liberal Democrat leader called vaccine passports 'divisive, unworkable and expensive'?
Tory	What political party opposed vaccine passports?
leader	Who is Ed Davey?
Democrats	Along with Tory MPs, what party opposed vaccine passports?
Answers extracted using the baseline model	
Ed Davey	Which Liberal Democrat leader called vaccine passports 'divisive, unworkable and expensive'?
vaccine passports	What did Ed Davey call 'divisive, unworkable and expensive'

Table 8: Extracted keyphrases and generated corresponding questions for the sentence: `There had been opposition from Tory MPs on the Covid Recovery Group as well as the Liberal Democrats, whose leader Ed Davey called vaccine passports 'divisive, unworkable and expensive'.`

Answer	Question
Answers extracted using the method based on POS sequences and NER tags	
russischen	Welche Nationalität sind die Pelmeni?
Pelmeni	Wie ist der russische Name für Pirggen?
Piroggen	Was wird manchmal mit gebrannten Zwiebeln angerichtet?
gebratenen Zwiebeln	Mit welchen Arten von Zwiebeln werden die russischen Pelmeni angerichtet?
Answers extracted using the baseline model	
-	-

Table 9: Extracted keyphrases and generated corresponding questions for the sentence: `Ähnlich wie die russischen Pelmeni werden Piroggen manchmal mit gebratenen Zwiebeln angerichtet.`

A.2 Answer comparison

Below we show the difference between gold-standard answers extracted from the reference and test answers obtained with the Question Answering system, using the MT output as context.

Question	Gold-standard Answer	Test Answer
MT Output: The men‘s 100 metres semi-final begins at Sunnybrown Haquim (left).		
In what distance is Sani Brown Hakim in the men‘s semifinals?	100m	100 metres
Who is Sani Brown Hakim in the 100m semifinals?	the men	Sunnybrown Haquim
Who started in the men‘s 100m semifinals?	Sani Brown Hakim	Sunnybrown Haquim
MT Output: Sani Brown Hakeem (left) will start the men‘s 100 metres semi-final.		
In what distance is Sani Brown Hakim in the men‘s semifinals?	100m	100 metres
Who is Sani Brown Hakim in the 100m semifinals?	the men	Sani Brown Hakeem
Who started in the men‘s 100m semifinals?	Sani Brown Hakim	Sani Brown Hakeem

Table 10: Extracted keyphrases, generated corresponding questions and answers extracted from MT output for the reference: `Sani Brown Hakim (left) starting in the men‘s 100m semifinal.`

Question	Gold-standard Answer	Test Answer
MT Output: Recently I flew from Moscow, where I was trained," Andrei Borovikoff said.		
Who said that he flew from Moscow to study?	Andrei Borovikov	Andrei Borovikoff
Where was I studying?	Moscow	Moscow
MT Output: Recently, I flew from Moscow, where he was trained ", Andrey Borovikov told.		
Who said that he flew from Moscow to study?	Andrei Borovikov	Andrey Borovikov
Where was I studying?	Moscow	Moscow

Table 11: Extracted keyphrases, generated corresponding questions and answers extracted from MT output for the reference: `Recently I flew from Moscow where I was studying," said Andrei Borovikov.`

A Fine-Grained Analysis of BERTScore

Abstract

BERTScore (Zhang et al., 2020), a recently proposed automatic metric for machine translation quality, uses BERT (Devlin et al., 2019), a large pre-trained language model to evaluate candidate translations with respect to a gold translation. Taking advantage of BERT's semantic and syntactic abilities, BERTScore seeks to avoid the flaws of earlier approaches like BLEU, instead scoring candidate translations based on their semantic similarity to the gold sentence. However, BERT is not infallible; while its performance on NLP tasks set a new state of the art in general, studies of specific syntactic and semantic phenomena have shown where BERT's performance deviates from that of humans more generally.

This naturally raises the questions we address in this paper: what are the strengths and weaknesses of BERTScore? Do they relate to known weaknesses on the part of BERT? We find that while BERTScore can detect when a candidate differs from a reference in important content words, it is less sensitive to smaller errors, especially if the candidate is lexically or stylistically similar to the reference.

1 Introduction

While manual, human evaluation of machine translation (MT) systems is still the gold standard, automatic evaluation metrics have long been used for their relative speed and inexpensiveness. Early automatic metrics were easy to implement and somewhat correlated with human judgements, but have clear limitations: BLEU (Papineni et al., 2002) relies on n-gram overlap, and is thus not robust to differing word order or choice. In contrast, METEOR (Lavie and Agarwal, 2007) requires training, but depends on token alignment, which is also a fraught task.

With the advent of deep learning, new automatic metrics have arisen, both in response to and making use of the technical advances brought by deep learning. In particular, metrics like COMET (Rei et al., 2020) and BERTScore use large pre-trained language models (LLMs) to generate scores for candidate sentences. The use of these LLMs allows for metrics that take advantage of the linguistic capabilities of these LLMs, and no longer rely solely on surface-level features such as n-grams.

The expressiveness of these models is both a boon and a danger. While they can (and do, based on correlation with human judgments) generate more useful scores for translations, how they arrive at the score, and which types of sentences they will score accurately is not immediately obvious.

Moreover, these LLMs are known to have flaws. BERT in particular has been shown to be, in certain scenarios, insensitive to negation (Ettinger, 2020) and word order (Pham et al., 2020). BERT also has inexact representations of numbers (Wallace et al., 2019) and fails to be robust to named entities (Balasubramanian et al., 2020). All of these phenomena could result in poor-quality scores from BERTScore. However, it is difficult to say for certain how these issues might manifest in BERTScore, as it employs BERT in an unsupervised scenario distinct from that of these analyses.

Thus, in this paper, we analyze BERTScore. We first formally define desiderata for a MT metric. Then, we consider how BERTScore fulfills these requirements under conditions of interest. We find that BERTScore violates some of these requirements, specifically the requirement that incorrect translations be rated below correct ones; this occurs most often when the incorrect translation is lexically similar to the reference, or especially if the difference is only in function (not content) words.

2 Desiderata for MT metric quality

The most common method of measuring the quality of a MT metric is correlation with human judgments (Fomicheva and Specia, 2019); however, these correlations provide little information regard-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 507–517
November 10–11, 2021.

ing when and why an MT metric differs from human judgment. In this paper, we consider three ways of examining MT metric quality, with the aim of determining the failure cases of MT metrics.

In all of our experiments, we assume the following setup. We have a MT metric, which we take to be a function M that takes as input a reference and candidate translation, and outputs a score in $[0, 1]$. We also have a dataset $\mathcal{D}$, consisting of triples (x, Y, B) where x is a source sentence, Y is a list of at least two reference translations, and B is a list of at least one "bad" translation, which contains errors.

Then we state that a good MT metric[1] M fulfills, for any triple $(x, Y, B) \in \mathcal{D}$, where $Y = \{y_1, y_2, \ldots, y_n\}$, and $B = \{b_1, b_2, \ldots, b_m\}$, the following conditions:

(i) For any pair (y, y') of reference translations from Y, $M(y, y') \approx M(y, y') \approx 1$.

(ii) For any reference translation $y \in Y$ and candidate translation $b \in B$, $M(y, b) < 1$ and $M(b, y) < 1$. It follows that given another reference translation $y' \in Y$, we should have that $M(y, b) < M(y, y')$ and so on.

(iii) If we know the relative quality of the bad translations in B, let B be a list sorted in decreasing order of translation quality, such that b_1 is better than b_2, and so on. Then for any reference translation y, and bad translations b_i, b_j from B, where $i < j$, $M(y, b_i) > M(y, b_j)$.

Put simply, (i) reference translations should be scored near 1 when compared to each other, (ii) bad candidate translations should be scored worse than reference translations, and (iii) the scoring of bad candidate translations should reflect their relative quality.

To use this framework to investigate the failure points of MT metrics, we simply need a dataset that contains phenomena of interest; for example, we might be interested in knowing if a MT metric is able to distinguish between translations that do and do not correctly render negation. Then, we simply compute the quantities discussed in conditions (i) through (iii) for each example, and see which, if any, conditions are violated. If, for example, condition (i) is violated when two equivalent references employ different types of negation, this might imply that our metric is not robust to this sort of negation phenomenon.

Note that these desiderata only concern the scores given to the reference and candidate sentences; the source-language sentence is ignored. This is because we define these desiderata keeping in mind that many MT metrics (including BERTScore) operate only in the target language[2]. We can thus avoid assuming the existence of a source sentence whatsoever, allowing the construction of datasets consisting only of reference and bad candidate translations that exhibit phenomena of interest. However, it may be desirable to use real translations, so that the dataset reflects the distribution of real-world translation errors.

3 BERTScore and BERT

3.1 BERTScore

In this paper, our metric of interest is BERTScore (Zhang et al., 2020). To compute BERTScore, we first feed a reference and candidate translation for a given sentence into BERT, and retrieve their token level vector representations. Let z be the representations of the reference and $\hat{z}$ those of the candidate. Then we compute the precision and recall metrics for BERTScore by comparing each token representation z_i of the reference translation to each token representation $\hat{z}_j$ of the candidate translation as follows:

$$P_{BERT} = \frac{1}{|\hat{z}|} \sum_{\hat{z}_j \in \hat{z}} \max_{z_i \in z} z_i^\top \hat{z}_j$$

$$R_{BERT} = \frac{1}{|z|} \sum_{z_i \in z} \max_{\hat{z}_j \in \hat{z}} z_i^\top \hat{z}_j$$

The F_1 score can be defined as usual. As BERTScore can range from -1 to 1, but most often inhabits the upper end of that range, its creators suggest the use of baseline scaling, which generally leaves BERTScore in the range [0,1], as desired for use with our prior formalization. Baseline rescaling is performed for P_{BERT} as

$$\hat{P}_{BERT} = \frac{P_{BERT} - a}{1 - a}$$

and likewise for R_{BERT}; a is an empirical lower bound on observed BERTScore.

[1] We assume WLOG that the metric's scores are normalized such that better translations receive higher mean scores, and equally good candidates receive a score near 1.

[2] In the long term, explicit inclusion of the source sentence in MT evaluation would be useful but that is not the concern of this work.

The form of BERTScore naturally leads to its interpretation as a similarity-based metric. It penalizes candidates containing words whose representations are not similar to any of the reference's words' representations (precision), and vice-versa (recall). As a result, the quality and characteristics of these representations, derived from BERT, will play a key role in the quality of BERTScore.

3.2 BERT

What, then, is known about BERT, and its syntactic and semantic capabilities? Of the two, it is syntax that BERT is most widely claimed to capture within its internal representations: Hewitt and Manning (2019) use structural probing to find dependency trees in BERT's vector geometry, while Tenney et al. (2019) use probing to find part of speech tags and dependency arc labels, among other types of syntactic information. Analysis of BERT's attention has shown that certain heads attend to not only relevant linguistic units such as determiners of nouns and coreferent mentions (Clark et al., 2019), but also dependency relations (Htut et al., 2019).

However, these analyses of internal representations and the information contained therein occasionally come at odds with targeted evaluations of BERT's syntactic abilities. Despite BERT's supposed knowledge of syntax, its predictions often remain the same, even when its inputs are shuffled (Pham et al., 2020). Moreover, BERT does not seem to understand negation (Ettinger, 2020); this may be due to BERT encoding syntactic information, but not necessarily using it in its predictions (Glavas and Vulić, 2021).

For semantics, the situation is even more complicated. While BERT's performance on natural language understanding tasks set a new state of the art, more targeted tests of its semantic abilities have yielded less positive results. BERT has limited knowledge of lexical semantic relations such as hypernymy (Ravichander et al., 2020) and antonymy (Staliunaite and Iacobacci, 2020). Moreover, it has fragile representations of named entities (Balasubramanian et al., 2020), and imprecise representations of numbers (Wallace et al., 2019). These flaws comprise specific linguistic phenomena that BERTScore, due to its use of BERT, might be unable to handle, and thus merit investigation.

German Source: Ich habe mich konzentriert.
Good Translation 1: I focused.
Good Translation 2: I've been concentrating.
Bad Translation 1: I've focused me.
Bad Translation 2: I have focussed.
Broad phenomenon: Verb Tense / Aspect / Mood
Specific phenomenon: Reflexive - Perfect

Figure 1: Example data from TQ-AutoTest.

4 Experiments

For our experiments, we utilize the framework described in Section 2 to investigate the questions about BERT described in Section 3. As the number of datasets that fit our framework is few, we limit ourselves to three primary experiments.

4.1 TQ-AutoTest

First, we apply our framework to the TQ-AutoTest dataset (Macketanz et al., 2018). Originally used for targeted evaluation of MT systems, it includes German source sentences that each exhibit one of 14 different linguistic phenomena, such as ambiguity, composition, and subordination.

Each example contains a source sentence, annotated with the broader and more specific phenomenon it exhibits, as well as 1-2 reference translations and 0-2 incorrect translations; see Figure 1 for a sample. As the dataset released is small, we filter out phenomena containing fewer than 5 examples.

We can thus test condition (i) by computing the BERTScore between the two references, and verifying it is close to 1. We also test condition (ii) by comparing the BERTScore assigned (with respect to a given reference) to the other reference, and that which is assigned to a bad translation; the former should be greater than the latter. We cannot test condition (iii), as the dataset does not provide multiple bad translations sorted by quality.

4.2 PE^{2}rr

Second, we use the PE^{2}rr dataset (Popović and Arčan, 2016), which is a manually annotated error analysis of MT output. Each example in the dataset consists of a source sentence, one MT output, and two correct translations, along with two error annotations. These annotations are word-level annotations into 8 broadly non-linguistic classes, such as

German Source: Frauen , die in Burkina Faso zu Hexen abgestempelt werden , weisen in der Regel einige gemeinsame gesellschaftliche Merkmale auf .
Original Translation (Annotated): Women in Burkina Faso `[miss]` are branded as witches , usually `[miss]` some common social features .
Post-edit: Women in Burkina Faso who are branded as witches usually have some common social features .
Original Reference: Women declared as witches in Burkina Faso usually have several common characteristics .

Figure 2: Example data from PE^{2}rr. The "`[miss]`" tokens inserted in the original translation correspond to one of the annotator's error notations, indicating a missing word.

"addition", "lexical error", or "untranslated". See Figure 2 for an example.

Despite the difference in annotation type, we apply our framework just as with the prior experiment. For consistency with the prior experiment, we use only the portion of the dataset where the target language is English (i.e., the German-English portion). We also filter out any examples in which the machine translation output is totally correct, as this would leave no bad examples with which to test conditions other than (i). This once more allows us to test conditions (i) and (ii).

4.3 Grammatical Error Correction

Finally, we use two non-MT datasets for grammatical error correction (GEC): the CoNLL 2014 shared task dataset (Ng et al., 2014), as well as additional annotations released by Bryant and Ng (2015). The former consists of non-native English speakers' essays on genetic testing, paired with annotated corrections from two annotators for each sentence. The latter adds additional annotators' corrections for each sentence, yielding 11 in total.

Of special interest in this dataset is the presence of, for each example, an incorrect sentence and 11 sets of error-annotated corrections that can be applied to obtain correct sentences. Thus, for each original, ungrammatical sentence, we have 10 (often distinct) grammatical sentences, whose meaning should be roughly the same; these act as reference sentences. This allows us to test conditions (i) and (ii).

We can also test condition (iii) by using the following moderate assumption: a sentence, originally grammatically incorrect, is more correct if more corrections have been applied to it. That is, applying one or more corrections (from the same annotator) brings an incorrect candidate sentence closer to the shared meaning of the reference sentences. This assumption can be false: sometimes a group of corrections, rather than one alone, is needed to increase the grammaticality of a sentence. But, this assumption allows us to apply an arbitrary number of corrections to an initially incorrect sentence, to generate intermediate incorrect sentences, with controlled, graded, levels of incorrectness.

So, we generate two incorrect candidates by applying different numbers of edits from the same annotator to one original sentence. We then generate a reference sentence by applying all of another annotator's edits. Finally, we calculate the BERTScore of each candidate with respect to this reference; the candidate that received more edits should receive a higher BERTScore. Note that the reference must be generated by a different set of edits; comparing partially-corrected sentences to a correct sentence generated from same edits would make this a trivial string comparison problem. Figure 3 provides an example of this process.

5 Results

In the following section, we detail the experiments performed and their results. In all experiments, the original authors' implementation of BERTScore[3] is used, with default baseline rescaling.

5.1 TQ-Autotest

As discussed in Section 4.1, we test conditions (i) and (ii) with the TQ-Autotest dataset. First, we filter the dataset to include only those examples for which there are at least two good translations (y, y'). Then, to test condition (i), we compute the BERTScore (BERTScore(y, y')) assigned to the pair of good translations, then compute the mean score for each category.

Note that one should not make absolute comparisons between the mean BERTScore assigned to each category and the desired value (1.0) of the mean score. Because BERTScore can easily be rescaled, it is more useful to verify that good translation pairs receive similar scores across categories;

[3] Available at https://github.com/Tiiiger/bert_score

Original: As a result , if the situation keep go on in this unexpected trend , it will cause a bad effect on the young generation .
Corrections (Annotator 2):
(7, 8, 'keeps', subject-verb agreement)
(8, 10, 'following', word choice)
(10, 11, '', preposition)
(17, 18, 'have', word choice)
(23, 24, 'younger', word form)
Original + 1 correction (b_1): As a result , if the situation keeps go on in this unexpected trend , it will cause a bad effect on the young generation .
Original + 4 corrections (b_4): As a result , if the situation keeps following this unexpected trend , it will have a bad effect on the young generation .
Alternate reference (Annotator 7) (y): As a result , if the situation keeps going on in this unexpected trend , it will have a bad effect on younger generations .

Figure 3: Creation of graded ungrammatical sentences from GEC data. Each correction is a tuple of (start index, end index, new text, error made). We apply a correction via string replacement (i.e. in Python: `original[start_index:end_index] = new_text`). Having received more corrections, b_4 should be closer to y than b_1 is. Thus, we should have BERTScore(y, b_4) > BERTScore(y, b_1).

Linguistic Phenomenon	BERTScore (F_1)

Coordination & ellipsis	0.885
Named entitiy & term.	0.859
MWE	0.874
Average	0.815

Table 1: TQ-AutoTest: Mean BERTScore (F_1) assigned to gold reference, gold candidate pairs, by linguistic phenomenon

Linguistic Phenomenon	Accuracy
LDD & interrogatives	82.4
Composition	60.0
Punctuation	40.0
Function word	42.9
Subordination	75.0
Non-verbal agreement	60.0
Ambiguity	100.0
Verb tense/aspect/mood	73.6
Coordination & ellipsis	80.0
Named entity & terminology	85.7
MWE	100.0
Average	75.5

Table 2: TQ-AutoTest: Average Accuracy by broad linguistic phenomenon. Credit is given when BERTScore(y, y') is greater than BERTScore(y, b), and BERTScore(y, b'), if a b' is provided.

these scores could then easily be rescaled to 1.0. Thus, in this section, we explore only which types of correct sentence pairs BERTScore is more or less able to assign a high score, compared to the average score given to correct sentence pairs.

We see in table Table 1 that the average BERTScore for each category falls near the average. There are some notable exceptions: for example, the "function word" category, which falls well below the mean. This indicates that BERTScore gives different correct translations of the same sentence lower scores, when that sentence contains difficult function words. In contrast, the "coordination & ellipses" and "multi-word error" categories fall well above the mean, suggesting that alternate correct translations of sentences containing these phenomena are scored more highly.

In the second experiment, we test condition (ii) via the following procedure. Once more, we filter the dataset, such that every example includes two good translations and one bad translation, (y, y', b), with potentially another bad translation b' as well. Then, we test the accuracy of BERTScore on these examples. BERTScore is deemed to correctly answer an example if BERTScore(y, y') > BERTScore(y, b). If b' is present, as in 71% of examples, it is also necessary that BERTScore(y, y') > BERTScore(y, b'). We then report the mean accuracy for each category of linguistic phenomenon.

In this second experiment, see Table 2, the differences are more pronounced. In some categories, namely those such as "ambiguity", and "multi-

Error Type	Count	BERTScore (F_1)
reordering	135	0.560
untranslated	55	0.553
lexical	171	0.584
inflection	72	0.571
derivation	16	0.537
missing	164	0.578
contraction	14	0.560
Average	90	0.587

Table 3: PE^{2}rr: Mean BERTScore (F_1) for reference sentence pairs where the original machine translation contains at least one error of the given type.

Error Type	Acc. (Easy)	Acc. (Hard)
reordering	97.0	44.4
untranslated	100.0	72.7
lexical	98.2	46.2
inflection	100.0	50.0
derivation	100.0	50.0
missing	97.0	46.3
contraction	100.0	50.0

Table 4: PE^{2}rr: Average accuracy by error type, for both the easy and hard problem scenarios. Credit is given when BERTScore(y, y') is greater than BERTScore(y, b).

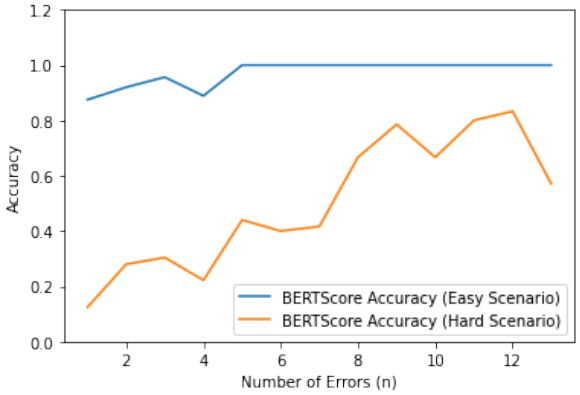

Figure 4: PE^{2}rr: BERTScore accuracy on sentences with n errors, in the easy and hard scenarios.

word error" which are likely to result in totally incorrect word choice (i.e. an obvious lexical difference), BERTScore has a high accuracy. In contrast, BERTScore struggles with difficult punctuation as well as composition errors and function words; notably, the last category also has the lowest score in Table 1. These errors are all somewhat subtle. Errors in function words are by definition not errors in more obvious content words. Similarly, in compositional phenomena like phrasal verbs, an error can appear simply as the omission or incorrect substitution of a mere preposition.

In order to provide context for these results, we also run the second experiment (which corresponds to Table 2) using BLEU score[4] as our metric. As with BERTScore, we mark an example as correct when BLEU(y, y') is greater than BLEU(y, b), and BLEU(y, b'), if a b' is provided. We omit the category-level results for brevity, but find that the mean accuracy for BLEU is significantly lower, at 36.2%, compared to 75.5% in Table 2. This suggests that although BERTScore is flawed, it is at least more accurate than BLEU.

5.2 PE^{2}rr

Using the PE^{2}rr dataset, we again test conditions (i) and (ii). We use an approach like that taken with the TQ-AutoTest dataset. First, we filter out examples in which the two references translations provided are identical; in this case, the BERTScore will be trivially 1. For all other examples (y, y'), we compute BERTScore(y, y'). Then, for each error category, we compute the mean BERTScore (F_1) among all examples that contain at least one of that error. Results are reported in Table 3.

We find that the average BERTScore assigned to pairs of correct translations in this dataset, 0.587, is much lower than in TQ-AutoTest, where the average BERTScore assigned to correct translations pairs was 0.815. Moreover, PE^{2}rr examples with no errors in their machine translation have a higher BERTScore assigned to their correct translations.

Testing condition (ii) with the PE^{2}rr dataset is somewhat more challenging. First, we filter out any of the machine translations that have no errors (as we need a bad translation to test condition (ii)). Normally, the next step would be to compute and compare, using our two references translations y, y' and one bad translation b, BERTScore(y, y') and BERTScore(y, b).

However, a difficulty arises: while each example has two correct translations, and one incorrect machine translation, the two correct translations are not generated in the same way. One is a post-edit of the machine translation, while the other is an original reference, generated from the German text without the machine translation.

[4]We calculate BLEU as implemented in the *multi-bleu.perl* script at https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

If we choose the original reference to be y, and the post-edit to be y', this is a fair comparison; however, if we choose the post-edit to be y, the task becomes much more challenging. This is because BERTScore(y, b) will be comparing a post-edited machine translation to the original machine translation, and there will naturally be a good deal of overlap, even though b contains errors. So, we report results in two cases in Table 4: the easy case, where y is the original reference, and the hard case, where y is the post-edit.

This choice has a major effect on the ability of BERTScore to distinguish good translations from bad ones. When we choose the original reference as y, BERTScore has a high accuracy in all categories. In contrast, in the hard problem setting, BERTScore does poorly (at or below chance) in all categories except sentences with an untranslated word, which is likely easy for BERTScore to detect.

We again compare BERTScore to BLEU to contextualize our results for condition (ii) (in Table 4). We find that once more BERTScore outperforms BLEU, which achieves accuracies below 50% in all categories in the easy setting, and below 13% in the hard setting. The disparity between the easy and hard setting performance reflects the fact that BLEU also struggles to penalize bad translations with high n-gram overlap, compared to those with less overlap.

Finally, to provide an alternate explanation for the trend in BERTScore accuracies, we plot in Figure 4 the BERTScore accuracy for examples with n errors, in both the easy and hard scenarios. While in the easy scenario, BERTScore has an accuracy near 1 for $n >= 5$, in the hard scenario, the accuracy is lower, but increases with n. This suggests that it is easier for BERTScore to distinguish between translations that are good and those that are bad, but lexically similar to the postedited reference, when the latter contain more errors. Alternatively, we can view this as BERTScore being less sensitive to translation errors (except when they are numerous), and relatively more sensitive to the stylistic differences that exist between the post-edited and original reference sentences.

5.3 Grammatical Error Correction

For GEC, we test all three conditions. To test the first, we use the 11 annotators' corrections to create post-edited versions $(y_1, \ldots, y_{11})$ of the original sentences; these should all have the same meaning. Then, we compute the mean BERTScore (F_1) for each pair of annotators' post edits; these are reported in Figure 5. The mean BERTScore falls in a very narrow range (0.84-0.88), except for Annotators 1 and 8, who provided similar annotations.

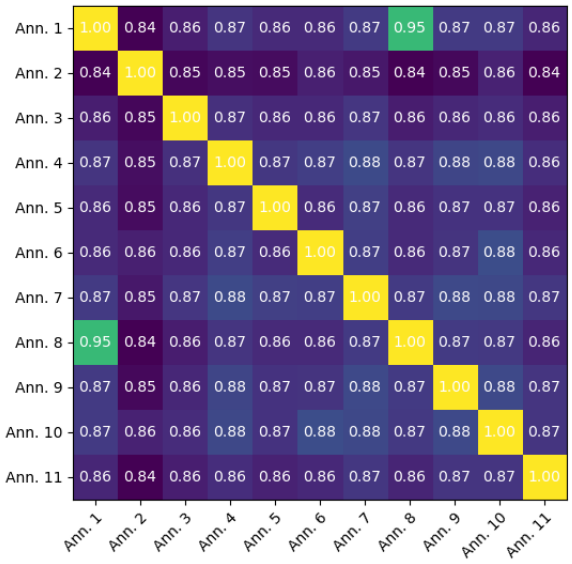

Figure 5: GEC: Heatmap of Average BERTScore (F_1) assigned when comparing references from a given pair of annotators

n: # of Errors	b_n: With Errors	b_0: Without Errors	y': Alternate Reference
1	0.841	0.850	0.865
2	0.830	0.844	0.860
3	0.820	0.839	0.856
4	0.814	0.828	0.847
5	0.812	0.821	0.842

Table 5: GEC: Average BERTScore (F_1) assigned when comparing a reference y to a) b_n, a sentence with n errors in it, b) b_0, the same sentence, but with all errors corrected, and c) y', an alternate reference sentence.

We test conditions (ii) and (iii) jointly. To do so, we need two correct translations, created independently of one another. We also need two partially correct translations (of different levels of correctness) and one correct translation; these must be created from the same set of edits, independent of the first two. To create these, we first select three annotators, and assign them roles: reference annotator, alternate reference annotator, and "error" annotator. Next, for $n = 1, \ldots, 5$, we filter out all examples where the error annotator made fewer than n error annotations. Then, for each example, the reference and alternate reference annotators' an-

notations are used to create one reference sentence (y) and alternate reference sentence (y'). The error annotator's annotations are used to create both a third, fully corrected sentence (b_0), and a sentence with n errors in it (b_n); the errors that remain are chosen at random.

Finally, we compute BERTScore(y, y'), BERTScore(y, b_0), and BERTScore(y, b_n); the mean values for each of these is reported in Table 5. Note that although b_0 and y' have no errors, their mean BERTScore still changes with n because we filter out examples that have fewer than n errors according to the error annotator. Thus, the downward trend with growing n reflects the fact that, as the number of errors in a sentence increases, the annotators' corrections diverge.

We can see that BERTScore does respect conditions (ii) and (iii) within the GEC data. The alternate reference and error-free sentence are always assigned a higher score than the sentence with errors (ii). Moreover, the sentences with more errors are assigned a lower score than those containing fewer errors (iii).

Also of note is the absolute magnitude of the BERTScores assigned in this experiment, which is much higher than those in the prior PE^{2}rr experiment. The mean BERTScore assigned to even examples containing 5 errors (0.812, Table 5), is much higher than the mean BERTScore assigned to PE^{2}rr reference pairs (0.587, Table 3). As before, we suggest that this occurs due to sensitivity to style. Although b_5 contains errors, it is stylistically similar to the reference, as they are both edits of the same sentence; in contrast, the two references in the PE^{2}rr dataset are very distinct from one another.

Finally, we perform this same evaluation with BLEU, again omitting full results for brevity. We find that BLEU, regardless of n, gives the alternate reference y' a higher score than the other sentences. However, the BLEU scores assigned to b_n and b_0 were similar, and b_0 did not consistently receive higher scores. Thus, we conclude that BERTScore also performs better on this task.

6 Discussion

From our experiments on three datasets, we draw three main findings. First, we find that the performance of BERTScore with respect to conditions (i) and (ii) can vary based on linguistic phenomena. Second, while BERTScore is generally capable, it has difficulties on a challenge dataset that tasks it with penalizing lexically similar incorrect translations and preferring translations that are lexically different but more correct. Third, BERTScore does, in certain circumstances, respect our third condition—it ranks worse bad translations below better bad translations.

With respect to the first finding, penalizing translations that incorrectly render function words seems to be the most difficult for BERTScore. In TQ-Autotest, this includes sentences with tag questions; in one example, the reference is "You're crazy, aren't you?", and secondary good translation is "You're crazy, right?", while incorrect sentences are "You're crazy, or?" and "You're crazy, are not you?". That is, the differences do not affect the main content of the sentence. In contrast, sentences with incorrectly resolved word ambiguity or larger, multi-word errors were easily penalized.

The second finding also confirms that BERTScore can more easily detect bad translations when there is less lexical overlap. In the easy problem setting, where both the good and bad candidate translations were lexically distinct from the reference, BERTScore easily distinguished the good translation from the bad. But, in the hard problem setting, where the bad translation has high lexical overlap with and was stylistically similar to the reference, BERTScore struggled. Due to this style sensitivity, BERTScore may be better-suited to scoring candidates from widely-differing systems, as opposed to closely-related systems, or multiple candidates from one system.

Our third finding, provides more positive results. In the GEC scenario, BERTScore was able to fulfill all three of the conditions we defined. It not only gave high scores to similar sentences and worse scores to sentences with errors; it also gave better scores to more grammatically correct sentences, even when they were not perfectly correct.

Unfortunately, the GEC dataset does not necessarily reflect the kinds of errors that occur in machine translation. It focuses primarily on grammatical errors, and thus contains fewer semantic errors. Moreover, since the GEC annotators had only the incorrect text, and no source text to work with, their annotations are occasionally in disagreement, as they each independently inferred the intended meaning of the incorrect text.

7 Related Work

The original paper introducing BERTScore (Zhang et al., 2020) naturally compared BERTScore's correlations with human judgments to that of other metrics. However, various other surveys of MT metrics, as well as datasets and methodologies have been conducted, offering insights into how MT system and metric performance should be measured.

Naturally, the WMT Metrics task, most recently run in 2020 (Mathur et al., 2020b) is one such forum for the evaluation of metrics. In this last iteration, metrics were evaluated based on their correlation with human judgment scores on the sentence, paragraph, and document level. BERTScore was not included even in the most recent iteration of the metrics task.

More recently, Kocmi et al. (2021) run a large-scale comparison of MT metrics, including BERTScore using a large dataset of translations with human judgments; they find that BERTScore's performance is middle-of-the-road, though better than BLEU, and recommend COMET (Rei et al., 2020) for general use.

Unfortunately, while these studies evaluate MT metrics, using human judgments alone cannot tell us when or why they may succeed or fail. In response to the results of 2019 WMT Metrics Task (Ma et al., 2019), Mathur et al. (2020a) note that correlations of metrics with human judgment can be highly sensitive to the number of systems in question, as well as outliers.

Fomicheva and Specia (2019) propose moving beyond correlation with human judgment alone as a standard for MT metric evaluation. To this end, they conduct a comprehensive study of MT metrics, and review datasets that have more fine-grained error and quality annotations. Despite this, datasets for MT metric evaluation with linguistic annotations or other annotations regarding sentence content are few.

8 Conclusion

BERTScore is a new metric for MT evaluation that uses BERT, and is as a result difficult to interpret. We define desiderata for BERTScore and other such metrics' performance, and use targeted datasets to find when BERTScore fails. We find that BERTScore fails to assign low scores when a bad candidate sentence has high lexical overlap with the reference in terms of content words. Despite this, in less challenging scenarios, BERTscore does well, and is able to rank sentences in order of their quality. Moreover, BERTScore outperforms BLEU score across the datasets and conditions we tested. However, these experiments are limited in scope, due to limited available data with appropriate annotations. Development of datasets for MT metric evaluation with linguistic annotation would aid in further work on this topic.
