Abstract

Despite the increasing number of large and comprehensive machine translation (MT) systems, evaluation of these methods in various languages has been restrained by the lack of high-quality parallel corpora as well as engagement with the people that speak these languages. In this study, we present an evaluation of state-of-the-art approaches to training and evaluating MT systems in 22 languages from the Turkic language family, most of which being extremely under-explored (Joshi et al., 2019). First, we adopt the TIL Corpus (Mirzakhalov et al., 2021) with a few key improvements to the training and the evaluation sets. Then, we train 26 bilingual baselines as well as a multi-way neural MT (MNMT) model using the corpus and perform an extensive analysis using automatic metrics as well as human evaluations. We find that the MNMT model outperforms almost all bilingual baselines in the out-of-domain test sets and finetuning the model on a downstream task of a single pair also results in a huge performance boost in both low- and high-resource scenarios. Our attentive analysis of evaluation criteria for MT models in Turkic languages also points to the necessity for further research in this direction. We release the corpus splits, test sets as well as models to the public[1].

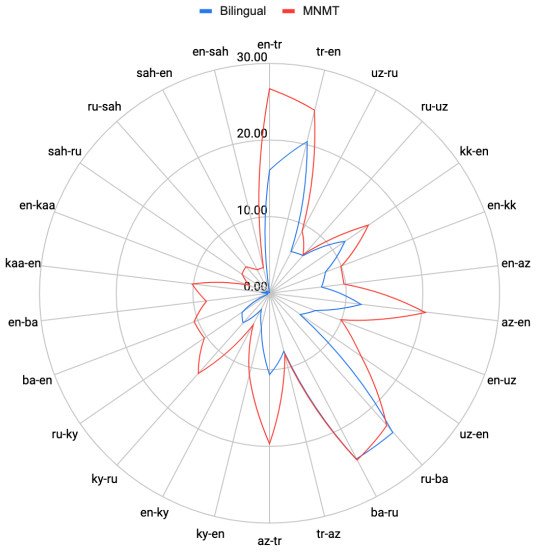

Figure 1: Performance comparison between bilingual baselines and the MNMT model on X-WMT test set.

1 Introduction

The last few years have seen encouraging advances in low-resource MT development with the increasing availability of public multilingual corpora (Agić and Vulić, 2019; Ortiz Suárez et al., 2019; Schwenk et al., 2019; El-Kishky et al., 2020; Tiedemann, 2020; Goyal et al., 2021; ∀ et al., 2020) and more inclusive multilingual MT models (Arivazhagan et al., 2019; Tiedemann and Thottingal, 2020; Fan et al., 2020). In this study, we take the Turkic language family into focus, which has not been studied at large in MT research (detailed review in Section 2). Most recently, in a wide evaluation of translation between hundreds of languages with a multilingual model (M2M-124) trained on large web-mined parallel data, translation into, from, and between Turkic languages was shown to be very challenging compared to other language families (Goyal et al., 2021). With the promise of strong transfer capabilities of multilingual models especially for related languages, we hope that the inclusion of a wider set of Turkic languages into a joint model can unlock automatic translation even for the very low-resourced Turkic languages where no prior translation models exist (Koehn, 2005; Choudhary and Jha, 2011; Post et al., 2012; Nomoto et al., 2018; Esplà-Gomis et al., 2019; ∀ et al., 2020).

To this aim, we adopt the TIL Corpus (Mirzakhalov et al., 2021) compiled by the Turkic Inter-

Table 1: (The table indicates the language codes used for the Turkic languages along with the number of L1 speakers, amount of available data (in sentences) in our corpus. The column MT? indicates if there are currently available online machine translation systems for the language. K: thousand, M: million.)

lingua[2] community (Mirzakhalov, 2021) including X-WMT test sets with a few key improvements (Section 3). We train a multi-way NMT (MNMT) model on the entire parallel corpus, which constitutes the first large-scale multilingual translation model specifically for Turkic languages (Section 4). We perform an extensive analysis of the strengths and weaknesses of this model, comparing it to the bilingual baselines and evaluating it under a domain shift. We find that the MNMT model outperforms almost all bilingual baselines in the out-of-domain tests while it performs comparably or underperforms in the in-domain tests. We further analyze its capacity for transfer learning by fine-tuning the model on several language pairs all of which experience gains, both in- and out-of-domain scenarios. In addition, we complement the automatic evaluation with a human evaluation study for multiple languages (Section 5), gaining insights into types of common mistakes that the model makes and the suitability of different automatic metrics for Turkic languages. We plan on releasing the improved corpus, evaluation sets, and all the models to the public.

This work will not only enrich the landscape of languages currently considered in MT research and spur future research on NLP for Turkic languages but will hopefully also inspire the building of new translation engines and derived technologies for populations with millions of native speakers (Table 1).

2 Related Work

This section discusses the previous work on MT of these languages including the available corpora and languages resources. The 19 Turkic languages covered in the study are: Altai, Azerbaijani, Bashkir, Crimean Tatar, Chuvash, Gagauz, Karachay-Balkar, Karakalpak, Khakas, Kazakh, Kumyk, Kyrgyz, Sakha, Turkmen, Turkish, Tatar, Tuvan, Uyghur, and Uzbek. There are several other widely spoken languages that are left out from our study such as Shor, Salar, Urum, Nogai, Khorasani Turkic, Qashqai, and Khalaj, due to the lack (or very limited amount) of any available parallel corpora. Future work will focus on extending the corpus to these languages as well.

2.1 MT of Turkic Languages

The need for more comprehensive and diverse multilingual parallel corpora has sped up the creation of such large-scale resources for many language families and linguistic regions (Koehn, 2005; Choudhary and Jha, 2011; Post et al., 2012; Nomoto et al., 2018; Esplà-Gomis et al., 2019; ∀ et al., 2020). Tiedemann (2020) released a large-scale corpus for over 500 languages covering thousands of translation directions. The corpus currently includes 14 Turkic languages and provides bilingual baselines for all translation directions present in the corpus. However, most of the 14 Turkic languages contain a few hundred or a dozen samples. In addition, the varying and limited size of the test sets does not allow for the extensive analysis and comparisons between different model artifacts, linguistic features, and translation domains. More recently, Goyal et al. (2021) extended the previous Flores benchmark by providing human translated evaluation sets for 101 languages, among which 5 of them are from the Turkic family: Azerbaijani, Kazakh, Kyrgyz, Turkish, and Uzbek. Similarly, they train a large MNMT model and evaluate its performance

[2] https://turkicinterlingua.org/

using the benchmark.

A Russian-Turkic parallel corpus was curated for 6 different Turkic languages, and their bilingual baselines have been reported for both directions using different NMT-based approaches Khusainov et al. (2020). However, the dataset, test sets, and models are not released to the public which limits its use to serve as a comparable benchmark. Additionally, a rule-based MT framework for Turkic languages has been presented with 4 language pairs Alkım and Çebi (2019). Also, several rule-based MT systems have been built for Turkic languages which are publicly available through the Apertium[3] website Washington et al. (2019).

For individual languages in our corpus, there are several proposed MT systems and linguistic resources: Azerbaijani (Hamzaoglu, 1993; Fatullayev et al., 2008), Bashkir (Tyers et al., 2012), Crimean Tatar (Gökırmak et al., 2019; Altıntaş, 2001), Karakalpak (Kadirov, 2015), Kazakh (Assylbekov and Nurkas, 2014; Sundetova et al., 2015; Littell et al., 2019; Briakou and Carpuat, 2019; Tukeyev et al., 2019), Kyrgyz (Çetin and Ismailova), Sakha (Ivanova et al., 2019), Turkmen (Tantuğ and Adalı, 2018), Turkish (Turhan, 1997; El-Kahlout and Oflazer, 2006; Bisazza and Federico, 2009; Tantuğ et al., 2011; Ataman et al., 2017), Tatar (Salimzyanov et al., 2013; Khusainov et al., 2018; Valeev et al., 2019; Gökırmak et al., 2019), Tuvan (Killackey, 2013), Uyghur (Mahsut et al., 2004; Nimaiti and Izumi, 2012; Song and Dai, 2015; Wang et al., 2020), and Uzbek (Axmedova et al., 2019). Yet to our knowledge, there has not been a study that covers Turkic languages to such a large extent as ours, both in terms of multilingual parallel corpora and multiway NMT benchmarks across these languages.

3 TIL Corpus

As we adopt the TIL Corpus as the training data, we perform a few key modifications to better the quality of the datasets.

First, we notice that the alignments for the Bible[4] and TedTalks[5] datasets were not optimal as most "sentences" were actually comprised of multiple sentences in order to preserve the quality of the alignment with target sequence. For example, in the case of TedTalks, the original speech utterance may have been 2-3 sentences in text but the translation of that speech may end up differing by 1 or even more sentences depending on the translator. Common practice in this situation, as seen through multiple corpora across OPUS[6], is to leave the entire utterance as is to preserve the quality of the alignment even if the number of sentences do not match. Instead, we drop the examples where the total number of sentences do not match and split (and realign) the cases where they do. This naturally increased the overall number of sentence alignments in both the Bible and TedTalks corpora for all language pairs.

Second, we perform a corpus-wide length and length-ration filtering where we drop sentence pairs that are single words as well as the entries where source and target ratio is over 2.

Third, we re-curate the in-domain evaluation sets following the improvements to the corpus. Details on the evaluation sets are described further in Section 3.1.

3.1 Curation of evaluation sets

The original TIL Corpus introduced three evaluation sets with different domains (Bible, TedTalks, and X-WMT). To simplify the analysis of the models, we re-curate the in-domain evaluation sets by randomly sampling from each corpora. X-WMT is used as the out-of-domain test set since it is from the news domain with substantial amount of new words/terms that most of the language pairs lack. The curation steps for the test sets are presented below.

3.1.1 In-domain Evaluation Sets

In-domain development and test sets are randomly sampled from each language pair and can serve as evaluation sets for both bilingual and multilingual models. The size of the development and test sets depends on the amount of training data available. More specifically, development and test sizes are 5k each if the train size is over 1 million parallel sentences, 2.5k if over 100k, 1k if over 10k, and 500 if over 2.5k. All test and development samples are removed from the training corpus for that language pair. Overall, this yields development and test sets for exactly 400 language pairs.

Table 2: X-WMT test sets. Bolded entries indicate the original translation direction.

3.1.2 X-WMT Test Set

X-WMT is a challenging and human-translated test set in the news domain based on the professionally translated test sets in English-Russian from the WMT 2020 Shared Task (Mathur et al., 2020). It was originally introduced in the TIL Corpus and we adopt the test sets as they are. Currently, the test set extends into 8 Turkic languages (Bashkir, Uzbek, Turkish, Kazakh, Kyrgyz, Azerbaijani, Karakalpak, and Sakha) paired with English and Russian. Table 2 highlights the currently available test set directions. Bolded entries in the table indicate the original direction of the translation.

4 Experimental Setup

4.1 Bilingual Experiments

To serve as initial baselines, we train 26 bilingual baselines using the corpus and report the performance on the in-domain test set as well as the X-WMT set (out-of-domain) as described in Section 3.1.2. The selection of the language pairs was constricted by the availability of both in-domain and out-of-domain test sets to enable more meaningful insights from the experiments.

4.1.1 Model details

All models are Transformers (*transformer-base*) (Vaswani et al., 2017b) and are trained using the JoeyNMT framework (Kreutzer et al., 2019). In the preprocessing stage, we use Sacremoses for tokenization and apply byte pair encoding (BPE) (Sennrich et al., 2015; Dong et al., 2015) with a joint vocabulary size of 4k and 32k. Models use 512-dimensional word embeddings and hidden layers and are trained with the Adam optimizer (Kingma and Ba, 2015). A learning rate of $3{*}10^{-4}$ is applied along with a dropout rate of 0.3. We use a batch size of 4096 BPE tokens with 8 accumulations to simulate training on 8 GPU machines. All models, except English-Turkish and Turkish-English, are trained on Google Colab's freely availably preemptible GPUs.

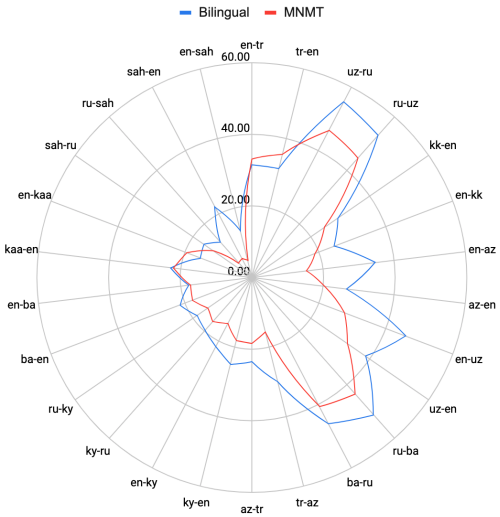

Figure 2: Performance comparison between bilingual baselines and the MNMT model on the in-domain test set.

4.2 Multilingual Experiments

To examine the extent of transfer learning and generalization within our corpus, we train a multiway multilingual NMT model on the entire dataset covering almost 400 language directions. We then compare the performance of the model on the in-domain and out-of-domain test sets across a range of language pairs.

4.2.1 Data Preprocessing

Similar to the bilingual data preprocessing, the entire corpus has been tokenized using Sacremoses[7] and samples longer than 300 words have been filtered out. In addition, we perform cross-filtering of test and dev sets of all language pairs from the training corpus, as it is very necessary to do so in any MNMT model using a multiway corpus. Since the corpus is relatively unbalanced, we perform a temperature-based sampling with a value of 1.25. Although a higher temperature value between 2 and 3 would further balance our corpus, it would increase the dataset size by 8x with t=2 and 25x with t=3. This increase would limit our ability to train the model due to the restrained compute resources. Originally, the overall training set size is at around 133 million samples and this increases to 244 million after the sampling procedure. We ap-

Table 3: Experiments results from bilingual baselines and MNMT model evaluated on the in-domain and out-of-domain test sets. *BLEU* and *Chrf* uses the SacreBLEU implementation and *PPL* refers to the internal perplexity of the MNMT model.

ply the sentencepiece[8] implementation of the byte pair encoding (BPE) (Sennrich et al., 2016) with a joint vocabulary size of 64k. Following the method from Ha et al. (2016) and Johnson et al. (2017), we prepend a target language token to the source sentences to enable many-to-many translation.

4.2.2 Model details

We train the model using the Transformer architecture in the *transformer-base* configuration. More specifically, we use the *transformer_wmt_en_de* version from Fairseq (Ott et al., 2019) implementation[9] with 6 layers both in the encoder and decoder. Configuration of the model closely follows the original implementation of the Transformer (Vaswani et al., 2017a) with the model dimension set at 512 and hidden dimension size at 2048. We apply a dropout rate of 0.3, the learning rate of $5 * 10^{-4}$, and warm-up updates of 40k. The effective batch size is 16,384 BPE tokens. The model is trained using 4 NVIDIA V100 GPU machines for a little over 1 million steps which takes about 36-48 hours.

4.3 Evaluation of Models

Automatic evaluation metrics used to compare the performance of bilingual baselines and MNMT are token-based corpus BLEU (Papineni et al., 2002) and character-based Chrf (Popović, 2015). While corpus BLEU is the de-facto standard in MT (Marie et al., 2021), Chrf might work better for morphologically rich languages because it can reward partially correct words. We also report the MNMT model's internal perplexity to better highlight the language pairs in which the model struggles most. We evaluate the models on the in-domain and X-WMT evaluation sets. The gap between scores on in-domain

	Bilingual		MNMT		Gain	
	BLEU	**Chrf**	**BLEU**	**Chrf**	**BLEU**	**Chrf**
XX-En	6.92	0.31	13.78	0.42	+6.86	+0.11
En-XX	4.57	0.30	9.37	0.36	+4.80	+0.06
XX-Ru	9.03	0.36	13.06	0.41	+4.03	+0.06
Ru-XX	8.86	0.38	11.21	0.40	+2.35	+0.02
XX-XX	8.99	0.38	12.49	0.41	+3.49	+0.04

Table 4: Performance comparison with different language groups and their overall gains in the MNMT setup. XX refers to the Turkic languages in the corpus.

	Adequacy				Fluency			
	Avg	**k**	**LL**	**UL**	**Avg**	**k**	**LL**	**UL**
en-tr	2.97	0.33	0.23	0.43	3.20	0.12	0.04	0.21
tr-en	2.95	0.45	0.36	0.55	3.18	0.40	0.30	0.50
en-uz	2.77	0.18	0.10	0.26	2.93	0.28	0.17	0.38
uz-en	3.05	0.28	0.20	0.37	3.19	0.29	0.18	0.39
ba-ru	2.74	0.58	0.48	0.67	3.34	0.63	0.54	0.73
ru-ba	2.81	0.27	0.17	0.37	3.06	0.19	0.09	0.29

Table 5: **Avg** represents the average score for either Adequacy or Fluency given by the annotators for each language pair. **k** represents the Cohen's Kappa score. **LL** represents the Lower Limit within 95% confidence. **UL** represents the Upper Limit within 95% confidence.

versus out-of-domain translations is particularly interesting since it gives us an estimate of domain robustness and generalization, as well as mimics a realistic shift from the training domain to the domain of interest for potential users or downstream applications.

4.4 Bilingual baselines vs MNMT

Table 3 shows all the results for the bilingual baselines and MNMT as evaluated on two test tests. The first obvious trend in the table is the dominance of the bilingual baselines on the in-domain test sets as they overperform the MNMT model in most of the high- to mid-resource language pairs. As the train size decreases, the results become more comparable in terms of BLEU and even better for MNMT when evaluated in Chrf. When tested under a domain shift with the X-WMT set, MNMT results in gains across almost all pairs. However, it is important to note that there is a noticeable performance drop that follows the domain shift as can be seen in Figures 1 and 2. This highlights a realistic phenomenon of generalization and sets an expectation of the model's capabilities in real-world use cases.

Another observation in Table 3 is that all of the language pairs having fewer than 100k training samples (8 total) in our bilingual baselines barely pass the mark of 1 BLEU score or 0.2 Chrf in the out-of-domain test. However, in the MNMT setup, the average BLEU and Chrf score for those 8 low-resource pairs are 5.98 and 0.27 respectively. While these scores indicate that these pairs are still extremely low in quality and potentially unusable in practice, gains are promising given the amount of resources and a moderately-sized MNMT model.

To examine the generalization of the MNMT model into different language groups, we calculate the average gains for all pairs translating into English (XX-En), from English (En-XX), into Russian (XX-Ru), from Russian (Ru-XX), and direct pairs (XX-XX). Table 4 shows the average gains per category in terms of BLEU and Chrf. As it looks, translating from and into English sees the most gains, which is very consistent with the findings from the community (Arivazhagan et al., 2019; Goyal et al., 2021). A positive trend is the increasing quality of direct pairs which are very comparable to the non-Turkic pairs. We hypothesize that one of the main reasons for this is that the TIL Corpus is a multi-centric dataset with training data between almost all language pairs which allows us to train a complete Multilingual Neural Machine Translation (cMNMT) (Freitag and Firat, 2020). As shown in (Freitag and Firat, 2020; Fan et al., 2021), MNMT models trained on multi-centric parallel corpora tend to result in performance gains between non-English pairs.

4.5 BLEU vs Chrf

Figure 3 compares BLEU and Chrf for all bilingual and multilingual models on X-WMT. We distinguish between translating into and from Turkic languages since all Turkic languages feature agglutination. As hinted above, we suspect that BLEU might underestimate translation quality when translating into Turkic languages. The graph shows a clear distinction that confirms this: For translations into non-Turkic languages, the relation between Chrf and BLEU is almost linear, with a Pearson correlation of 0.98 and a rank correlation of 0.98 as well. For translation into Turkic, the trend follows a more curved line, with a largely higher Chrf-to-BLEU ratio. The Pearson correlation is much lower at 0.87, but the rank correlation is only slightly lower than for non-Turkic languages at 0.92. Consequently, we can expect the same BLEU score to correspond to a higher Chrf score when translating into Turkic languages than from them. This means that while Chrf and BLEU are likely to pro-

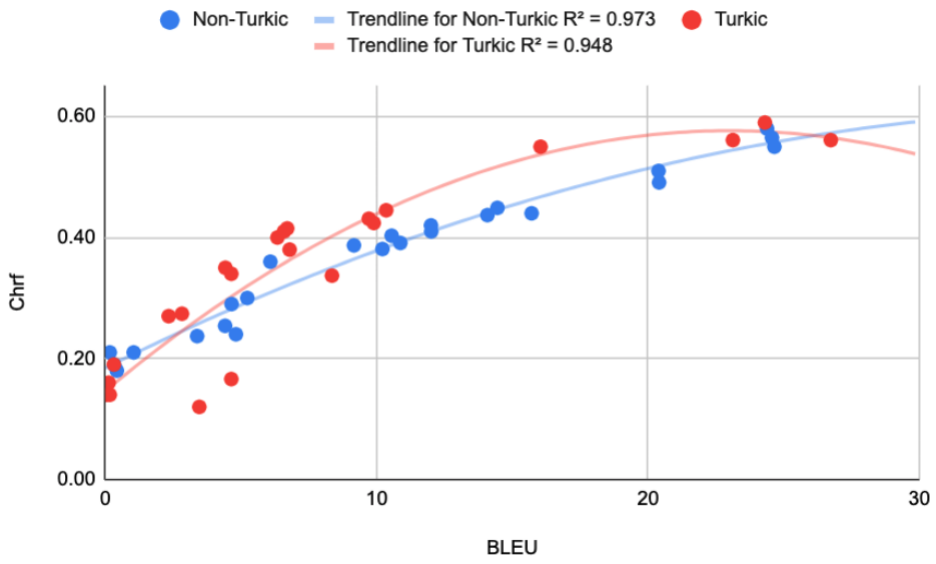

Figure 3: Correlations between BLEU and Chrf scores when the target language is Turkic and non-Turkic.

duce similar rankings of systems (at least in our scenario with standard comparable Transformer models), the Chrf score might better characterize the absolute translation quality. Our human evaluation does not cover sufficient language pairs (three from and three into Turkic languages) to yield a reliable empirical confirmation for this hypothesis. Future studies of larger scale as in the WMT metrics shared task (Mathur et al., 2020) will be needed.

5 Human Evaluation of MNMT

5.1 Human evaluation setup

To facilitate analysis on how well evaluation metrics measure the quality of the translations, we conduct human evaluations using the outputs from the MNMT model on the X-WMT set. We use Direct Assessment (DA) and follow the TAUS guidelines[10] with the only exception being the number of annotators per language pair, where we employ 2 annotators per language pair instead of 4[11]. In our DA, two hundred sentences of the MNMT model's output per language pair are evaluated based on its adequacy and fluency on respective 1-4 point scales. Annotators received an explanation of the rating scales with the task (e.g. "Adequacy: On a 4-point scale rate how much of the meaning is represented in the translation: 4: Everything 3: Most 2: Little 1: None"). To measure the inter-annotator agreement (IAA) between the two annotators of each language pair, we compute the Weighted Cohen's Kappa statistic (Cohen, 1960).

The language pairs involved in this human study are English-Turkish, Turkish-English, Bashkir-Russian, Russian-Bashkir, Uzbek-English, and English-Uzbek. These pairs were selected on the basis of language and script diversity, their performance on the X-WMT test set, and the availability of annotators.

5.2 Discussion and Results

The results of the average adequacy and fluency for each language pair are shown by Table 5. Most of the chosen language pairs received an average score of around 3 for both adequacy and fluency. This indicates that the model was largely able to convey most intended meaning in a good grammatical sense to a native speaker. Fluency is consistently rated higher than adequacy, which is a common theme in NMT evaluation (Martindale et al., 2019). The large difference in BLEU (5 BLEU points) between en-uz and uz-en is still noticeable, but much smaller according to the human evaluation. Chrf estimates a quality difference of 0.3 here, which is closer to the human estimate.

The Cohen's Kappa scores for each language pair are present in Table 5. As Cohen's Kappa is a measure from 0–1 of how well the two annotators agreed with their evaluations while removing possible agreements by chance, Cohen's Kappa score serves as one metric in deciding the reliability of

Table 7: Experiment results from the finetuning of the MNMT model.

the evaluations. We see that the reliability varies across language pairs and between adequacy and fluency. Translation into English or Russian has a higher agreement on average than in the opposite direction (en/tr is a tie).

5.3 Qualitative Analysis

To gain better qualitative insight into the model outputs in each of the 6 language directions, we asked the annotators to identify 2 examples that highlight the most commonly witnessed mistakes during their review. Table 6 showcases those examples along with a brief explanation for their scores. From this analysis, it seems that the severity of mistakes that the MNMT model makes in *adequacy* tends to range from certain words being translated to a slightly different meaning to the original intention of the sentence being lost. As for *fluency*, the errors seem to range from awkward wording to clear grammatical mistakes. There are a few cases where there is an off-target translation for a word or a segment of the sentence.

6 The Promise of MNMT: Cross-lingual Knowledge Transfer

One of the biggest advantages of a large MNMT model is its capacity for transfer learning as can be accomplished through fine-tuning. Since we plan on releasing the model to the public, we believe many understudied and underperforming language pairs could benefit from cross-lingual knowledge transfer. This phenomenon is well-known in the broader NLP community as well as in MT research. To test this hypothesis, we fine-tune our MNMT model on 4 language pairs ranging from high(er)-resource to extremely low-resource in training data available. Table 7 shows the results of the experiments. As it can be seen, the performance of the models improves steadily across all resource types, low-resource cases experiencing gains up to 44 BLEU points (or 0.4 Chrf) from the bilingual baselines in the in-domain evaluation. However, in out-of-domain scenarios, gains are not as significant. Mid- to high-resource pairs improve modestly in the range of 1–5 BLEU points (or 0–0.1 Chrf) while a low-resource pair, Russian-Sakha gains up to 22 BLEU points (0.19 Chrf).

7 Future Work and Conclusion

In this work, we train and evaluate the first large-scale MNMT model for the Turkic language family which consists of many underexplored languages. Among many results, we find it very promising to train and finetune a MNMT model with a language family corpus as it boosts the cross-lingual knowledge transfer between the related languages and consistently improves over the strong bilingual baselines in out-of-domain scenarios. Our analysis also shows that Chrf and BLEU do not correlate in the same when the target language group if different: BLEU underestimates the translations for the Turkic languages.

In the future work, we hope to include more of the underrepresented Turkic language pairs in the study and explore the potential of transfer learning into the translation of unseen languages and language pairs (”zero-shot”).

Acknowledgements

We thanks all of the members and partners of the Turkic Interlingua (TIL) community for their contributions to the project. Namely, we would like to thank our dedicated translators and annotators: Nurlan Maharramli, Sariya Kagarmanova, Iskander Shakirov, Aydos Muxammadiyarov, Ziyodabonu Qobiljon qizi, Alperen Cantez, Doniyorbek Rafikjonov, Mukhammadbektosh Khaydarov, Madina Zokirjonova, Erkinbek Vokhabov, Petr Popov, Abilxayr Zholdybai and Akylbek Khamitov. We also acknowledge and appreciate significant dataset contributions from Rasul Karimov, Khan Academy O’zbek[12], and the Foundation for the Preservation and Development of the Bashkir Language[13].

Extending Challenge Sets to Uncover Gender Bias in Machine Translation Impact of Stereotypical Verbs and Adjectives

Abstract

Human gender bias is reflected in language and text production. Because state-of-the-art machine translation (MT) systems are trained on large corpora of text, mostly generated by humans, gender bias can also be found in MT. For instance when occupations are translated from a language like English, which mostly uses gender neutral words, to a language like German, which mostly uses a feminine and a masculine version for an occupation, a decision must be made by the MT System. Recent research showed that MT systems are biased towards stereotypical translation of occupations. In 2019 the first, and so far only, challenge set, explicitly designed to measure the extent of gender bias in MT systems has been published. In this set measurement of gender bias is solely based on the translation of occupations. With our paper we present an extension of this challenge set, called *WiBeMT*[1], which adds gender-biased adjectives and sentences with gender-biased verbs. The resulting challenge set consists of over $70,000$ sentences and has been translated with three commercial MT systems: DeepL Translator, Microsoft Translator, and Google Translate. Results show a gender bias for all three MT systems. This gender bias is to a great extent significantly influenced by adjectives and to a lesser extent by verbs.

1 Introduction

The problem of unfair and biased models has been recognized as an important problem for many applications of machine learning (Mehrabi et al., 2019). The source of unfairness typically is based on biases in the training data. In many domains, unfairness is caused by sampling biases. In machine translation (MT), however, the main source of unfairness is due to historical or social biases when there is a misalignment between the world as it is and the values or objectives to be encoded and propagated in a model (Suresh and Guttag, 2019; Bolukbasi et al., 2016). One source of imbalance in natural language is the association of specific occupations with gender. Typically, occupations in more technical domains as well as occupations with high social status are associated with male gender (Cheryan et al., 2017).

In natural language processing (NLP), gender bias has been investigated for word embeddings (Bolukbasi et al., 2016). Analogy puzzles such as "man is to king as woman is to x" generated with *word2vec*[2] yield $x = queen$ while for "man is to computer programmer as woman is to x", the output is $x = homemaker$. Only few publications exist that directly address gender bias and MT. Although gender bias is particularly relevant for translations into gender-inflected languages, for instance from English to German, where biased models can result in translation errors (Saunders and Byrne, 2020). For the English sentence "The doctor told the nurse that she had been busy.", a human translator would resolve the co-reference of 'she' to the doctor, correctly translating it to 'die Ärztin'. However, a neural machine translation model (NMT) trained on a biased dataset, in which most doctors are male might incorrectly default to the masculine form, 'der Arzt'. Hovy et al. (2020) investigated the prediction of age and gender of a text's author before and after translation. They found that *Bing Translator*, *DeepL Translator*, and *Google Translate* all skew the predictions to be older and more masculine, which shows that NMT systems and the expression of gender interact.

According to Saunders and Byrne (2020), the first systematic analysis of gender bias in MT is from Stanovsky et al. (2019). They introduce *WinoMT* which is the first challenge set explicitly designed to quantify gender bias in MT sys-

November 10–11, 2021.

tems. Furthermore, they introduce an automatic evaluation method for eight different languages. Evaluating six MT systems, they found a strong preference for masculine translations in all eight gender-inflected languages. The above example sentence, where 'doctor' has been errouneously translated into its male German form (*Arzt*) is one of the $3,888$ sentences used in *WinoMT*.

WinoMT focuses solely on the translation of occupations to evaluate gender bias. In this paper, we present the extended data set *WiBeMT* to uncover gender bias in neural machine translation systems. Gender stereotypical occupations are augmented by gender stereotypical adjectives and verbs and we investigate how congruent and incongruent combinations impact translation accuracy of the NMT systems DeepL, Microsoft Translator and Google Translate. In the next section, the original *WinoMT* data set is introduced together with our extensions. Afterwards, results for the three NMT systems based on 70,686 sentences are presented, followed by a discussion and an outlook.

2 Constructing the Extended Challenge Set WiBeMT

To construct a more diverse challenge set, we extend *WinoMT*, respectively its core data base *WinoBias*. Therefore, we identify verbs and adjectives of high stereotypicality with respect to gender. A gender score is determined by the cosine similarity of these words to a list of gender specific words. To calculate the similarity different pretrained word embeddings are used, where each of these words is represented by a vector. With the resulting most feminine and masculine adjectives the original sentences of *WinoBias* are extended. Furthermore, new sentences are created combining occupations with gender stereotypical verbs.

2.1 WinoBias and its Extension

WinoMT is based on two previous challenge sets, *Winogender* (Rudinger et al., 2018) and *WinoBias* (Zhao et al., 2018). Both were introduced to quantify gender bias in co-reference resolution systems. Since *WinoBias* constitutes 81.5% of *WinoMT*, we use it as basis for our extension. In total *WinoBias* consists of $3,168$ sentences, of which $1,582$ are feminine and $1,586$ are masculine sentences. The sentences are based on 40 occupations. An example sentence of *WinoBias* involving a cleaner and a developer is:

- WinoBias sentence: *The cleaner hates the* ***developer*** *because* ***she*** *always leaves the room dirty.*
- DeepL translation: *Die Reinigungskraft hasst* ***den Entwickler****, weil* ***sie*** *das Zimmer immer schmutzig hinterlässt.*

DeepL fails to correctly translate **developer** to the female inflection **die Entwicklerin**, but instead favors the stereotypical male inflection **der Entwickler**.

The *WinoBias* set is constructed such that each sentence is given in a stereotypical and an anti-stereotypical version. Stereotypical in this context means that the gender of the pronoun matches the predominant gender in the sentences occupation. The example sentence above is the anti-stereotypical version for the occupational noun 'developer', where the stereotypical version contains a 'he' instead of a 'she'.

We argue that a measurement of gender bias solely based on the translation of occupational nouns does not do justice to the complexity of language. Therefore, we want to diversify the given approach by taking gender-stereotypical adjectives and verbs into account. This is realized in two steps: First, *WinoBias* sentences are extended such that each occupational noun is preceded with an adjective which is congruent or incongruent with respect to the gender stereotypical interpretation of the occupation. For instance, a developer might be *eminent* (male) or *brunette* (female). By adding feminine and masculine adjectives to each WinoBias sentence, we create a new subset of extended WinoBias sentences.

Second, we create completely new sentences based on feminine and masculine verbs. One example with a feminine verb being: "The X **dances** in the club", and one with a masculine verb: "The X **boasts** about the new car.". Those base sentences are then extended with 99 occupations from Zhao et al. (2018), Rudinger et al. (2018), and Garg et al. (2018), resulting in a new subset of verb sentences. All 100 occupational nouns used in *WinoBias* and in the new verb sentences are listed in Table 1 which is based on numbers from the US Bureau of Labor Statistics[3]. After concatenating both subsets, the complete extended gender-bias challenge set consists of $70,686$ sentences. Overall, 100 occupa-

tions are used in the set, 42 gender-verbs, and 20 gender-adjectives.

We hypothesize that gender-stereotypical verbs and adjectives influence the gender of the translation of the occupational nouns, when translating from English to the gender-inflected language German:

Hypothesis 1

1 Sentences with a feminine verb result in significantly more translations into the female inflection of an occupation than sentences with a masculine verb.

Hypotheses 2

2a WinoBias sentences extended with a feminine adjective result in significantly more translations into the female inflection of an occupation than original WinoBias sentences (without a preceded adjective).

2b WinoBias sentences extended with a masculine adjective result in significantly more translations into the masculine inflection of an occupation than original WinoBias sentences (without a preceded adjective).

2.2 Finding Gender-Stereotypical Verbs and Adjectives

To determine gender-stereotypicality of adjectives and verbs, large collections of these word types have been scored with respect to their similarity to a list of gender specific words given by Bolukbasi et al. (2016). As input we used a list of 3.250 verbs from patternbasedwriting.com[4] and a combined list of 4.889 adjectives from patternbasedwriting.com and from Garg et al. (2018).

Calculation of gender score is based on word embeddings and the cosine-similarity, following the work of Bolukbasi et al. (2016) and Garg et al. (2018). In their work similarity of the words to the pronouns "she" and "he" has been used. We extended scoring using a longer list of feminine and masculine words such as "mother", "uncle", "menopause" or "semen" to enhance robustness of the gender-score. This list, containing 95 feminine and 108 masculine words, is taken from Bolukbasi et al. (2016), who used it for their debiasing methods of word embeddings.

Two families of *word embeddings* were used: two pre-trained versions of *fastText*[5] from Mikolov et al. (2017) and two pre-trained versions of *GloVe*[6] from Pennington et al. (2014). All four word embeddings have a vector size of 300 dimensions.

UMBC News	3.2	—	—	—
Common Crawl	—	630	—	840

Table 2 gives an overview of all word embeddings and their training data.

Cosine Similarity is a measure of similarity between two normalized and non-zero vectors and can take values in the range between -1 and 1. Equation 1 shows the calculation of the cosine similarity between the vectors $\mathbf{a}$ and $\mathbf{b}$ of two words:

$$\cos(\theta) = \frac{\mathbf{a} \cdot \mathbf{b}}{\|\mathbf{a}\|\|\mathbf{b}\|} = \frac{\sum_{i=1}^{n} a_i b_i}{\sqrt{\sum_{i=1}^{n} a_i^2}\sqrt{\sum_{i=1}^{n} b_i^2}} \quad (1)$$

where a_i and b_i are components of vector $\mathbf{a}$ and $\mathbf{b}$ respectively.

Since word embeddings inherit to some extend the meaning of words, it is possible to use the cosine similarity as a measure for the similarity in meaning or, furthermore, the relationships between words. This enables mathematical operations on the vectors representing words such that: $cos(\overrightarrow{brunette} \cdot \overrightarrow{her}) \geq cos(\overrightarrow{brunette} \cdot \overrightarrow{him})$ becomes true for "brunette" and other gender-biased adjectives. If the feminine-gender value ($cos(\overrightarrow{brunette} \cdot \overrightarrow{her})$) is then subtracted from the masculine-gender value ($cos(\overrightarrow{brunette} \cdot \overrightarrow{him})$) the resulting single float value indicates whether a word is gender-biased in the word embedding with which the cosine-similarity was computed.

The total gender-score is the sum of eight single scores resulting from the combination of the four different word embeddings with the cosine similarity with "she" and "he" and with the list of feminine and masculine words. Since different word embeddings vary in the strength of the inherited gender-bias and all word embeddings should have equal impact on the overall score, the interim results were normalized to fit a range between $a = -1$ and $b = 1$, as Equation 2 shows:

$$x' = a + \frac{(x - \min(x))(b - a)}{\max(x) - \min(x)} \quad (2)$$

To validate the procedure to determine a gender score for adjectives and verbs, the same method has been applied to the occupations given in Table 1. The gender-score for these occupations shows a strong correlation to the percentage of women working in each given occupation (see Figure 1).

Gender-score has been calculated for all verbs and adjectives for which word embeddings existed. They were sorted ascending from the most negative – and therefore most feminine – score value, to the most positive, i.e., most masculine, value.

Verbs: Of the $3,250$ *verbs*, $3,210$ could be ranked ($med = 0.151$, $std = 0.165$). After sorting the verbs by their gender-score, the most stereotypical verbs which could be used in a sentence in which person P actively does action A were picked. The gender score of the 21 selected feminine verbs ranges from -0.772 to -0.233 and of the masculine verbs from 0.445 to 0.733:

- Feminine verbs: crochet, sew, accessorize, bake, embroider, primp, gossip, shriek, dance, undress, milk, giggle, marry, knit, twirl, wed, flirt, allure, shower, seduce, kiss.
- Masculine verbs: draft, tackle, swagger, trade, brawl, reckon, preach, sanction, build, boast, gamble, succeed, regard, retire, chuck, overthrow, rev, resign, apprehend, appoint, fool.

Adjectives: Of the $5,441$ *adjectives*, $4,762$ could be ranked ($med = 0.189$, $std = 0.142$). After calculating the gender-score for the $4,762$ adjectives, beginning with the most feminine, respectively, most masculine, adjectives were tested for their suitability considering the extension of existing WinoBias sentences until 10 most feminine and suitable as well as 10 most masculine and

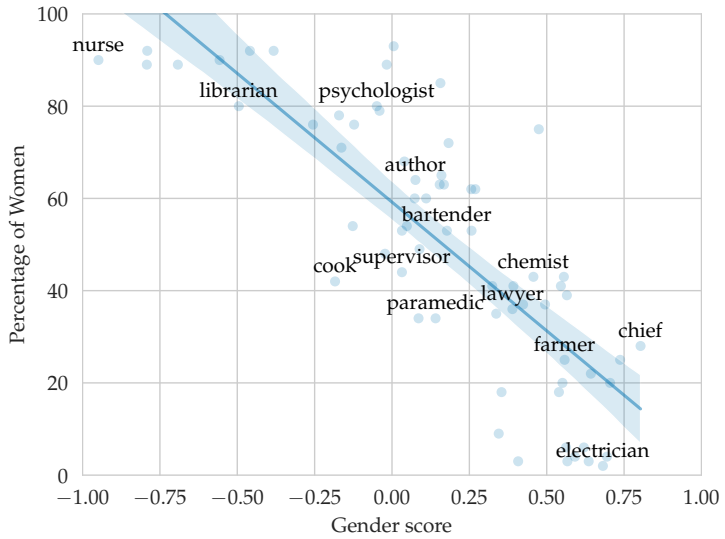

Figure 1: Scatter plot of the 99 single word occupations with the percentage of women in the profession y-axis and the gender score on the x-axis.

suitable adjectives had been selected. Words that semantically could not be combined with occupations were discarded (examples: hormonal, satin, luminous, philosophical, topographical). Furthermore, adjectives like "pregnant" – which only apply to persons with a uterus – were also discarded. The gender score of the 10 selected feminine adjectives ranges from -0.600 to -0.205 and of the masculine adjectives from 0.480 to 0.654:

- Feminine adjectives: sassy, perky, brunette, blonde, lovely, vivacious, saucy, bubbly, alluring, married.
- Masculine adjectives: grizzled, affable, jovial, suave, debonair, wiry, rascally, arrogant, shifty, eminent.

2.3 Translation of *WiBeMT* and Evaluation Design

To test the extent to which machine translation systems inherit a gender-bias, three different services were tested with *WiBeMT*: *Google Translate*, *Microsoft Translator*, and *DeepL Translator*. All three NMT systems were accessed via their API, and all translation processes took place in July 2020.

To test our hypotheses that adjectives and verbs significantly influence the gender in translations of NMT systems, translations from English to German have to be categorized as either (correctly) feminine, masculine, neutral, or wrong. Stanovsky et al. (2019) use an automated method in the form of different morphological analyzers such as *spaCy* to determine the gender of the occupation in the translated sentence. While this method is convenient for an automated approach that other researchers can use with different data, it also suffers from a certain degree of inaccuracy. To measure the accuracy of their automated evaluation method, Stanovsky et al. (2019) compared the automated evaluations with a random sample of samples evaluated by native speakers. They found an average agreement of 87% between automated and native speaker evaluations. To evaluate NMT systems with respect to *WiBeMT*, we preferred to augment automated evaluation by "manual" evaluation to gain higher accuracy.

Evaluating the gender of all translations is based on a nested list, we refer to as *classification-list*, and a set of rules for automated evaluation and manual evaluation for all remaining ambiguous translations. The classification-list contains four sublists for each occupation: a sublist of correct feminine translations, a sublist of correct masculine translations, a sublist of correct neutral translations, and a sublist of inconclusive or wrong translations. The gender of the translated occupation is then classified by checking in which sublist the occupation is listed and the gender is labeled as the sublist's category.

To control classifications for possible errors, $N = 665$ (1%) of the WinoBias sentences extended by adjectives were manually controlled for

each translation system (in total $N = 1,995$ sentences). Not a single one was miscategorized. Of the verb-sentences translations, even 5% were manually controlled by the authors, and here also, not a single one of the 618 translations was miscategorized.

3 Results

After the creation of the *WiBeMT* challenge set and the translation of all $70,686$ sentences with each NMT system, the translations were categorized as *feminine*, *masculine*, *neutral*, or *inconclusive / wrong*. The latter will be referred to as "wrong". Due to these discrete categories the Chi^2 test of independence will be used for all statistical tests. As the extended *WinoBias* sentences include a pronoun that defines the gender, the results considering these data can be divided into *true* and *false*, and *feminine* and *masculine* translations. On the other hand, the verb sentences do not include any cue for a *correct* gender in the translation. Therefore, they are just analyzed for feminine and masculine translations. The calculated *feminine-ratio* ($\%TFG$) results from all feminine-translations divided by the sum of feminine- and masculine-translations. The calculated *correct-gender-ratio* ($\%TCG$) results from all translations with correct gender divided by the sum of all translations with correct and incorrect gender. All Chi^2-tests were, if necessary, Bonferroni corrected. First, the results for the verb-sentences; Second, the results for the extended WinoBias sentences; And third, further results are presented.

3.1 Hypothesis 1: Verb Sentences

The statistical tests regarding Hypothesis 1 yielded mixed results, depending on which NMT system is looked at. Of the 2.079 sentences with a feminine verb DeepL translated the occupations in 242 (11.9%) sentences into the female gender ($\%TFG$) compared to Microsoft Translator with 149 (7.5%), and Google Translate with 120 (6.0%). Of the 2.079 sentences with a masculine verb DeepL (DL) translated the occupations in 135 (6.6%) sentences into the female gender compared to Microsoft Translator (MS) with 104 (5.2%), and Google Translate (GT) with 109 (5.4%). For DeepL and Microsoft Translate the difference becomes significant with $\Delta\%TFG_{DL} = 5.3\%$, $Chi^2_{DL} = 33.7$ and $p_{DL} < 0.001$, and $\Delta\%TFG_{MS} = 2.3\%$, $Chi^2_{MS} = 8.4$ and $p_{MS} = 0.004$. For Google Translate the difference does not become significant. As two of three NMT systems inherit a gender bias that is influenced as expected by verbs, meaning that translations of sentences with feminine verbs result in a significantly higher $\%TFG$ than translations of sentences with masculine verbs, $H1$ is accepted. Figure 2 gives an overview of the translations to the female gender ($\%TFG$) for all three NMT systems and the two categories of verb sentences.

3.2 Hypothesis 2: Extended WinoBias Sentences

Both hypotheses assume that adjectives that inherit a gender-bias in word embeddings also influence the gender of translations from English to German. While the results confirm the assumptions of Hypothesis $H2_a$, they also yield unexpected results for Hypothesis $H2_b$. Of the 3,168 original WinoBias sentences DeepL translated $1,259$ (41.7%), Microsoft Translator translated $1,041$ (35.8%), and Google Translate translated 976 (33.2%) to the female inflection of the occupation. These percentages are used as the baseline to test, whether feminine and masculine adjectives skew the outcome of translations into the expected direction.

Of the sentences extended with a feminine adjective DeepL translated 49.5%, Microsoft Translator translated 42.5%, and Google Translate translated 40.1% to the female inflection. The difference to the percentage of translations to the female inflection of the original WinoBias sentences becomes significant for all three NMT systems: $\Delta\%TFG_{DL} = 7.8\%$, $Chi^2_{DL} = 66.3$ and $p_{DL} < 0.001$; $\Delta\%TFG_{MS} = 6.7\%$, $Chi^2_{MS} = 49.0$ and $p_{MS} < 0.001$; and $\Delta\%TFG_{GT} = 6.9\%$, $Chi^2_{GT} = 53.8$ and $p_{GT} < 0.001$. Therefore Hypothesis $H2_a$ is accepted.

Of the sentences extended with a masculine adjective DeepL translated 44.6%, Microsoft Translator translated 39.3%, and Google Translate translated 37.9% to the female inflection. The difference to the percentage of translations to the female inflection of the original WinoBias sentences becomes significant for all three NMT systems: $\Delta\%TFG_{DL} = 2.9\%$, $Chi^2_{DL} = 9.1$ and $p_{DL} = 0.008$; $\Delta\%TFG_{MS} = 3.5\%$, $Chi^2_{MS} = 13.3$ and $p_{MS} < 0.001$; and $\Delta\%TFG_{GT} = 4.7\%$, $Chi^2_{GT} = 25.1$ and $p_{GT} < 0.001$. While all differences are significant, they contradict our assumption that preceding masculine adjectives to Wino-

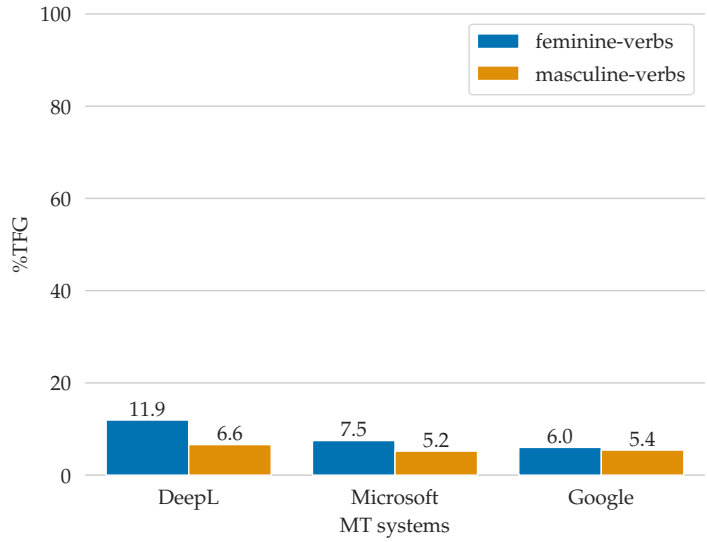

Figure 2: Percentage of translations to female gender ($\%TFG$) of occupations in verb sentences, organized by the category of verbs.

Bias sentences results in less translations to the female inflection. Instead the preceded masculine adjectives have the opposite effect. Therefore, Hypothesis $H2_b$ is rejected. Figure 3 gives an overview of the translations to the female gender ($\%TFG$) for all three NMT systems and the three categories of sentences. Table 3 lists all numbers of different translation categories for a deeper insight.

3.3 Influence of Gender-Stereotypical Verbs and Adjectives on Translations

Our findings show that gender stereotypical verbs and adjectives influence gender bias in translations of NMT systems. In the following, we discuss our results in more detail.

Hypothesis 1: In general, the results from verb sentences differ drastically from the ones of the extended WinoBias sentences, with far fewer sentences being translated to their feminine gender. The percentage of sentences translated to their feminine gender ($\%TFG$) in the verb sentences ranges from 5.2% for masculine verb sentences translated by Microsoft Translator, to 11.9% for feminine verb sentences translated by DeepL. In comparison to that, $\%TFG$ ranges from 33.2% in original WinoBias sentences without adjective translated by Google Translate, to 49.5% in extended WinoBias sentences with feminine adjectives translated by DeepL Translator.

Two reasons could be responsible for the low $\%TFG$. Firstly, the generic masculine in German: As mostly the masculine gender is used to address all genders, this must be present in the training data of all three NMT systems. Therefore, they tend to use the male inflection whenever the gender bias for a specific occupation does not outweigh the bias by the generic masculine. Secondly, the verb-sentences lack a gender pronoun like "her" or "him", which urges the NMT system to decide which gender would be correct in the translation. This probably leads to the strong bias towards male inflections in translations.

To check whether the bias induced by occupations and the generic masculine outweighed an existing bias of verbs, we analyzed the data of the verb sentences again, looking at the different groups of occupations[7]: feminine, neutral and masculine. For all three NMT systems the $\%TFG$ for verb sentences with neutral and masculine occupations was below 2% regardless of the stereotypical feminine verbs. The $\%TFG$ in sentences with female occupations was 25.1% in DeepL, 19.0% in Microsoft Translator and 17.6% in Google Translate. All differences to sentences with neutral and masculine occupations were significant with p-values below 0.001 and Chi^2 values reaching from 352 to 256.

Hypotheses 2a & 2b: As gender bias works both ways in word embeddings, meaning that words can be stereotypical feminine or stereotypical mascu-

[7]With the calculated gender score we split the list of occupations in three equally sized categories (each $n = 33$)

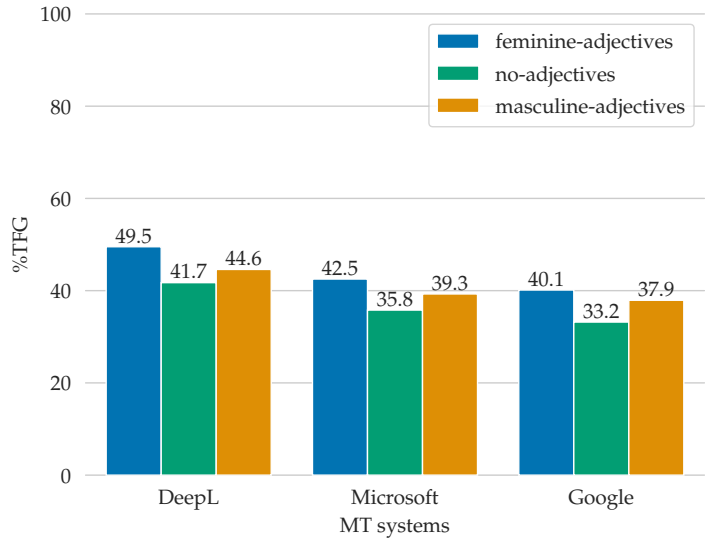

Figure 3: Percentage of translations to female gender ($\%TFG$) of occupations in all three types of EWB sentences: feminine adjective, masculine adjective, and no adjective.

line, we assumed that, depending on their gender-score derived from word embeddings, feminine adjectives would skew translations of NMT systems more often to their feminine gender and vice versa that masculine adjectives would skew translations more often to their masculine gender. This assumption was also supported by the findings of Stanovsky et al. (2019), who preceded "handsome" to occupations of sentences which would be correct, if translated to their masculine gender, and "pretty" to occupations of sentences which would be correct if translated to their feminine gender. With this measure, they could improve the accuracy of NMT systems and reduce gender bias.

Contrary to the prior assumptions, adjectives preceded to occupations led to significantly more translations with feminine gender, regardless of their gender-score derived from word embeddings. Finding that masculine adjectives also lead to more translations with feminine gender does not only result in the rejection of $H2_b$, but also weakens the acceptance of $H2_a$. Therefore, we introduce a new Hypothesis $H2_c$: "WinoBias sentences extended with a feminine adjective result in significantly more translations into the female inflection of an occupation than WinoBias sentences extended with a masculine adjective.".

The difference between the percentage of translations to the female inflection of WinoBias sentences extended with feminine and WinoBias sentences extended with masculine adjectives becomes significant for all three NMT systems: $\Delta\%TFG_{DL} = 4.9\%$, $Chi^2_{DL} = 147.6$ and $p_{DL} < 0.001$; $\Delta\%TFG_{MS} = 3.2\%$, $Chi^2_{MS} = 59.1$ and $p_{MS} < 0.001$; and $\Delta\%TFG_{GT} = 2.2\%$, $Chi^2_{GT} = 29.2$ and $p_{GT} < 0.001$. Therefore, Hypothesis $H2_c$ is accepted which strengthens $H2_a$, as stereotypical feminine adjectives preceded to occupational nouns lead to significantly more translations to the female gender than stereotypical masculine adjectives preceded to occupational nouns.

3.4 Influence of Adjectives on Correct Gender in Translations

The comparison of all three NMT systems was not one of the main research questions. Nevertheless, the extent of gender bias in the NMT systems can be of interest to users. Therefore, and because of the surprising findings considering Hypothesis 2_b a short comparison is presented in the following paragraphs.

To better understand our results regarding hypotheses $H2_a$, $H2_b$ and $H2_c$ we plotted percentage of translations with the correct gender ($\%TCG$) organized by NMT systems and the type of sentence: original WinoBias sentence (no adjective), with masculine adjective extended WinoBias sentence (M adjective), and with feminine adjective extended WinoBias sentence (F adjective). Additionally, we split each type of sentence into sentences with male pronouns (M pronouns) and sentences with female pronouns (F pronouns). Figure

Table 3: Numbers of the categorizations of the gender of translations of extended WinoBias sentences sorted by the gender-class of the adjective.

		NMT system		
adjective gender	translation category	DeepL	Microsoft	Google
feminine	true feminine	**13,341**	11,352	10,177
	false masculine	1,553	3,405	**4,593**
	true masculine	**13,833**	13,814	13,312
	false feminine	1,751	1,382	**1,826**
	neutral	**550**	440	472
	wrong	652	1,287	**1,300**
masculine	true feminine	**12,497**	8,966	8,724
	false masculine	2,378	3,405	**4,533**
	true masculine	**14,425**	11,943	12,128
	false feminine	1,028	963	**1,450**
	neutral	**483**	346	447
	wrong	869	**6,057**	4,398
no adjective	true feminine	**1,162**	916	812
	false masculine	324	503	**652**
	true masculine	**1,434**	1,365	1,313
	false feminine	97	125	**164**
	neutral	75	**77**	53
	wrong	76	**182**	174

4 shows the resulting plot.

The results are quite astonishing: while the $\%TCG$ slightly decreases for sentences with male pronouns and any adjective ($1 \leq \Delta\%TCG \leq 5$) it drastically improves for sentences with female pronouns and any adjective ($12 \leq \Delta\%TCG \leq 13$). Considering that sentences with female and male pronouns are equally prevalent in original WinoBias sentences and extended WinoBias sentences, it shows that preceding an occupational noun with any adjective likely improves the overall percentage of translations to the correct gender inflection. This reflects the findings of Stanovsky et al. (2019), who preceded "handsome" and "pretty" to occupational nouns of WinoMT sentences. With this measure, they could improve the accuracy hence $\%TCG$ of NMT systems and reduce gender bias. Our findings give more insight to this result: Stanovsky et al. (2019) very likely could have added either "handsome" or "pretty" to all sentences, regardless of their pronoun and would nonetheless have been able to record a higher accuracy.

Furthermore, Figure 4 shows that DeepL Translator performed best when it comes to $\%TCG$. Google Translate and Microsoft Translator again show more similar results, but Google Translate performed notably worse than Microsoft Translator. With the least discrepancy in $\%TCG$ between sentences with a feminine pronoun and sentences with a masculine pronoun in all three conditions (feminine adjective, masculine adjective, no adjective) DeepL Translator, therefore, inherits the lowest gender bias.

4 Conclusions and Further Work

The three neural machine translation systems evaluated with respect of their gender bias are black boxes, in so far as the architecture is not publicly available and – even more important – it is not transparent on what data these systems are trained. It is most likely that the gender bias in all three systems is inherited from the data used for training and their use of word embeddings.

To give a closer look on gender-bias of the NMT systems DeepL, Microsoft, and Google Translate, an extension of the *WinoMT* challenge set – the first challenge set designed to measure gender bias in NMT systems – has been presented. While *WinoMT* relies solely on the gender of the translation of occupations, our extended set *WiBeMT* includes gender-adjectives and gender-verbs. Thereby, a more detailed assessment of gender bias has been possible. The number of sentences in our challenge set is, with over $70,000$ sentences, nearly 20 times as large as the original WinoMT challenge set. This makes it less prone to overfitting when used to evaluate or reduce gender bias in NMT systems.

We could show that adjectives do significantly

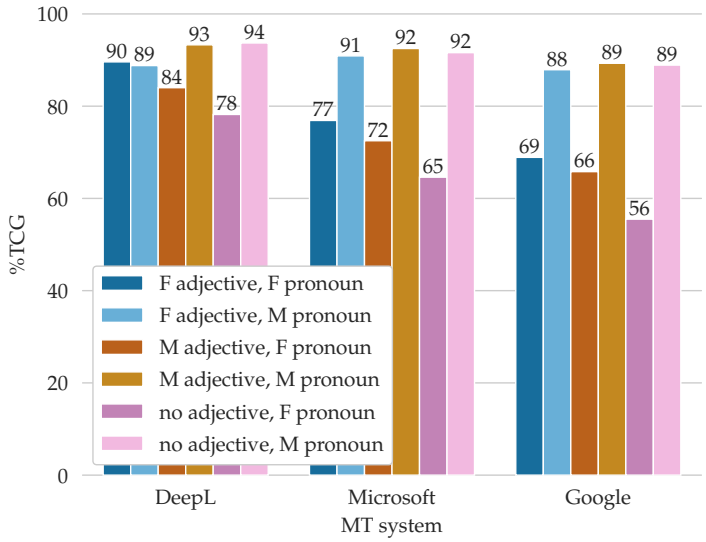

Figure 4: Bar plot of the percentage of translations into the correct gender ($\%TCG$) of original WinoBias sentences and extended WinoBias sentences.

influence the gender of translated occupations. Against the hypotheses, feminine as well as masculine adjectives skew the translations of NMT systems to more translations with the feminine gender. Nevertheless, feminine adjectives still produce significantly more translations with the feminine gender than masculine adjectives do.

All three NMT systems prefer translations to the generic masculine when no pronoun defines a correct gender for the translation. Despite this preference, 5.7% to 9.3% of all verb sentences are translated to their feminine gender by the MT systems. This can mostly be attributed to a gender bias in translating occupations, as our results regarding verb sentences and occupation categories show. The effect of gender-verbs on the gender of translations only became significant in DeepL and Microsoft Translator and was smaller than the effect of the occupations gender-categories. It can be assumed that Google Translate only performed better on the verb sentences task, as it generally has the strongest tendency to translate sentences to their masculine gender.

Surprisingly, gender-adjectives drastically improve the overall accuracy of all three NMT systems when it comes to the correct gender in translations. While the accuracy slightly drops for sentences with masculine pronouns, it drastically improves for sentences with feminine pronouns. Therefore, the discrepancy in accuracy between masculine and feminine pronoun sentences decreases, resulting in lower discrimination. One could even argue that gender-adjectives reduce gender bias in the output of NMT systems, but at the same time, it can be discriminating in itself that, as soon as you add an adjective to describe a person, the instance of this person is more likely to be translated to its feminine gender. Further research is certainly needed to find reasons for this effect and to assess the potentials of discrimination.

The sentences in our *WiBeMT* challenge set are – as the original *WinoMT* challenge set – constructed in a systematic way. While this allows for a controlled experiment environment, it might also introduce some artificial biases (Stanovsky et al., 2019). A solution could be to collect real-world examples of sentences, which are suitable for gender bias detection. Furthermore, the limitation on one source language (English) and one target language (German) does not allow for a generalization of the results.

Another limitation of our study – as most other studies – is that it does not take into account that gender should not be seen as a binary, but rather a continuous variable. Cao and Daumé (2019), for example, outline why "trans exclusionary" co-reference resolution systems can cause harm, which is probably also valid for MT systems. A further extension of the challenge set could help to shine a light on the shortcomings of the inclusion of transgender persons of NMT systems.

Continual Learning in Multilingual NMT via Language-Specific Embeddings

Alexandre Bérard
NAVER LABS Europe
alexandre.berard@naverlabs.com

Abstract

This paper proposes a technique for adding a new source or target language to an existing multilingual NMT model without re-training it on the initial set of languages. It consists in replacing the shared vocabulary with a small language-specific vocabulary and fine-tuning the new embeddings on the new language's parallel data. Some additional language-specific components may be trained to improve performance (e.g., Transformer layers or adapter modules). Because the parameters of the original model are not modified, its performance on the initial languages does not degrade. We show on two sets of experiments (small-scale on TED Talks, and large-scale on ParaCrawl) that this approach performs as well or better as the more costly alternatives; and that it has excellent zero-shot performance: training on English-centric data is enough to translate between the new language and any of the initial languages.

1 Introduction

Multilingual Neural Machine Translation models are trained on multilingual data to translate from and/or into multiple languages (Firat et al., 2016; Johnson et al., 2017). Multilingual NMT is a compelling approach in production, as one only needs to train, deploy and maintain one model (instead of $2 \times N$ ones, where N is the number of languages). It has also been shown to improve MT quality for low-resource languages (at the cost of a slight degradation for high-resource languages) and it can allow translation between languages that have no aligned data ("zero-shot translation").

However, such models can be costly to train, as they usually involve larger architectures and large datasets. Moreover, because they are trained jointly on all the languages, they require to know in advance the full set of languages. Adding a new language to an existing model usually means re-training the model on the full multilingual dataset. Naively fine-tuning the original model on the new language's data is not an option because of vocabulary mismatch (the shared vocabulary needs to be modified to include the new language's tokens) and catastrophic forgetting (the model will quickly forget how to translate in the other languages).

In this paper, we study the problem of multilingual NMT *incremental training* or *continual learning* and propose a novel way to efficiently add a new source or target language.

Some desirable properties of an incremental training method are:

- No degradation on the existing language pairs;
- Efficient training (e.g., no re-training on the existing language pairs);
- Minimal amount of added parameters: the approach should scale to many languages and the model fit on a single GPU;
- Minimal degradation in inference speed;
- Good zero-shot performance: when training with X-EN (or EN-X) data, where X is a new language, we would like the model to be able to translate from X to any known language Y (resp. from Y to X).

We propose a novel technique for incrementally adding a new source or target language, which consists in substituting the shared embedding matrix with a language-specific embedding matrix, which is fine-tuned on the new language's data only while freezing the other parameters of the model. In some cases (e.g., when the new language is on the target size), a small number of additional parameters (e.g., adapter modules) have to be trained to match the performance of the re-training baseline. We perform two sets of experiments, with a 20-language Transformer Base trained on TED Talks, and a 20-language Transformer Big (with deep encoder and shallow decoder) trained on ParaCrawl; and show that this approach is fast and parameter-efficient and that it performs as well or better as the more costly alternatives.

2 Related work

Some previous works study how to adapt a multilingual MT model to unseen low-resource languages, but without seeking to maintain good performance in the initial languages (Neubig and Hu, 2018; Lakew et al., 2019). Garcia et al. (2021) introduce a "vocabulary substitution" approach for adding new languages to a multilingual NMT model. They create a new shared BPE vocabulary that includes the new language and initialize the embeddings of the overlapping tokens with their previous values. Then they fine-tune the entire model on the initial model's training data combined with parallel or monolingual data in the new language. Contrary to ours, their approach assumes access to the initial model's training data and results in a small performance drop in the existing languages.

Lyu et al. (2020) and Escolano et al. (2020, 2019, 2021) propose multi-decoder / multi-encoder architectures which they show to be compatible with incremental training. To add a new target (resp. source) language, one just has to freeze the model's encoder (resp. decoder) and train a new language-specific decoder (resp. encoder). However, this results in an enormous number of parameters.

Artetxe et al. (2020); Pfeiffer et al. (2021) incrementally train language-specific embeddings for cross-lingual transfer of BERT classification models. This approach consists of four stages: 1) train a monolingual BERT on language L_1; 2) train embeddings on language L_2 using the masked LM objective while freezing the other parameters; 3) fine-tune the L_1 BERT model on the desired classification task using labeled data in language L_1; 4) substitute the L_1 embeddings with the L_2 embeddings in the classification model and use it for L_2-language classification. Artetxe et al. (2020) also combine their approach with L_2-specific adapter layers and position embeddings. While this algorithm is close to ours, it is used on encoder-only Transformers for classification tasks. Our work extends this algorithm to encoder-decoder Transformers for multilingual MT.

Also similar to our technique, Thompson et al. (2018) do domain adaptation by freezing most of the NMT parameters and only fine-tuning one component (e.g., the source embeddings). Philip et al. (2020) show that adapter modules can be used to adapt an English-centric multilingual model to unseen language pairs, but whose source and target languages are known. We wanted to go further and use adapter layers to adapt a multilingual model to unseen languages. However, we obtained the surprising result that adapting the embedding matrix is sometimes enough. In the other cases, adapter modules can be used sparingly to match baseline performance. Üstün et al. (2021) introduce "denoising adapters" which they show can be used to incrementally adapt a multilingual MT model to new languages using monolingual data only.

3 Techniques

Figures 1 and 2 illustrate our technique for a new source and a new target language respectively.

The initial model is a many-to-many model with a shared vocabulary and source-side language codes (to indicate the target language).

3.1 New source language

To add a new source language (e.g., Greek), we build a new (smaller) vocabulary for this language only and replace the source embedding matrix with a new embedding matrix corresponding to that vocabulary. Note that some tokens may appear in both vocabularies. Similarly to Pfeiffer et al. (2021); Garcia et al. (2021), we initialize the new embeddings for those tokens with the existing embedding values. We train this new embedding matrix on Greek-English parallel data while freezing all the other parameters. There is no loss in performance in the existing languages as we do not modify the original parameters. At inference, to translate from the initial set of languages, we use the initial shared vocabulary and embeddings. To translate from Greek, we use the Greek embeddings and vocab.

To better adapt to the new source language, we also try combining this language-specific embedding matrix with other language-specific components in the encoder. We either fine-tune the first encoder layer while freezing the other layers, train the full encoder, or plug in adapter modules after encoder layers (Bapna and Firat, 2019) and train these while freezing the Transformer parameters.

Data augmentation As we will show in the experiments, source lang-specific parameters tend to give poor zero-shot results, i.e., when training them on Greek-English data, the resulting model might have trouble translating into other languages than English. For this reason, we try training such models on additional data. One solution is to use a multi-aligned Greek corpus (i.e., Greek paired with all the initial languages), but this might not always

be possible. We experiment with tiny amounts of such data (e.g., 1000 line pairs per initial language); and with synthetic data: translate the English side of the Greek-English corpus into the other languages with the initial model, then use the resulting fake line pairs for training. We call this approach "back-translation" (BT) even though it is arguably closer to distillation than back-translation because the synthetic text will be on the target side.

3.2 New target language

The same incremental training techniques can be used to learn a new target language (e.g., Greek) with some modifications. The decoder has a target embedding matrix and vocabulary projection matrix, which are usually tied and shared with the source embeddings (i.e., the same parameters are used for all 3 purposes). We need to adapt both the target embeddings and output projection to the new Greek vocabulary. Like in the initial model, we tie these two parameters. Additionally, the initial model does not have a "translate into Greek" language code. We add this language code to the source embedding matrix and freeze all source embeddings but this one. It is initialized with the "to English" language code embedding of the initial model. We combine this approach with language-specific parameters (adapter modules or fine-tuned Transformer layers) in the decoder and/or encoder.

3.3 New source and target languages

To translate between two new languages (e.g., Greek to Ukrainian), we train language-specific parameters for each of these languages separately, as described previously. Then, at inference time, we combine these parameters. This is done by taking the new source Greek embedding matrix and target Ukrainian embedding matrix (and vocabulary projection). The "translate into Ukrainian" language code embedding is concatenated to the Greek embedding matrix. Similarly, the combined model includes language-specific layers and adapters from both models. When both models have adapter modules at the same layers (e.g., last encoder layer), we stack them: the target-language adapters are plugged in after the source-language adapters.

3.4 Baselines

We compare our incremental training techniques with two types of baselines: bilingual models trained from scratch with only the new language's parallel data; and re-training, i.e., training a new multilingual model that includes the new language. To save computation time, similarly to Garcia et al. (2021), we start from the initial model and substitute its vocabulary with a new vocabulary trained with the same settings and data as before plus text in the new language. This ensures a large overlap between the old and new vocabularies. Then, we initialize the embeddings of the overlapping tokens with their previous values and fine-tune the full model on the entire dataset.

Note that these baselines do not meet our criteria for a good incremental training technique. Bilingual models are parameter-inefficient and cannot do zero-shot translation (except via pivot translation, which is twice as slow). Re-training assumes access to the initial model's training data and can be very slow. It could also result in a drop in performance in the initial languages.

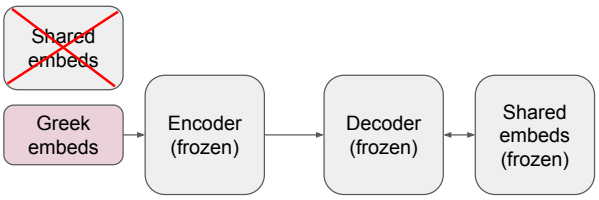

Figure 1: Adding a new source language with our incremental training technique. The source embedding matrix is replaced with the new language's embeddings and fine-tuned on the new language's data, while the other parameters are frozen.

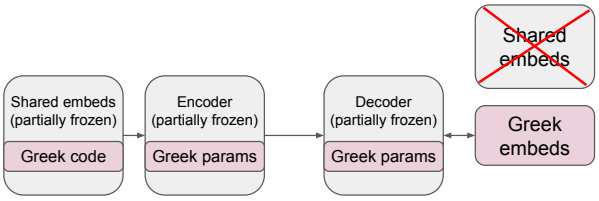

Figure 2: Adding a new target language with our incremental training technique. The tied target embedding matrix and output projection are replaced with the new language's embeddings. Some language-specific parameters can be added in the decoder or encoder, and a new language code is added in the source embedding matrix. Everything is kept frozen except for these new parameters.

4 TED Talks Experiments

We adapt a 20-language model trained on TED Talks to Greek (EL), either on the source side or target side. We pick Greek as the new language as it is from an unseen language family and uses an unseen alphabet. We also do experiments with Ukrainian

(UK), Indonesian (ID), or Swedish (SV) as the new language,[1] which are shown in Appendix.

4.1 Data and hyper-parameters

We use the TED Talks corpus (Qi et al., 2018) with the same set of 20 languages as Philip et al. (2020); Bérard et al. (2021).[2] This corpus is multi-parallel, i.e., it has training data for all 380 (20×19) language pairs. It also includes official valid and test splits for all these language pairs. Table 8 in Appendix shows the training data size per language.

The initial model is the "multi-parallel" baseline from Bérard et al. (2021), a Transformer Base (Vaswani et al., 2017) trained in two stages: English-centric training (38 directions) for 120 epochs; then multi-parallel fine-tuning (380 directions) for 10 epochs.[3] More hyper-parameters are given in Appendix (Table 23).

The shared vocabulary is created using BPE (Sennrich et al., 2016) with 64k merge operations and inline casing (Bérard et al., 2019). Both BPE and NMT training use temperature sampling with $T = 5$ (Arivazhagan et al., 2019). Single characters with a total frequency higher than 10 are added to the vocabulary. The Greek vocabulary is obtained with the same BPE settings but on Greek monolingual data with 4k merge operations. The bilingual baselines use a joint BPE model of size 8k and the same settings as in Philip et al. (2020). Our re-training baselines are obtained by creating a new shared BPE model of size 64k including all 20 initial languages plus Greek and fine-tuning the multi-parallel model for 10 more epochs with this vocabulary. Note that there is a vocabulary mismatch with the initial model (which did not have Greek). We initialize the known embeddings with their previous values and the new ones at random and reset the learning rate scheduler and optimizer. We also do a re-training baseline that includes all 4 new languages. Note that contrary to our incremental training approach, those models are trained with the new language(s) on both sides and use multi-aligned parallel data.

Finally, we train a model that follows more closely Garcia et al. (2021): we fine-tune the multi-parallel model for 10 epochs, by replacing the initial vocabulary with a vocabulary of the exact same size that includes Greek, and whose new tokens are initialized with the outdated embeddings from the old model. Like Garcia et al. (2021), we upscale the new data's sampling frequency by a factor of 5.

[1] They all use a known script (Latin or Cyrillic). Indonesian is from an unseen language family.

[2] {en, ar, he, ru, ko, it, ja, zh_cn, es, fr, pt_br, nl, tr, ro, pl, bg, vi, de, fa, hu}

[3] Note that an "epoch" when using multi-parallel data corresponds to approximately 9 English-centric epochs in terms of updates.

	Model	→EN	←EN	/ EN
1	SOTA – bilingual	32.4	**24.4**	15.0
2	SOTA – multilingual	30.9	22.3	14.8
3	English-centric	31.8	24.2	13.5
4	(**3**) + multi-parallel	32.8	24.3	16.3
5	(**4**) + EL	**33.3**	24.3	**16.6**
6	(**4**) + {EL,UK,SV,ID}	33.2	24.0	16.5

Table 1: BLEU scores (average to English, from English, and between non-English languages) of the baseline models on TED test. "SOTA" corresponds to the bilingual and multi-parallel baselines of Philip et al. (2020). (**3**) and (**4**) are from Bérard et al. (2021).

4.2 Evaluation settings

The TED Talks models are evaluated on the provided multi-parallel validation and test sets. Since those are already word-tokenized, we run SacreBLEU with the `--tok none` option.[4]

We report BLEU scores from/into English and average BLEU from/into the 19 other languages than English (which correspond to a zero-shot setting when the incremental training is done on Greek-English only data). We also report chrF scores obtained with SacreBLEU on the test and validation sets in Appendix.[5]

4.3 Results and analysis

Table 29 in Appendix details the notations used in this paper and the tables.

Baselines. Table 1 compares our initial models and re-training baselines against the state of the art on the initial set of 20 languages. In this instance, fine-tuning the initial model with more languages (**5**, **6**) does not degrade BLEU. Appendix Table 9 shows valid and test chrF on more baselines, including our implementation of the vocabulary substitution approach of Garcia et al. (2021).

New source language. Table 2 shows the test BLEU scores of several incrementally-trained models with Greek as a new source language. More re-

Table 2: TED test BLEU scores of incremental training with Greek on the source side. "EL → / EN" corresponds to an average BLEU from Greek into all 19 non-English languages. "Params" gives the number of new parameters introduced by each approach. The initial model (**4**) has 80.2M parameters in total. (⋆) obtained by using the "translate into X" lang code embeddings from the initial model. The table is divided in 4 parts: baselines trained with multi-aligned data; Greek-English incremental training; incremental training with multi-aligned data (i.e., line pairs between Greek and all 20 languages); and multilingual English-centric incremental training (i.e., on 4 new source languages at once).

sults on Greek, Ukrainian, Indonesian and Swedish are given in Appendix (Tables 10, 11, 12, and 13).

Training the source embeddings only (**7**) outperforms the bilingual baselines (**1**) and comes close to the costly re-training baselines (**5**, **6**). In particular, it nearly matches the performance of the latter in the zero-shot EL → / EN directions, even though the baselines have training data for those directions. Initializing the known tokens in the new vocabulary with their old embeddings does not improve final performance (**7** vs **8**). But using language code embeddings from the initial model is necessary to be able to translate into non-English languages. Figure 4 shows that such initialization improves final performance under low-resource settings. Figure 7 in Appendix also shows that it speeds up training.

Training additional components in the encoder, like adapter modules (**11**, **12**, **13**) or the first encoder layer (**14**) helps improve EL → EN performance and outperform all baselines, though it is less useful when the new language is from a known family (see Ukrainian and Swedish scores in Appendix Tables 11 and 13). However, this results in abysmal zero-shot performance (EL → / EN). As they only encounter the "to English" language code during training, those models quickly forget how to interpret the other lang codes. This catastrophic forgetting is illustrated by Figure 3, where we see a plunge in EL → FR performance after just a few epochs of training. Only tuning the encoder layer norm parameters and biases (**9**) gives slightly higher EL → EN performance without suffering from catastrophic forgetting in the other languages. Note that language code forgetting is less pronounced when the initial model is English-centric (see Table 18 in Appendix). In this setting, adapter modules do not hurt zero-shot translation.

The third quarter of Table 2 shows how multi-aligned Greek data can be used to achieve excellent performance in both EL → EN and EL → / EN directions. The best tradeoff between EL → EN and EL → / EN performance is achieved by incrementally training with the entire Greek dataset of 2.41M line pairs. However, such data might not

Table 3: TED test BLEU scores of incremental training with Greek on the target side. "/ EN → EL" corresponds to an average BLEU from the 19 non-English languages to Greek. "Params" gives the number of new parameters introduced by each approach.

always be accessible for the new language. Close performance can be reached by training with the same amounts of synthetic data instead (**17**). And more interestingly, only a tiny amount of real (**18**) or back-translated data (**19**, **20**, **21**) in the other 19 languages is needed to obtain good zero-shot results without any loss in EL → EN performance.

New target language. Table 3 shows test BLEU scores when incrementally adding Greek on the target side. Additional results on Greek, Ukrainian, Indonesian and Swedish are provided in Appendix (Tables 14, 15, 16, and 17).

With new target languages, only adapting the embedding matrix (tied with vocabulary projection) is not enough and strongly underperforms the baselines (**24** vs **1**, **5** and **6**). Training decoder-side adapter modules (**26**) gets us closer to baseline performance; and tuning the last decoder layer (**30**) bridges the gap with the baselines. However, the most effective strategy is to train some components in both the encoder and decoder (**27**, **29**, **31**, **32**, **33**, **34**, **35**). We observed that it was important for the model to have a way to modify the output of the encoder before it is read by frozen decoder components. Interestingly, only having a large adapter module after the last encoder layer (**28**) is enough to match baseline performance. Adding small adapters after each decoder layer (**29**) further improves BLEU and brings the best parameter count / performance tradeoff.

At the same parameter budget, training adapter modules after every encoder layer (**32**, **34**, **35**) gives worse / EN → EL performance than an adapter at the last encoder layer combined with decoder-side parameters (**31**, **33**), which is likely caused by the encoder overfitting to English.

In this setting, there is no clear advantage to incremental training with multi-aligned Greek data (**36**), as this hurts EN → EL performance, without any notable improvement for / EN → EL. Finally, multilingual incremental training (with 4 new target languages at once) is entirely possible (**37**) and gives competitive results to the baselines.

Table 25 in Appendix analyzes the usefulness of learning a new language code, by comparing with three other strategies: incremental training without any language code; with the "to English" language code; or with the language code of a similar language. Interestingly, the more new parameters are learned (esp. encoder-side), the less useful it is to learn a new language code. Moreover, adapting to Swedish by using a fixed English language code gives reasonable performance as the two languages are from the same family. And the proxy "to Russian" language code gives the same results as learning a new language code when adapting to

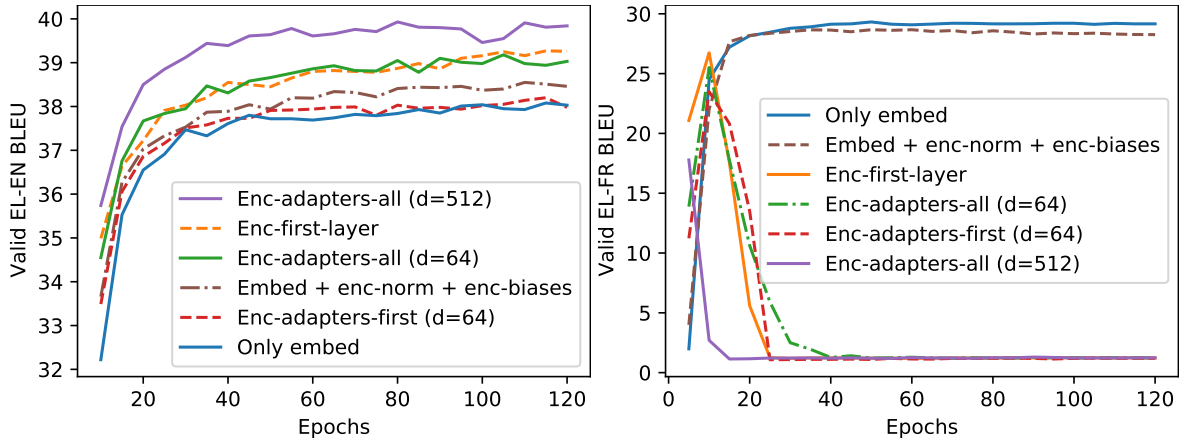

Figure 3: TED validation BLEU on EL-EN and EL-FR while incrementally training with EL-EN data only (**7**, **9**, **10**, **11**, **12**, **14**).

Table 4: TED test BLEU scores on {EL,UK,SV,ID}→{EL,UK,SV,ID} (average over 12 directions) by combining source-language and target-language incrementally-trained parameters. ($\star$) instead of combining model parameters, translate to English with (**14**), then to the target language with (**31**).

Ukrainian because both languages are very similar.

New source and target languages Table 4 combines incrementally-trained parameters at inference time to translate between two new languages. Interestingly, combining target-language parameters with source-language parameters that had very poor zero-shot performance (**14**) gives excellent results. We hypothesize that the language code forgetting issue is less pronounced here because solely activating some language-specific parameters will make the model translate into that language.

Despite showing the best EL → EN performance, source-language encoder adapters (**19**) tend to perform more poorly when combined with target-language parameters. While better performance is obtained by pivot translation through English with two incrementally trained models (**14** and **31**), combining the parameters of these two models gives close results at a faster inference speed.

Discussion Figure 4 shows final BLEU scores of our techniques when training with smaller amounts of data. We observe that incremental training is more data-efficient than bilingual models and can achieve decent performance even with tiny amounts of training data, making it a good fit for adaptation to low-resource languages.

Figure 7 in Appendix illustrates the training speed of our approach compared to our implementation of Garcia et al. (2021). In addition to maintaining the exact same performance on the previous languages and needing only English-centric data, our approach reaches higher performance in much fewer updates than the alternatives. Note that retraining might be an efficient solution if one wants to add several languages at once and on both sides.

Finally, Tables 18 and 19 in Appendix show that

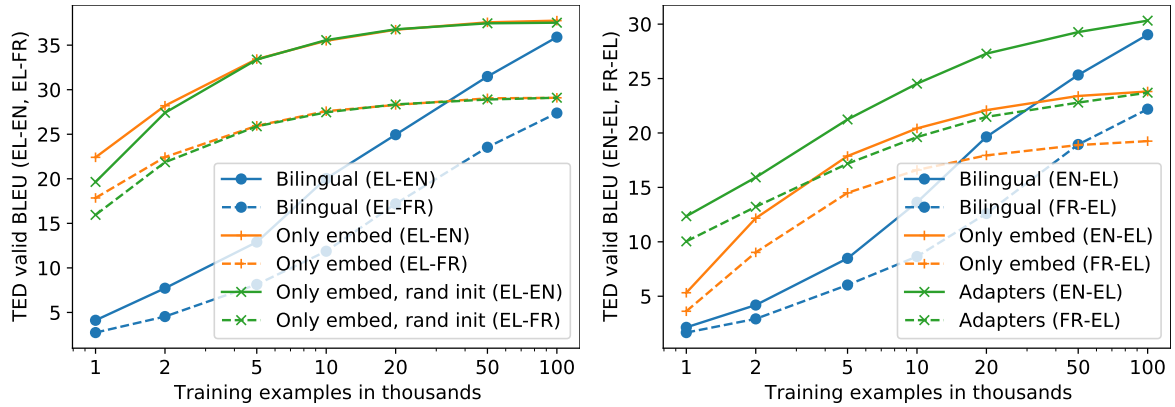

Figure 4: TED validation BLEU from Greek (left) and to Greek (right) by training corpus size, with incremental training (**7**, **8**, **24**, **27**) versus bilingual baselines (**1**).

Table 5: FLORES devtest spBLEU scores of the ParaCrawl/UNPC baselines. Average to English (19 directions), from English (19 directions) and between non-English languages (342 directions). (**39**, **40**, **41**, **42**) are the same models as in (Bérard et al., 2021).

our incremental training approach can be applied to English-centric initial models with similar results.

5 ParaCrawl Experiments

In this section, we test our approach in a more realistic, large-scale setting: a 20-language Transformer Big initial model trained on ParaCrawl (Bañón et al., 2020). The incremental training experiments are done in three languages: Arabic (AR), Russian (RU), and Chinese (ZH). Arabic and Chinese are both from unseen language families and use unseen scripts. Russian is close to a known language (Bulgarian) and uses the same script. For training on those languages, we use UNPC (Ziemski et al., 2016).

5.1 Data and hyper-parameters

We download ParaCrawl v7.1 in the 19 highest-resource languages paired with English.[6] Then, like Freitag and Firat (2020), we build a multi-parallel corpus by aligning all pairs of languages through their English side (effectively removing any English duplicate). See Appendix Table 21 for training data statistics. We create a shared BPE vocab with 64k merge operations and inline casing, by sampling from this data with $T = 5$ and include all characters whose frequency is higher than 100.

Our initial model is the Transformer Big 12-2 (i.e., with a deep encoder and shallow decoder) multi-parallel model of Bérard et al. (2021). Like in the previous section, it was trained in two stages: English-centric training (with $T = 5$) for 1M steps; then multi-parallel fine-tuning (with $T = 2$) for 200k more steps. More hyper-parameters are given in Appendix (Table 24).

Incremental training is done for 120k steps with English-centric data from UNPC v1.0 (see Table 22 in Appendix for statistics), which we clean by removing any line pairs where either side is detected as being in the wrong language by `langid.py` (Lui and Baldwin, 2012). We use monolingual BPE models of size 8k. The Chinese data is tokenized with Jieba[7] before learning the BPE model.

The English-centric bilingual baselines are Transformer Big 6-6 models trained on UNPC for 120k steps with joint BPE vocabularies of size 16k. We do two "re-training" baselines, by fine-tuning either the English-centric or multi-parallel model on their initial ParaCrawl data plus UNPC data in all three new languages. We sample UNPC line pairs in each of the new directions with probability 0.05. The remaining 0.7 probability mass is distributed among the initial ParaCrawl directions with $T = 5$. The new BPE vocabulary is trained

Table 6: FLORES devtest spBLEU scores of the ParaCrawl/UNPC incrementally-trained models. The top half of each table corresponds to the baselines (SOTA, bilingual or re-training). "Params" gives the number of new parameters introduced by each approach. The incremental training is always done on one language only (i.e., one row can correspond to 3 different models). Note that the parameter counts given in this table are for Arabic (8.63M embedding parameters). Russian and Chinese embeddings have respectively 8.51M and 13.60M parameters.

with the monolingual ParaCrawl/UNPC data in all 23 languages (with $T = 5$). The new embeddings for the known tokens are initialized with their old values and the other embeddings at random.[8] Note that contrary to the TED Talks experiments, we do not have multi-aligned data for the new languages.

5.2 Evaluation settings

For validation, we use our own split from TED2020 (Reimers and Gurevych, 2020): 3000 random line pairs for each translation direction. We report chrF scores[9] computed on these valid sets in Appendix.

As test sets, we use FLORES devtest (Goyal et al., 2021). We report scores computed with their new "spBLEU" metric,[10] which runs BLEU on top of a standardized multilingual BPE tokenization.

[8] 78% of the new tokens were in the initial vocabulary, and 84% of the old tokens are in the new vocabulary.

[9] `chrF2+n.6+s.false+v.1.5.1`

5.3 Results and analysis

Baselines. Table 5 compares our initial model (**42**) with other baselines. Our multi-parallel model beats the M2M-124 model of Goyal et al. (2021) in all three settings. This is not so surprising, as their model only has 615M parameters for 124 languages, compared to 255M parameters for our 20-language model. Last, we can observe that our "re-training" baselines (**43** and **44**) perform almost as well as the initial 20-language models (**40**, **42**).

New source or target language. Training only source embeddings (**46**) is a good strategy for Russian, but underperforms the baselines in the more linguistically distant Arabic and Chinese. Learning more parameters (+8% per source language) can match baseline performance in all 3 languages (**47** and **48**), but gives poor zero-shot performance. Adding small amounts of "back-translated" data (**49**) achieves close non-English performance

	Source model		Target model	spBLEU
38	M2M-124 (Goyal et al., 2021)			15.0
45	Bilingual baselines (pivot through English)			**18.3**
44	Multi-parallel (**42**) + {AR,RU,ZH}			13.0
50	(**44**) + pivot through English			16.8
46	Only embed	**53**	Dec-last-layer	13.5
		54	Dec-last-layer + enc-adapters-last (d=1024)	13.9
47	Enc-adapters-all (dim=512)	**53**	Dec-last-layer	13.0
		54	Dec-last-layer + enc-adapters-last (d=1024)	13.8
		54	Pivot through English	17.7
48	Enc-first-layer	**53**	Dec-last-layer	10.2
		54	Dec-last-layer + enc-adapters-last (d=1024)	10.6
49	Enc-first-layer + 20k (BT)	**53**	Dec-last-layer	12.4
		54	Dec-last-layer + enc-adapters-last (d=1024)	12.7

Table 7: FLORES devtest spBLEU scores of the ParaCrawl/UNPC models on {AR,RU,ZH}→{AR,RU,ZH} (average over 6 directions) by combining source-language and target-language incrementally-trained parameters.

to the pivot translation baselines without hurting English-centric scores. For new target languages, the best strategy is to train the last decoder layer with an adapter module at the last encoder layer (**54**), which matches the re-training baselines in all 3 languages and gets close performance to the parameter-inefficient bilingual baselines. Interestingly, target-side incremental training is very sensitive to training data noise. In a first iteration of our experiments, we trained with unfiltered UNPC data and observed catastrophic performance (**55**). Simple language ID filtering solved this issue.

New source and target languages. Table 7 combines source-language with target-language incrementally-trained parameters to translate between two new languages. The results are not as good as in our TED Talks experiments. The best combination in this setting (**46** with **54**) performs considerably worse than pivot translation through English with the baselines. However, it outperforms the "re-training" baseline (**44**), which has only seen English-centric data for the new languages. And pivot translation with two incrementally-trained models (**47** with **54**) gives excellent results, close to the bilingual baselines.

6 Conclusion

We propose a new technique for incrementally training multilingual NMT models on a new source or target language. It consists in creating a new monolingual BPE vocabulary for that language, substituting the shared embedding matrix with language-specific embeddings, and training those while freezing the other model parameters. At inference, translating in any of the initial languages is done by using the initial shared embeddings, and translating in the new language is done by using the newly trained embeddings. This approach does not change performance on the initial languages as the initial parameters are kept aside and not modified. For new source languages, it can achieve close performance to the more costly and less flexible bilingual and re-training baselines. For new target languages, this technique can be combined with language-specific parameters (fine-tuned Transformer layers or adapter modules) to match baseline performance at a small parameter cost. We validate this technique on two sets of experiments: small-scale on TED Talks and large-scale on ParaCrawl; and show that it is compatible with two architectures: Transformer Base 6-6 and Big 12-2. We also show that incremental training on data aligned with English is enough to learn to translate between the new language and any of the initial languages. Translation between a new source and a new target language is also possible by combining their respective parameters at inference. Finally, we provide supplementary material to facilitate reproducibility.[11]

Table 28: TED2020-valid chrF scores of the ParaCrawl/UNPC models on {AR,RU,ZH}→{AR,RU,ZH} (average over 6 directions) by combining source-language and target-language incrementally-trained parameters. ($\star$) instead of combining model parameters, translate to English with (**48**), then to the target language with (**54**).

English-centric	Denotes a parallel corpus that only has alignments with English (i.e., 38 language pairs in our settings). Also denotes many-to-many models that are trained with such data. In this setting, translation between non-English language pairs is called "zero-shot."
Multi-parallel	Denotes a parallel corpus that has alignments between all possible language pairs (380 in our case), and by extension, models that are trained with such data (AKA "complete multilingual NMT", Freitag and Firat, 2020).
Enc-adapters-X ($d = N$)	Train adapter modules of bottleneck dimension N after the encoder layer X.
Enc-adapters-all ($d = N$)	Train adapter modules of bottleneck dimension N after all encoder layers.
Enc-layer-X	Fine-tune the Xth Transformer encoder layer.
Enc-norm + enc-biases	Fine-tune the layer norm parameters and all the biases in the Transformer encoder.
+ random embed init	Initialize the new language-specific embeddings at random, instead of initializing the embeddings of the known tokens with their previous values.
+ non-tied	Train separate target embeddings and output projection matrix (by default they are tied, i.e., they correspond to the same parameter).
+ EL multi-aligned	Train with multi-aligned EL data: not just paired with English, but with all of the 20 languages (2.41M lines pairs instead of 134k).
+ EL multi-aligned (BT)	Like above, but the non-EN data is obtained by translating the English side of the EL-EN corpus to the other 19 languages with (**3**). For better comparison with the above method, we back-translate the same number of lines per language as in the multi-aligned EL corpus.
+ N lines per lang	Append to the EL-EN training data N line pairs for each of the 19 non-English languages.
+ N lines per lang (BT)	Like above, but the N line pairs per language are obtained by translating the English side of the EL-EN corpus with (**3**).
/ EN	19 non-English languages in the initial model. As a column header, it means an average score over all 342 non-English translation directions.
$\rightarrow$ EN	Average score over all 19 X $\rightarrow$ EN translation directions.
$\leftarrow$ EN	Average score over all 19 EN $\rightarrow$ Y translation directions.
Re-training + $\{L_1, L_2 \ldots\}$	Fine-tune the initial model with an updated BPE vocabulary and embedding matrix that include the new languages (L_1, L_2, etc.), and on the multi-aligned data of all the 20 initial languages plus the new ones.
(K) + $\{L_1, L_2 \ldots\}$	Use the incremental training technique K, but on several languages at once (L_1, L_2, etc.) This means that a single shared BPE is trained for all these languages (whose size is multiplied by the number of languages) and the newly-trained parameters are shared between them.

Abstract

Recently, the Machine Translation (MT) community has become more interested in document-level evaluation especially in light of reactions to claims of "human parity", since examining the quality at the level of the document rather than at the sentence level allows for the assessment of suprasentential context, providing a more reliable evaluation. This paper presents a document-level corpus annotated in English with context-aware issues that arise when translating from English into Brazilian Portuguese, namely ellipsis, gender, lexical ambiguity, number, reference, and terminology, with six different domains. The corpus can be used as a challenge test set for evaluation and as a training/testing corpus for MT as well as for deep linguistic analysis of context issues. To the best of our knowledge, this is the first corpus of its kind.

1 Introduction

Machine translation (MT) is now widely used in a variety of fields, mainly due to advancements in neural models (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017). As a result of these recent advances, scientists have been increasingly attempting to include discourse into neural machine translation (NMT) systems (Wang, 2019; Lopes et al., 2020). Thus, researchers started to consider a more suitable evaluation for these document-level systems as the standard MT automatic evaluation metrics have been shown to underestimate the quality of NMT systems (Shterionov et al., 2018) and the appropriateness of these metrics for document-level systems has been challenged (Smith, 2017) since they are not sensitive to their improvements (Voita et al., 2019).

Accordingly, document-level human evaluation of MT has attracted the community's attention since it allows for a more thorough examination of the output quality with context. While a few works have taken into account document-level human evaluation (Läubli et al., 2018; Toral et al., 2018; Barrault et al., 2019; Castilho, 2020, 2021), one common practice for document-level evaluation is the usage of test suites with context-aware markers (Bawden et al., 2018; Guillou et al., 2018; Müller et al., 2018; Voita et al., 2019; Cai and Xiong, 2020). However, the concept of document-level evaluation, in terms of how much text must be shown, remains uncertain (Castilho et al., 2020). While most research on document-level MT evaluation works with contrastive pairs, very few works have tried to use full documents for human evaluation (Läubli et al., 2018; Castilho, 2020, 2021) and challenge test sets (Rysová et al., 2019; Vojtěchová et al., 2019). Methodologies for assessing MT at the document-level have been looked into (Barrault et al., 2019, 2020) as well as the types of issues that come with different methodologies (Castilho, 2020, 2021).

We present a document-level corpus annotated with context-aware issues when translating from English (EN) into Brazilian-Portuguese (PT-BR). In total, 60 documents from six different domains (literary, subtitles, news, reviews, medical, and europarl) were annotated with context-aware issues, namely gender, number, ellipsis, reference, lexical ambiguity, and terminology. The corpus can be used as a challenge test set for the evaluation and as a training/testing corpus for MT and quality estimation, as well as for deep linguistic analysis of context issues. Moreover, we believe that the annotation can be also used for close-related languages such as Spanish.

2 Related Work

Document-level MT evaluation has attracted interest in the field as it allows for the evaluation of

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 566–577
November 10–11, 2021.

suprasentential content, which in turn, provides more meaningful insights on the MT output. However, the definition of what constitutes a document-level MT evaluation is still unclear (Castilho et al., 2020).

Context plays an important role as it is widely used in translation and interpreting literature (Baker, 2006), although it lacks a precise definition for practical purposes, including in everyday work of a professional translator (Melby and Foster, 2010). For Melby and Foster (2010, p 3), context in translation could be studied "either for the purpose of analysing existing translations or for the purpose of improving the production of new translations". For the authors, context can be categorised into *non-text* (non-linguistic variables) and *text* (linguistic aspects), where the latter is divided into four aspects of context: relating to the source text: *co-text* (the version of the document itself) and *chron-text* (past and future versions); and relating to other text: *rel-text* (monolingual related texts) and *bi-tex* (bilingual related texts). In this work, we adopt Melby and Foster's view of context that is important to the analysis of translations, and focus (i) on the co-text, i.e. the boundaries within the document translated, and (ii) in the non-text, where the name of the authors, speakers, and products have an effect on the translation.

In a survey with native speakers, Castilho et al. (2020) tested the context span for the translation of 300 sentences in three different domains, namely reviews, subtitles, and literature. The results showed that over 33% of the sentences tested were found to require more context than the sentence itself to be translated or evaluated, and from those, 23% required more than two previous sentences to be properly evaluated. The authors found that ambiguity, terminology, and gender agreement were the most common issues to hinder translation. Moreover, differences in issues and context span were found between domains. Their recommendations include to show whole documents when possible, include information on text type, topic, product, hotel and movie names in case of reviews, and include visual context whenever possible (non-text). This shows that document-level evaluation enables the assessment of textual cohesion and coherence types of errors which are impossible at times to recognise at sentence level.

Regarding overall MT evaluation, a few attempts have been made to perform human evaluation with document-level set-ups. Läubli et al. (2018) compared sentence-level evaluation versus document-level evaluation with pairwise rankings of fluency and adequacy to evaluate the quality of MT against human translation (HT) with professional translators. Their results show that document-level raters clearly preferred HT over MT, especially in terms of fluency. The authors argue that document-level evaluation enables the identification of certain types of errors, such as ambiguous words, or errors related to textual cohesion and coherence.

The Conference for Machine Translation (WMT), which has been running since 2006 and only evaluated sentences, attempted document-level human evaluation for the news domain for the first time in 2019 (Barrault et al., 2019). Their direct assessment (DA) (Graham et al., 2016) required crowdworkers to assign a score (0-100) to each sentence. They asked raters to evaluate (i) whole texts, (ii) single consecutive segments in their original order, and (iii) single random phrases. In the following year, WMT20 changed the approach and expanded the context span to include full papers, requiring raters to evaluate specific segments while seeing the complete document, as well as to assess the content's translation (Barrault et al., 2020).

Castilho (2020, 2021) tested for the differences in inter-annotator agreement (IAA) between single sentence and document-level set-ups. In Castilho (2020), the author asked translators to evaluate the MT output of freely available online systems in terms of fluency, adequacy (Likert scale), ranking and error annotation in two different set-ups: (i) translators give one score per single isolated sentence, and (ii) translators give one score per document. The results showed that IAA scores for the document-level set-up reached negative levels, and the level of satisfaction of translators with that methodology was also very low. Nonetheless, it avoided cases of misevaluation that happen in isolated single sentences. Following on from that work, Castilho (2021) modifies the document-level set-up and re-runs the experiment with more translators, where she compares the IAA in evaluation of (i) random single sentences, (ii) evaluation of individual sentences where translators have access to the full source and MT output, and (iii) evaluation of full documents. Results showed that a methodology where translators assess individual sentences within the context of a document yields a good level

of IAA compared to the random single-sentence methodology, while a methodology where translators give one score per document shows a very low level of IAA. The author demonstrates that the methodology of assigning one score per sentence in context avoids misevaluation cases which are extremely common in the random sentences-based evaluation set-ups. Moreover, the author posits that the higher IAA agreement in the random single sentence set-up is because "raters tend to accept the translation when adequacy is ambiguous but the translation is correct, especially if it is fluent" (Castilho, 2021, p 42), and asserts that the single random sentence evaluation method should be avoided as the misevaluation issue is especially problematic when assessing the quality of NMT systems as they have an improved fluency level.

One current way of evaluating document-level issues is the use of test suites designed to better evaluate translation of the addressed discourse-level phenomena. Commonly, these test suites are contrastive, that is, each sample sentence in the test has both correct and wrong translations for a given phenomena (Bawden et al., 2018; Guillou et al., 2018; Müller et al., 2018; Voita et al., 2019; Cai and Xiong, 2020). The higher the accuracy of the model in rating correct translations over incorrect ones, the better the quality is deemed to be. Test suites with document-level boundaries are still scarce, e.g. Vojtěchová et al. (2019) present a test suite designed to evaluate coherence when testing MT models trained for the news domain on audit reports, and Rysová et al. (2019) designed a document-level test suite to assess three document-level discourse phenomena, namely information structure, discourse connectives, and alternative lexicalisation of connectives.

Given the above, the need to move toward document-level methodologies in MT is indisputable. Moreover, with the lack of resources for the topic of document-level MT, the document-level corpus annotated with context-aware issues presented here can be used as a challenge test set for evaluation and as a training/testing corpus for MT as well as for deep linguistic analysis of context issues.

3 Corpus Compilation

The corpus was collected from a variety of freely available sources. Following a pre-determined list of context issues found in Castilho et al. (2020) that hindered the translation of single sentences and sentence pairs, the annotators searched for challenging English texts for the MT systems when translating into PT-BR. In total, 60 full documents (57217 tokens) were collected from six different domains: literary, subtitles, news, reviews, medical, and legislation (europarl). Table 1 shows the statistics of the corpus.

Domains	#Docs	#Sent.	Av. Sent. Lgth
Subtitles	9	1074	18.69
Literary	4	756	9.76
News	15	634	17.17
Reviews	28	608	13.42
Medical	3	339	13.02
Legislation	1	272	23.70
TOTAL	60	3683	15.57

Table 1: Full corpus statistics, where *average sentence length* is calculated as words per sentence.

Each domain has their plain text and .xls versions of the documents segmented into sentences with sentence id and document boundary tags, and all documents contain the source (url or corpus) where the documents were retrieved from. What follows is a detailed description of each domain is provided.[1]

3.1 Subtitles

To compile the corpus for the subtitle domain, nine full TED Talks were selected from the Opus Corpus (Tiedemann, 2012) from a variety of different topics and speakers, where: doc1: education, doc2: climate change, doc3: astronomy, doc4: computers, doc5: creativity, doc6: science, doc7: technology, doc8: anthropology, and doc9: psychology. We chose these talks specifically in order to obtain a blend of different topics and speakers' genders.

	#Sent.	#Tokens	Av. Sent. Lgth
doc1	105	1671	15.91
doc2	98	1309	13.35
doc3	40	650	16.66
doc4	71	1213	17.08
doc5	176	3654	20.88
doc6	130	2485	19.26
doc7	77	1384	18.45
doc8	167	4213	25.53
doc9	210	3346	16.00
TOTAL	1074	19925	18.55

Table 2: Corpus statistics for each document in the subtitle domain.

[1] Although some of the documents were already segmented by sentence (i.e. Opus and WMT), the full corpus was manually checked for sentence segmentation.

3.2 Literary

	#Sent.	#Tokens	Av. Sent. Lgth
doc1	205	2921	14.24
doc2	122	2002	16.40
doc3	76	689	9.06
doc4	353	1767	5.00
TOTAL	756	7379	9.76

Table 3: Corpus statistics for each document in the Literary domain.

To compile the corpus for the literature domain, four documents[2] were selected:
doc1: one chapter from a fan-fiction story.[3]
doc2: one excerpt from "The Road to Oz" book.[4]
doc3: a short story generated with the PlotGenerator website.[5]
doc4: a short play generated with the PlotGenerator website.

Note that a blend of contemporary and classic excerpts, combining descriptive and fast moving styles, were gathered. Note too that the synthetic stories (doc3 and doc4) were generated as they allowed the researchers to add a good number of possible issues, including lexical ambiguities cases that can only be solved with a larger context than two consecutive sentences which is rather difficult to find in "natural" texts. Nonetheless, English native speakers then revised both stories for fluency and readability. Table 3 shows the statistics for each document in the literary domain.[6]

3.3 News

The news domain was compiled with 15 documents gathered from different sources. Table 4 shows the statistics of the corpus.[7]

Five documents were gathered from the WMT series (four documents from WMT19[8] and one from WMT20[9]), and their size varied from 13 to 32 sentences. Ten documents were gathered from several news websites,[10] and they varied from 23-35 sentences.

	#Sent.	#Tokens	Av. Sent. Lgth
docs 1-5	112	2293	20.47
docs 6-15	521	8578	16.46
TOTAL	633	10871	17.17

Table 4: Corpus statistics for each document in the news domain.

3.4 Reviews

The reviews domain was compiled with 28 documents gathered from reviews available on Amazon[11] and TripAdvisor[12] websites. Table 5 shows the statistics of the corpus.[13]

Reviews gathered from Amazon consist of users' reviews about a variety of products and movies, totalling 25 reviews, and vary from 6 to 84 sentences. The reviews were sought by searching products that could generate lexical ambiguities, such as "plant", "ship", etc. Reviews gathered from TripAdvisor consist of 3 reviews about places, and vary from 23-35 sentences.

	#Sent.	#Tokens	Av. Sent. Lgth
docs 1-25	520	6901	13.27
docs 26-28	88	1261	14.32
TOTAL	608	8162	13.42

Table 5: Corpus statistics for each document in the review domain. Documents 1-25 are product reviews gathered on the Amazon website, and documents 26-28 are location reviews gathered on the TripAdvisor website.

3.5 Medical

The medical domain corpus was compiled with three full documents, where two of them were collected from Autopsy reports available on the Medical Transcriptions website,[14] and one document was collected from the leaflets available on the

[2] Excerpts of two copyrighted books are in the process of being granted permission, and if so, they will be added to the corpus.

[3] "Harmonic Resonances" (based on the Carrie film) fan fiction (archiveofourown.org/works/26524723/chapters/64650841), last accessed 01 June 2021.

[4] Chapter 3 "Queer Village" (www.gutenberg.org/files/485/485-h/485-h.htm#chap03), last accessed 21 June 2021.

[5] https://www.plot-generator.org.uk/ last accessed 21 June 2021.

[6] Note that the Av. Sent. Lgth for the literature domain is skewed because of doc4, which – due to its play format where the names of each character is given in a single line before they speak – contains a great number of very short sentences. The Av. Sent. Lgth for literature when doc4 is left out is 13.9.

[7] Note that for the news domain, we grouped documents due to space constraints.

4 Methodology for Annotation

Following literature on document-level test suites (see Section 2), together with issues found when trying to define how much context span is needed to translate and evaluate MT (Castilho et al., 2020), we compiled a list of context-aware issues that are challenging for MT when translating from EN into PT-BR to be annotated:

1- Gender	2- Number
3- Ellipsis	4- Reference
5- Lexical Ambiguity	6- Terminology

Three annotators tagged those issues that might occur in a translation from EN into PT-BR when no context information is given. For example, in the following single sentence given to a translator to translate:

"And thanks for the case."

The translator will not be able to translate this sentence with absolute certainty because:
i) it is not possible to know the gender of the person who is saying 'thanks' as Portuguese differentiates between masculine and feminine genders.
ii) it is not possible to know what the word "case" is as this word has a few different meanings that would fit this sentence, i.e it could be some type of protective box (a case for my phone, a case for my glasses), a woman's bag, a pencil case, a folder, a suitcase, or a police case to be investigated, each one with a different translation in Portuguese. Consequently, the translation of "for" will have a different gender depending on the meaning of the word "case".

When evaluating the translation of the source sentence given by 3 different MT systems (Google Translate[17] (GG), Microsoft Bing[18] (MS) and DeepL[19] (DPL) the translator has to evaluate all three systems' outputs as correct:
GG: "E obrigado pelo caso." (masculine, police case)
MS: "E obrigado pelo estojo." (masculine, pencil case)
DPL: "E obrigado pela caixa." (masculine, box)

That is because without a wider context, it is impossible to know the correct translation or the sentence, which should be:

HT: *"E obrigada pela capa."* (feminine, phone case)

Therefore, the issues tagged in the corpus are issues that might arise in the translation of sentences when the full context is not given. Annotators used different MT systems to help check for issues that would go unnoticed when only looking at the source text.

Moreover, a few modifications to the source text were performed in order to add those issues and make the translation more challenging for MT, such as modifying the gender, substituting the name of a product for 'it', splitting a sentence into two, etc. These modifications are explained in the spreadsheet file for each line modified, so researchers can decide if they can use or not documents that had the source modified.

4.1 Annotation of Context-Related Issues

As previously mentioned, six context-related issues were tagged in the corpus when they could not be solved within the sentence they appeared. A detailed guideline was developed as the annotators gathered the corpus and discussed how the annotation would be better performed. Figure 1 shows the decision tree that guides the annotation of the context-related issues.

[18] https://www.bing.com/translator
[19] https://www.deepl.com/en/translator

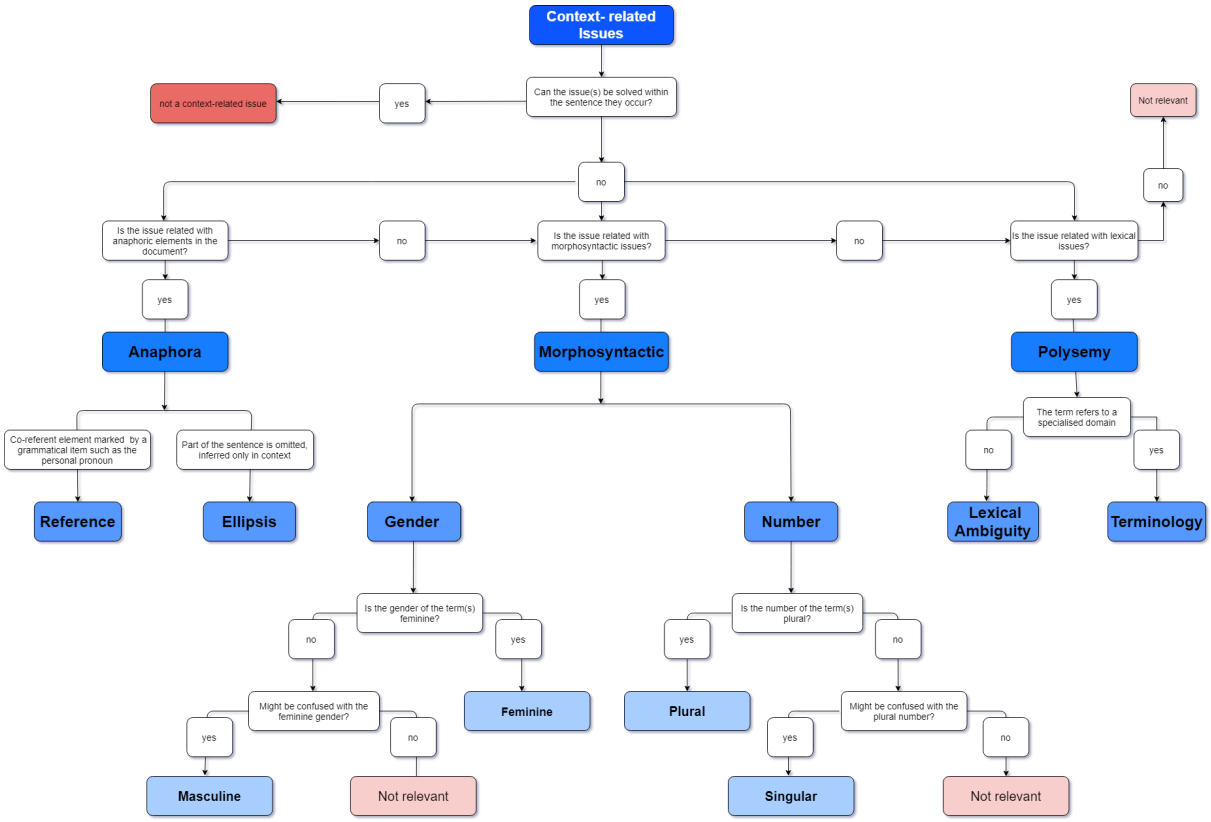

Figure 1: Decision tree used to guide the annotation of context-related issues.

4.1.1 Reference

Reference is associated with the notion that "anaphoric references and noun phrase organizers may serve as cohesive ties linking separate sentences into unified paragraphs [aiding] the reader's memory structure" (Fishman, 1978, p 159). Differently from ellipsis which is generally dependent on the previous clause, reference can reach back a long way in the text and extend over a long passage (Halliday and Matthiessen, 2013), thus being of significance for the present work.

In the annotation guide, we annotated the reference whenever we faced a disruption or ambiguity in the referential chain, e.g., we only annotated dependent referential units. Moreover, and similar to all annotated categories, the disagreement had to be expressed at the document level, e.g. the issue could not be solved only by looking at the sentence. In example **A)**, we annotate the second individual *it* as being a referential issue because there is not enough lexical material in the sentence to properly establish the referent, thus affecting translation correctness and final text readability.

A) *It is understandable though since* ***it*** *was shipped from China.*
reference –> it = the ship
it = o navio.

In example **B)**, we annotated *they* as being a referential unit issue, due to the fact that there is not enough lexical material in the sentence to determine its referent. Moreover, we also tagged this issue as a gender problem since there is no information in the source sentence that allows one to determine that the referential unit should be translated into PT-BR as a plural feminine pronoun.

B) *They actually hurt*
reference –> they = the choices
gender –> they = feminine
They actually hurt = Elas / As escolhas realmente machucam.

4.1.2 Ellipsis

Ellipsis is a form of anaphoric cohesion where there is an omission from a clause, and, so, the reader must "presuppose something by means of what is left out" (Halliday and Matthiessen, 2013, p 635). Ellipsis differs from reference as the relationship it entails is lexicogrammatical rather than semantic

(Halliday and Matthiessen, 2013).

In the annotation guide, we annotate ellipsis exclusively when the omission of information affects the translation of that specific single sentence which needs a broader context to be understood. For example, in **C)**, ellipsis is tagged because the omission with the explicit indication of "do" causes lexical ambiguity that cannot be solved within the sentence.[20] Therefore, the tags and the solution for the issues are both ellipsis and lexical ambiguity, with the translation of the ellipsis also containing an explanation of the lexical ambiguity caused by it.

C) *In my laughter, I bellied out a "YES, I do!!"*
ellipsis –> do = think
lexical ambiguity –> do = make (incorrect) *vs* think (correct)
Sim, eu faço! (Yes, I make, incorrect) *vs*
Sim, eu **acho!** (Yes, I "think", correct)

In example **D)**, ellipsis is tagged because the omission causes gender issues that cannot be solved within the sentence. Therefore, the tags and the solution for the issues are both ellipsis and gender, with the translation of the ellipsis also containing an explanation of the lexical ambiguity caused by the ellipsis:

D) *Several more are planned for the rest of the year, including The Angry Beavers Seasons 1 & 2, Danny Phantom Season 1, Aaahh!! Real Monsters Season 1, Catdog Season 1 Part 1 and The Wild Thornberrys Season 2 Part 1.*

ellipsis –> several more = releases
gender –> several more are planned = feminine
Several more are planned... = Vári**as** outr**as** estão planejad**as**..."

Sentence **E)** is an example of ellipsis with the auxiliary *do* that has not been tagged in the corpus because the omission is solved within the sentence:

E) *Also, not once did I **feel a blast of hot** air like I **do** when taking things out of the oven.*
do = feel a blast of hot air

[20]It is only with the previous sentence "*He came back in the house and said 'So you think this is funny?!' up the stairway at me and I LOST IT*" that we can solve "I do" as being "I think so".

4.1.3 Gender

As Portuguese is a language in which grammatical gender (feminine and masculine) plays a very significant role, the definition of gender used is from a grammatical standpoint, where word classes like adjectives, articles or pronouns are bound to respect and reflect a word's gender (Grosjean et al., 1994).

In the annotation guide, we annotated gender whenever facing a gender issue e.g., gender disagreement, unsolvable within the sentence itself and requiring broader context information.[21] For example, in example **F)**, gender (feminine) is tagged because the issue is not possible to be solved within the sentence. Since the default of the PT-BR is to have everything in the masculine, translations (both HT and MT) follow the same pattern. Therefore, we tag the word that needs to be in a different gender and the solution for its gender marker, with the translation containing an explanation:

F) *I'm surprised to see you back so early.*
gender –> surprised = feminine
surprised = surpresa

In example **G)**, we note that not only the pronoun "they" needs to be tagged with the feminine gender tag, but also the expression "staying at", as it is translated with an adjective in Portuguese:

G) *She waited for a few minutes longer, but nothing happened, no one followed her, so she made her way back to the motel they were staying at.*
gender –> they = feminine
gender –> staying at = feminine
they were staying at = elas estavam hospedadas

Gender was also tagged even when the most used translation for the the given term was a neutral one, because the adjective could still be translated with one of its synonyms. For instance, in example **H)**, the adjective "glad" has its most common translation as "feliz" which is used for both masculine and feminine gender. If a

[21]Note that gender was most exclusively tagged as *feminine* when a problem with the agreement was obvious. As the MT systems typically tend to translate the gender into the masculine form (when no specific gender markers are given in the single sentence) for PT-BR, the masculine gender was only tagged when there was an ambiguity in the sentence.

translator chooses to translate the text as "I'm glad = Estou feliz", no gender marking is needed. However, synonyms of that translation would need to be translated into feminine (satisfeita, grata, encantada, animada), and so, gender is tagged for that case:

H) *I'm so glad that it comes with the extender, so I have more levels to use to continue to get smaller.*
gender –> glad = feminine
reference –> it = waist cincher

4.1.4 Number

Number agreement is one of the basic coherence devices within a text, and it is "part of the code, used to signal that linguistic constituents carrying the same number are linked regardless of whether they appear together or apart in an utterance"(Bock et al., 1999, p 330), in the entirety of the text, and thus is significant for the present work.

In the annotation guide, we annotated number whenever we faced a number disagreement within the referential chain, e.g. (i) noun or pronoun, (ii) verb and noun/pronoun, (iii) adjective, caused by lack of enough contextual information within the sentence.[22] In example **I)**, the number category was applied to the word *you* because it is not possible to identify within this single sentence whether we are facing a pronoun in the plural or singular.

I) *I was praying for you.*
number –> you = plural
you –> vocês

Example **J)** depicts a mistranslated number agreement chain into PT-BR which originated from the absence of contextual evidence in the sentence that allowed us to determine whether *you* should be translated in the plural rather than in the singular. Furthermore, as a consequence of this initial mistranslation, the adjective *agreeable* was affected, being translated in the singular rather than the plural.

J) *You should be more agreeable.*
number –> you = plural
number –> agreeable = plural
number –> should be = plural
gender –> agreeable = feminine
You should be more agreeable. –> Você**s** dever**iam** ser mais simpátic**as/** agradáv**eis**.

4.1.5 Lexical Ambiguity

Lexical ambiguity refers to the fact that "a single word form can refer to more than one different concept" (Rodd, 2018, p 2). Lexical ambiguity can be divided into two categories: (i) one takes into account a word's morphological aspect (verbs, adjectives) referred to as syntactic ambiguity, e.g. the word "play" can be either the act of taking part in a sport or the conducting of a sporting match; and (ii) the second focuses on the fact that a word can assume different meanings according to context, e.g. the word "ball" as in *They danced till dawn at the ball* versus *This dog can be entertained all day with a ball* (Small et al., 2013, p 4), which is referred as semantic ambiguity.

In the annotation guide, we annotated lexical ambiguity, the more generic term, whenever we faced one of the two cases above ((i) and (ii)) and whenever they appeared to be detrimental to the translation and understandable only within the broader context, rather than at sentence level. In example **K)**, lexical ambiguity is tagged because the clause *I lost it*, without context, can be interpreted either as someone losing something or someone losing control:

K) *He came back in the house and said "So you think this is funny?!" up the stairway at me and I LOST IT.*

lexical ambiguity –> lose something *vs* to lose control
I lost it –> Eu o/a perdi *vs* Eu perdi o controle

In example **L)**, lexical ambiguity is tagged because the word *Period* is polysemic, meaning simultaneously menstruation, a portion of time, and a punctuation mark, and by the fact that there is not enough lexical information at a sentence level to disambiguate the complete meaning.

L) *Period.*
lexical ambiguity –> period = era/menstruation *vs* full stop
Período *vs* Ponto final

[22] Note that number was most exclusively tagged as *plural* for the pronoun "you" (and its referential chain (verb/adjectives)) when a problem with the agreement was obvious. As the MT systems typically tend to translate "you" in the singular (when no specific plural markers are given in the single sentence) for PT-BR, the pronoun was only tagged for singular when there was an ambiguity in the sentence.

4.1.6 Terminology

Terminology, according to Sager and Nkwenti-Azeh (1990) (as cited in (Kast-Aigner, 2018)), can have three different definitions: (i) the theory behind the relationship between a concept and a term; (ii) terminology curatorship activities, e.g. collection, description, processing and presentation of terms; and (iii) the vocabulary of a specific field. In the present work, we perceived terminology as (iii) i.e. the lexical expression of a domain-specific area.

In the annotation guide, we annotated terminology whenever we faced a wrongly domain-specific word translation caused by contextual poor sentences. In the following example **M)**, the category terminology was applied to the word 'farm' because its meaning shifts from "a piece of land used for crops and cattle raising", its more generalised conceptualisation, into a more domain-specific concept, "an area of land with a group of energy-producing windmills or wind turbines".

M) *The center will also conduct testing (power curve, mechanical loads, noise, and power quality) at its own experimental wind farm*
terminology –> generalised lexic (farm) *vs* domain-specific lexic (park)
wind farm –> parque eólico

4.2 Format

The annotation was performed for each sentence, which are tagged one per line, in the order they appear in the sentence, followed by their explanation/solution, along with modifications performed in the source (if any) and translations of some cases and notes. Sentences with no context-related issues are followed by two Xs for the issue and the solution. For Reference and Ellipsis, the term that contains the issue is stated along with an equals sign (=) and the explanation of what it refers to. For Gender and Number, the issue is tagged along with an equals sign (=) and the solution (feminine/masculine or singular/plural) is given. For Lexical Ambiguity and Terminology, the term (or terms) is stated along with an equals sign (=) and a contrasting solution is given, the wrong meaning(s) compared to (vs) the correct one. Table 8 illustrates how the annotation format is performed for each issue.

The corpus will be made freely available in two formats. One is a spreadsheet (.xls) containing the tagged corpus in all domains and full information. This .xls format will allow for filtering specific issues or sentences and enable users/researchers to see the rationale of the annotation. The corpus will be also available in plain text (.txt) format, containing the segment id, sentence, issue and explanation all in one line.[23] This format will allow for an automatic use of the corpus, for training or as a test suite. Figure 2 shows the .xls and .txt formats.

4.3 Agreement

As previously mentioned, three annotators compiled and annotated the corpus. Their backgrounds include linguistics, translation and computational linguistics. Throughout the process of compilation and annotation, the annotators worked closely together to discuss the corpus compilation and also what issues should be tagged. Disagreements were discussed and resolved, and then the annotation process would resume. This process helped to refine the list of issues as well as to develop and finalise the guidelines. The corpus annotation carried out by the three first annotators was corrected at the final stage in order to ensure that it follows the established version of the guidelines.

In order to reveal some possible weaknesses of the annotation guidelines and the decision tree, another expert annotator was involved at the final stage. The fourth annotator worked with 9% of the documents from the original collection, where at least one document of each domain was selected randomly. The annotation was done according to the guidelines and the decision tree used by the first three annotators (see Figure 1). During the annotation process, the annotator was given the guidelines, decision tree and was explained what the goal of the annotation was, but was not allowed to communicate with the other annotators. We then calculated inter-annotator agreement using Cohen's Kappa (Cohen, 1960) treating the first annotation (performed by the three annotators) as the gold standard.

Results show that the overall Kappa score was 0.61 meaning that, by using the guidelines and the decision tree on a first try, we could reach a substantial agreement (Landis and Koch, 1977). We note that the majority of disagreement cases are related to agreeing whether or not a sentence contains an issue to be annotated, while our gold

standard has 170 issues annotated in this portion of the corpus, the fourth annotator found 106 issues. After this IAA was calculated, we discussed the annotation produced by annotator 4 and revised the corpus.

5 Conclusion

We have presented a document-level corpus annotated with context-aware issues when translating from EN into PT-BR, namely gender, number, ellipsis, reference, lexical ambiguity, and terminology. This first version of the corpus contains 60 documents, with 3680 sentences, in six different domains: subtitles, literary, news, reviews, medical and legislation. To the best of our knowledge, this is the first corpus of its kind.[24]

With the rise in NMT quality and the claims of human parity, the need to move towards a more fine-grained evaluation involving the whole document is beyond question. Moreover, with the lack of resources for the document-level MT area, this document-level corpus can be used as a challenge test set for evaluation and as a training/testing corpus for MT as well as for deep linguistic analysis of context issues. We believe that the annotation can be also used for closely-related languages such as Spanish.

We intend to increase the corpus, adding more documents, domains and more context-aware issues. The full translation into PT-BR is ongoing, and we want to annotate it for other languages, starting with the Romance language family.

[24]The corpus and guidelines will be freely available at https://github.com/SheilaCastilho/DELA-Project

Multilingual Domain Adaptation for NMT: Decoupling Language and Domain Information with Adapters

Abstract

Adapter layers are lightweight, learnable units inserted between transformer layers. Recent work explores using such layers for neural machine translation (NMT), to adapt pre-trained models to new domains or language pairs, training only a small set of parameters for each new setting (language pair or domain). In this work we study the compositionality of language and domain adapters in the context of Machine Translation. We aim to study, 1) parameter-efficient adaptation to multiple domains and languages simultaneously (full-resource scenario) and 2) cross-lingual transfer in domains where parallel data is unavailable for certain language pairs (partial-resource scenario). We find that in the partial resource scenario a naive combination of domain-specific and language-specific adapters often results in 'catastrophic forgetting' of the missing languages. We study other ways to combine the adapters to alleviate this issue and maximize cross-lingual transfer. With our best adapter combinations, we obtain improvements of 3-4 BLEU on average for source languages that do not have in-domain data. For target languages without in-domain data, we achieve a similar improvement by combining adapters with back-translation. Supplementary material is available at https://tinyurl.com/r66stbxj.

1 Introduction

Multilingual Neural Machine Translation (NMT) has made a lot of progress recently (Johnson et al., 2017; Bapna and Firat, 2019; Aharoni et al., 2019; Zhang et al., 2020; Fan et al., 2020a) and is now widely adopted by the community and MT service providers. Multilingual NMT models handle multiple language directions at once and allow for knowledge transfer to low-resource languages. Machine translation systems often need to be adapted to specific domains like legal or medical text. However, when adapting multilingual systems, in-domain data for most language pairs might not exist. We would like to be able to leverage data in a subset of language pairs to transfer domain knowledge to other languages.

Straightforward methods of domain adaptation include fine-tuning (Freitag and Al-Onaizan, 2016) or usage of domain tags (Kobus et al., 2017; Britz et al., 2017) for different domains. For these methods each new domain request would require retraining the whole model, which is a costly procedure. And naive training on a subset of languages typically reduces performance on all other languages (Garcia et al., 2021), a phenomenon known as 'catastrophic forgetting' (McCloskey and Cohen, 1989).

An alternative technique for adapting such models to new language-pairs or domains are 'adapter layers' (Bapna and Firat, 2019), lightweight, learnable units inserted between transformer layers. A previously trained large multilingual model can be adapted to each language-pair by learning only these small units, and keeping the rest of the model frozen. This procedure also allows for the incremental adding of new language pairs and/or domains to the pre-trained model, reducing the cost of adaptation. Previous studies have shown it is possible to combine language-specific (as opposed to language-pair specific) adapters (Philip et al., 2020), or language and task adapters (Pfeiffer et al., 2020) trained independently, enabling zero-shot compositions of adapters. Our ultimate goal is, for ease of deployment and storage, a single model that can handle all languages and domains. In this work we analyse how to combine *language adapters* with *domain adapters* in multilingual NMT, and study to what extent the domain knowledge can be transferred across languages.

First, we show it is hard to decouple language

*Work done during an internship at NAVER LABS Europe.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 578–598
November 10–11, 2021.

knowledge from domain knowledge when fine-tuning multilingual MT systems on new domains. In Section 5.2 we demonstrate that adapters learnt on a subset of language pairs fail to generate into languages not in that subset. Such generation into the wrong language is referred to as 'off-target' translation. We additionally find combinations of domain and language adapters not seen at training time lead to bad performance. We examine how adapter placement and other techniques can improve the compositionality of language and domain adapters when dealing with source or target languages that do not have in-domain data (which we refer to throughout this work as "**out-of-domain languages**"). Our key contributions are:

- We examine domain adaptation capacity in the multi-lingual, multi-domain setting. We find that encoder-only adapters can be just as effective as default adapters added in every layer, and that composing domain adapters with language adapters outperforms language adapters alone, although fine-tuning with domain tags performs better for most domains.
- We improve the cross-lingual transfer of domain knowledge for adapters. We analyse different language and domain adapter combinations that improve performance and reduce off-target translations. Our best results for translation into out-of-domain languages use decoder-only domain adapters, regularisation with domain adapter dropout, and data augmentation with English-centric back-translation.

2 Related Work

Cross-lingual transfer Many works have demonstrated that large pre-trained multilingual models (Devlin et al., 2019; Conneau et al., 2020; Liu et al., 2020) fine-tuned on high-resource languages (or language pairs) can transfer to lower-resource languages in various tasks: Natural Language Inference (Conneau et al., 2018), Question Answering (Clark et al., 2020), Named Entity Recognition (Pires et al., 2019; K et al., 2020), Neural Machine Translation (Liu et al., 2020) and others (Hu et al., 2020).

Domain adaptation in NMT Domain adaptation has been discussed extensively for bilingual NMT models. A typical approach is to fine-tune a model trained on a large corpus of 'generic' data on a smaller in-domain corpus (Luong and Manning, 2015; Neubig and Hu, 2018). A common technique to make use of monolingual in-domain data is to do back-translation (Sennrich et al., 2016a; Berard et al., 2019a; Jin et al., 2020). Although effective, it is expensive to create back-translated data, especially when one needs to cover multiple language pairs. Multi-domain models can be trained with domain tags (Kobus et al., 2017; Britz et al., 2017; Berard et al., 2019a; Stergiadis et al., 2021) that can encode domain-specific information. However, domain tags do not allow *incrementally* adding new domains to a model: each new domain adaptation requires retraining the full model (as opposed to adapter layers that can be trained independently for each language/domain). There are a number of works (Jiang et al., 2020; Britz et al., 2017; Dabre et al., 2020) trying to explicitly decouple domain-specific representations from domain independent representations in bilingual settings. In our work we try to decouple language and domain specific representations through adapter layers.

Adapter layers Bapna and Firat (2019) introduce adapter layers for NMT as a lightweight alternative to fine-tuning. They study both adding language-pair specific adapters to multilingual NMT models to match the performance of a bilingual version, and domain-specific adapters for parameter-efficient domain adaptation. Philip et al. (2020) train adapters for each *language* instead of *language-pair* and show that composing such adapters improves zero-shot translation in English-centric settings, and can adapt a model to all language directions in a scalable way. Pfeiffer et al. (2020, 2021) study adapter layers for pre-trained language models evaluated on NLU tasks. They show it is possible to compose language and task adapters. Combining language adapters trained with a masked language modelling objective for language x and task adapters trained on a classification task in language y can transfer to classification in language x. We have a similar objective to Pfeiffer et al. (2020), but for NMT where in addition to encoding sentences we need to generate text for new language and domain combinations.

To the best of our knowledge none of the works above study composing language and domain adapters for generation tasks (such as translation) which is the goal of this work.

3 Composing Adapter Modules

Adapter modules (Rebuffi et al., 2017; Houlsby et al., 2019) are randomly initialised modules inserted between the layers of a pre-trained network and fine-tuned on new data. An adapter layer is typically a down projection to a bottleneck dimension followed by an up projection to the initial dimension, which we write as $\text{FFN}(\mathbf{h}) = W_{\text{up}} f(W_{\text{down}}\mathbf{h})$, with $f(\cdot)$ a non-linearity. The bottleneck controls the parameter count of the module; typically NMT requires slightly larger parameter counts than classification to match fine-tuning (Bapna and Firat, 2019; Cooper Stickland et al., 2021). With a residual connection and a near-identity initialization the original model is (approximately) retained at the beginning of optimization, keeping at least the performance of the parent model.

3.1 Stacking Domain and Language Adapters

In this work we study 'stacking' adapter modules, i.e. each language and domain has a unique adapter module associated with it. When passing a batch with source language x, target language y, and domain z, we only 'activate' the adapters for $\{x, y, z\}$. The encoder adapters for x and decoder adapters for y are activated.

We mostly follow the architecture of Bapna and Firat (2019). Language adapters LA are defined as:

$$\text{LA}(\mathbf{h}_l) = \text{FFN}_{\text{lg}}(\text{LN}_{\text{lg}}(\mathbf{h}_l)) + \mathbf{h}_l \quad (1)$$

where $\mathbf{h}_l$ is the Transformer hidden state at layer l and LN_{lg} is a newly initialised layer-norm. Let $\mathbf{z} = \text{LA}(\mathbf{h}_l)$; when stacking domain and language adapters, the layer output $\mathbf{h}_{l,\text{out}}$ is given by:

$$\mathbf{h}_{l,\text{out}} = \text{FFN}_{\text{dom}}(\text{LN}_{\text{dom}}(\mathbf{z})) + \mathbf{z} \quad (2)$$

For all models without any stacking we obtain layer output as in Eq. 2 but replace $\text{LA}(\cdot)$ with the identity operation.

Pfeiffer et al. (2020) use a different formulation that empirically performed well for them, but that in initial experiments produced worse results in our setting. We list the corresponding equations and results in Appendix B and Appendix D.

3.2 Improving the Compositionality of Adapters

In our initial experiments (Section 5.2) we found that (unlike Pfeiffer et al., 2020) naive stacking of language and domain adapters does not work very well for unseen combinations of language and domains, and often results in off-target translation (i.e. translations into the wrong language). Therefore, we study several strategies to improve the compositionality of adapters in the context of NMT:

1) Using **decoder-only** domain adapters when translating from an out-of-domain source language into an in-domain[1] target language, and **encoder-only** domain adapters when translating from an in-domain source language into an out-of-domain target language. This means we never stack together a combination of language and domain adapter that was not seen at training time. We also find empirically that decoder-only adapters work well with back-translation, perhaps because they can 'ignore' the noisy synthetic source-side data.

2) **Domain adapter dropout** (DADrop). Similar to layer-drop (Fan et al., 2020b) but specialised to adapter layers, or AdapterDrop (Rücklé et al., 2020) but without targeting specific layers, we randomly 'drop' (i.e. skip) the domain adapter[2] and only pass the hidden state through the language adapter. This means the adapter stack in the layer above can more easily adapt to unfamiliar input, and encourages domain and language adapters to be more independent of each other.

3) **Data augmentation**. We often have access to monolingual data in a domain even when no parallel data is available. In this work we leverage English-centric back-translation (BT), i.e. translating monolingual data in some languages into English (thus avoiding the more expensive step of translating from each language into every other language). We examine the ability of such data to help cross-lingual transfer to unseen combinations of source and target language (BT means we have artificial data for every language in combination with English). We briefly explore '*denoising auto-encoder*' style objectives as in unsupervised MT (Lample et al., 2018) or sequence-to-sequence pre-training (Lewis et al., 2020).

[1] Reminder we refer to the subset of languages we have parallel data for in a particular domain as 'in-domain', and all other languages as 'out-of-domain'.

[2] We could additionally drop the language adapter, but since this was frozen in many experiments we limit ourselves to domain adapters for simplicity

4 Experimental Settings

4.1 Data

For studying the domain transfer across languages we select four diverse domains that have data available in most language directions: translations of the Koran (**Koran**); medical text from the European Medicines Agency (**Medical**); translation of TED Talks transcriptions (**TED**); various technical IT text, e.g. the Ubuntu manual (**IT**). All data was obtained from the OPUS repository (Tiedemann, 2012). We create validation and test sets of around 2000 sentences each, and avoid overlap with training data (including parallel sentences in any language) with a procedure described in Appendix A. Note that Medical, Koran and IT are from the same source as those of Aharoni and Goldberg (2020), although the train/test splits are different due to expanding the number of languages and wanting a consistent pipeline for obtaining the data.

Domain	Langs.	Avg size (lines)
ParaCrawl	12	125M
Koran	10†	52k
Medical	11‡	500k
IT	12	196k
TED	12	138k

Table 1: Basic statistics for the datasets we use; number of languages covered, and average number of training examples across all language directions. †: missing nb & da, ‡: missing nb.

4.2 Models

In **multilingual settings** we concentrate on 12 high-resource European languages[3] due to the availability of domain-specific parallel data for most language pairs. Our **baseline model** is a Transformer Base (Vaswani et al., 2017) trained on English-centric ParaCrawl v7.1 data (Bañón et al., 2020) with all 12 languages (803M line pairs in total). It is trained with fairseq (Ott et al., 2019) for 800k updates, with a batch size of maximum 4000 tokens and accumulated gradients over 64 steps (Ott et al., 2018).[4] The source/target embeddings are shared and tied with the output layer. We tokenize the data with a shared BPE model of size 64k with inline casing (Berard et al., 2019b) Both the multilingual models and BPE model are trained with temperature-based sampling with $T = 5$ (Arivazhagan et al., 2019). We calculate all BLEU scores with Sacrebleu[5] (Post, 2018). On the recommendation of Marie et al. (2021) we additionally report chrF (Popović, 2015) calculated using Sacrebleu[6] for most models in the Appendix. We use adapter bottleneck size of 1024 unless stated otherwise, and when using DADrop (Section 3.2) use a 20% chance of skipping the domain adapter.

We additionally train monolingual language adapters (Philip et al., 2020) for all 12 languages on multi-parallel ParaCrawl data, which we obtain by aligning all languages through their English side, like Freitag and Firat (2020). The adapters are trained for another 1M steps, without accumulated gradients. We report the results of models fine-tuned on both all the domains simultaneously, or each domain separately, with access to in-domain data available for all the languages. Both serve as a potential upper bound for cross-lingual transfer.

We train the same model (i.e. with access to all languages) with domain tags: one special token per domain prepended to each source sequence (Kobus et al., 2017). We also measure the cross-lingual transfer ability of domain tags, by training a model with domain tags on all 4 domains but with in-domain data in only 4 languages (fr, de, cs and en). Because the latter model exhibits catastrophic forgetting issues in the other languages, we also train the same model with ParaCrawl data in all language directions (with a "paracrawl" domain tag). ParaCrawl line pairs are sampled with probability 0.5. More training hyper-parameters are given in Appendix A.

4.3 Our model pipelines

We perform two series of experiments.

Multilingual multi-domain models. Firstly, we experiment with different ways of multi-domain adaptation of multilingual models. We adapt the English-centric ParaCrawl pre-trained model to four domains (Koran, Medical, IT and TED) and every language direction simultaneously. We test models with language adapters, language + domain adapters, and domain tags. There is no cross-lingual domain transfer needed[7] since all language

[3] {cs, da, de, en, es, fr, it, nb, nl, pl, pt, sv}

[4] This corresponds to an effective batch size of ≈207k tokens and training length of 7 epochs.

[5] Signature: BLEU+case.mixed+lang.m2m-en+numrefs.1+smooth.exp+tok.13a+version.1.5.0.

[6] Signature: chrF2+numchars.6+space.false+version.1.5.1

[7] There is obviously cross-lingual domain transfer that may take place when all the domains are trained jointly, but we do

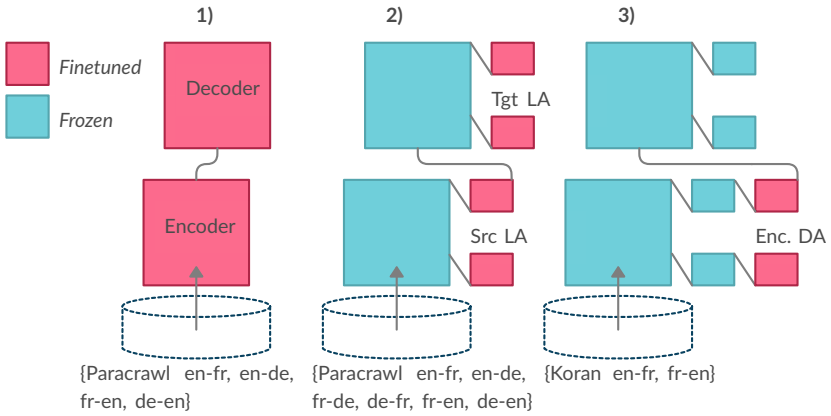

Figure 1: Toy diagram showing one of our proposed pipelines for training language and domain adapters, on a example subset of languages: {en,fr,de}, with 'domain-agnostic' data from ParaCrawl and specialised data from the Koran. Red indicates a fine-tuned model component, blue indicates a frozen component. LA = language adapter, DA = domain adapter. From left to right we show: 1) Training an encoder-decoder model with English-centric ParaCrawl. 2) Training mononlingual language adapters with multiparallel Paracrawl data. 3) Training domain adapters stacked on language adapters in the encoder, on a subset (here {en, fr}) of languages for the domain of interest (e.g. Koran). Here we show domain adapters added only to the encoder, but we consider various other configurations in this work.

directions are included in the training data. Results for this scenario are reported in Section 5.1.

Cross-lingual domain transfer. In the second experiment we try to decouple the notion of domain from language via analysing the zero-shot composition of domain and language adapters. This is described in a toy diagram in Figure 1. We first extend the baseline multilingual English-centric model with 12 (one for each language) monolingual language adapters (Philip et al., 2020) trained on multi-parallel ParaCrawl. We then test the cross-lingual domain transfer ability of our proposed combinations of adapters by training on data in a particular domain with a subset of four languages (referred to as '**in-domain**'; in Figure 1 *en* and *fr* would be in-domain). We test our model on all language directions from the set of all twelve languages. This will include cases where we don't have in-domain data for either the source or target language, which we refer to as '**out-of-domain**' (in Figure 1 *de* would be out-of-domain).

Finally, we extend the above mentioned scenario with back-translated (BT) data from *out-of-domain* languages into English. To create the BT data, we use the model with language adapters trained on ParaCrawl **(11)** (which has not seen any in-domain data) on the English-aligned training data for each language and domain, and use beam search with a beam size of 5. Results for this scenario are reported in Section 5.2.

To train language and domain adapters, we freeze all model parameters except for adapter parameters, and use a fixed learning rate schedule with learning rate 5×10^{-5}. Following Philip et al. (2020), when training language adapters without domain adapters we build homogeneous batches (i.e. only containing sentences for one language direction) and activate only the corresponding adapters. When training language *and* domain adapters together, we build homogeneous batches that only contain sentences for the same combination of language direction and domain.

5 Results and Discussion

First, in Section 5.1 we discuss the results of experiments testing the domain adaptation capacity of various models, assuming access to data for all language pairs. In Section 5.2 we analyse domain transfer across languages with adapters and other methods. We first demonstrate problems with cross-lingual generalisation during domain adaption for 'naive' methods, and then propose potential solutions. Note we concentrate on the medical domain and a particular language subset for convenience. Appendix D has results in

not explicitly study this in the first experiment.

ID	Model	IT	Koran	Medical	TED	Params (M)
(1)	Base (En-centric)	23.2	7.0	25.7	19.0	N/A
(2)	Finetuned	40.8	16.0	42.7	26.6	79
(3)	Finetuned + domain tags	**43.6**	**20.3**	**46.0**	27.2	79
(4)	Single adapter per layer ($d = 1024$)	39.6	14.7	41.8	26.2	12.6
(5)	LA ($d = 1365$)	42.0	17.6	43.7	26.8	202
(6)	LA ($d = 2048$)	42.2	18.1	43.8	26.9	303
(7)	LA + dec. DA ($d = 1024$)	42.1	18.5	43.6	27.1	177
(8)	LA + enc. DA ($d = 1024$)	42.3	19.3	43.8	27.5	177
(9)	LA + enc & dec. DA ($d = 1024$)	42.7	20.1	44.0	**27.7**	202

Table 2: BLEU scores averaged across all the language-directions for various multilingual multi-domain adaptation strategies, i.e. training on all language directions from the 12 languages and all domains. LA = language adapters, DA = domain adapters. 'Params (M)' refers to the number of trainable parameters in millions. Note that unlike in Table 3 the LA here are not pre-trained on ParaCrawl; they are trained jointly with domain adapters.

ID	Model	All	In→in	Out→in	In→out	Out→out
	Oracles					
(10)	Finetune (all langs)	44.3	43.9	44.8	44.2	44.2

(25)	**(23)** + DADrop + BT	35.2	44.5	33.4	**38.2**	31.8

Table 3: BLEU score of various models trained on the {en, fr, de, cs} subset of the Medical domain, except 'Oracle' models trained on all language pairs. LA = language adapters, DA = domain adapters. 'Out→in' is the average score when translating from an out-of-domain source language into {en, fr, de, cs}. 'In→out' corresponds to when the out-of-domain language is the target language. 'In→in' refers to average score when source and target are in the set {en, fr, de, cs}. 'Out→out' is the average score when both the source and target language are unseen during domain adaptation. We note percentage of **on-target** (correct language) translations in brackets, when it is less than 90% only.

other domains and language subsets, and also chrF (Popović, 2015) scores; we find similar trends to those reported in Section 5.2.

5.1 Multilingual multi-domain models

Table 2 reports the results from the challenging task of adapting a multilingual NMT model to multiple domains and language directions simultaneously. In this scenario, we assume access to in-domain data in all the language directions, and so we are testing the capacity of various models for domain adaptation, rather than cross-lingual transfer. Models are compared against a baseline **(1)** not trained on in-domain data.

We report the results for naive fine-tuning on the concatenation of in-domain parallel datasets for all the languages and all the domains **(2)**. On all domains we improve on these results by fine-tuning with domain tags **(3)** (a similar result to Jiang et al. (2020) in the bilingual setting). Fine-tuning with domain tags **(3)** outperforms the model with stacked adapters **(9)**. A fine-grained comparison of these models is in Figure 5 in the Appendix. For the IT and Medical domains the model with tags **(3)** is clearly better for all language directions. For the lowest resource domains, Koran and TED, most of the differences are not statistically significant, except for English-centric language pairs for TED, where the adapter model **(9)** is better. Exploring the combination of domain tags and adapters could be an interesting future research direction.

Stacking domain and language adapters **(9)** results in better performance than a model with the same parameter budget devoted to language adapters only **(5)**. We believe this is because it allows the model to (partially) decouple domain from language-specific information, and better exploit the allocated parameter budget. Even a higher capacity language adapter model **(6)** does not perform as well.

We also note that usage of encoder-only domain adapters **(8)** outperforms the decoder-only domain adapter model **(7)**. This is perhaps because the encoder representations influence the whole model (it is directly connected to the decoder at all layers with encoder-decoder attention) as opposed to the the decoder adapters that only impact decoder representations. We find a similar trend in bilingual domain adaptation, see Appendix C.

The strong performance of encoder-only adapters has interesting implications for inference speed. With an auto-regressive decoder, the computational bottleneck is on the decoder side. The encoder output is computed all at once, while computing the decoder output requires L steps, where L is the output length. This implies devoting more capacity to encoder adapters would achieve similar performance and faster inference (more details in Appendix C).

5.2 Cross-lingual Domain Transfer

To study the capacity of our models to transfer domain knowledge across languages, we perform domain adaptation using parallel datasets for a *subset* of language pairs, and evaluate on the test sets available for *all* language pairs. In this section we report the results for adaptation to the *medical* domain using the subset of all the language directions including {en, fr, de, cs} languages (Table 3). We refer to these languages as *in-domain* languages, and *out-of-domain* languages would include all the other languages, {de, nl, sv, es, it, pt, pl } (referred to as *In* and *Out* respectively in Table 3).

We report BLEU scores averaged across test sets of different categories of language-directions depending on whether the source/target language was observed during the domain adaptation training: In→in for language pairs observed during DA, Out→out for fully zero-shot DA performance, and In→out, Out→in for translation directions combining *in-domain* and *out-of-domain* languages.

First, we report the results for *Oracle* models providing an upper bound for the scores models could achieve with access to in-domain data for *all* the languages: model **(10)** was fine-tuned on *medical* data for all the language directions[8], and a model with domain tags **(3)** discussed in section 5.1.

Baseline models include the default multilingual English-centric model **(1)**, as well as model **(11)** with language adapters trained on multi-parallel ParaCrawl data. Comparing against this baseline shows us improvements from domain-specific (rather than language-specific) information.

Straightforward Methods We train several 'straightforward' adapter models for the subset of *in-domain* languages on the top of the baseline model, one with no language adapters, model **(12)**, and model **(13)** with domain *and* language adapters (where language adapters are frozen), stacking them in the encoder and decoder.

[8]This is different from the model **(3)** which was fine-tuned on *all* the domains and all the language directions.

Both of these models achieve good scores when translating into *in-domain* languages (the In→in and Out→in categories), on par or better than *Oracle* scores and much higher than the baselines. On the other hand they suffer from significant drops in performance when translating into *out-of-domain* languages (the In→out and Out→out categories).

The model **(16)** trained with tags on a subset of *in-domain* languages suffers from the same low performance translating into *out-of-domain* languages and additionally has low performance with out-of-domain *source* languages.

Looking closer at the translations of the above models, we see that many translations are either generated in English, copy the source language, or mix words between English and the true target language; see Table 4 in the Appendix for illustrative examples. We refer to this phenomenon as "off-target" translation. We report the percentage of translations generated in the correct target language in Table 3 when it is lower than 90% [9].

We believe this phenomenon is partly due to decoder domain adapters having never been exposed to *out-of-domain* language generation. Encoder domain adapters seem to be less sensitive to composition with new language adapters (as observed by Pfeiffer et al. (2020) for NLU tasks, and Table 3 in the Out→In column).

To investigate this, we train models **(14)** and **(15)** with encoder-only and decoder-only adapters. Figure 2 compares the performances of these models as well as model **(13)** trained with encoder and decoder domain adapters, **(14)**, **(15)** against the baseline model **(11)**. The decoder-only model **(15)** can better translate *from* out-of-domain languages and the encoder-only model **(14)** slightly improves for translations *into* out-of-domain languages. However the problem of off-target translation persists for both models and neither improves over ParaCrawl LA **(11)**. Therefore, we conclude that a straightforward combination of domain and language adapters leads to catastrophic forgetting both in the encoder and the decoder, but the encoder is less important for this effect.

Effect of data augmentation We train models **(17)**,**(18)** **(19)**, **(20)** with additional data (either a portion of ParaCrawl data, or back-translation of in-domain data) to alleviate potential forgetting of representations for *out-of-domain* languages. All of these models improve the translation quality into *out-of-domain* languages. The model with tags **(17)** reaches competitive results and can be considered as a strong baseline.

For models with back-translation data, the decoder-only adapter **(20)** model outperforms the encoder-only adapter **(19)** model on out-of-domain target languages (as opposed to the case without BT) and has the strongest results overall on translating into out-of-domain languages. While the BT models are trained on exactly the same data, this effect is possibly due the encoder adapters being more influenced by potentially noisy synthetic source-side data, whereas decoder adapters are more influenced by clean reference translations. The decoder-only BT model **(20)** improves over the baseline for all the language directions except for translation into English; see Figure 3.

We report results for the other data augmentation methods (see Section 3.2) in Appendix D; these only improve over the ParaCrawl LA baseline in limited settings.

Domain adapter dropout Models **(21)** and **(22)** trained with dropping domain adapters (DADrop; see Section 3.2) also allow to reduce catastrophic forgetting, although only combining DADrop with Data Augmentation (model **(22)**) allows to solve the problem of off-target translation. We also note slight decreases in *in-domain* performance for those models, perhaps due to underfitting.

Increasing adaptation capacity When naively increasing model capacity by unfreezing LA stacked with decoder DA **(23)**, the model seems to mostly devote this capacity to In→in category, and suffers on other language pair groups. This trend seems to be similar to the un-augmented model with tags **(16)**. However, once regularized with DADrop **(24)**, and augmented with back-translation **(25)** it reaches very competitive results.

Figure 4 shows fine-grained results for different models with DADrop, back-translation and unfrozen LA. Back-translation improves performance on the Out→out and In→out groups, but decreases performance on the Out→in group. Finally, unfreezing language adapters decreases the performance on Out→in but improves on the Out→out group.

[9] This percentage is computed against the reference translations that were correctly tagged by 'langdetect', a Python language identifier (`https://pypi.org/project/langdetect/`). This is to exclude very short and numerical examples which can be quite frequent in some domains.

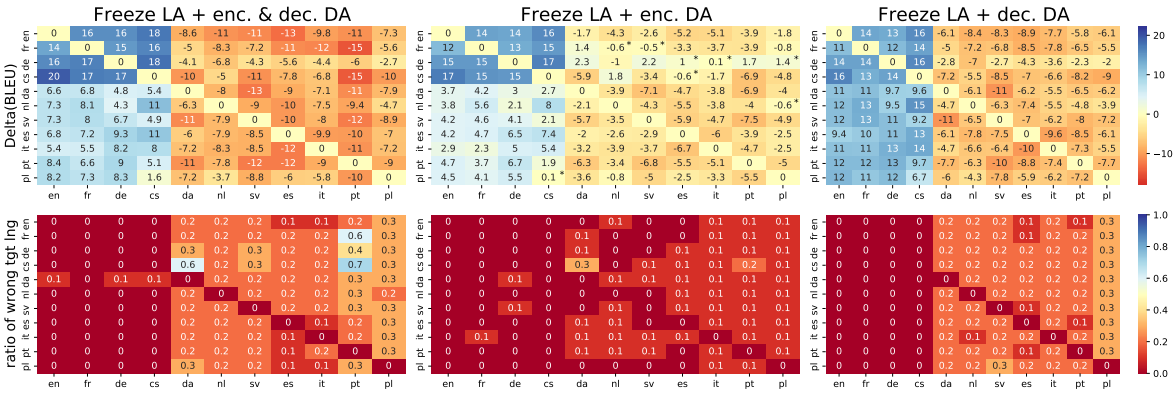

Figure 2: Comparing models with encoder-decoder adapters, encoder-only adapters and decoder-only adapters. x-axis shows the target language and y-axis shows the source language. Languages are grouped so the in-domain languages are in the top left corner. Top: Difference in BLEU compared to the baseline **(11)** (negative scores indicate a decrease w.r.t. the baseline, "*" indicates *not* statistically significant). Bottom: proportion translating into the wrong target language. Best viewed in .pdf form.

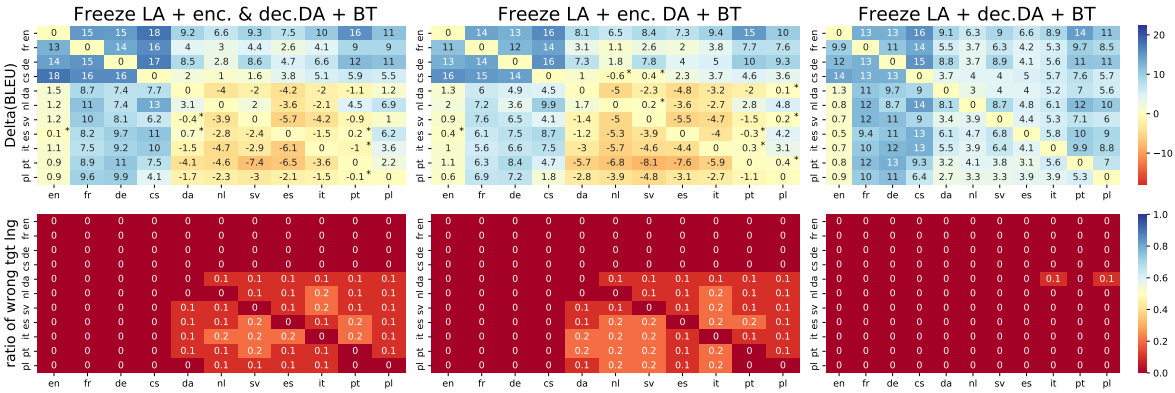

Figure 3: Comparing adapter models trained with back-translation. Top: Difference in BLEU compared to the baseline **(11)** ("*" indicates *not* statistically significant). Bottom: proportion translating into the wrong target language. See Figure 2 for more details.

Adapters vs. tags As mentioned previously, model **(17)** with tags augmenteed with ParaCrawl reaches competitive scores overall. Note that this model was trained on a concatenation of *all* the domains, unlike the models with adapters which were trained *only* on the medical domain. Therefore it has been exposed to more data overall. On the other hand, several of our models fine-tune only a single adapter per-layer and use frozen LA. Thus, encoder-only or decoder-only models only require 6.3 million tunable parameters, compared to 79 million for tag-based models. Additionally adapter models can easily be 'mixed-and-matched' by activating a particular adapter for a particular language pair. For example we could activate model **(15)** on 'Out→in' (out-of-domain source, in-domain target) data, model **(18)** on in-domain data and model **(20)** otherwise. Such models could easily be extended to new domains by training more adapters, in contrast to tag-based models which update all parameters for each domain adaptation request.

6 Conclusion

In this work we studied multilingual domain adaptation both in the full resource setting where in-domain parallel data is available for all the language pairs, as well as the partial resource setting, where in-domain data is only available for a small set of languages.

In particular, we study how to better compose language and domain adapter modules in the context of NMT. We find that while adapters for encoder architectures like BERT can be safely composed, this is not true for NMT adapters: domain adapters learnt in the partial resource scenario struggle to generate into languages they were not trained

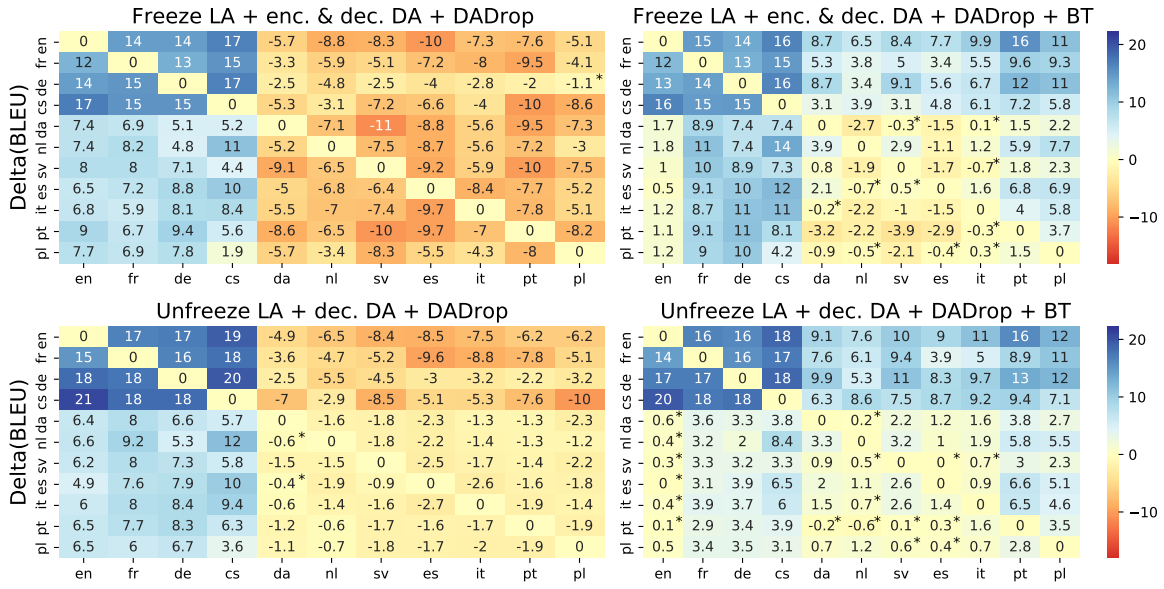

Figure 4: Comparing models with DADrop, back-translation and unfrozen language adapters. Difference in BLEU compared to the baseline **(11)** ("*" indicates *not* statistically significant). See Figure 2 for more details.

on, even though the original model they are inserted in was trained on those languages. We found that randomly dropping the domain adapter and back-translation can regularize the training and lead to less catastrophic forgetting for when generating into out-of-domain languages, although they do not fully solve the problem of off-target translation.

We experimented with different adapter placement and found that devoting additional capacity to encoder adapters can lead to better results compared to when the same capacity is shared between the encoder and the decoder. Similarly, in the partial resource scenario, models with encoder-only domain adapters suffer less from catastrophic forgetting when translating into out-of-domain languages. In contrast, decoder-only domain adapters perform well when translating *from* out-of-domain into in-domain languages, and combine well with back-translation, perhaps due to their ability to ignore noisy synthetic source data.

Finally we note that a model fine-tuned with domain tags serves as a very competitive baseline for multilingual domain adaptation. On the other hand, domain adaptation with adapters offers modularity, and allows incrementally adapting to new domains without retraining the full model. Future research directions could explore multi-task training combining parallel and monolingual in-domain data in other ways to alleviate the need for back-translation.

Our work is the first attempt to combine domain adapters and language adapters for a generation task (NMT). Although such combinations have shown to be successful for NLU tasks, obtaining good representations for generating unseen target languages proves to be a difficult problem. We believe a fine-grained study of where to use language or domain-specific capacity could lead to better cross-lingual domain transfer in future. Finally, we provide supplementary material to facilitate reproducibility.[10]

A Data and Hyper-parameters

For **bilingual** domain adaptation we use a Transformer Base (Vaswani et al., 2017) model trained for 12 epochs on German to English WMT20 data (47M parallel lines), with a joint BPE (Sennrich et al., 2016b) vocabulary of size 24k with inline casing (Berard et al., 2019b) (i.e. wordpieces are put in lowercase with a special token indicating their case.). For bilingual domain adaption we use the same datasets as Aharoni and Goldberg (2020), namely parallel text in German and English from five diverse domains: Koran, Medical, IT, Law and Subtitles.

For multilingual settings we use the following hyper-parameters. We share embeddings between encoder and decoder. We use the Adam optimizer (Kingma and Ba, 2014) with an inverse square root learning rate schedule for pre-training, and a fixed learning rate schedule for training adapters. We speed up training with 16 bit floating point arithmetic. We use label smoothing 0.1 and dropout 0.1. We train for either 20 epochs or 1 million updates, whichever corresponds to the smallest number of training updates. We use early stopping, checking performance after each epoch or every 100,000 training steps, and use average validation negative-log-likelihood on all of the training data (but not out-of-domain language data) as our criteria for choosing the best model. We otherwise use default Fairseq (Ott et al., 2019) parameters. We train all models on a single Nvidia V100 GPU, and training takes between 8 and 36 hours depending on dataset size.

In order to create validation and test splits that had no overlap with training data in any language, we first set aside a number of English sentences. Then we aligned all language pairs to these sentences, i.e. the German to French test set is composed of German and French sentences that share the same English sentence. Finally we remove all sentences in any language from the train splits of all parallel data if those sentences are aligned with any English sentences in the subset we set aside for validation/test splits. Both validation sets and test sets contain around 2000 examples for every domain and language-pair.

B MAD-X Style Stacking

Pfeiffer et al. (2020) use the following stacking formulation,

$$\mathrm{LA}(\mathbf{h}_l, \mathbf{r}_l) = \mathrm{FFN}_{\mathrm{lg}}(\mathbf{h}_l) + \mathbf{r}_l. \quad (3)$$

The residual connection $\mathbf{r}_l$ is the output of the Transformer's feed-forward layer whereas $\mathbf{h}_l$ is the output of the subsequent layer normalisation. When stacking domain and language adapters the layer output is given by applying the model's pre-trained layer norm $\mathrm{LN}_{\mathrm{pre}}$,

$$\mathbf{h}_{l,\mathrm{out}} = \mathrm{LN}_{\mathrm{pre}}(\mathrm{FFN}_{\mathrm{dom}}(\mathrm{LA}(\mathbf{h}_l, \mathbf{r}_l)) + \mathbf{r}_l) \quad (4)$$

and using the output of the Transformer's feed-forward layer as a residual instead of the language adapter output. We refer to this as '**MAD-X**' style after Pfeiffer et al. (2020). This leaves the layer output 'closer' to the pre-trained model, with the same layer-norm and residual connection, contrary to Eq. 2 which has a newly initialised layer-norm and a residual connection. For all models without any stacking we obtain layer output as in Eq. 4 but replace $\mathrm{LA}(\cdot)$ with the identity operation.

C Additional Results for Bilingual Domain Adaptation

Before studying multilingual domain adaptation, we validate some of our ideas on a simpler, *bilingual* German → English domain adaptation setting. Table 11 reports the results of this experiment. First, we note that *encoder-only* adapters perform similarly to *encoder & decoder* adapters, while *decoder-only* adapters perform worse.

Moreover, adding adapters to only the last three layers of the encoder almost matches the performance of adapting every layer, while adding adapters to the first three layers decreases performance. We believe this is because the last encoder layer directly influences every layer of the decoder through cross-attention.

Table 12 presents results of bilingual domain adaption with smaller adapter bottleneck dimension. The same trends emerge: encoder-only adapters perform better, and the last three layers of the encoder are better than the first three. The last three encoder layers also perform better than the first three for a multilingual model, see Table 7 models **(38)** and **(39)**. Interestingly the multilingual last three encoder layer DA model is roughly halfway between encoder-only and decoder-only on Out→in and In→out performance, suggesting it might be a useful compromise between the two.

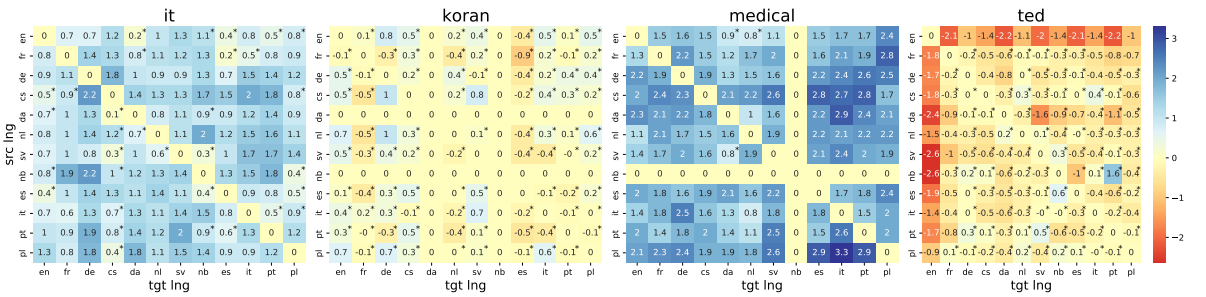

Figure 5: Difference in BLEU score for each domain between the model trained with adapters **(9)** and model trained with domain tags **(3)**, for the multilingual multi-domain models. A positive number corresponds to the case where model **(3)** has higher score than the model **(9)**. The "*" indicates the cases when the difference is *not* statistically significant.

D Additional Results for Cross-lingual Transfer

Does language diversity increase transfer? Table 5 compares models trained on a mix of language families (fr, de, cs, en) and mostly romance languages (fr, it, es, en) to test whether diversity of languages in our in-domain training set improved transfer. Positive numbers in this table indicate diversity of training languages improves performance. Diversity helps for translating out-of-domain languages into in-domain. We have unclear results for when both source and target are out-of-domain; it seems when using back-translation (BT), i.e. when all languages have been seen (albeit with artificial English parallel data) diversity helps, but without BT it mostly hurts performance. We speculate that training on mostly romance languages means the domain adapter encodes less 'language information', but leave further exploration to future work.

Additional results and metrics We present additional results for the setting discussed in Section 5.2 of the main paper in Table 9 (Koran domain), Table 10 (Koran results for the romance language subset), and Table 7 (additional Medical results). We use the chrF metric as discussed in the main paper, and find the conclusions based on BLEU score are unchanged. For the Koran domain, we see similar trends with decoder-only domain adapters (DA) performing best on out-of-domain source to in-domain target languages, and vice versa for encoder-only DA. Additionally we see as before that combining BT with decoder-only DA works the best, and achieves the highest overall performance. We report on-target (correct language) percentage for all medical domain models in Table 8.

We briefly experiment with denoising objectives, where we simply copy target data in out-of-domain languages to the source side (and optionally add 'noise' to the source side, e.g. swap tokens or mask tokens (Lewis et al., 2020)). Although we got reasonable improvements (models **(42)** and **(41)**) for out-of-domain target languages, we were mostly unable to improve over the pre-trained ParaCrawl LA, and so concentrate on back-translation.

We experiment with a setting where we jointly train on all language directions for IT, Koran and TED Talks domains and a subset of languages for Medical, and similarly with only a subset of Koran (models **(43)**, **(44)** etc.). These models stack language and domain adapters. Such models don't require any pre-trained LA, and improve out-of-domain performance and decrease off-target translation compared to freezing ParaCrawl LA and training DA. However these scores are still worse than simply using pre-trained 'domain-agnostic' ParaCrawl LA **(11)**.

Translation Transformers Rediscover Inherent Data Domains

Abstract

Many works proposed methods to improve the performance of Neural Machine Translation (NMT) models in a domain/multi-domain adaptation scenario. However, an understanding of how NMT baselines represent text domain information internally is still lacking. Here we analyze the sentence representations learned by NMT Transformers and show that these explicitly include the information on text domains, even after only seeing the input sentences without domains labels. Furthermore, we show that this internal information is enough to cluster sentences by their underlying domains without supervision. We show that NMT models produce clusters better aligned to the actual domains compared to pre-trained language models (LMs). Notably, when computed on document-level, NMT cluster-to-domain correspondence nears 100%. We use these findings together with an approach to NMT domain adaptation using automatically extracted domains. Whereas previous work relied on external LMs for text clustering, we propose re-using the NMT model as a source of unsupervised clusters. We perform an extensive experimental study comparing two approaches across two data scenarios, three language pairs, and both sentence-level and document-level clustering, showing equal or significantly superior performance compared to LMs.

1 Introduction

Neural machine translation (NMT, Bahdanau et al., 2015; Vaswani et al., 2017b) heavily depends on training data and the text domains covered in it. Full-scale NMT Transfomer models (Vaswani et al., 2017b) are usually trained on a mix of corpora from several domains (Barrault et al., 2020). However, the field lacks an understanding of how these NMT models represent the training data domains in their inner vector spaces.

This paper consists of two main parts. First, we analyze domain representations learned by the NMT Transformer. We consider sentence-level as well as document-level representations via mean pooling of token contextual embeddings. Our analysis shows that NMT models explicitly learn to include the domain information in their representational spaces across layers. Furthermore, we show that text representations preserve enough domain-specific information to reveal the underlying domains with Principal Component Analysis and k-means clustering without supervision. In the case of document-level clustering, the result of k-means matches the original corpora almost perfectly. In the case of sentence-level clustering, we observe some deviation between automatic clusters and the original corpora that the sentences belong to, showing corpus heterogeneity on the sentence level.

Aharoni and Goldberg (2020) previously revealed that a similar property exists in pre-trained language models (LMs). We compare LMs with NMT Transformers in how well we can extract unsupervised domain clusters from them and show the superiority of NMT models.

In the second part of the paper, we show how to effectively utilize our analysis to improve an existing approach to NMT domain adaptation which uses automatically extracted domains (Tars and Fishel, 2018; Currey et al., 2020). This method targets the case when training domain labels are not precise (e.g. Currey et al., 2020) or missing overall, as in case of heterogeneous corpora (e.g. Paracrawl, Esplà et al., 2019). This framework has so far been used with external models for clustering, which automatically makes us rely on clusters not necessarily aligned with the objectives of translation or target data domains.

We propose exploiting clusters extracted from the NMT baseline (already trained as a part of the framework) to improve translation quality without relying on external language models. We test our

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 599–613
November 10–11, 2021.

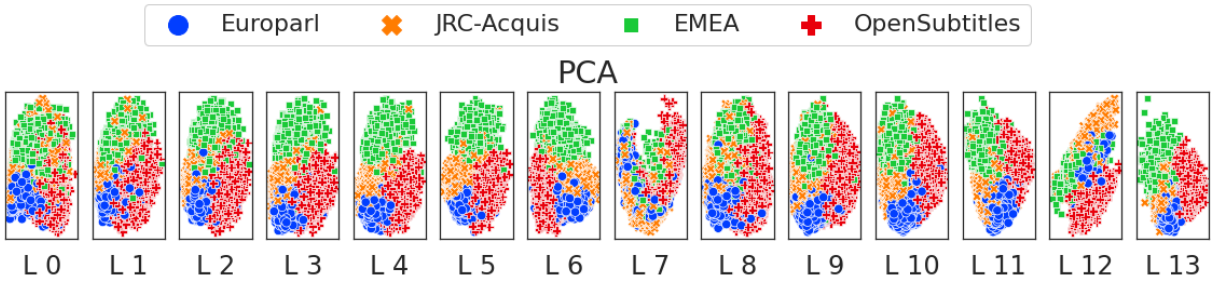

Figure 1: PCA plots of sentence representations extracted from all layers of the 60th checkpoint of the trained baseline NMT model. Representations are computed with English sentences. The dots, denoting sentences, are colored according to the domain the corresponding sentences come from. The model learns to distinguish between domains in its hidden space, despite not being explicitly provided with any information about domains. L0 corresponds to fixed encoder embeddings, L1–L6 are encoder layers' representations, L7 shows fixed decoder embeddings and L8–L13 – the decoder layers' representations. The figure shows that representations from the same domain cluster together.

proposal empirically, covering three language pairs and two data settings: a mix of corpora with known domain labels and a heterogeneous corpus without such labels. We show that fine-tuning the NMT models to the automatically discovered clusters on average matches or surpasses tuning to the original corpus labels (when available) and deep LM-based clusters.

Our contributions are thus two-fold:[1]

- we analyze the NMT encoder's representations, showing their ability to automatically discover inherent text domains and cluster unlabelled corpora, testing both sentence-level and document-level representations (Section 3);
- we utilize findings from our analysis to improve an existing Automatic Domains for NMT approach (Section 4) and perform an extensive experimental study, showing the superiority of our method (Section 5);

2 Related Work

Aharoni and Goldberg (2020) found that BERT (Devlin et al., 2019) produces meaningful unsupervised domain clusters and used this finding for NMT data selection. In this work we analyse (sentence-level and document-level) hidden representations produced by a baseline NMT model and find that it learns superior unsupervised clusters by itself.

In NMT, domain-specific information on the word level was recently analyzed by Jiang et al. (2020) in the context of domain mixing in a joint modular multi-domain NMT system. They found that representations contain domain-specific information related to the multiple domains in different proportions on the word level. We analyze representation on the sentence and document level, revealing that domain-specific information in representations converges to the one specific domain with a broader context.

Currey et al. (2020) used contextual embeddings and mean-pooled representation clustering for domain adaptation. We compare our approach to Currey et al. (2020), however in their case the representations were extracted from multilingual BERT (mBERT). We cluster based on the NMT encoder's representations directly and also experiment with document-level representations in addition to sentence-level ones.

Before Currey et al. (2020), the automatic domains framework has been used in NMT only with external models for clustering as well. Tars and Fishel (2018) used fixed embeddings from FastText (Bojanowski et al., 2017) for clustering mean-pooled sentence representations and then either tuning NMT systems to these clusters or supplying the cluster identity to the NMT system as additional input for multi-domain translation.

3 Analysis

In this section, we perform an analysis of inherent domain representations in translation transformers. We reveal how well the domain-specific information in text representations is preserved in NMT models. We focus on "out-of-the-box" NMT systems without any changes and explore the extent

[1]We release our code at https://github.com/TartuNLP/inherent-domains-wmt21

to which we can use their internal representations to match the original text domains using Principal Component Analysis (PCA) and k-means clustering. We also measure the effect of using broader document-level representations.

Additionally, we compare NMT representations to the ones extracted from a pre-trained language model, for which Aharoni and Goldberg (2020) revealed a high degree of domain-specific information.

3.1 Models and Data

In our analysis, we start by following Currey et al. (2020) and similarly to them use a multilingual LM (XLM-R, Conneau et al., 2020) to obtain clusters. XLM-R is a multilingual masked language modeling transformer covering 100 languages.

We then train *Transformer-base* (Vaswani et al., 2017a) NMT models, which have ∼97M parameters each. We train the models on parallel data covering four corpora/text domains: parliament speeches (Europarl, Koehn, 2005), medical (EMEA, Tiedemann, 2012), subtitles (OpenSubtitles, Lison and Tiedemann, 2016) and legal (JRC-Acquis, Steinberger et al., 2006). We sub-sampled the larger corpora in order to balance the size of training data across domains. The NMT models were trained for 60 epochs. A detailed description of the setup, models, and data is provided in Appendix B.

We focus on sentence-level and document-level representations, and two language pairs: English→Estonian (EN-ET) and German→English (DE-EN).

3.2 Dimensionality Reduction

We start by unsupervised dimensionality reduction using PCA to visualize domain placement. We take the development set data, extract token embeddings from each model's layer, and average them to obtain sentence representations. Then we apply cosine-based PCA and t-SNE dimensionality reduction to the representations to visualize the data in a 2D space, and post factum color each data point (sentence) according to its corresponding domain. We show the resulting visualizations in Figure 1 (best viewed in color) for ET-EN (and in Figure 4 for t-SNE in the Appendix A, which mirrors the PCA result).

Figure 1 shows that NMT partitions the domains quite well at all encoder hidden layers and deep decoder layers. Encoder layer 0 corresponds to the fixed embeddings, and the latent space is not well partitioned there yet; however, as we go deeper into the network, the separation increases. Layer 7 is the decoder's embedding layer, and there the same logic applies. While the encoder learns to partition the hidden space based on domains from scratch, the decoder has access to the encoder hidden states via encoder-decoder attention, which might simplify its task.

In summary, Figure 1 is our initial evidence that the NMT encoder places the domains separably.

3.3 Clustering

Our primary method, however, is unsupervised k-means clustering. We consider four data clustering setups: sentence-level XLM-R clusters, sentence-level NMT clusters, document-level XLM-R clusters, and document-level NMT clusters. The first one is the baseline clustering approach investigated by Aharoni and Goldberg (2020) while the remaining three are our original contributions.

3.3.1 Per-layer Clustering Purity

Metric In our analysis, we estimate how well the NMT model preserves domain-specific information in its internal text representations. To do that, we measure the goodness-of-fit between unsupervised clusters and oracle domains. Specifically, we follow Aharoni and Goldberg (2020) and use the *clustering purity* metric. To compute clustering purity, we align domains and clusters by the highest overlap in numbers of sentences. The number of overlapping data points for each cluster-domain pair gives us the number of 'correctly predicted' examples. Then, the sum of all 'correctly predicted' examples divided by the total number of examples will be the clustering purity score.

Embedding and Clustering We first take the concatenation of a small subset of sentences (3k) from each of the four domains and try to partition them into four clusters based on the representations from each layer of XLM-R and NMT Transformer. We only use source sentences since we do not have targets at runtime in NMT. Specifically, we follow the steps below for each layer of each of the two models:

1. For each sentence in the dataset, we extract contextualized token embeddings from a layer of the model.
2. We use the average of contextualized token embeddings as sentence representations.

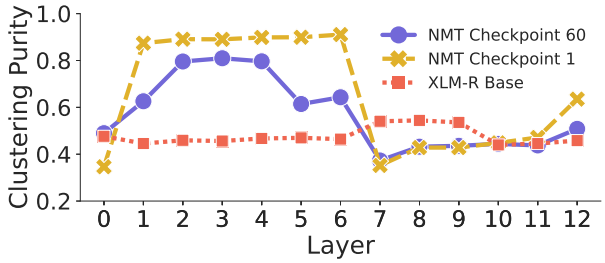

Figure 2: Sentence-level clustering purity between clusters obtained with k-means over 3k of EN-ET development set sentences and actual data domains. Representations extracted from XLM-R, NMT Baseline after epoch 1, and NMT Baseline after training has finished (epoch 60). While XLM-R is relatively poor in its ability to rediscover original domains, representations extracted from the trained NMT model largely outperform it at layers 1-6. Layers 1-6 are the encoder and 7-12 the decoder. The results are for the best clustering (with least variance) over 10 k-means runs.

3. We apply k-means clustering to sentence representations to assign a cluster label to each sentence.

4. We compute clustering purity for predicted labels and oracle domains.

We perform ten random restarts of k-means clustering, selecting the iteration with the smallest within-cluster variance.

Results Figure 2 shows per-layer clustering purity computed for sentence representations for XLM-R and two NMT Baseline checkpoints (after the first epoch and after the 60th epoch of training). Figure 2 shows that NMT surpasses the language model in its ability to rediscover domains. About 3.5x higher performance at the encoder layers shows that the encoder is the part that learned to be very aware of the input domains (in an unsupervised way). Figure 2 also shows that the checkpoint saved after the 1st training epoch rediscovers clusters slightly better then 60th checkpoint. However, this does not suggest that an NMT model should be trained for one epoch since the translation quality is suboptimal early on. Instead, we assume that the model quickly learns domain-specific information (perhaps due to the common lexical statistics) and then slightly "moves away" towards a higher level of abstraction as training progresses. This abstraction is necessary to successfully learn a task as complex as NMT.

	EN-ET			DE-EN		
	train	dev	test	train	dev	test
sentence						
XLM-R	53.47	52.9	50.07	44.04	49.2	48.6
NMT	67.21	72.56	70.7	66.32	70.02	72.28
document						
XLM-R	85.77	72.89	70.14	97.64	91.74	95.23
NMT	99.61	100.0	99.1	99.21	97.58	99.78

Table 1: Clustering purity. We trained the NMT model on about 2m EN-ET or DE-EN sentences from multiple corpora and used pre-trained XLM-R Base model. Based on the Figure 2, we used the 4th layer to extract source representations from the NMT model and 8th layer for XLM-R. The results are for the best clustering (with least variance) over 10 k-means runs. Both NMT and XLM-R rediscover inherent data domains when document level representations are used, and seem to produce more customized separations when clustered based on sentence-level. NMT tends to be better at rediscovery.

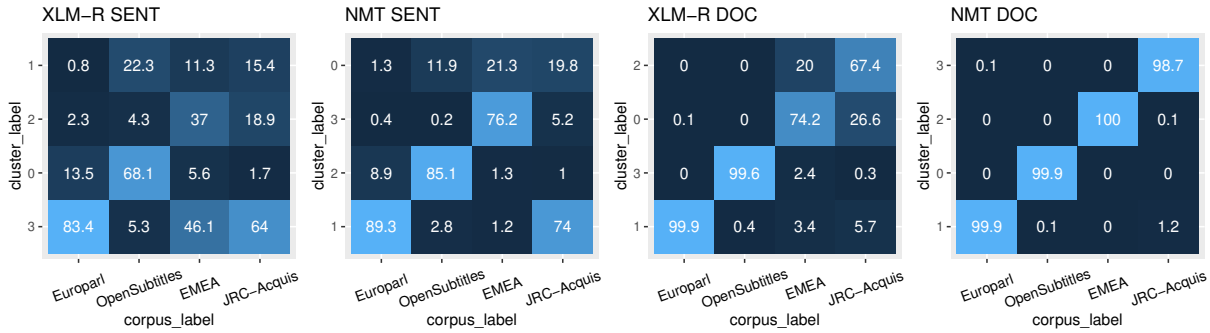
3.3.2 Large-scale Clustering

Next, we repeat the same steps for the entire training dataset and include a second language pair. Specifically, we pick one of the best performing layers (4th for NMT and 7th for XLM-R) based on the experiment above and use it to cluster the training part of the multi-domain machine translation training set (about 500k examples per domain, 2M in total). We then predict cluster labels for the training examples and use the same model to cluster unseen examples from the development and test set.

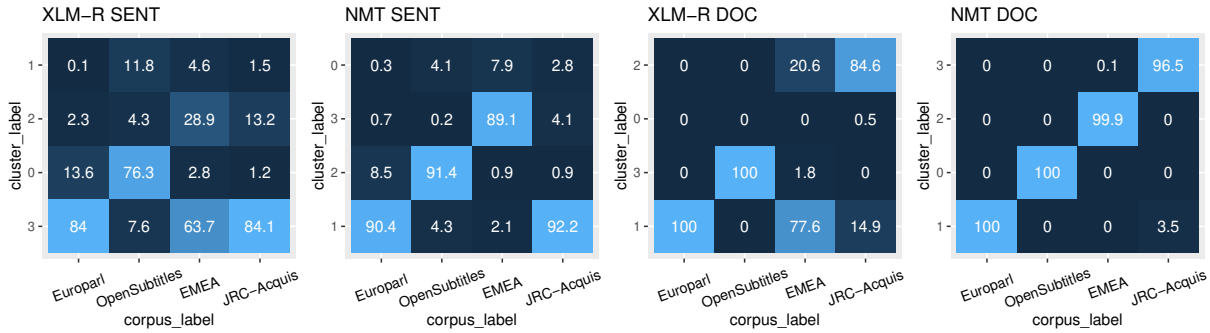
We also extend our analysis to the document-level scenario. Specifically, we average over sentence representations to get document embeddings and cluster-based on them. Then, we assign the predicted label for each document to each sentence in that document.[2]

Results We present large-scale clustering confusion matrices in Figure 3 and clustering purity in Table 1. These show that sentence-level NMT is generally better than sentence-level XLM-R at rediscovering domains. However, they both show quite modest results for both language pairs. At the same time, document-level clusters are much better at rediscovering original domains.

[2]Sentence pairs coming from the same XML file were considered to belong to the same document. The training, development and test sets in all experiments were constructed in such a way that a document is always included in one set in its entirety.



(a) EN-ET Train



(b) EN-ET Test

Figure 3: Corpus-cluster confusion tables for about 2M sentences for EN-ET for (a) the training and (b) test sets. The numbers are percentages for each domain (column). NMT document clusters almost perfectly match original data domains. On the sentence level, however, both NMT and XLMR learn a more customized notion of clusters, with NMT being more aligned with original domains.

The reason for that might be that sentence-level clustering largely relies on the more shallow information in the text. For example, we observed that both sentence-level NMT and XLM-R produced a cluster responsible for extremely short sentences (the average sentence length is about four tokens for these clusters). On the other hand, document-level representations factor out these shallow stylistic features by averaging over sentence representations. Therefore, the models are inclined to cluster by topics. An alternative explanation is that domain-specific lexical statistics, which not all sentences might preserve, get more robust as we average sentence embeddings to get a document embedding.

Even though sentence-level clustering maintains a general idea about oracle domains, they split sentences into clusters quite freely. For example, JRC-Acquis consistently gets mixed with Europarl, which both belong to legal domains. We can see it from *NMT SENT* for both language pairs.

For documents, the rediscovery trend is common and pronounced for both language pairs, and separation is generally consistent between train and test. However, for *EN-ET XLM-R DOC* we can observe that EMEA and JRC-Acquis got split between two clusters in the training set. Considering that we perform ten random k-means restarts and choose the best iteration, this suggests that XLM-R may become inconsistent (as a source of sentence representations on the document level) in some cases.

Figure 5 in Appendix A shows similar heatmaps for DE-EN. DE-EN is consistent with what we observe for EN-ET apart from XLM-R DOC, where the DE-EN diagonal is cleaner.

4 Practical Application

Our analysis in Section 3 revealed that NMT models represent domains in their embedding space separately, similarly to what pre-trained language models do (Aharoni and Goldberg, 2020). We demonstrated that simple clustering on NMT representations allows recovering original data domains to a large degree.

This section proposes to utilize this finding to improve an existing framework of automatic domain generation for NMT. In this framework, related work first clusters the training data using representations from an external encoder, and then the base-

line NMT model is adapted (fine-tuned) on each cluster separately. We propose to re-use the NMT baseline itself as the encoder in this framework.

Representations extracted from translation Transformers are specific to the task of translation. We hypothesise that it might result in clusters most suitable for downstream translation tasks like fine-tuning to specific domains/clusters.

Moreover, an advantage of our scenario is that we cluster the same data (with our NMT model) that we use for NMT model training. It is a frequent multi-domain NMT setup, where multiple target domains are available in training. In the pre-trained language model setup, the data will be more out-of-domain, despite the model's generality.

4.1 Existing Framework (Background)

In this subsection we describe an existing framework which uses automatic domains (clusters) to perform NMT domain adaptation (Tars and Fishel, 2018). Recent work (Currey et al., 2020) employs large pretrained language models as part of the framework. It consists of several steps.

In step 1.1, we begin with a single heterogeneous dataset ("Original Dataset") and train a baseline NMT model on it. At the same time (step 1.2), we pass this dataset through the external pre-trained XLM-R model to extract hidden sentence/document representations for the whole dataset. In step 2, we use the extracted sentence/document representations to train a k-means clustering model. In step 3, we use this k-means model to separate the original dataset into sub-datasets corresponding to the clusters. Lastly, we use the cluster-specific datasets to fine-tune the baseline NMT model from step 1.1 on each dataset separately, resulting in a set of specialized models. We use the k-means model at runtime to determine which NMT model to use to translate a new sentence/document. If we only use sentence clusters, the approach is equivalent to the one proposed by Currey et al. (2020). Refer to Figure 6 from Appendix A for the illustration of the steps described above.

4.2 Improved Framework (Ours)

In this subsection we describe our modification to the existing automatic domains pipeline presented in Section 4.1.

We propose reusing an NMT baseline to produce sentence representations for the clustering step instead of using an external encoder. Specifically, in step 1, we train a baseline NMT model just like in the existing framework. However, we found we can omit using the XLM-R model (step 1.2). Instead, to extract sentence/document representations for step 2, we reuse the trained NMT baseline. The rest of the pipeline remains the same. Figure 7 (Appendix A) illustrates the updated framework.

Moreover, to produce clusters in both frameworks, we additionally study text representations on the level of documents.

5 Experiments

In this section we perform an extensive experimental study comparing performance of the existing automatic domains framework (Section 4.1) with our proposed version (Section 4.2). We experiment with both sentence-level and document-level representations as a basis for k-means algorithm on three language pairs and two data scenarios.

We first train baseline Transformer NMT models on concatenated data from all domains (same baseline as in Section 3) and then cluster the training, development, and test data using either this same baseline or XLM-R. Next, we fine-tune[3] our baseline models to the different obtained data partitions (clusters) and compare the translation quality of resulting fine-tuned (adapted) models.

5.1 Setup

We explore two data scenarios. First, we perform experiments on a mixture of distinct corpora. For these experiments, we reuse the data and *concat* baseline NMT model (Transformer-base) described in Section 3 (EN-ET and DE-EN). In this setting, we can compare the performance of models fine-tuned to automatically discovered domains to that of oracle models (fine-tuned using known domains/datasets). We also randomly partition the data (into equal parts) and fine-tune the baseline models to them to get our lower bound estimates.

Second, we explore a scenario with a single corpus, which is highly heterogenous, and thus may contain multiple domains which are unknown. In this setting, we use the ParaCrawl (Esplà et al., 2019) parallel corpus[4], which consists of diverse documents crawled from the web. We use three language pairs: English→Estonian (EN-ET), German→English (DE-EN), and English→Czech

[3] We use the terms "fine-tuning" and "NMT domain adaptation" interchangeably.

[4] https://paracrawl.eu/

(EN-CS). We use ∼3M sentence pairs for all languages for training, and ∼3,000 sentence-pairs for development and testing. The exact experimental setup with data sizes, training and preprocessing details can be found in in Appendix B.

For our *concat* baselines we follow the setup from Section 3.1 (described in more detail in Appendix B). In the mixture of corpora experiments, baseline fine-tuning is performed for 50 epochs, and in the single heterogenous corpus experiments for 25 epochs (fine-tuning hyperparameters can be found in Appendix B). For comparison, we also continue training the baseline models for longer as suggested by Gururangan et al. (2020) (*concat-cont*). We continue training for the same number of epochs fine-tuning is done for in the corresponding experiment.

For each of the models, we evaluate the checkpoint which shows the highest BLEU score on the particular model's development set, and translate the test sets with beam size set to 5. We use the BLEU score (Papineni et al., 2002), specifically, the sacreBLEU implementation (Post, 2018) to assess the models' translation performance. To test for statistical significance, we use paired bootstrap resampling (Koehn, 2004).

5.2 Labelled Domain Mix Experiments

In this section we consider a scenario which can be practically interesting in cases where the data consists of several distinct domains with the labels unavailable or corrupted as in Currey et al. (2020). Moreover, it serves as an oracle experiment showing how well automatic domains perform compared to the golden labels. This way we have a better idea what to expect when applying them to unlabeled data as in Section 5.3.

Table 2 shows the results for DE→EN. We see that, for all corpora except Europarl, at least one model of the two that are based on document-level clustering always manages to surpass the oracle performance obtained by fine-tuning to known domains, and on Europarl the document-level models perform comparably to oracle. In most cases, document-level models show significantly better translation quality than XLM-R sentence-level models, which have been used in previous work, while NMT sentence-level models closely match the performance of XLM-R sentence ones. When scores are averaged over all four domains, document clustering obtained from the NMT encoder is the overall winner.

	EP	OS	JRC	EMEA	avg
concat	37.2	21.7	52.3	73.8	46.25
concat-cont	37.2	22.3	52.4	73.7	46.40
oracle	**37.4**	22.6	53.4	74.7	47.03
sentence					
XLM-R	36.6	22.4	52.8	73.9	46.43
NMT	36.6	22.3	52.8	74.0	46.43
document					
XLM-R	37.3**	**22.9***	53.0	75.0**	47.05
NMT	37.3**	22.5	**53.7****	**75.4****	**47.23**
random	36.8	22.4	51.7	73.3	46.05

Table 2: BLEU scores of the DE-EN baseline models, models fine-tuned to known corpora (oracle), to the proposed automatic domains, and to a random partitioning of the data. EP, JRC, EMEA and OS stand for Europarl, JRC-Acquis, EMEA and OpenSubtitles test sets, respectively. Statistically significant improvements of our proposed methods over sentence-level XLM-R clustering are marked with * ($p \leq 0.05$) or ** ($p \leq 0.01$). Document-level clustering matches and slightly surpasses the performance of fine-tuning on oracle domains.

Table 3 shows results for the EN→ET language pair. While fine-tuning on oracle domains yields an average improvement of 0.8 BLEU points over the baseline, fine-tuning on unsupervised document clusters obtained from the NMT encoder allows us to match that performance. However, for the EMEA test set XLM-R sentence clusters turn out to be the most successful approach, showing significantly higher BLEU scores than all other automatic partitions and outperforming the oracle by 1.2 BLEU points, while document-level NMT clustering also manages to surpass the oracle performance, albeit slightly. For OpenSubtitles and JRC-Acquis, oracle shows the highest overall scores, with document-level NMT clustering a close second, outperforming XLM-R sentence clustering by a noticeable margin. For OpenSubtitles, however, none of the automatic domain approaches manage to improve the baseline performance (and neither does continued training of the baseline), and even the oracle partition does not manage to do so by a statistically significant degree. For Europarl, all automatic domain approaches yield comparable BLEU scores, with none being significantly better or worse than XLM-R sentence clusters.

Document-level XLM-R automatic domains have a low average score due to underperforming on the EMEA test set. We see from Figure 3 that this is a case of train-test mismatch: the EMEA

	EP	OS	JRC	EMEA	avg
concat	28.7	19.1	47.3	47.8	35.725
concat-cont	28.8	18.5	48.4	48.5	36.050

NMT	29.1	19.0*	49.8**	48.4††	**36.575**
random	28.5	18.5	47.1	47.0	35.275

Table 3: BLEU scores of the EN-ET baseline models, models fine-tuned to known corpora (oracle), to the proposed automatic domains, and to a random partitioning of the data. EP, JRC, EMEA and OS stand for Europarl, JRC-Acquis, EMEA and OpenSubtitles test sets, respectively. Statistically significant improvements of our proposed methods over sentence-level XLM-R clustering are marked with * ($p \leq 0.05$) or ** ($p \leq 0.01$), daggers mark results which are significantly lower than for sentence-level clustering based on XLM-R († and †† denote $p \leq 0.05$ and $p \leq 0.01$, respectively). Document-level clustering as well as XLM-R based sentence-level clustering match the performance of the fine-tuning on oracle domains.

test set is mostly translated by the model fine-tuned on cluster 1, whose training set predominantly consists of Europarl data. Cluster 0, which sees the most EMEA examples during fine-tuning, is not used to translate the test set at all, as we see from Figure 3.

5.3 Heterogeneous Corpus Experiments

In this subsection we present results for our method applied to the Paracrawl dataset, which constitutes a heterogeneous corpus of data crawled from the web with no training-time domain information known.

EN-ET We first experiment on the EN-ET language pair. While in the multi-corpus setup we chose the number of clusters to match the number of different corpora in our training set, in the ParaCrawl experiments we do not have a predefined number of domains. Therefore, we experiment with separating the dataset into 3, 4, 5, and 8 clusters.

The resulting BLEU scores for EN-ET are shown in Table 4. Fine-tuning based on NMT and XLM-R clustering of the data outperforms a strong *concat-cont* baseline by 0.2-1.6 BLEU points depending on the choice of embedding model and clustering

N of clusters	3	4	5	8
concat	46.1	46.1	46.1	46.1
concat-cont	46.6	46.6	46.6	46.6
sentence				
XLM-R	**47.0**	46.8	47.1	47.0
NMT	46.9	47.1	**47.6****	47.4*
document				
XLM-R	46.8	**47.2***	47.3	47.6**
NMT	46.8	47.0	47.2	**48.2****
random	46.1	45.9	45.5	45.3

Table 4: BLEU scores of models trained on EN-ET ParaCrawl and fine-tuned to different numbers of automatic clusters and to a random partitioning of the data. Statistically significant improvements of our proposed methods over sentence-level XLM-R clustering are marked with * ($p \leq 0.05$) or ** ($p \leq 0.01$). For different numbers of clusters different approaches score best, but the best result overall is obtained with document-level NMT and 8 clusters.

level. The best result overall is achieved by our document-level NMT clustering, which also outperforms all other approaches with 8 clusters by at least 0.6 BLEU. Both document-level approaches improve their performance with a growing number of clusters. With 3 clusters, all clustering methods show comparable results, with none being significantly better or worse than sentence-level XLM-R. Document-level XLM-R and sentence-level NMT significantly outperform sentence-level XLM-R with 4 and 5 clusters, respectively.

EN-CS & DE-EN As separating the data into 8 clusters yields the highest BLEU score among all fine-tuning scenarios for EN→ET, we choose this number of clusters for experiments on other language pairs. Table 5 shows the BLEU scores for EN→ET, EN→CS, and DE→EN models fine-tuned to automatic domains.

For EN-CS, only the NMT sentence-level clustering manages to outperform the baseline, noticeably surpassing all other automatic domain extraction methods as well.

For DE-EN, none of the approaches outperform the baseline model by a considerable margin. Sentence-level clustering based on XLM-R performs comparably to the baseline. Document-level NMT clustering shows a slightly lower score, but the difference is not statistically significant. At the same time, document XLM-R and sentence NMT perform worse than sentence XLM-R.

	EN-ET	EN-CS	DE-EN
concat	46.1	44.4	48.2
concat-cont	46.6	44.3	48.1
sentence			
XLM-R	47.0	44.2	**48.3**
NMT	47.4*	**44.9****	48.0†
document			
XLM-R	47.6**	44.2	47.9††
NMT	**48.2****	44.2	48.0
random	45.3	43.6	47.5

Table 5: BLEU scores of models trained on ParaCrawl and fine-tuned to automatic clusters and to a random partitioning of the data on three language pairs. For each language pair we use ~3M training examples and split the data into 8 clusters. Statistically significant improvements of our proposed methods over sentence-level XLM-R clustering are marked with * ($p \leq 0.05$) or ** ($p \leq 0.01$), Daggers mark results which are significantly lower than for sentence-level clustering based on XLM-R († and †† denote $p \leq 0.05$ and $p \leq 0.01$, respectively).

N of clusters	4	12
concat	50.6	50.6
concat-cont	50.9	50.9
sentence		
XLM-R	50.9	50.6
NMT	51.0	**50.9***
document		
XLM-R	**51.1**	50.8
NMT	**51.1**	50.8
random	50.2	49.8

Table 6: BLEU scores of models trained on 10M sentence pairs from DE-EN ParaCrawl and fine-tuned to 4 and 12 automatic clusters. The data size is increased compared to the previous experiments, the NMT model size remains the same. We see an improvement in baseline performance, but no improvement in the performance of fine-tuned models. Statistically significant improvements of our proposed methods over sentence-level XLM-R clustering are marked with * ($p \leq 0.05$).

5.4 Additional Exploration

While automatic domains demonstrate reasonable performance for EN-ET and EN-CS language pairs, DE-EN does not seem to benefit from either XLM-R or NMT-based clustering. In this section we perform additional experiments with DE-EN data to see whether there are conditions under which automatic domains could be beneficial in this case.

Data Size and Number of Clusters First, we increase the training data size and vary the number of clusters. Specifically, we use 10M parallel sentence pairs for training instead of 3M, and partition the dataset into 4 and 12 clusters instead of 8.

The resulting BLEU scores for DE-EN are shown in Table 6. We do not observe any significant improvement over the *concat-cont* baseline for any of the methods. With the data separated into 12 clusters, sentence-level NMT clustering significantly outperforms sentence-level XLM-R, but still does not beat continued training of the baseline.

Model Size It is also possible that NMT needs different model capacity for handling different language pairs, so we experiment with decreasing the model size. We use the same number of layers, but decrease the width of the model (4 attention heads, embeddings of size 160, dimension of the feed-forward layer 320) so that the total number of parameters decreases five-fold. We compute NMT clusters based on the new, smaller baseline model. Our motivation for this is to understand whether automatic domains are not useful for DE-EN ParaCrawl at all, or could aid a weaker baseline.

The results are shown in Table 7. The smaller baseline does benefit from adaptation to automatic domains (clusters). While NMT clusters are generated by a model which is 5 times as small, XLM-R and NMT show equivalent performance.

6 Discussion

Our analysis is implicit inductive evidence for the high degrees of domain-specific information in sentence and document NMT representations. However, it is still open to what kind of information is preserved (topical/stylistic/lexical).

For example, our approach could result in clusters by domain/dataset due to standard lexical statistics and not sentence semantics. However, on the practical side, we show that adapting NMT to these types of clusters is just as good or better as to other possible types of clusters since it benefits the baseline performance. Moreover, previous work that uses pre-trained language models to obtain the clusters is likely to suffer from the same issue.

Moreover, while XLM-R is a general-purpose encoder, NMT models are only that helpful for domains we train them on. However, the data constitutes all domains of interest by definition for a multi-domain NMT (the task we tackle). Thus, NMT models are a perfect fit that simplifies and outperforms an existing approach.

Model size	Base	Small
concat	48.2	44.2
concat-cont	48.1	44.8
sentence		
XLM-R	**48.3**	45.2
NMT	48.0†	**45.4**
document		
XLM-R	47.9††	45.1
NMT	48.0	**45.4**
random	47.5	44.0

Table 7: BLEU scores of models trained on 3M sentence pairs from DE-EN ParaCrawl and fine-tuned to 8 automatic clusters. The Base NMT model has the same configuration as in previous experiments (*Transformer-base*), while the Small model has 5 times fewer parameters. The smaller model benefits from fine-tuning to automatic domains, but does so starting from a weaker baseline performance. Daggers mark results which are significantly lower compared to sentence-level clustering based on XLM-R († and †† denote $p \leq 0.05$ and $p \leq 0.01$, respectively).

7 Conclusion

In this work, we made a two-fold contribution. The first is to the field of NMT interpretation and analysis. We have shown that a baseline Transformer NMT encoder preserves enough domain-specific information to distinguish between oracle domains in a mixed corpus without supervision. We showed an evolution of this property across the Transformer layer using PCA and k-means clustering on the level of sentences and documents. Comparison to XLM-R based clusters demonstrated that both sentence-level and document-level NMT clusters show higher cluster purity (similarity to original text domains).

Next, we utilized our analysis insights to improve an existing practical cluster-based multi-domain NMT approach (Tars and Fishel, 2018; Currey et al., 2020). In a setting with preset domains (i.e., available corpus/domain labels), tuning to NMT clusters on average matches or surpasses XLM-R clusters. Additionally, NMT cluster-based tuning mostly matches the translation quality when tuning to original corpus labels, with some exceptions that we also analyze and explain.

Finally, in the case of a heterogeneous corpus (ParaCrawl), the performance of fine-tuned NMT models depends on the number of clusters, language pairs, and other parameters. We see significant improvement for EN-ET and EN-CS translation when comparing XLM-R and NMT-based clusters (on both sentence and document levels). For DE-EN, the domain tuning results depend on the NMT model's capacity for learning each language pair's translation.

A Analysis

A.1 Additional Figures

Figures 4 and 5 support our analysis in Section 3 while Figures 6 and 7 illustrate frameworks from Section 4.

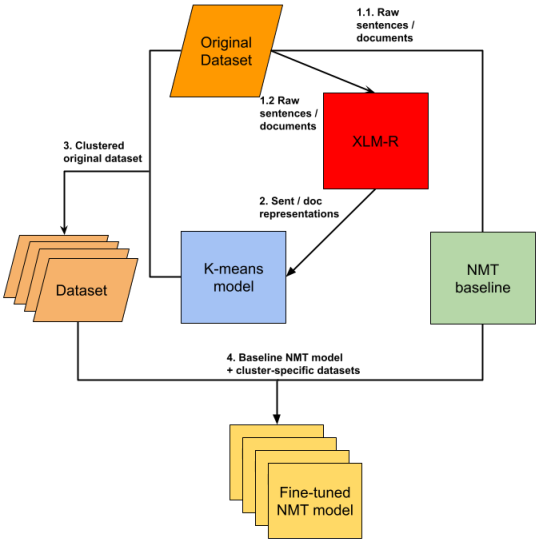

Figure 6: Existing automatic domains framework (previous approach).

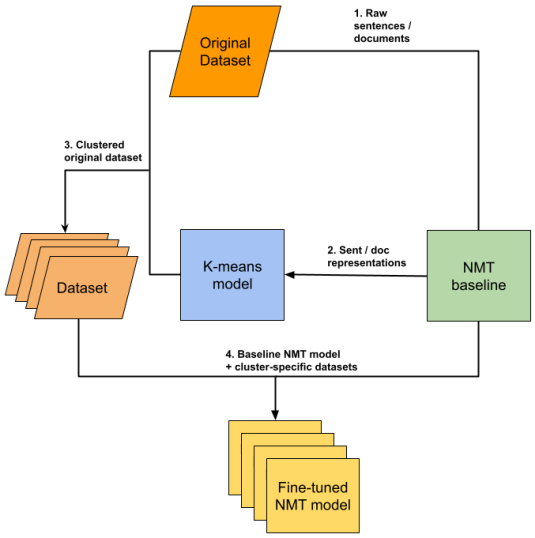

Figure 7: Updated automatic domains framework (ours).

A.2 Language Model

XLM-R Base Our model of choice from the family of BERT-like models is the Base version of the XLM-R (Conneau et al., 2020). It is a single multilingual model covering about 100 languages, which is very useful when dealing with machine translation systems, where for different language pairs we may not have a separate monolingual BERT for each source language. We choose XLM-R as opposed to the multilingual BERT (Devlin et al., 2019) since it is a more recent and better performing (Hu et al., 2020) model. We choose the Base version because it is most compatible to our NMT baseline in terms of capacity.

B Experiments Setup

B.1 Data

For multi-domain fine-tuning (Section 5.2) we experiment on German→English (DE-EN) and English→Estonian (ET-EN), and for the heterogenous corpus task (Section 5.3) we also evaluate on English→Czech (EN-CS).

We use Europarl (proceedings of the European Parliament) (Koehn, 2005), JRC-Acquis (legal documents of the European Union) (Steinberger et al., 2006), EMEA (documents of the European Medicines Agency) (Tiedemann, 2012) and OpenSubtitles (movie and TV subtitles) (Lison and Tiedemann, 2016)[6] in the multidomain fine-tuning experiments. Data from the four corpora was approximately balanced. Around 500,000 training sentence pairs were taken from each of the corpora (except for EN-ET EMEA, where only 400,000 sentence pairs were available after cleaning), making the total size of the training set 1.9M sentence pairs for EN-ET and 2M for DE-EN. Development and test sets contain at least 3,000 sentences per corpus. The exact sizes of training, development and test sets can be found in Table 9. We test sentence-level and document-level clustering of the texts. For Europarl, JRC-Acquis, EMEA and OpenSubtitles, sentence pairs coming from the same XML file were considered to belong to the same document. The training, development and test sets in all experiments were constructed in such a way that a document is always included in one set in its entirety (hence the irregular sizes of the train, development and test sets).

For the single heterogeneous corpus experiments we use v.7.1 of publicly available[7] Paracrawl dataset for all three language pairs. The training set sizes are 3M for all sentence pairs unless otherwise noted. Development and test sets contain at least 3,000 sentences per corpus in all experiments. The exact sizes of training, development and test sets in each of the experiments can be found in Tables 8, 9,

[6] https://opus.nlpl.eu/
[7] https://paracrawl.eu/

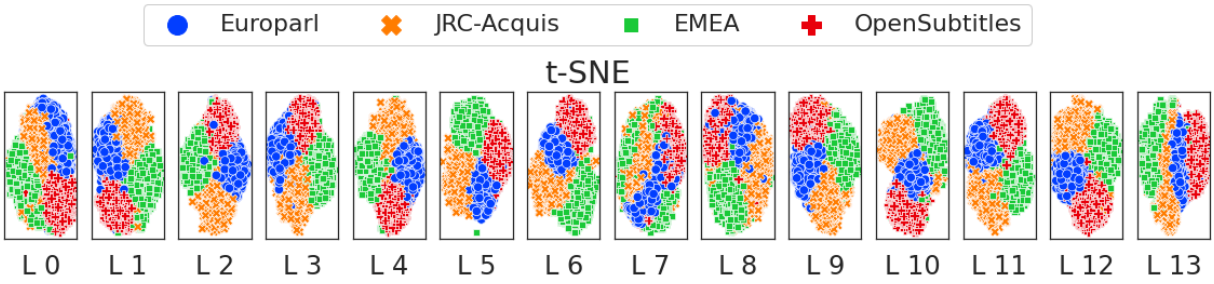

Figure 4: t-SNE plots of sentence representations extracted from all layers of the 60th checkpoint of the trained baseline NMT model. The dots, denoting sentences, are colored according to the domain the corresponding sentences come from. The model learns to distinguish between domains in its hidden space, despite not being explicitly provided with any information about domains. The figure shows that representations from the same domain cluster together.

and 10. In the ParaCrawl experiments, documents were matched by the source sentence URLs. The dataset is separated into webpage-based documents which we use to compile document-based clusters of representations produced by the baseline NMT and XLM-R models. The training, development and test sets in all experiments were constructed in such a way that a document is always included in one set in its entirety.

Several basic cleaning steps were applied to the corpora. Sentence pairs were discarded if:

- either the source or the target side was an empty string;
- either the source or the target side contained more than 100 tokens;
- one of the sentences in the pair contained at least 9 times as many tokens as the other;
- more than half of the characters in either the source or the target sentence were non-alphabetic characters (noisy source or target)

In some corpora there are many sentence pairs that occur multiple times. Therefore, to avoid unfairly inflating the test scores, sentence pairs that also occur in the training set were removed from the development and test sets for BLEU score calculation in the multi-corpus experiments.

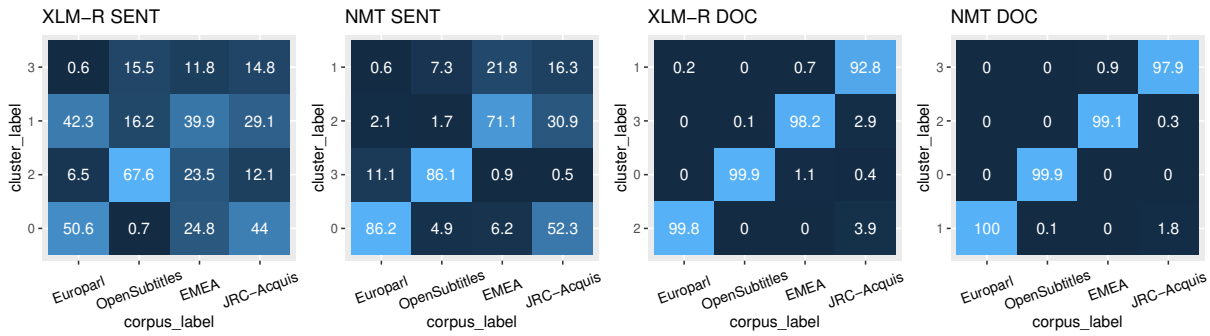
The data was split into subwords using SentencePiece (Kudo and Richardson, 2018) with vocabulary size set to 32,000. No other pre-processing steps were applied.

B.2 NMT Training

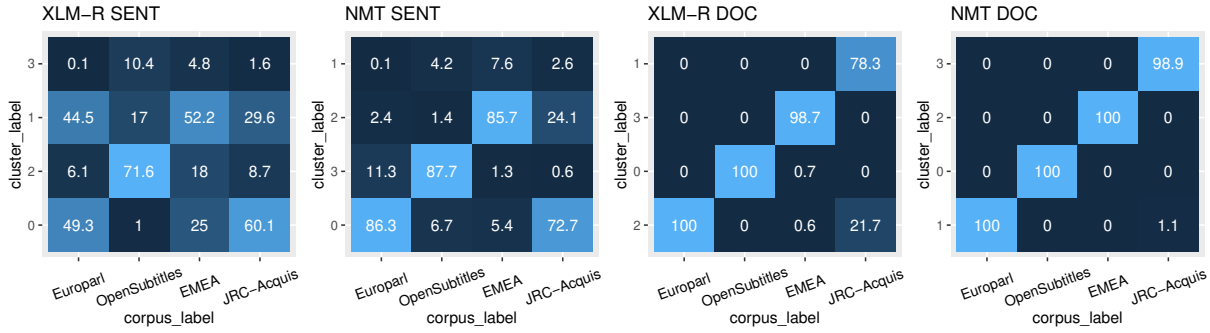
We train Transformer machine translation models using the Fairseq toolkit (Ott et al., 2019). The models have a standard configuration, mostly following the *Transformer-base* settings (Vaswani et al., 2017a): 6 encoder and 6 decoder layers, embedding dimension 512, feed-forward layer dimension 2048. The initial learning rate was set to 5×10^{-4}, with inverse square root learning rate scheduler with 4,000 warm-up updates. The loss function is label-smoothed cross entropy with label smoothing α equal to 0.1. We use Adam optimizer, with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. Dropout probability is set to 0.3. The source and target vocabularies are shared. Model checkpoints are saved at the end of each epoch.

When fine-tuning, we pre-train the model without any explicit domain specific information, and then initialize each model with the parameters of the baseline's checkpoint from the 60th epoch. In the mixture of corpora experiments, fine-tuning is performed for 50 epochs, and in the single heterogenous corpus experiments for 25 epochs (our experiments show that for the overwhelming majority of models the checkpoint which has the best BLEU score on the development set occurs before 25 epochs of fine-tuning). Fine-tuning was performed with initial learning rate 1.25×10^{-4}, reducing by a factor of 0.5 every time the development loss has not improved for 3 consecutive epochs. For comparison, we also continue training the baseline model for the same number of epochs fine-tuning is done for. For each of the models, the translation is done with the checkpoint which has the highest BLEU score on the particular model's development set.

We use the BLEU score (Papineni et al., 2002), specifically, the sacreBLEU implementation (Post, 2018) to assess the models' translation performance. To test for statistical significance, we use



(a) DE-EN Train



(b) DE-EN Test

Figure 5: Corpus-cluster confusion tables for about 2M sentences for DE-EN for the training (a) and test (b) sets. Document clusters rediscover original domains and NMT while sentence clusters tend to learn more customized notion of clusters. In general, NMT is more aligned to the oracle domains then BERT.

paired bootstrap resampling (Koehn, 2004).

The models were pre-trained and fine-tuned either on one NVIDIA V100 GPU with 32GB of RAM with maximum batch size 15,000 tokens per node or on two NVIDIA V100 GPU's with 16GB of RAM with maximum batch size 7,500 tokens per node. The only exception is the DE-EN ParaCrawl model with 10M training sentence pairs, which has the largest volume of training data, and was pre-trained on 4 NVIDIA V100 GPU's with 32GB of RAM with maximum batch size 15,000 tokens per node.

Improving Machine Translation of Rare and Unseen Word Senses

Abstract

The performance of NMT systems has improved drastically in the past few years but the translation of multi-sense words still poses a challenge. Since word senses are not represented uniformly in the parallel corpora used for training, there is an excessive use of the most frequent sense in MT output. In this work, we propose CMBT (**C**ontextually-**m**ined **B**ack-**T**ranslation), an approach for improving multi-sense word translation leveraging pre-trained cross-lingual contextual word representations (CCWRs). Because of their contextual sensitivity and their large pre-training data, CCWRs can easily capture word senses that are missing or very rare in parallel corpora used to train MT. Specifically, CMBT applies bilingual lexicon induction on CCWRs to mine sense-specific target sentences from a monolingual dataset, and then back-translates these sentences to generate a pseudo parallel corpus as additional training data for an MT system. We test the translation quality of ambiguous words on the MuCoW test suite, which was built to test the word sense disambiguation effectiveness of MT systems. We show that our system improves on the translation of difficult unseen and low frequency word senses.

1 Introduction

Recent NMT systems have remarkable performance for many languages (Vaswani et al., 2017; Xia et al., 2019) but there are still numerous areas for improvement. One such important area concerns the disambiguation and translation of multi-sense words. It is particularly challenging to MT systems as sense distribution is skewed with some senses rarely seen or missing in the parallel corpora. This results in the MT system producing translation errors for these rare/unseen senses, causing incomprehensible output sentences.

In this work we aim at improving the translation of rare and unseen senses of ambiguous words.

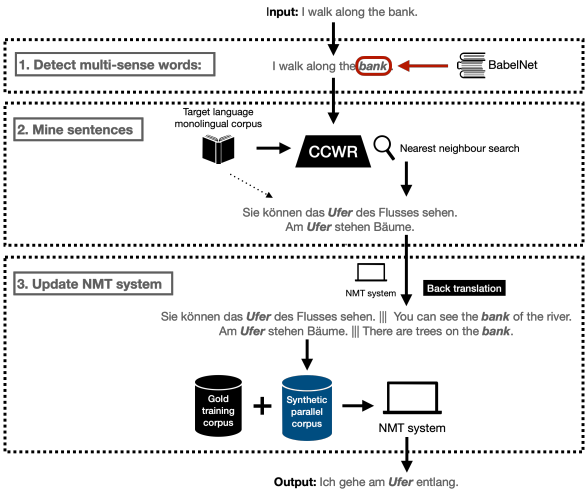

Figure 1: The pipeline of CMBT. Note that each step of the pipeline is run on the full corpus (source side of MuCoW test set). Here we just show the procedure on a single sentence as an illustration.

Previously Tang et al. (2018, 2020) showed that encoder-decoder based NMT systems integrate information relevant for WSD into the encoder hidden states, but finding the correct sense is still a challenging task and NMT systems are biased toward the most frequent senses of words (Liu et al., 2018). Disambiguation errors are often due to over-reliance on training data artifacts, such as frequent word co-occurrences (e.g. *hot spring* is always translated as the thermal activity and not as a season), instead of a deeper understanding of the multi-sense words given the input sentences (Emelin et al., 2020). Additionally, MT systems tend to learn and use frequent words more often and disregard less frequent ones (Vanmassenhove et al., 2019). Previous work has improved the translation of ambiguous words, e.g., by leveraging lexical resources (Pu et al., 2018) or sense specific embeddings (Liu et al., 2018), but they are restricted to the senses seen in the parallel training corpus and not trained on missing senses.

In contrast, we propose a method to mine addi-

November 10–11, 2021.

tional data containing the contextual translations of rare and unseen senses without relying on them being in parallel corpora. Our method, called CMBT (**C**ontextually-**m**ined **B**ack-**T**ranslation), relies on contextualized cross-lingual word representations (CCWRs) to translate source language multi-sense words and find target language sentences containing the translations of the right senses. We then build a synthetic parallel corpus by back-translating these sentences, making sure that the original multi-sense words are contained on the source side, in order to extend the training corpus for better sense coverage. We illustrate our method in Figure 1. The advantage of our approach is that CCWRs, such as mBERT (Devlin et al., 2017) or XLM-R (Conneau et al., 2020), can be trained on cheap and large monolingual corpora covering a wide frequency range of word senses. By leveraging CCWR-mined sentences containing the translations of these senses in the form of a synthetic parallel corpus, our MT system is not restricted to frequent senses seen in the parallel training corpus.

We test our approach on English→German using the *MuCoW* test suite (Raganato et al., 2019, 2020). Although it was built to test overall WSD performance of MT systems, we create subsets of the provided training corpus to test on unseen and rare senses more directly. Our experiments show that using mined sentences as additional data for our NMT systems consistently improves the translation performance (F_1) of rare and unseen senses. Our proposed approach can be effectively applied to other language pairs as well, since the required resources are widely available.

2 Related Work

The problem of WSD is long-standing and extensively studied. Multiple neural systems were proposed, e.g., by relying on sequence-to-sequence architectures (Raganato et al., 2017), using sense embeddings (Kumar et al., 2019) or pre-trained language models (Pasini et al., 2021). It was shown that WSD positively impacts the performance of downstream applications, such as information retrieval (Zhong and Ng, 2012), sentiment analysis (Pilehvar et al., 2017) or topic classification (Shimura et al., 2019).

WSD is an important problem for MT as well. Previously it was shown that the translation performance can be improved by integrating word sense information into MT systems. In (Pu et al., 2017) sense labels were assigned to each multi-sense word using K-means clustering, which served as additional information for a statistical MT system. Similarly, explicit word sense information using WordNet was integrated into NMT systems in (Pu et al., 2018). Liu et al. (2018) leveraged sense embeddings induced by specialized LSTM modules, while lexical chains of semantically similar words within a document were employed in (Rios et al., 2017). Although these approaches do improve WSD performance, they are restricted to the senses seen frequently in the parallel training corpus.

In contrast, we focus on the improvement of senses that are missing or very rare by building a synthetic parallel corpus containing these senses using back-translation (Sennrich et al., 2016). Similarly, Huck et al. (2019) back-translated a carefully selected set of sentences to improve the translation of out-of-vocabulary (OOV) words, i.e., words that are contained in the text to be translated but not in the training corpus. They used bilingual fastText (Bojanowski et al., 2017) embeddings to find all translations of OOVs independent of their contexts. In contrast, we consider the whole sentence when translating multi-sense words in order to determine the right translation of the right sense used in the right context using CCWRs, which we show to be crucial to improve missing and rare sense translation. Arthaud et al. (2021) proposed a data augmentation approach to adapt MT systems to novel vocabulary in human-submitted translations using CCWRs. They generate training samples for the novel words by mining parallel sentence pairs with similar contexts and adding the novel words to them. In contrast, our approach does not rely on parallel sentences, using only monolingual data and back-translation.

Various datasets were proposed to test WSD, such as those released by the series of Senseval (Edmonds and Cotton, 2001; Mihalcea et al., 2004) and SemEval (Agirre et al., 2010; Navigli et al., 2013; Moro and Navigli, 2015) shared tasks. While most datasets are monolingual, Pasini et al. (2021) introduced XL-WSD supporting 18 languages allowing to evaluate zero-shot cross-lingual WSD approaches. To test how well MT systems can disambiguate multi-sense words in their outputs Rios et al. (2017) created the parallel corpus called ContraWSD where for each source sentence containing an ambiguous word two translations are given with

the correct and incorrect senses respectively which have to be scored by the MT systems. The MuCoW dataset was introduced for a more direct evaluation where instead of scoring given target language sentences the translations of multi-sense words in the MT systems' outputs are evaluated (Raganato et al., 2019, 2020). We use MuCoW to evaluate our approach.

3 Approach

The goal of CMBT is to incorporate context-dependent word translation that is able to deal with rare and unseen senses and leverage cheap monolingual data as additional training data for our NMT system for better multi-sense word translation. The main steps of our approach are the following: i) we detect multi-sense words in the source side of test corpus using BabelNet (Navigli and Ponzetto, 2012), which ii) we translate using CCWRs and mine target language sentences containing these translations. iii) We back-translate these sentences to the source language using a baseline NMT system. We use a special marker placed in the target language sentences, which are replaced with the multi-sense words on the source side, in order to ensure the presence of rare and unseen senses in the new corpus. Finally, we fine-tune our base NMT system using the gold and additional synthetic parallel data. We summarize the pipeline in our approach in Figure 1 and detail the three main steps below:

3.1 Multi-Sense Word Detection

As the first step, we identify multi-sense words in the test corpus relying on BabelNet, a publicly available multilingual lexical resource covering 284 languages (Navigli and Ponzetto, 2012). Since the MuCoW dataset focuses on nouns only, we first take all English nouns from the test corpus.[1] We then filter out single sense nouns by keeping only those which are contained in at least two synsets. However BabelNet has a very fine grained set of synsets which would result in a list containing many single sense nouns as well due to their inclusion in multiple synsets. Thus before filtering we merge some of the synsets using English-German interlingual links in BabelNet which specify possible German translations of the words in a given English synset. More precisely, we merge English synsets which have overlapping sets of translations. The filtering procedure using the merged synsets resulted in 3 732 multi-sense nouns containing 181 out of the 206 gold multi-sense words in the MuCoW test corpus.[2]

We note that although BabelNet covers a large set of languages, the language of the application area might not be supported. However, CMBT only requires a list of source language multi-sense words as input which can be acquired using unsupervised WSD systems as well, such as the word embeddings based *SenseGram* (Pelevina et al., 2016). We argue that our approach is robust against false positive multi-sense words, since we would mine sentences containing their single sense, thus the use of a high recall list is preferable in such cases.

3.2 Sentence mining

Given the multi-sense words we mine target language sentences containing the translations of their different senses. However we do not mine all possible senses of the words but only those which are contained in the input corpus to be translated, i.e., the source side of the test corpus in our case. For this we perform bilingual token-level sense retrieval (BTSR) (Liu et al., 2019) where the task given a source word in a context (sentence) is to retrieve its translation having the same sense along with a matching target context. More formally, given a $(w_s, c_s) \in V_s \times D_s$ pair the task is to retrieve $(w_t, c_t) \in V_t \times D_t$, such that w_t is the translation of w_s and the sense of w_s in context c_s matches the sense of w_t in c_t. V_s, V_t and D_s, D_t are the vocabularies and the monolingual datasets of the source and target languages respectively.

To mine relevant sentences, we take each multi-sense word contained in each source sentence as the input (w_s, c_s) pairs. Since a given word type is contained in multiple sentences, we perform mining using these sentences individually. As the translation target candidates, we take a target language monolingual corpus (see Section 4.3 for more details) and consider each word in each sentence as a candidate (w_t, c_t) pair. For each source input pair, we take the top-5[3] most similar target pair scored

[1] We used UDPipe (Straka and Straková, 2017) for POS tagging.

[2] Note that BabelNet was also used to build the list of multi-sense words in MuCoW but its output was further refined with parallel data and gold WSD annotations.

[3] Top-5 is common for bilingual lexicon induction.

by:

$$sim((w_s, c_s), (w_t, c_t)) = cos(E_{(w_s,c_s)}, E_{(w_t,c_t)}) \quad (1)$$

where $E_{(w,c)}$ is the CCWR of word w in context c and cos is the cosine similarity of two embeddings. As CCWR of a given word we averaged the corresponding vectors of the upper XLM-R layers (12-24), motivated by the findings of Ethayarajh (2019). We discuss further details of the used CCWR models in Section 4.1. Finally, the retrieved sentences are considered as the output of the mining process and used in the next step.

3.3 NMT System Update

In the last step, we update our baseline English→German NMT system with the gold parallel data and the sentences mined above. Using a system similar to the baseline but built in the reverse direction we back-translate the mined target language sentences by making sure that the original multi-sense word is contained in the back-translation. To achieve this we replace the related word in the target sentence with a special marker which is copied to the source side during translation. After translation we replace the special markers on both sides with the correct words. The following example depicts the process using a mined sentence for the multi-sense word *bank*:

Input:	*Ich gehe am **Ufer** entlang.*
Replace:	*Ich gehe am **<MARK>** entlang.*
Translate:	*I walk along the **<MARK>**.*
Restore:	*I walk along the **bank**.*

To learn the copy mechanism of the special marker we use parallel sentences containing the marker to train the NMT system used for back-translation. More precisely, 1% of the parallel sentences have one randomly selected source word and it's corresponding translation (determined by aligning the parallel data) replaced with the marker. Note that there is a small chance that the MT system does not generate the marker in the output in which case no replacement is performed. Finally, we update our baseline English→German MT system by running further training steps on the concatenated gold and synthetic parallel corpora. For further parameters we refer to Section 4.4.

4 Experimental Setup

4.1 Cross-Lingual Word Representations

As CCWRs we make use of XLM-R large[4] (Conneau et al., 2020), as previous works have shown good context-dependent cross-lingual correspondence in such multilingual models (Ethayarajh, 2019; Liu et al., 2019; Cao et al., 2019). Although they are multi-lingual, it was shown that their cross-lingual performance can be improved by applying an additional mapping step. Thus following Liu et al. (2019), we train a linear orthogonal mapping on XLM-R's context-average word type representations of word pairs extracted from the automatic word alignments in the parallel corpus which is used for MT training as well. The context-average representations are first length normalized and then mean centered prior to alignment as it was shown to improve the mapping quality (Artetxe et al., 2018). On top of the orthogonal mapping, we also apply the meeting-in-the-middle technique proposed by Doval et al. (2020) that learns additional linear mappings of both source and target languages to further improve their alignment. For exact details about the complete mapping process we refer to (Liu et al., 2019).

4.2 Baselines

Other than comparing CMBT with XLM-R to the *baseline* NMT system, we compare the approach to Huck et al. (2019), since it is able to leverage monolingual data to improve the translation of a list of words. More precisely, we translate multi-sense words with BWEs instead of XLM-R, to show the importance of context based word translation for the translation of multi-sense words. Since BWEs tend to rank the translations of words according to their frequency, this approach is comparable to the general back-translation approach, i.e., updating NMT systems on randomly sampled sentences, but focusing more on the ambiguous words. We build 300 dimensional *fastText* skipgram embeddings (Bojanowski et al., 2017) on Wikipedia dumps and align them using the same approach as for XLM-R (Liu et al., 2019). Similarly to CMBT, words are translated using cosine similarity taking top-5 most similar candidates. However, since BWE based bilingual lexicon induction (BLI) is

[4]Besides XLM-R, we experimented with mBERT (Devlin et al., 2017) as well but chose the former due to its superior word retrieval performance (See the experiment's results in Appendix A).

context independent, we pick all sentences containing any of the translations, which are then down sampled to match the number of sentences mined by CMBT for comparability. The rest of the steps, i.e., back-translation and system training, are the same as for CMBT. Our experiments show that although top-5 translations based on BWEs can cover multiple senses of some words, it is important to take the contexts into consideration as well in order to perform i) a more sense specific word translation and ii) mine sentences which do not only contain the target words but have similar contexts compared to the source sentences in the test corpus for an efficient MT tuning.

4.3 Monolingual Dataset

We use $2M$ randomly sampled German Wikipedia sentences for the mining process and restrict the vocabulary for translation candidates to the $500K$[5] most frequent words. We mine relevant sentences for all senses of the detected multi-sense words, including their frequent senses, since the frequency of senses in the training corpus is not known. The mined corpus contains 252 898 unique sentences.

4.4 MT Systems

We train base Transformer NMT models (Vaswani et al., 2017) on the gold parallel data discussed below with early-stopping based on validation perplexity. The model is trained on 4 Nvidia GTX 1080ti GPUs with a per-GPU batch size of 4096 tokens and by delaying stochastic gradient descent updates with a factor of 2. The final model is an average of the best 10 checkpoints, where checkpoints are saved every 500 updates. We use dropout and label smoothing with a value of 0.1.

Fine-tuning this initial system with the concatenation of the gold and synthetic data is done using the same hyper-parameters with early-stopping based on validation perplexity. The average of the best 10 checkpoints is chosen as the initial starting point for fine-tuning.

As a development set we merge newstest 2017-2019. We use a beam size of 4 for back-translation and 5 for the translation of MuCoW. All models are built using fairseq (Ott et al., 2019). The datasets are tokenized using Moses[6]. We use BPE splitting[7] with 32K merge operations computed jointly on the source and target data. Word alignment is performed using fastalign (Dyer et al., 2013).

4.5 MuCoW Dataset

We run experiments on the English→German translation direction of the MuCoW dataset (Raganato et al., 2020). It was created specifically to test translation quality of ambiguous words by specifying the word and its gold sense for each test sentence. The dataset provides small and big training parallel corpora containing $1.2M$ and $3.0M$ sentence pairs respectively. In order to test on rare and unseen senses more directly, we create two subsets of the latter. We remove sentence pairs containing the rarest sense of any of the given multi-sense words to test on *unseen* senses ($2.9M$ pairs). Secondly, we take a random 10% sample of the sentence pairs containing a multi-sense word and all pairs containing no multi-sense words in *sample-10* ($2.4M$ pairs) to test on rare senses. By sampling data uniformly random in case of the latter, we make sure that only the frequency of the multi-sense words gets decreased, while keeping their original sense distribution. Note that we only change the training set to have more word types with unseen and rare senses during training but keep the test set unchanged. Our *baseline* NMT system is trained on these training sets without the additional mined data.

We evaluate our MT systems on word level (F_1) using the official MuCoW evaluation script which calculates precision and recall values as:

$$P = \frac{|correct\ senses|}{|correct\ senses| + |incorrect\ senses|} \quad (2)$$

$$R = \frac{|correct\ senses|}{|test\ cases|} \quad (3)$$

where a test case is an occurrence of a multi-sense word in a test sentence. The dataset provides multiple correct translation options for a given sense, thus an occurrence of a multi-sense word (sense) is correctly translated if any of the translations of the correct sense are contained in the output sentence. A sense is incorrect if any of the translations of the wrong senses of the given multi-sense word are contained in the output sentence. A sense is

[5] We increase the $200K$ limit used in most BLI works in order to cover more rare words.

	CMBT	**28.30**	**43.90**	**73.51**$\uparrow^{2.81}$
sample-10	baseline	-	-	74.58
	BWEs	17.94	28.74	73.75
	CMBT	**28.30**	**43.90**	**75.86**$\uparrow^{1.28}$

Table 2: Evaluation of all (including frequent) senses when using *unseen* or *sample-10* training sets. Number of overall test cases are $25.3K$ in both sets. BLI results are the same for both training sets as they only affect the NMT system.

neither correct nor incorrect if none of the possible translations of the multi-sense word is contained. Furthermore sentences are lemmatized, thus all morphological variants of a word are accepted.

We also calculate BLEU scores using *sacrebleu* (Post, 2019) to show general MT performance. In addition, we evaluate the word translation accuracy of XLM-R and BWEs on the gold MuCoW multi-sense words contained in each test sentence. Similarly to BLI (Vulić and Korhonen, 2016), we calculate acc@n ($n \in 1, 5$) scores by testing if any of the correct translations of the gold sense in a given test example is among the n most similar translation candidates.

5 Results and Discussion

Unseen and rare sense translation We present both the intrinsic performance of BWEs (Huck et al., 2019) or CMBT (XLM-R) based word translation (acc@n) and extrinsic MT system based translation (F_1) in Table 1. We show results on senses in the test corpus which are missing from the *unseen* training corpus and detailed results on word senses that are rare (relative frequency compared to the other senses of a given word is between 20% and 40%) and very rare (with relative frequency between 0% and 20%) on *sample-10*.

In terms of acc@n CMBT word translation performs significantly better than BWEs. This is not surprising, since the context independent BWEs predict the same translations for a given multi-sense word for each sentence it is contained in. In contrast, XLM-R shows a better WSD performance by relying on the context in the sentences. Our improved NMT system using CMBT outperforms the baseline system in all setups in terms of F_1. It is especially effective on the unseen and very rare senses due to the additional synthetic sentence pairs containing these senses and their translations. In addition, it is also effective for the rare senses in the higher relative frequency range bin. BWEs based mining is also helpful for the unseen and very rare senses but it is less effective compared to CMBT. Although BWEs are context independent, by taking top-5 translations some of the senses can still be improved. On the other hand, BWEs have minor negative effects for the higher frequency range.

All sense translation We show results on all senses, i.e., senses with relative frequency higher than 40% as well, using the two training sets in Table 2. CMBT is also effective when evaluating on the whole MuCoW test dataset, but its performance is more prominent on the lower frequency ranges. In contrast, BWEs achieved only a slight improvement on *unseen* and some performance drop on *sample-10*.

Lexicon-regularized translation As mentioned, we built the list of English multi-sense words using BabelNet. Since it also contains translation options for each word, we investigate whether we can make use of this additional information. Fortunately, CMBT can be naturally extended to leverage such lexical resources.[8]

During sentence mining with the lexicon-regularized version of our approach (CMBT+), we restrict the set of translation candidates when translating a given word with XLM-R to its possible

[8]In comparison, it is not straightforward how we can add this information into a baseline NMT system where we cannot easily track translation for specific source words.

train	bin	system	F_1
unseen	0-0	ALL+	$25.21\downarrow^{9.59}$
		CMBT+	$34.55\downarrow^{0.25}$
	all	ALL+	$72.00\downarrow^{1.51}$
		CMBT+	$73.83\uparrow^{0.32}$
sample-10	0-20	ALL+	$43.37\downarrow^{3.65}$
		CMBT+	$46.75\downarrow^{0.27}$
	20-40	ALL+	$65.04\uparrow^{0.55}$
		CMBT+	$66.82\uparrow^{2.23}$
	all	ALL+	$75.95\uparrow^{0.09}$
		CMBT+	$76.50\uparrow^{0.64}$

Table 3: Evaluation of the senses per frequency bins as well as all senses using the lexicon-regularized systems on the two datasets. Differences compared to the best system (CMBT in tables 1 and 2) are indicated.

translations as given by BabelNet. Furthermore, we mine sentences based on all possible translations (ALL+) instead of taking top-5 ranked by XLM-R. Table 3 shows that the regularized systems achieved improvements compared to CMBT only in the higher frequency ranges but not in the missing or very rare sets. ALL+ achieved only minor improvements overall (*all*) on *sample-10*, while the performance decreased on *unseen*. This indicates that without focused data mining, sentences containing rare and unseen senses are suppressed by the frequent senses. In contrast, CMBT+ achieved improvements on both setups by following the sense distribution of the test set. However, the improvements are marginal which shows that the unregularized CMBT system is already able to retrieve the relevant senses of words without the additional information coming from BabelNet.

BLEU evaluation Finally, we show general MT performance on our training setups including the original MuCoW *big* setup as well for comparison in Table 4. It can be seen that our approach achieved improvements in terms of BLEU as well, further motivating its use. Similarly to F_1 scores the improvements are more prominent when evaluating only on sentences containing missing or rare senses. CMBT achieves best scores on the full test sets (all) of the *unseen* and *sample-10* setups, and a minor decrease on *big*. However, BLEU score differences are minor and they do not correlate well with F_1 improvements. As we show next, the minor differences in BLEU scores here are due to the fact that our approach mainly affects the translation of multi-sense words while leaving

train	bin	baseline	BWE	CMBT
unseen	0-0	23.0	23.2	**23.3**
	all	25.5	25.6	**25.7**
sample-10	0-20	22.3	22.3	**22.6**
	20-40	24.5	24.6	**24.7**
	all	25.0	25.0	**25.1**
big	all	**26.5**	**26.5**	26.4

Table 4: Machine translation performance (BLEU) on the complete MuCoW test set using the unmodified *big* and our two custom training sets. We show results on the missing (0-0) and rare senses (0-20 and 20-40) as well as on the complete test set (all). BLEU score achieved by Raganato et al. (2020) on big-all is 22.6.

the translation of other words intact. It is worth pointing out that BLEU scores may not be the ideal metric in this study as they are less sensitive to word-level translation improvement as compared with F1 scores. This is similar to the findings of Arthaud et al. (2021), who showed that improving the translation of a few selected words could lead even to a slight drop in BLEU.

Analysis We manually looked at the translations of a few multi-sense words to have a better understanding of our system. We present a few examples of the typical improvements and errors we found in Table 5. In example 1 both the BWEs based system and CMBT correctly translated *bank* to *Ufer* (river bank) which shows the positive effects of the additional data. In contrast, in 2 and 3 which are examples produced under the *sample-10* and *unseen* conditions respectively, only CMBT managed to pick the right senses due to the better exploitation of the given context. All systems are incorrect in 4, however the output of CMBT (brake pedal) is related to vehicle/gas pedals (the correct sense), while the base system's output, *Beschleuniger* is more related to physics and chemical reactions, such as particle accelerator or a catalyst. We reviewed the top-5 translations given by BWEs and XLM-R for *accelerator* when it has the *gas pedal* sense in a test sentence, and found that the translations reflect the outputs of the MT systems. This shows the effectiveness of the MT system's update process and that improving CCWR based translation could lead to further improvements.

In example 5 CMBT is misled by the *mossy bank*, thus outputs the *river bank* instead of the *bench* sense in contrast to the baseline which correctly used the frequent *Bank* word. Example 6 is incorrectly translated by all systems with different

errors.

Additionally, by comparing the full outputs of the systems it can be seen that our approach is non-invasive, i.e., it mostly affects the translations of multi-sense words and leaves the other parts of the sentences unchanged compared to the baseline, which is a big advantage of our approach and also explains the small BLEU differences in Table 4.

Finally, we present mined sentences based on two example source sentences containing the word bank in Table 6. The sentences indicate that our XLM-R based mining technique not only outputs the translation of the right sense but the mined sentences have similar contexts to the source sentences. This allows the fine-tuned MT system to leverage information learned from sentences that are closely related to the input sentence during translation.

6 Conclusions

In this paper we proposed CMBT, a simple and effective approach for improved rare and unseen word sense translation. It serves as a general framework that effectively exploits the context-dependent cross-lingual correspondence from a pre-trained CCWR for an MT system. We show CMBT brings significant improvements for multi-sense word translation on the English→German MuCoW test set. The improvements are the most pronounced when we directly targeted the evaluation of the difficult rare and unseen senses. As the only requirement of CMBT, on top of the parallel data necessary for the training of the MT system, is a monolingual corpus and an off-the-shelf pre-trained multilingual model, CMBT can be applied

A mBERT vs. XLM-R

We report the results of our initial word translation accuracy experiments using off-the-shelf mBERT and XLM-R (large) on all the multi-sense words provided by the gold MuCoW test set in Table 7. For efficiency, we randomly sampled $100K$ target sentences from Wikipedia as the candidate pool instead of the $2M$ described in Section 4.3. We take the average of the top-half layers of mBERT (top 6 layers) and XLM-R (top 12 layers) respectively when calculating word representations. We show that XLM-R performs significantly better than mBERT.

Model	$acc@1$	$acc@5$	$acc@10$
mBERT	21.40	32.16	37.29
XLM-R	**27.13**	**38.76**	**43.81**

Table 7: Comparing the translation accuracy of off-the-shelf mBERT and XLM-R on the MuCoW test set.

Pushing the Right Buttons: Adversarial Evaluation of Quality Estimation

Abstract

Current Machine Translation (MT) systems achieve very good results on a growing variety of language pairs and datasets. However, they are known to produce fluent translation outputs that can contain important meaning errors, thus undermining their reliability in practice. Quality Estimation (QE) is the task of automatically assessing the performance of MT systems at test time. Thus, in order to be useful, QE systems should be able to detect such errors. However, this ability is yet to be tested in the current evaluation practices, where QE systems are assessed only in terms of their correlation with human judgements. In this work, we bridge this gap by proposing a general methodology for adversarial testing of QE for MT. First, we show that despite a high correlation with human judgements achieved by the recent SOTA, certain types of meaning errors are still problematic for QE to detect. Second, we show that on average, the ability of a given model to discriminate between meaning-preserving and meaning-altering perturbations is predictive of its overall performance, thus potentially allowing for comparing QE systems without relying on manual quality annotation.

1 Introduction

Quality Estimation (QE) is the task of predicting the quality of Machine Translation (MT) output in the absence of human reference translation. Recent QE models based on multilingual pre-trained representations (Ranasinghe et al., 2020) have shown impressive results achieving up to 0.9 Pearson correlation with human judgements of translation quality at sentence level (Specia et al., 2020). Not unlike other NLP systems, QE systems are typically tested on held-out datasets. On the one hand, such evaluation usually requires collecting additional human judgements and thus cannot be easily extrapolated to a different usage scenario, for example, a new language pair. On the other hand, evaluation on a given test set can hide performance issues related to the phenomena that are underrepresented in the data but are critical to the reliable performance of the system. Finally, a single statistic capturing overall performance does not provide any insights on the strengths and weaknesses of a given approach. As a way to overcome these limitations, we explore adversarial evaluation for QE. Specifically, we introduce two types of changes to high-quality MT outputs: meaning-preserving perturbations (MPPs) and meaning-altering perturbations (MAPs). Intuitively, we expect a strong QE system to assign lower scores to the sentences containing MAPs compared to the sentences with MPPs. Based on this intuition, we devise experiments to systematically test a set of five different QE systems by comparing the scores they produce for sentences containing MPPs and MAPs. We use the difference in the predicted scores as a way of detecting specific problems as well as for assessing the overall performance of the systems. Our main findings[1] can be summarised as follows:

- Overall, SOTA QE models are robust to MPPs and are sensitive to MAPs, thus supporting the claims that such models are indeed strong predictors of MT quality.
- SOTA QE models fail to properly detect certain types of MAPs, such as negation omission, which highlights the weaknesses of these models that cannot be detected using standard evaluation methods.
- The overall results of our probing experiments on a set of QE models are consistent with their correlation with human judgements. This suggests that the proposed evaluation methodology can be used to assess the performance of QE models with no need for collecting gold standard human annotation.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 625–638
November 10–11, 2021.

In the remainder of this paper, we first discuss related work on probing for NLP (Section 2). We then describe the dataset (Section 3) and QE models used in our experiments (Section 4). We introduce our probing setup and strategies in Section 5 and present and discuss the results in Section 6.

2 Related Work

Very few studies have analysed the performance of QE models beyond correlation with human judgements on held-out datasets. To the best of our knowledge, the only work that analyses the behaviour of QE models is Sun et al. (2020). On various datasets popularly used for training QE models, they show that they contain certain biases, such as a skew towards high-quality MT outputs and lexical artefacts that are picked up by the SOTA architectures, *e.g.,* sentences with certain tokens tend to have high or low scores. They also show that QE models can perform very well on these datasets by encoding only the source or target sentences. By contrast, we study the behaviour of the models under specific linguistic conditions. Our experiments show that the models are not sensitive to certain meaning errors, which is in line with (Sun et al., 2020)'s assumption that SOTA QE models do not capture adequacy.

For MT, various studies have shown that models can achieve high performance on clean data, they are very brittle to noisy inputs, where both synthetic (e.g. character flips) or natural (social media data) noise is used to probe models (Belinkov and Bisk, 2018; Khayrallah and Koehn, 2018; Li et al., 2019; Passban et al., 2020). For other NLP tasks, black-box methods for adversarial evaluation have been proposed that apply meaning-preserving perturbations in order to test whether the models are sensitive to changes in the input (Ribeiro et al., 2018). Different from this line of work, we probe the robustness of QE models to spurious changes but also sensitivity to relevant changes, such as meaning errors. Ribeiro et al. (2020) recently devised a general methodology for behavioural testing of NLP models. They generate a subset of simple examples meant to test general linguistic capabilities expected from an NLP system. However, the linguistic capabilities tested within this framework are not directly applicable to the QE task. They could not, for example, capture the ability of a QE system to detect omission errors or copy errors in translation.

3 Dataset

The dataset used in this paper is a subset from the WMT 2020 Quality Estimation Shared Task 1, sentence-level prediction (Specia et al., 2020). This data consists of seven language pairs which can be classified as high-resource [English-German (En-De), English-Chinese (En-Zh)], medium-resource [Russian-English (Ru-En), Romanian-English (Ro-En), Estonian-English (Et-En)], and low-resource [Sinhala-English (Si-En), Nepalese-English (Ne-En)] pairs. Except for Ru-En, sentences are extracted solely from Wikipedia. The Ru-En data also contains additional sentences from Reddit (Fomicheva et al., 2020). The data was collected by machine translating sentences sampled from source-language articles using SOTA NMT models built using the *fairseq* toolkit (Ott et al., 2019). The data was annotated with a variant of Direct Assessment (DA) scores (Graham et al., 2017) by professional translators. Each translation was rated with a score in 1-100, according to the perceived translation quality by at least three translators (Specia et al., 2020). The goal of QE systems built on this data is to predict a *z-score* normalised mean DA for each *test* source-target pairs, which we further standardise between 0 and 1.

In the original dataset, 9K sentences per language pair were randomly split in training (7K), validation (1K) and test (1K). In this study, we focus on probing the models by modifying the target side (translations) with various perturbations. To keep the experiments consistent across the language pairs, we only consider the five pairs with English as the target language.

We use the standard training partition of the data to train our QE models. To evaluate our probes, the assumption made is that sentences with perturbations should lead to lower predicted QE scores than original sentences. However, this assumption only holds if we can ensure that the original sentences have high enough quality since perturbing very low-quality sentences with already very low scores would not necessarily lead to further degradations. Therefore, we create a subset of the validation + test sets by applying the threshold of 0.7 on the standardised human (DA) scores to reflect high quality, based on the definition of the DA scores used as guidelines for annotators in this dataset. Table 1 shows the resulting number of validation + test instances for each language. We hereafter refer to this set as our **test set**.

Language Pair	Ru-En	Ro-En	Et-En	Si-En	Ne-En
#sentences	1245	1035	766	404	100
Low-resource	No	No	No	Yes	Yes

Table 1: The number of selected sentences in our test set for each language pair. These are sentences judged to have high-enough quality by human translators.

4 QE Models

We choose three categories of heavy- to light-weight models for sentence-level QE models: first, the SOTA TransQuest with three variants MonoTransQuest, SiameseTransQuest and MultilingualTransQuest (Ranasinghe et al., 2020); second, the LSTM-based Predictor-Estimator approach (Kim et al., 2017) and third, the unsupervised method SentSim (Song et al., 2021).

MonoTransQuest (MonoTQ) This regression architecture encodes a concatenated source-target sentence pair using a transformer encoder. The architecture adds a softmax layer on top of the CLS token of the transformer to predict the quality of the translation. MonTransQuest architecture has separate pretrained QE models based on XLM-Roberta-Large (Conneau et al., 2020) for all seven language pairs from WMT 2020 QE Task 1.

SiameseTransQuest (SiameseTQ) This architecture uses a siamese network with two transformer models to encode the source and the target sentences separately. The architecture adds a max-pooling layer on top of the token embeddings of each transformer and calculates the cosine similarity between the outputs of the two pooling layers to predict the quality of the translation. Similar to *MonoTQ*, SiameseTQ has separate pretrained QE models based on XLM-Roberta-Large for all seven language pairs from WMT 2020 QE Task 1.

MultilingualTransQuest (MultiTQ) This architecture is based on MonoTQ but is trained on aggregated QE data for all seven language pairs from the WMT 2020 QE Task 1, resulting in one model for all the language pairs. This model is also based on XLM-Roberta-Large.

Predictor-Estimator (OpenKiwi) This is a two-stage architecture, where the Predictor model is an encoder-decoder RNN trained on parallel data (source-reference); in this case, the same data is used to train the respective NMT model for each language pair. Its output is then fed to the Estimator, a unidirectional RNN trained on QE data, to produce the quality estimates. Compared to TransQuest, the PredEst architecture does not rely on heavily pre-trained representations, resulting in a lighter model. For our experiments, we use the implementation in OpenKiwi (Kepler et al., 2019), which was provided as the baseline for the WMT 2020 QE Shared Task.

SentSim This is an unsupervised method to QE that uses a combination of cross-lingual word and cross-lingual sentence similarity scores to produce a sentence-level quality score. The word-level similarity is extracted using BERTScore (Zhang et al., 2020) between source and MT sentences, while sentence-level similarity is measured as the cosine similarity between the source and MT sentences representations. Both word and sentence-level representations are extracted using a cross-lingual pre-trained model, namely, XLM-Roberta-Base (Conneau et al., 2020).

5 Probing Strategies

In this section, we introduce the rationale for two types of probes: meaning-preserving and meaning-altering perturbations. We then describe each perturbation and discuss the experimental setup for the probing.

We define a **meaning-preserving perturbation (MPP)** as a small change in the target-side translation that might affect the translation but should not affect the overall meaning of the sentence. For example, removing punctuation marks from the translated sentence should not affect the meaning conveyed by the text. By contrast, **meaning-altering perturbations (MAP)** should alter the meaning conveyed by the translation, for example, replacing a random word with its antonym or randomly replacing a content word. By introducing MAPs, we focus on probing models for whether they capture (lack of) adequacy in translations. Given that SOTA QE models are based on pre-trained representations obtained from strong language models, it has been hypothesised that they could be biased by the fluency of translations (Sun et al., 2020).

We, therefore, design two types of perturbations: MPPs, which might affect fluency but not adequacy, and MAPs, which affect adequacy. Perturbations are only introduced in the translations to mimic translation errors. We have chosen perturbations that can be introduced using automated methods,

Table 3: An example of each MAP from our dataset for Ru-En. 'Translation' is the original machine translated sentence for the given source sentence, which was assigned an average DA score of 0.88 by human annotators (in 0-1). S1 are scores from MonoTransQuest architecture, and the reference translation is only shown for readability, as it was not used by humans nor QE models.

and we carefully select perturbations relevant for MT, *e.g.,* rare errors such as the omission of negation, and known errors such as omission of words from translation. Each type of perturbation is introduced independently of others, one perturbation per target sentence. We note that most of our perturbations are general enough such that they apply to all sentences in our test set. An exception is the removal of negation which can only be applied to sentences which contain a negation marker.

We analyse the behaviour of QE models by comparing the difference in the scores predicted after MPP/MAPs are applied to the test set compared to the original, unperturbed test set. We expect a strong QE model to predict lower scores to the version of the test set containing sentences with MPP and MAP, and – more importantly, a higher score to sentences with MPP than to sentences with MAP. Each of our probes is detailed below, categorised either as an MPP or as an MAP.

5.1 Meaning-Preserving Perturbations

We designed the following MPPs. In order to ensure sufficient randomisation of the experiments, we repeat MPP2, 4, 5 and 6, twenty times for each sentence and average the QE scores obtained for these twenty perturbations. Other MPPs, *e.g.,* removing all punctuations in the translation, can only result in one new version of the translation, and therefore, repetitions are not needed.

Removal of Punctuations (MPP1): We remove any punctuation marks from the translation using the standard *string* library in Python, for this perturbation.

Replacing Punctuations (MPP2): In this perturbation, each punctuation mark in the transla-

tion is replaced with another randomly chosen punctuation mark.

Removal of Determiners (MPP3): We use the *spaCy*[2] Part-of-speech (POS) tagger to identify determiners, and then remove them from the translation.

Replacing Determiners (MPP4): Each word labelled as a determiner with the help of spaCy POS tagger in the translation is replaced with another randomly chosen determiner from a list.

Change in Word-casing (MPP5/MPP6): We select random content words from the translation and convert them to UPPERCASE to generate a set of perturbed translations (MPP5). Additionally, we select content words randomly from the translation and convert them to lowercase to generate another set of perturbed translations (MPP6).

For each of the perturbations described above, we provide an example in Table 2, along with the scores predicted from our SOTA (MonoTQ) QE system.

5.2 Meaning-Altering Perturbations

We choose the following probes as MAP. We ensure sufficient randomisation of the experiments by repeating MAP2, 3, 4, 5, 6, and 7, twenty times for each sentence, and average the QE scores obtained for these twenty perturbations. For MAPs 1, and 8, we can produce only one version of the sentence.

Removal of Negation Markers (MAP1): For this perturbation, all the *negation markers* like "no", "not", "n't" *etc.* are removed.

Removal of Random Content Words (MAP2): We select a random content word from the translation and remove it.

Duplication of Random Content Words (MAP3): We choose a random content word from the translation and add it at the immediate next position index, thus duplicating its occurrence.

Insertion of Random Words (MAP4): We populate a vocabulary of words from the complete set of translations in our test set. From this vocabulary, we choose a word and insert it at a random position in the sentence, ensuring that the previous word and the next word are not the same to avoid duplication.

Replacing Random Content Words (MAP5): We choose a random content word from the translation and replace it with another word from the vocabulary created as discussed in MAP4.

BERT-based Sentence Replacement (MAP6): We obtain sentence replacements based on the BERT-base model (Devlin et al., 2019), with the help of a data augmentation library[3] (Ma, 2019). This library uses a word replacement approach proposed by Kobayashi (2018) and generates a sentence synonymous to the input provided. We observe that BERT-generated synonymous sentences replace content words which alter the inherent meaning of the input sentence and hence, treat this perturbation as MAP.

Replacing Words with Antonyms (MAP7): With the help of the data augmentation library[3], we generate perturbed translations where we replace random words in the sentence with their antonyms from the English Wordnet (Miller et al., 1990).

Source Sentence as Target (MAP8): We replace the translation with the source side sentence to observe the effect on QE scores when the source sentence is evaluated by the QE model, instead of the target side translation. Such a perturbation results in the model input to become *source-source* instead of *source-target*.

For each of the perturbations described above, we provide an example in Table 3, along with the scores predicted via SOTA (MonoTQ) system.

6 Results and Discussion

In this section, we discuss the results obtained from our probing experiments using various QE models.

6.1 Do perturbations affect SOTA QE models?

We start by analysing the behaviour of MonoTQ, as the best performing SOTA QE model on the dataset used in this paper, under different types

Table 4: Average predicted scores by all QE models on the test set for the original (unperturbed) machine translation (MT), versus its version with meaning-preserving perturbations (MPP) and meaning-altering perturbations (MAP). Between MPP and MAP, we boldface the lowest average scores, if lower than MT.

of perturbations. Figure 1 shows the difference between the average predicted score for our original test set (Table 1) before perturbations and the same subset of sentences perturbed using MPP and MAP. In comparison to the average scores for the initial set of translations, the expected behaviour for a strong QE model is to assign the same or slightly lower scores to and their MPP counterparts, but substantially lower scores to the MAP variants. Based on this premise, we can make the following observations from Figure 1. The other graphs obtained from SiameseTQ model, MultiTQ model, OpenKiwi system, and the Unsupervised method are present in Appendix A.

Models are robust to MPPs and sensitive to MAPs Overall, sentences with MPPs result in a small drop in the scores with respect to the original set of translations, especially when compared to the sentences containing MAPs. Conversely, perturbations that affect sentence meaning have a larger impact on the scores. Thus, SOTA QE models are indeed capable of discriminating between the two types of changes.

Models fail to detect important MAPs However, MonoTQ fails to discriminate between MPPs and specific types of MAPs. In particular, *perturbations that affect sentence polarity*, *i.e.,* MAP1 (Removal of Negation Markers) and MAP7 (Replacing Words with Antonyms) result in a similar drop in the predicted scores as MPPs. An exception is a slight increase in the case of Nepali-English where the number of instances with negation markers were limited to only 4, which makes it impossible to draw any conclusions. Omitting negation is a critical error in the practical applications of MT. But it does not frequently occur in the data, and therefore, cannot be detected by using the standard way of assessing the performance of QE systems, *i.e.,* by computing the correlation with human judgements on a test set.

MAPs that correspond to *omission and addition errors in translation* (MAP2 and MAP4, respectively) also result in a relatively small drop in the predicted scores and thus hardly be distinguished from MPPs. Omitting contents is a well-known issue for the current neural MT models (Yang et al., 2019). An omission is particularly dangerous as it can go unnoticed by the end-user of the MT system. The ability to detect such errors is thus a crucial task for QE and, as highlighted by our analysis, requires further work in this direction.

Finally, *copying the source sentence in the translation* (MAP8) is not adequately captured by MonoTQ. Note that this represents another critical translation error, as the source sentence is left untranslated. We hypothesise that the inability to detect copy errors is due to the fact that MonoTQ relies on the multilingual pre-trained representations and, unless presented with such cases during fine-tuning, would treat the two sentences in the source language as equivalent.

Comparison across languages Interestingly, we observe similar trends across language pairs. For all the language pairs, sentences with MAP produce a larger drop in performance than MPP, and the same MAPs result in incorrect behaviour.

6.2 Do perturbations affect other QE models?

Table 4 shows the actual average scores produced by different QE systems for the initial subset of high-quality MT sentences (column MT) and the same subset of sentences perturbed using MPP (column MPP) and using (column MAP). For strong QE models, we would expect both MPP and MAP scores to be lower than the initial MT outputs, especially for MAP. For most of the models and languages, the sentences perturbed with MAP receive lower average scores, thus confirming that,

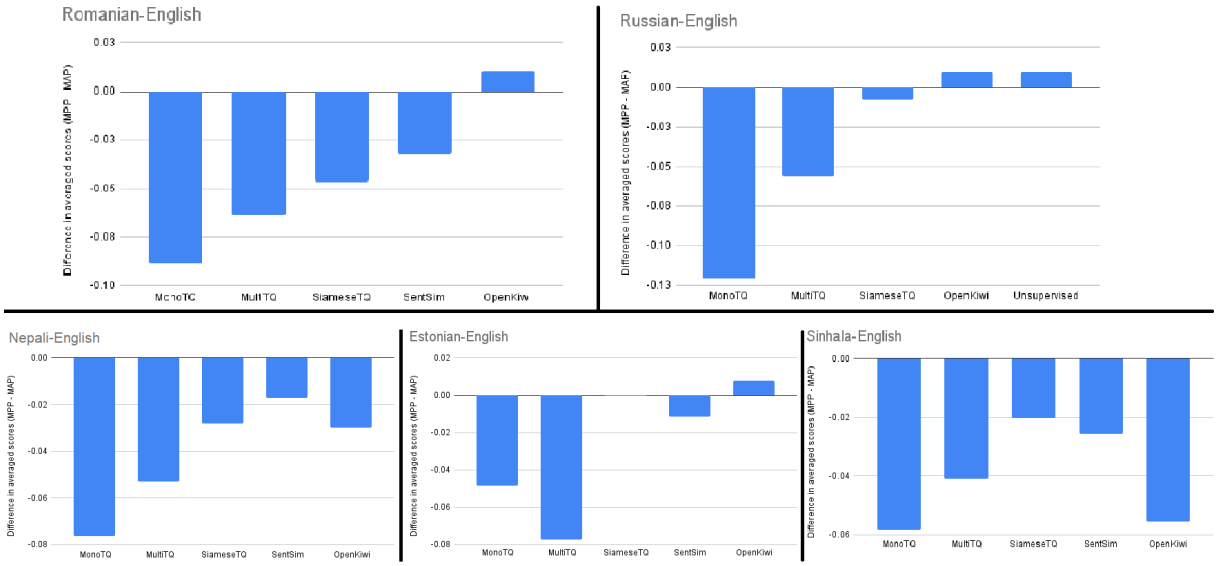

Figure 2: Ranking QE models using our method (MPP - MAP), where different QE models are shown on the X-axis, sorted as per the ranks obtained via Pearson correlation (among QE scores and human DA judgements). The size of the bars corresponds to the ability of the QE models to distinguish between MAP and MPP perturbations - the higher the negative bar, the better the QE model is at this task.

in general, QE models are sensitive to the changes that affect meaning. It is clear, however, that for some models, the difference between the MT, MAP and MPP is negligible. These cases are observed with OpenKiwi and SentSim, which are weaker QE models compared to the TransQuest variants (Specia et al., 2020) (see Table 5 for the overall results on the complete test+validation set of 2K sentences). Thus, we hypothesise that the ability of a QE model to discriminate between MAP and MPP could be predictive of its overall performance. We empirically test this hypothesis, and discuss below.

6.3 Can we use perturbations to rank QE models?

We pose that the overall performance of a QE system can be predicted based on how well it is able to discriminate between meaning-preserving and meaning-altering perturbations. To test this claim, we contrast the ability of a set of QE systems to discriminate between MAP and MPP with their overall performance measured in terms of Pearson correlation with human judgements. Table 5 shows sentence-level Pearson correlation with human judgements on the WMT 2020 QE Shared Task test set for all the QE models and language pairs considered in our experiments. As shown in Table 5, QE models vary a lot in terms of overall performance, the weakest system being OpenKiwi and SentSim, and the strongest corresponding to the SOTA approaches based on XLM-Roberta. To assess the discriminative power of the models, we compute the average difference (MPP - MAP) between the relative scores obtained via our method (such as shown in Figure 1). In Figure 2, we sort all the probed QE models in the decreasing order, according to the correlation with human judgements on the x-axis, and plot the corresponding MAP/MPP difference on the y-axis.

	Et-En	Ru-En	Ro-En	Si-En	Ne-En
MonoTQ	0.72	**0.77**	**0.88**	**0.88**	**0.75**
MultiTQ	**0.76**	**0.77**	0.87	0.87	0.74
SiameseTQ	0.55	0.71	0.84	0.84	0.60
SentSim	0.53	0.46	0.77	0.77	0.56
OpenKiwi	0.47	0.59	0.68	0.36	0.39

Table 5: Pearson correlation with human judgements for all QE models on the original, complete test+validation (2K) set. This is the metric used to rank participating QE systems in the WMT 2020 QE Shared Task 1. As can be seen, MonoTQ and MultiTQ consistently outperform all other models, with OpenKiwi performing the poorest.

Interestingly, for most of the language pairs, we observe that the system rankings are similar or identical to the Pearson correlation-based rankings; indicating that the ability of the model to distinguish between the proposed types of perturbations is indeed indicative of its overall performance. One exception is the difference corresponding to the OpenKiwi system for Sinhala-English and Nepali-

English. We attribute this to the fact that, by difference from the SOTA QE models, OpenKiwi is good at capturing the copy errors (MAP8) for these languages. OpenKiwi uses different vocabularies for the source and target languages, and therefore, copying the source sentence results in unknown tokens on the target side, leading to a low predicted score. Another exception is Estonian-English, where the systems appear to be ranked differently based on correlation vs. MAP/MPP difference. We note, however, that even in this case, the two top-performing systems (MonoTQ and MultiTQ) are clearly distinguished from the low-performing ones (SentSim and OpenKiwi).

Although generating MAPs and MPPs requires some initial set of high-quality translations, this could be selected using reference sentences from parallel data. Therefore, the proposed methodology allows for assessing the performance of QE models with no need for collecting explicit human judgements (*e.g.,* direct assessments).

7 Conclusions

In this work, we have proposed a methodology for analysing the performance of QE systems beyond correlation with human judgements. We have devised a set of perturbations to probe both the robustness of QE models towards changes in the input that do not affect sentence meaning and their sensitivity to meaning errors in translation. First, by applying the proposed methodology to a set of QE systems of varying accuracy, we are able to detect specific failures that cannot be detected by computing correlations between predicted scores and human judgements. Second, we have shown that, on an average, the ability of a given model to discriminate between the two types of perturbations is predictive of its overall performance, thus allowing us to compare QE systems without relying on manual quality annotation.

Our choice of specific perturbations was motivated by the errors that occur in neural MT and the potential weaknesses of QE models. In the future, we plan to extend this set by including perturbations that capture other critical MT errors. Furthermore, we plan to study whether the proposed perturbations can be used at training time to improve the ability of QE systems to detect critical errors in translation.

Abstract

The machine translation efficiency task challenges participants to make their systems faster and smaller with minimal impact on translation quality. How much quality to sacrifice for efficiency depends upon the application, so participants were encouraged to make multiple submissions covering the space of trade-offs. In total, there were 53 submissions by 4 teams. There were GPU, single-core CPU, and multi-core CPU hardware tracks as well as batched throughput or single-sentence latency conditions. Submissions showed hundreds of millions of words can be translated for a dollar, average latency is 5–20 ms, and models fit in 7.5–150 MB.

1 Introduction

The efficiency task complements the collocated news task by challenging participants to make their machine translation systems computationally efficient. This is the fourth edition of the task, expanding upon previous editions (Heafield et al., 2020; Hayashi et al., 2019; Birch et al., 2018).

Participants built English→German machine translation systems following the constrained data condition of the 2021 Workshop on Machine Translation news translation task. For translation quality measurement, we use the same news-focused WMT21 test set and human evaluation protocol as the news task. However, human assessment was conducted separately from the evaluation of the news task submissions.

Submissions are made as Docker containers so we can consistently measure their performance in terms of quality, speed, memory usage, and disk space. We run the containers in three different hardware environments: one GPU, one CPU core, and multiple CPU cores. Systems were tested for throughput by providing 1 million sentences upfront to allow batching and parallelization. We also tested for latency with a program that drip-feeds one input sentence, waits for the translation, and then provides the next input sentence. There were five conditions in total: GPU Batch (for throughput), GPU Latency, 1 CPU Core Batch, 1 CPU Core Latency, and 36 CPU cores Batch. We did not measure latency in a multi-core CPU setting because the test hardware has 36 cores and overhead for 36 threads is larger than the cost of arithmetic for the small tensors in optimized models.

	Edinburgh	HuaweiTSC	NiuTrans	TenTrans
GPU Batch	✓		✓	✓
GPU Latency	✓			
1 Core Batch	✓			
1 Core Latency	✓	✓		
36 Cores Batch	✓		✓	

Table 1: Participation in each of the hardware and batching conditions. Core refers to CPU hardware with 1 core or all 36 cores.

Participants were free to choose which conditions to participate in. The condition was passed to the Docker container as command line arguments. Table 1 shows the four participants and the conditions they submitted to.

Machine translation is used in a range of settings where users might choose different trade-offs between quality and efficiency. For example, a high-frequency trading system might prefer the lowest latency at the expense of quality given that the output will only be read by a machine. Conversely, in a post-editing scenario the personnel costs outweigh many computational costs. Therefore there is not a single best system, but a range of options that trade between quality and efficiency. We emphasize the Pareto frontier: the fastest systems at each level of quality, or the smallest systems at each level of quality. To explore the Pareto frontier, participants were encouraged to make multiple submissions covering the range of trade-offs. In total, 53 combinations of models, hardware, and batching were benchmarked.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 639–651
November 10–11, 2021.

2 Hardware

We chose modern hardware to encourage exploiting new hardware features. The GPU is an NVidia A100 from the Oracle Cloud `BM.GPU4.8` instance. The instance has eight GPUs and we limited Docker to using only one GPU. The GPU machine has an AMD EPYC 7542 CPU with all cores allowed. In practice, most submissions used only one core while NiuTrans's submissions used the CPU cores to parallelize preprocessing and postprocessing.

The CPU-only condition used a dual-socket Intel Xeon Gold 6354 from Oracle Cloud `BM.Optimized3.36` with a total of 36 cores. For the single-core CPU track, we reserved the entire machine then ran Docker with `-cpuset-cpus=0`. In the 36-core CPU track, participants were free to configure their own CPU sets and affinities.

The Oracle Cloud machines are bare metal servers, meaning there was no shared tenancy, no virtualization, and the test machines were otherwise quiescent.

3 Input Text

To amoritize loading time, avoid starving highly parallel submissions, and reduce the ability to cheat, we benchmark systems on 1 million sentences of input. The test set is hidden inside these 1 million sentences, shuffled with filler sentences. Many filler sentences are drawn from parallel corpora to check that systems are in fact translating all sentences, though we do not consider scores on noisy corpora reliable enough to report. The composition of this set changes each year and is decided after the submission deadline.

Filler data was gathered from parallel corpora and gender bias challenge sets: WMT news test sets from 2008 through 2021 (Barrault et al., 2020), the additional test inputs in WMT 2021, Khresmoi summary test v2 (Dušek et al., 2017), IWSLT 2019 (Jan et al., 2019), SimpleGen (Renduchintala et al., 2021), WinoMT (Stanovsky et al., 2019), TED 2020 (Reimers and Gurevych, 2020), and Tilde RAPID 2019 (Rozis and Skadiņš, 2017). We capped sentence lengths at 150 space-separated tokens, except for the WMT 2021 test set to preseve the ability to evaluate with it. Because WMT 2020 includes excessively long segments that are actually concatenated sentences, we also added sentence split versions of WMT 2020 and WMT 2021, though the difference on WMT 2021 was minor. Source sentences were concatenated, deduplicated, and shuffled. The Tilde RAPID corpus was clipped to make a total of 1 million deduplicated lines. Counts are shown in Table 2.

Corpus	Sentences
WMT 08–19	32,477
WMT 20 under 150 tokens	1,416
WMT 20 sentence split	2,048
WMT 21 sentence split	1,096
WMT 21 including additional tests	14,938
Khresmoi Summary Test v2	1,000
IWSLT 2019	2,278
SimpleGen	2,664
WinoMT	3,888
TED 2020 v1	293,562
Tilde RAPID 2019	654,995
Total	1,010,362
Deduplicated	1,000,000

Table 2: Corpora used for input text.

Input text and tools to extract test sets from system outputs are available at `http://data.statmt.org/heafield/wmt21-testdata.tar.xz`.

The input file has 1,000,000 lines, 19,951,184 space-separated words, and 124,257,215 bytes (most of which are characters since the file is English in UTF-8). This is an average of 20 words per sentence compared to 15 words per sentence the previous year (Heafield et al., 2020) due to raising the cap from 100 to 150 tokens per sentence and the lengthy text in the RAPID corpus.

Teams were responsible for their own tokenization and detokenization. We provided raw UTF-8 English input text with one sentence per line.

4 Metrics

4.1 Cost

Time was measured with wall (real) time reported by `time` and CPU time reported by the kernel for the process group. We do not measure loading time because it is small compared to translating 1 million sentences, some tools load lazily, and it is easily gamed by padding loading time.

Peak RAM consumption was measured using `memory.max_usage` in bytes from the kernel for the CPU and by polling `nvidia-smi` for the GPU. Swap was disabled.

Participants were told to separate their Docker

	Edinburgh	HuaweiTSC	NiuTrans	TenTrans
GPU Batch	3/10		4/4	4/4
GPU Latency	0/11			
1 Core Batch	0/6			
1 Core Latency	3/6	4/4		
36 Cores Batch	0/6		0/2	
Total	6/39	4/4	4/6	4/4

Table 3: Number of submissions by participant and condition (cores refers to the CPU hardware). The number after / is all submissions by the participant. The number before / is how many participants selected for focused human evaluation based on automatic metrics.

images into model and code files so that models could be measured separately from the relatively noisy size of code and libraries. A model was defined as "everything derived from data: all model parameters, vocabulary files, BPE configuration if applicable, quantization parameters or lookup tables where applicable, and hyperparameters like embedding sizes." Code could include "simple rule-based tokenizer scripts and hard-coded model structure that could plausibly be used for another language pair." They were also permitted to use standard compression tools such as `xz` to compress models; decompression time was included in results but small relative to the cost of translation. We report size of the model directory captured before the model ran. We also measured the total size of the Docker image (after compressing with `xz`), though participants were encouraged to prioritize shipping one container for multiple hardware conditions over the size of the container.

4.2 Quality

Translation quality is measured on the WMT 2021 news test set. The automatic metrics are COMET (Rei et al., 2020) `wmt20-comet-da` from version `1.0.0rc6`, BLEU from sacrebleu (Post, 2018) `nrefs:3|case:mixed|eff:no|tok:13a|smooth:exp|version:2.0.0`, and chrF also from sacrebleu. We use references A, C, and D because the organizers found postedited DeepL output in reference B. COMET does not natively support multiple references so we averaged as recommended by the authors.[1] We also averaged chrF across references. Results were presented to participants[2] who were encouraged to whittle down systems for a focused human evaluation. HuaweiTSC and TenTrans included all of their submissions. NiuTrans included their GPU submissions but not their CPU submissions that have lower automatic scores than Edinburgh's. This left GPU Batch and 1 Core Latency as the only conditions with multiple teams. Edinburgh kept systems that have competitors and are near the Pareto frontier. The number of submissions evaluated is shown in Table 3. Out of 53 submissions, we ran direct assessment on 18.

For human evaluation, as a source of the absolute quality measure we used document-level source-based direct assessments (DA) (Graham et al., 2013; Cettolo et al., 2017) following the procedure established at the WMT20 News Translation Task (Barrault et al., 2020). We also conducted contrastive evaluation using segment-level pairwise direct assessments (Novikova et al., 2018; Sakaguchi and Van Durme, 2018), because it can be a better discriminative tool for measuring relative quality difference between pairs of systems. We compared the 18 systems using source-based direct assessment and 58 pairs of systems with contrastive direct assessment. In total, we gathered 21,487 and 20,416 direct assessment scores in standard and contrastive campaigns respectively. All annotations were made by bilingual native German speakers with a translation or linguistics background. Annotations were collected using Appraise[3] (Federmann, 2018).

5 Results

All submissions are shown in Table 4. Source-based direct assessment scores appear for the submissions in the focused human evaluation with the number of wins against other systems (including those in other conditions), raw direct accessment score, and z-score after standardizing annotator scores to mitigate differences in annotator scores. Scores were averaged ("Ave.") across sentences. Rows are sorted by COMET because only some submissions have human assessment.

The system ranking based on the standard DA is presented in Table 5. Systems are ordered by the number of respective wins against other systems and average DA z-score. Ordering solely by z-scores would produce three clusters with all systems within a cluster considered tied according to Wilcoxon rank-sum test with $p < 0.05$.

Table 5: System ranking based on the standard direct assessment (DA) human evaluation. The rows are ordered by the number of respective wins against other systems, followed by the DA z-score. Systems within a cluster are considered tied according to Wilcoxon rank-sum test $p < 0.05$ with standard DA.

Figure 1 shows the trade-off between quality and speed of batched translation submissions. Since source-based DA is available for select GPU submissions, we include that comparison; the other plots rely on COMET to approximate quality. Each plot shows the Pareto frontier as a black staircase to highlight the best combinations of quality and speed. In Figure 2, we combine GPU and 36 Core CPU speed by using Oracle Cloud pricing. The GPU is cheaper for throughput-oriented tasks that allow batching.

Latency is shown in Figures 3 and 4. HuaweiTSC and Edinburgh were the two participants and shared the Pareto frontier. While the GPU is cheaper for throughput, both CPU and GPU entries appear on the Pareto frontier for latency. In fact, the lowest latencies are achieved by single-core CPU submissions, likely due to the overhead of launching small kernels on a GPU.

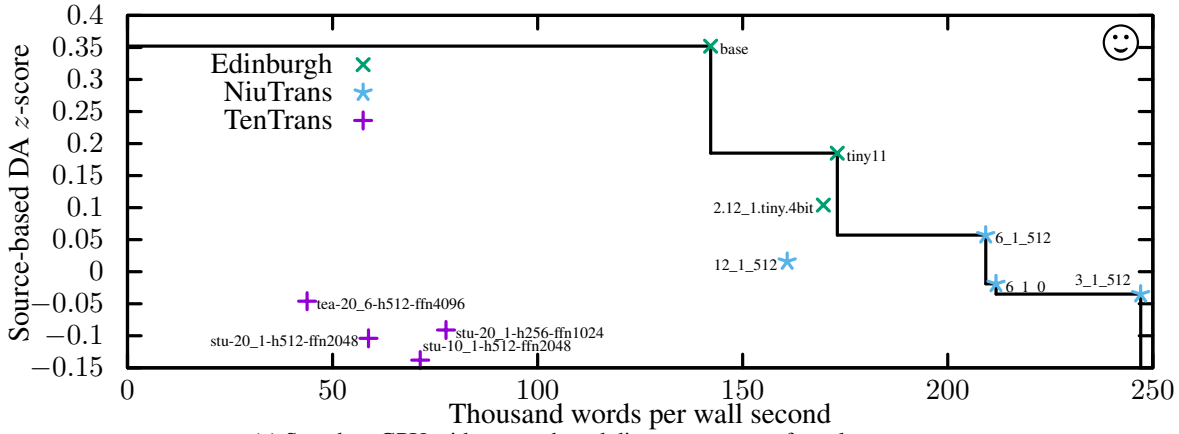
Model sizes at rest on disk appear in Figures 5 and 6. Participants were allowed to compress their models using their own tools and standard tools like `xz`. The entire Pareto frontier consists of Edinburgh submissions, resting partly on 4-bit integer compression. Docker image sizes, which include model and software, appear in Figure 7. HuaweiTSC optimized their image size well. Conversely, some others opted to optimize other metrics and included large Linux installations. We compressed all docker images with `xz` before measuring.

Memory (RAM) consumption appears in Figure 8. GPU memory consumption reflects batch size and some participants set a large batch size to maximize speed. Optimizing speed for multi-socket CPU machines implies having a copy of the model in RAM close to each socket, so memory consumption is larger beyond simply having temporary space for more batches. Finally, participants may have sorted the entire 118 MB input file in RAM to form batches of equal length sentences. NiuTrans is the clear winner on GPU RAM consumption and curiously the clear loser on CPU RAM consumption.

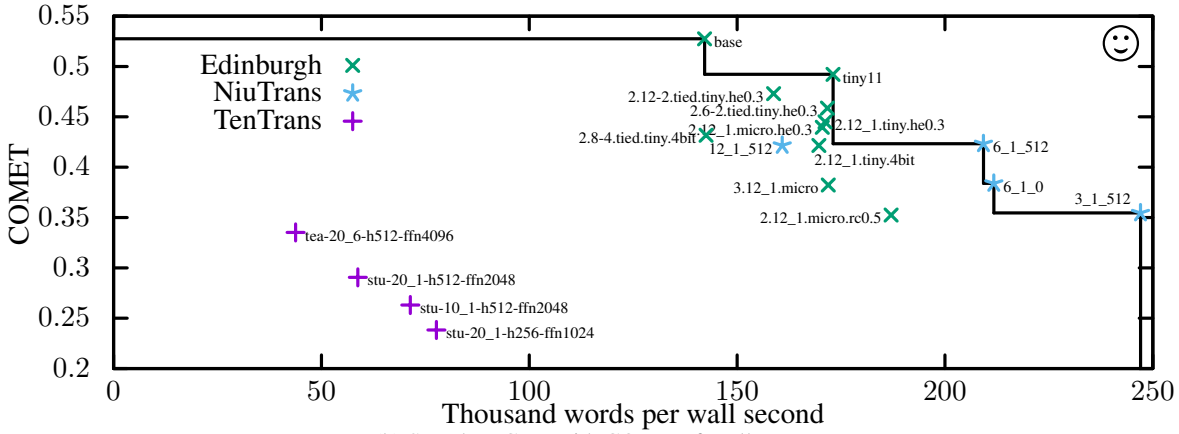
Many of the systems tied on standard DA and contrastive DA helps us pull them apart by directly comparing system outputs. Table 6 shows detailed results of contrastive DA including average scores, respective deltas between two systems and the outcome of significance testing. For groups of systems for which we evaluated each system from a group against each other system from the same group, we created separate rankings based solely on pairwise comparisons within the group, presented in Table 7.

6 Conclusion and Future Tasks

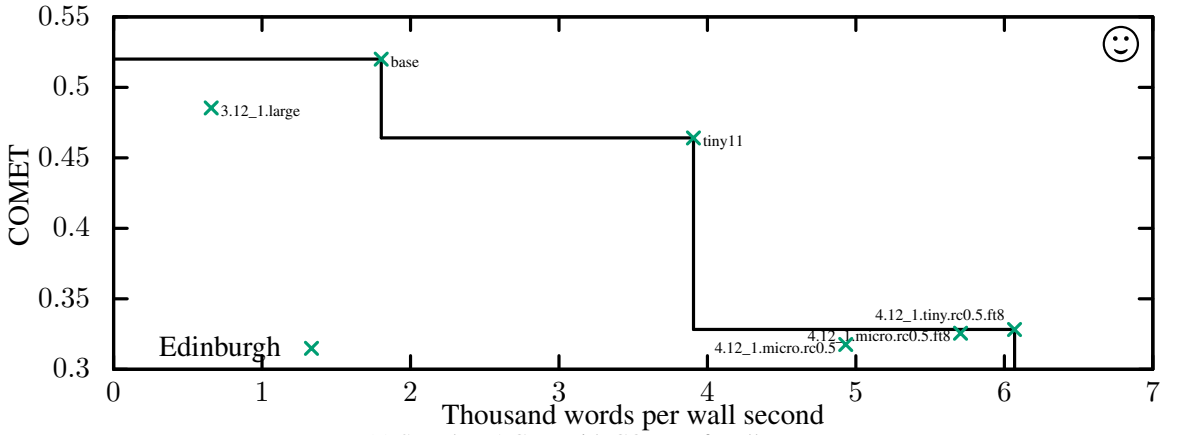
Using the highest quality system in this evaluation, translating 124,257,215 characters took 140 seconds on an A100 GPU that costs $3.05/hr in a cloud. That is $0.001/million characters. By comparison, Google Translate's cost is $20/million



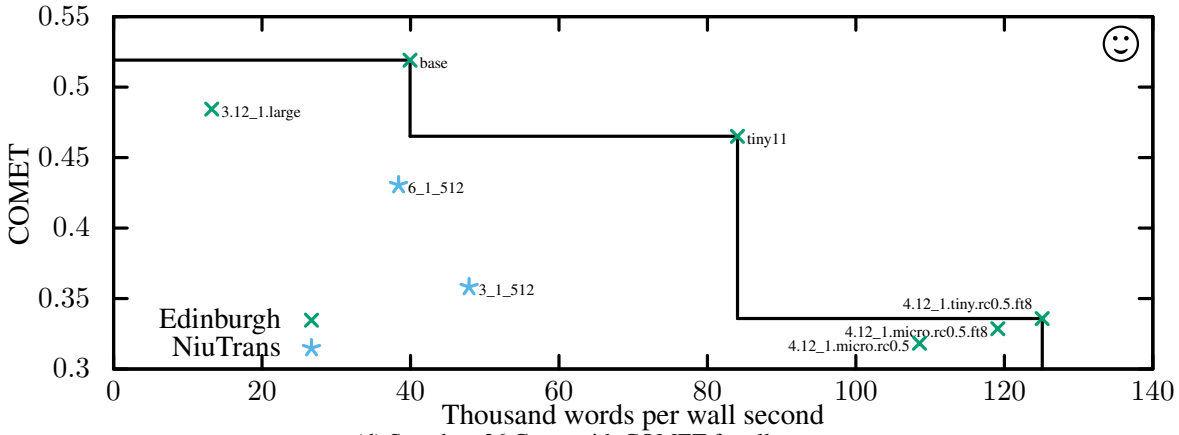
(a) Speed on GPU with source-based direct assessment for select systems



(b) Speed on GPU with COMET for all systems



(c) Speed on 1 Core with COMET for all systems



(d) Speed on 36 Cores with COMET for all systems

Figure 1: Speed and quality of batched submissions. The staircase shows the Pareto frontier.

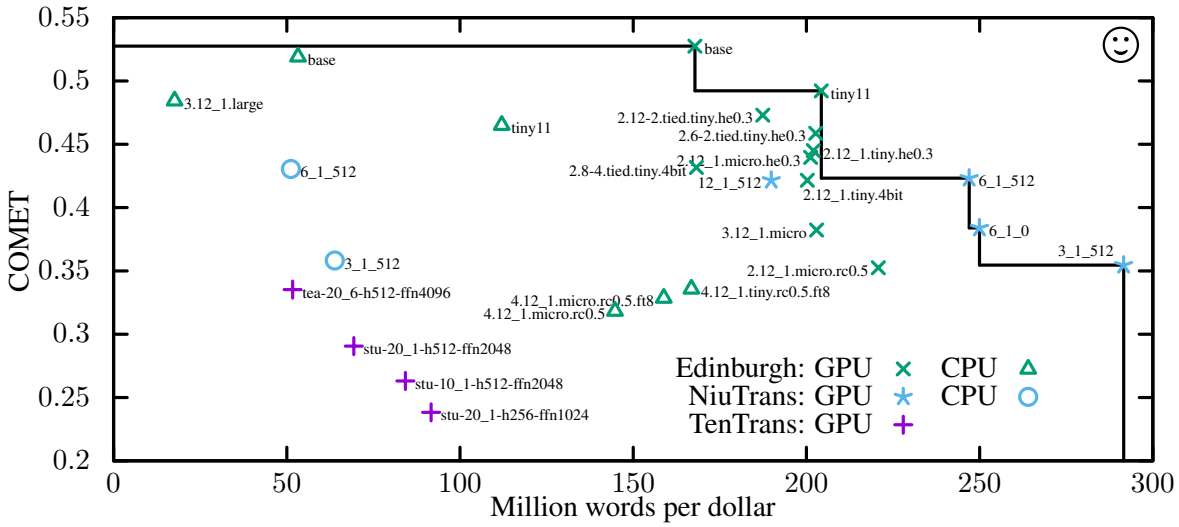


Figure 2: Cost of batched translation for an A100 GPU at $3.05/hr or 36 Cores of CPU at $2.7/hr on Oracle Cloud.

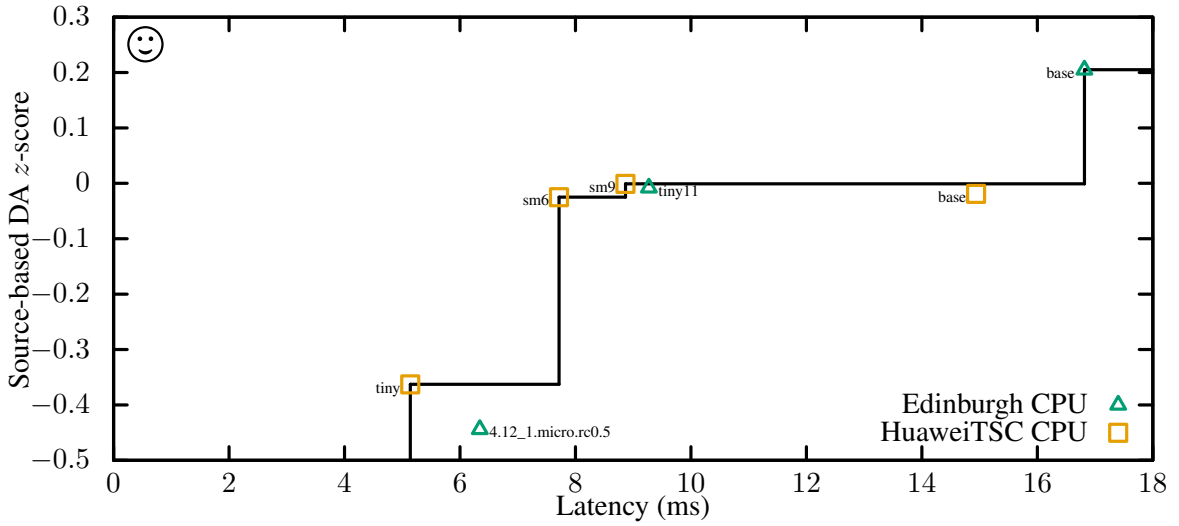

Figure 3: Latency of select CPU systems with source-based direct assessment. Contrastive direct assessment (Table 7) insignificantly ranked HuaweiTSC's base > Edinburgh's tiny11 > HuaweiTSC's sm9.

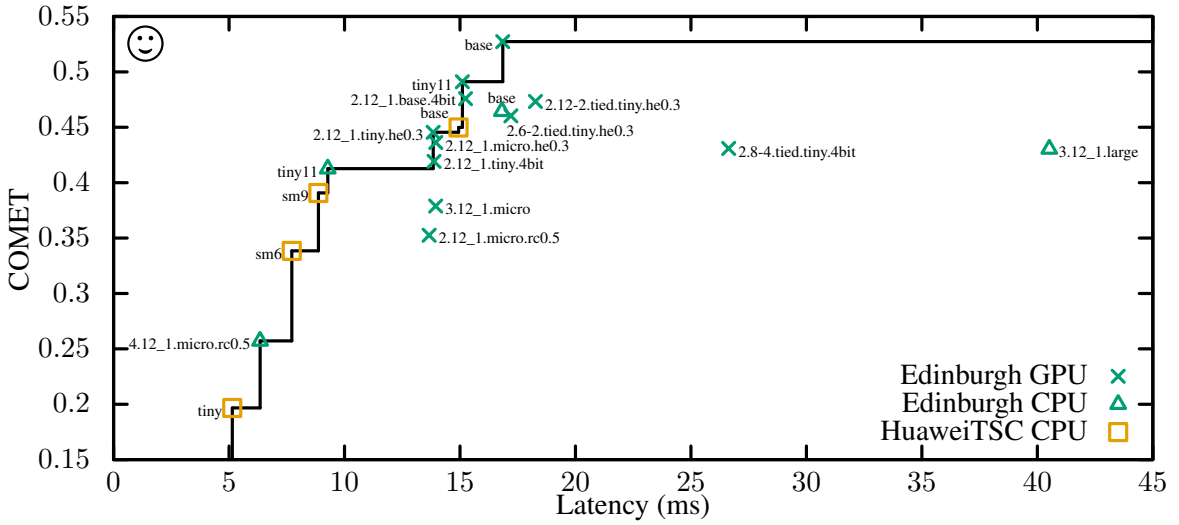

Figure 4: Latency of combined CPU and GPU systems with COMET scores. To improve the scale of the graph, low-quality variants 4.12_1.tiny.rowcol-0.5.ft8 and 4.12_1.micro.rowcol-0.5.ft8 from Edinburgh are not shown. Their respective COMET scores are -0.073 and -0.173.

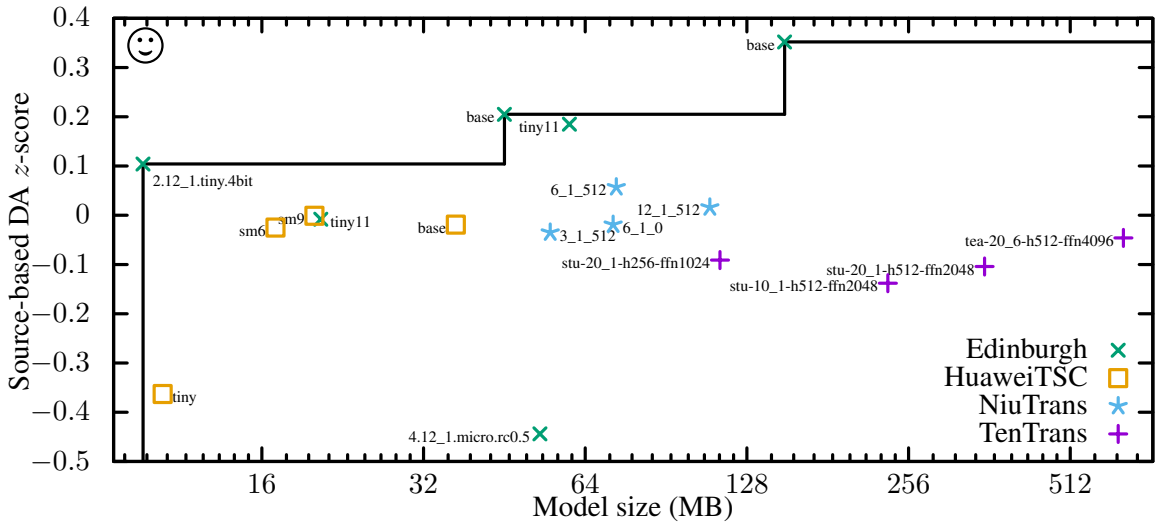

Figure 5: Model sizes of select systems in the human evaluation with source-based DA. Because selection for human evaluation focused on speed (and not model size), this is missing the smallest model, Edinburgh's 2.8-4.tied.tiny.4bit and a few other Pareto optimal systems identified by automatic metrics.

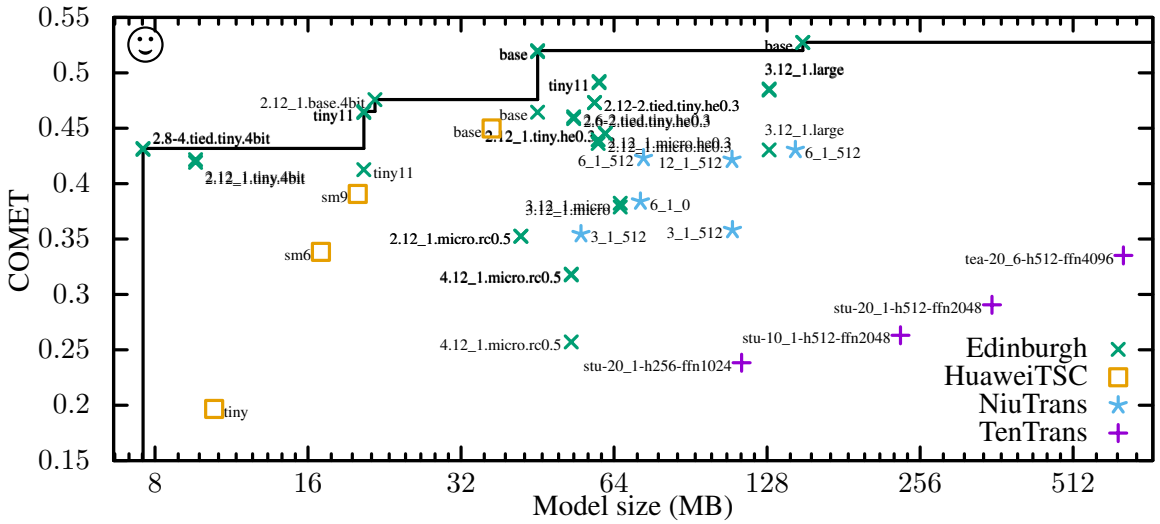

Figure 6: All model sizes with quality by COMET. Because models had slightly different output in different hardware conditions, the same variant label can appear multiple times like a shadow. Low-quality variants 4.12_1.tiny.rowcol-0.5.ft8 and 4.12_1.micro.rowcol-0.5.ft8 from Edinburgh are omitted for scale.

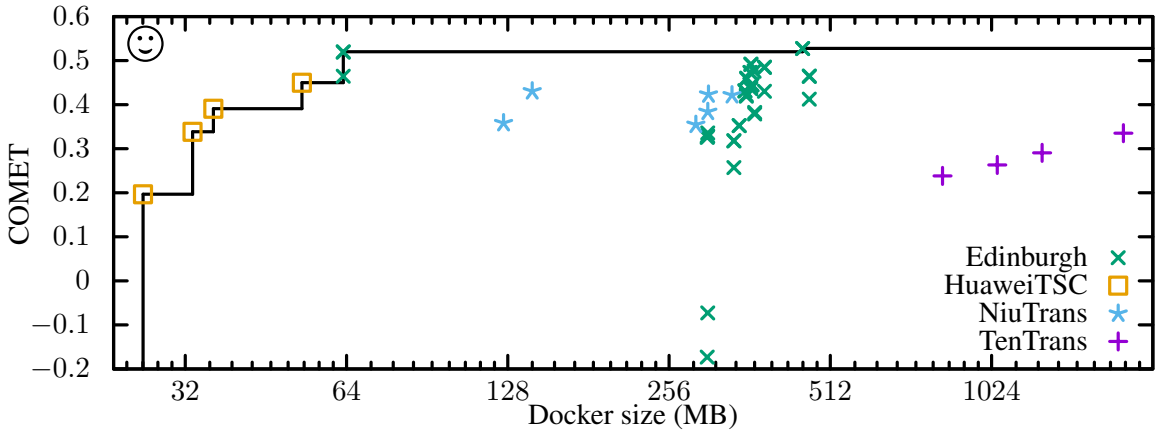

Figure 7: Size of all Docker images after compression with `xz` on a logarithmic scale. Some participants did not seek to prune image size and included large Linux installations. Labels are not shown due to crowding.

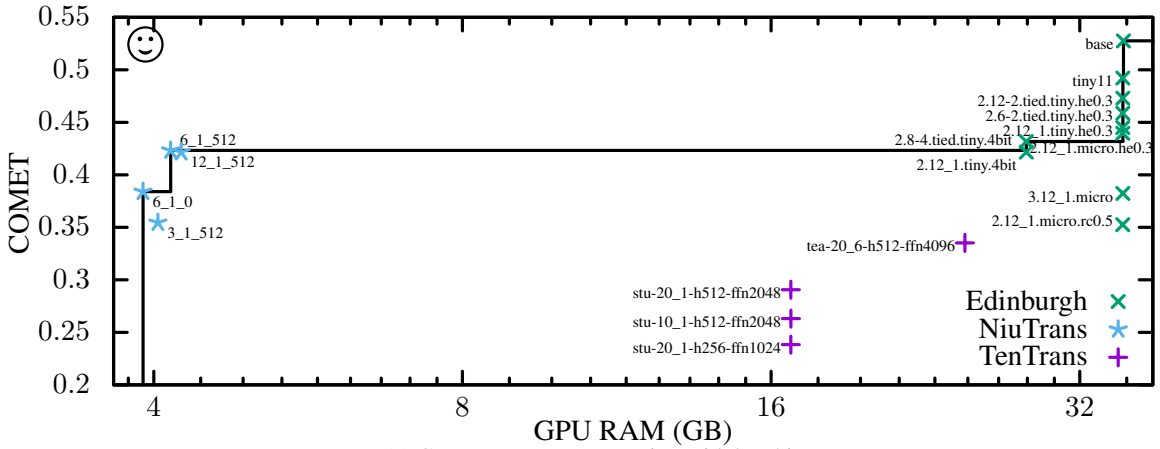
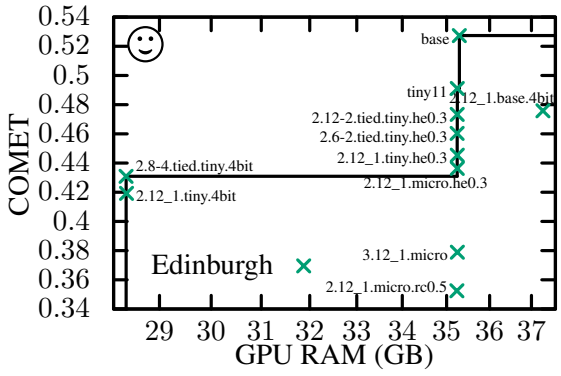
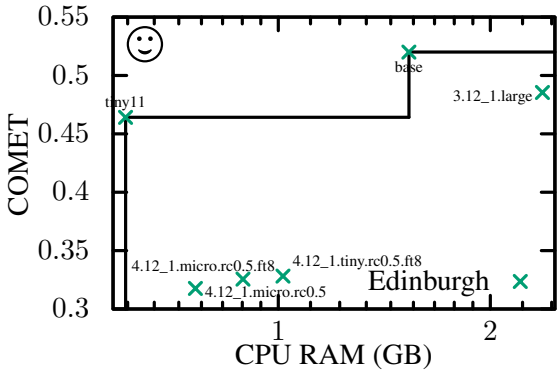


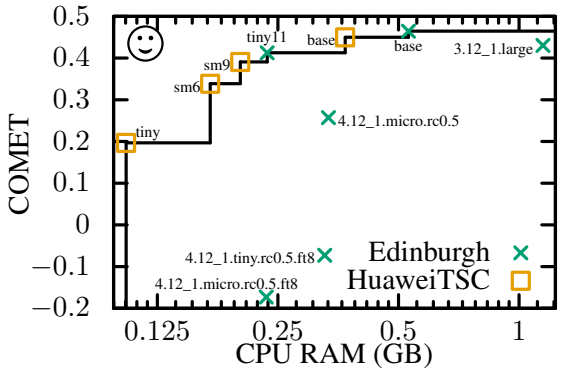
(a) GPU memory consumption with batching.



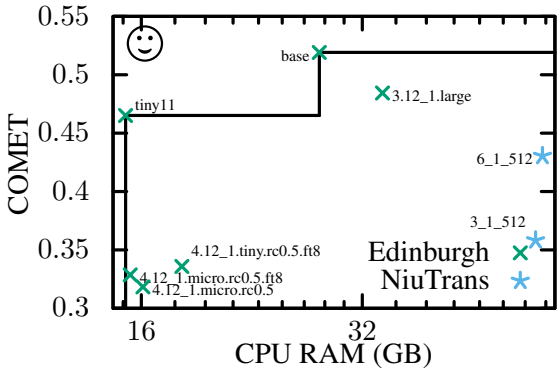
(b) GPU memory consumption with latency.



(c) 1 core CPU memory consumption with batching.



(d) 1 core CPU memory consumption with latency.



(e) 36 core CPU memory consumption with batching.

Figure 8: RAM consumption of all submissions on a logarithmic scale. Some participants used large batches to favor speed over memory consumption.

characters.[4]

The GPU latency track had been intended to attract non-autoregressive machine translation submissions in their ideal condition with a large GPU and no batch to parallelize. However, non-autoregressive papers (Libovický and Helcl, 2018; Gu and Kong, 2021) often rely on unreasonably poor autoregressive baselines in order to claim impressive-sounding speedups, when they are in fact slower than optimized autoregressive models seen here. While previous editions of the task did not measure latency, disabling batching is a simple command line modification to systems that existed at the time (Birch et al., 2018) but were omitted as baselines in non-autoregressive literature. All submissions this year are autoregressive.

An efficient training task is a natural extension. The challenge lies in defining proper development and testing conditions. Otherwise, participants will overfit by searching for the random seed that trains the fastest on a particular parallel corpus. Perhaps a parallel corpus could be halved to form development and test sets, but that would reveal the test set by omission and require trusting all participants. One participant was already caught cheating in a past edition of this shared task. Another option is that the test corpus could be a different surprise language pair, which would have the potentially positive effect that it also measures generalizability across languages. An interesting aspect of efficient training is that systems relying on backtranslation (Sennrich et al., 2016) incur substantial inference costs during their training cycle.

The one-month gap between the news task dead-

[4] https://cloud.google.com/translate/pricing

line and the efficient task deadline was too short and some teams noted this reduced the conditions they participated in. In addition, scaffolding would reduce the barrier to participation. This could take the form of providing a trained high-quality model, providing distilled (Kim and Rush, 2016) training data, or even optimized models where only the toolkit code is optimized. Providing this scaffolding would effectively require the organizers to perform the full task before releasing it to participants. If the training and test data are renewed each year as a countermeasure to overfitting and a participant that cheated, this would require more time between the news task and release of the news test set references.

German is a high resource language, which raises the computational cost of participation. A medium resource language would generally reduce training costs and explore whether results apply in this data condition.

The next task should aim to recruit more participants and perhaps separate the organization from one of the participants.

Abstract

Language domains that require very careful use of terminology are abundant and reflect a significant part of the translation industry. In this work we introduce a benchmark for evaluating the quality and consistency of terminology translation, focusing on the medical (and COVID-19 specifically) domain for five language pairs: English to French, Chinese, Russian, and Korean, as well as Czech to German. We report the descriptions and results of the participating systems, commenting on the need for further research efforts towards both more adequate handling of terminologies as well as towards a proper formulation and evaluation of the task.

1 Introduction

Language domains that require very careful use of terminology are abundant. The need to adequately translate within such domains is undeniable, as shown by e.g. the different WMT shared tasks on biomedical translation.

More interestingly, as the abundance of research on domain adaptation shows, such language domains are (a) not adequately covered by existing data and models, while (b) new (or "surge") domains arise and models need to be adapted, often with significant downstream implications: consider the new COVID-19 domain and the large efforts for translation of critical information regarding pandemic handling and infection prevention strategies.

In the case of newly developed domains, while parallel data are hard to come by, it is fairly straightforward to create word- or phrase-level terminologies, which can be used to guide professional translators and ensure both accuracy and consistency.

This shared task[1] replicated such a scenario, and invited participants to explore methods to incorporate terminologies into either the training or the inference process, in order to improve both the accuracy and consistency of MT systems on a new domain.

2 Shared Task Details

The shared task focused on five language pairs, with systems evaluated on:

- English to French
- English to Chinese
- English to Russian
- English to Korean
- Czech to German

The last three language pairs were "surprise" language pairs. This shared task construction follows a three-phase approach to ensure the generalizability of the findings, inspired by other multilingual shared tasks (Vylomova et al., 2020). In this setting, only part of the evaluation language pairs (or languages) are revealed from the beginning (the **Development Phase**). In this elongate period (a couple of months), the participants are provided with data in some language pairs to *develop* their methods. The second phase is the **Generalization phase**, which is a short time period (two to three weeks in this task's case), in which additional (surprise) language settings are revealed, only giving the shared task participants enough time to deploy a system, as opposed to allowing them enough time to also perform extensive optimization on the datasets. The final stage is the **Evaluation phase**, in which the test data are released and the methods are evaluated on these held-out data.

The goal of this 3-stage approach (with both development and surprise language pairs) is to avoid approaches that overfit on language selection, and instead evaluate the more realistic scenario of needing to tackle the new domain in a new language in a limited amount of time. The surprise language pairs were announced 3 weeks before the start of the evaluation campaign.

The organizers provided training/development

[1] http://statmt.org/wmt21/terminology-task.html

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 652–663
November 10–11, 2021.

data and terminologies for the above language pairs. Test sets were released at the beginning of the evaluation period. The participating teams were invited to participate in any or all of the language pairs.

2.1 Data

Training The shared task primarily focused on a constrained submission setting, in which the participants could only use any parallel or monolingual data listed in previous versions of WMT shared tasks to train their systems. Some pre-trained systems listed at the shared task announcement (mBERT, XLM, XLM-R, mBART, mT5, M2M100) were also allowed, but should be disclosed by the participants. We note that the training data allowed come from a "general" domain, as opposed to e.g. highly specialized biomedical data, which in theory should be more helpful for this setting.

Terminologies The shared task focused on adapting MT systems to the health domain in general, with a particular interest in the surge COVID-19 domain.

The terminologies for the English to French, Chinese, Russian, and Korean language pairs were taken from the publicly available TICO-19 project (Anastasopoulos et al., 2020), a multi-organizational project that created data to aid translators and evaluate MT systems on the COVID-19 domain. The terminologies were created by linguists at Google and Facebook in consultation with domain experts, providing translations for about 600 terms in each language. The terminologies are publicly available.[2]

The Czech-German medical terminology was generated automatically from Wikipedia. We considered all Wikipedia titles corresponding to the category *Health care* or to one of its subcategories, and all titles linked from the text. The list of (sub)categories was manually filtered to only include relevant articles. We treated all page titles as terms and relied on the Wikipedia language links to provide their translations. Furthermore, we used redirection links to obtain synonyms of both source and target terms.

For all terminologies, we truecased the terms using a pretrained truecaser and manually checked the results. The Czech-German terminology was eventually further reduced to only include terms which occurred in the EMEA medical corpus.

Development and Test The development and test data for French, Chinese, and Russian were taken from the publicly available TICO-19 evaluation data. The organizers additionally created Korean translations of the English source-side sentences, which will be made available as part of the original TICO-19 datasets.[3]

The primary source of the Czech-German development and test data is the EMEA[4] parallel corpus of the European Medicines Agency. We cleaned it using the Moses tools, searched for terms and their translations and tagged the occurrences. The surface forms used for the search were collected from a corpus of in-domain Wikipedia articles which includes links to the lemmatized Wikipedia titles/terms next to their inflected forms. Target options were retrieved from the terminology and enriched with surface forms. Out of all sentences with terms, we selected around 3.5k sentences for the dev set and 1.1k for the test set. The development and test sets were tagged automatically but the test set was manually corrected to get rid of the artifacts caused by the automatic generation.

2.2 Ensuring Terminology Consistency on the Evaluation Datasets

It is worth noting that, originally, none of the development and test data were created under the constraints imposed by the specific terminologies we use. As such, we needed to ensure that the data 'complied' with the terminologies in order to guarantee a meaningful, accurate, and fair to the participants evaluation of the shared task's research questions.

The TICO-19 project created the evaluation dataset independently of the terminologies.[5] In our preliminary analysis, we first searched for all terminology terms on the English side of the parallel data, also searching over the lemmatized versions of English sentences. The choice of starting from the English side is due to two reasons: (a) it reflects the actual translation direction the data was created with and that we evaluate on, (b) it reduces the rate of possible false negative/positive term matches due to the lack of morphological complexity of English.

Table 1: Examples (from English-French TICO-19) of expected annotations that ensure that the evaluation datasets are compliant with the terminologies. ('Term-compl. transl.' == 'terminology-compliant translation').

Having the source-side terms identified, we assume all of them should be translated according to the terminology. We then search the target side (both original and lemmatized) for the translation required by the terminology, and created a tag on the source-side term if we found an exact match. Last, we showed all sentences to professional translators, who were instructed to produce three types of annotations, for each source-side term. The first is a **label** describing whether (a) the automatically-annotated source-side term should not be translated by the terminology i.e. it is not really a term, (b) the tagged exact match is correct, (c) the translation is compliant with the terminology even though there is not an exact match, (d) the tagged exact match is incorrect, or (e) the source term translation is applicable in the context, but not used. The second annotation is a **tagged translation** for any terms labeled as (a), (c), or (d), denoting exactly which part of the target-side corresponds to the source-side term. The third annotation is a **tagged terminology-compliant translation**, where if any

source-side terms are labeled with (d) or (e), we ask the translators to rephrase the target side in order to make it compliant with the terminology.

Table 1 shows example sentences from the dataset, along with their expected annotations from the translators. Below we provide the exact instructions given to the annotators, which also reference the same examples.

[begin annotation instructions]
About: This task is about determining if a translation is compliant with a terminology data base and perform inline annotations on the translations to mark the terms used.
Annotators receive: Source side input, together with approximate terminology matches on the source side.
Annotators return: For each term match, please annotate a Label:

(a) `does_not_apply`: The terminology is not applicable in the context because of wrong meaning on the source side (Example 3). Please use *a) if you think the translation should not comply with the terminology matched*, irrespective of whether the translation uses it or not.
(b) `exact_match_correct`: The term translation is found exactly as is in the target and its usage is correct (it fits the context and agrees grammatically with the sentence). (Example 2)
(c) `variation_correct`: The translation is compliant with the terminology, however the term translation appears in a different form in the target (Examples 1 and 2). If only part of the term was preserved, use this label if this partial term is sufficient and completely preserves the meaning. Please use *b) or c) if you think the translation is compliant with the terminology*.
(d) `incorrect`: The term is found in the target, as an exact match or as a variant, but it is used incorrectly, either semantically or grammatically: e.g. the term use does not convey the required meaning, there is a wrong inflection or other grammatical disagreement.
(e) `not_used`: The term translation is applicable in the context, but not used (Example 2, 4). Make this only for clear omissions: everything else should be variation (correct or incorrect variation) Please use *d) or e) if you think the translation is not compliant with the terminology, but it should*.

Tagged translation: For any terms that are labeled as a), c) or d) please add inline markup to identify the fragments of the translation that they match.
For each source sentence, please generate a **Tagged Terminology-compliant translation**: if any of d) to e) apply to any term in the sentence, meaning the translation is not compliant with the terminology for at least one term, please provide an alternate translation that is compliant with the terminology w.r.t all the terms in the sentence. If there is no acceptable translation that would use the expected target term then you should annotate the target with a) does_not_apply. If all terms in sentence match a) b) or c), leave this empty.
[/end annotation instructions]

Through this process, we ended up modifying 284 (9.25%), 251 (8.17%), 450 (14.65%), and 809 (26.34%) sentences in the French, Chinese, Russian, and Korean datasets respectively, in order to make them terminology-compliant. Last, the Czech-German terminologies were directly derived from the parallel data hence they implicitly directly reflect the underlying data, so there was no need for the aforementioned process.

2.3 Evaluation

The evaluation of the shared task used several metrics, focusing on both translation accuracy and terminological consistency.

- Translation accuracy was evaluated with standard reference-based MT metrics (BLEU, chrF, BERTscore, COMET). In light of recent work (Kocmi et al., 2021), we rank systems according to the COMET metric.

- we also performed terminology-targeted evaluation (to evaluate for consistency). We use the metrics outlined by Alam et al. (2021), namely exact-match term accuracy, 1-TERm score, and window overlap accuracy. We rank systems according to term exact-match accuracy.

Briefly, the lemmatized exact-match term accuracy is an accuracy score that searches for exact term translation matches (of the terminology required output) over either the lemmatized or the original hypothesis. The window overlap accuracy identifies the translation of the term, and then

scores its context, to measure how well a translated term is placed in the hypothesis. Last, the 1-TERm score is a modification of the TER metric (Snover et al., 2006), biased to assign higher edit cost weights for words belonging to a term (and then simply reversed so that a higher score is better). We refer the reader to Alam et al. (2021) for further discussion of the metrics and supporting arguments for their use.

Last, we evaluate whether differences between systems are statistically significant using paired bootstrap resampling (Koehn, 2004), over sentence-level COMET and exact-match accuracy scores. Based on this information we cluster statistically-insignificantly-different (i.e. similarly performing) systems when we produce their final rankings.

Winning submissions will be the ones that are Pareto-optimal along the two evaluation metrics that a good but also terminology-compliant system should maximize: exact-match accuracy (which captures terminology consistency) and COMET (which captures general translation quality). As such, there is the possibility that each language pair will have multiple winning submissions.

3 Participants and System Descriptions

We received a total of 43 submissions from 9 teams. Below we provide a short description of each submission.

CUNI (Jon et al., 2021b) Authors competed on `En-Fr` language pair. The terminology constrains are inserted as done in (Jon et al., 2021a). The target translation of specific terms is appended to the source sentence as a suffix and separated by a special token (if multiple constraints occur for a single sentence, an additional token separator is added). In order to have more training data of this form, synthetic constraints are added by sampling random token subsequences from the target sentence and appending them to the source sentence as described earlier. Note that since no modification is done on target side of the parallel data, no post-processing of the MT output is needed. As NMT systems trained from this pre-processed data sometimes fail to generate inflection in the translation output, terminology tokens appended to the source are lemmatized for both training and inference which brings improvements over the different shared task metrics.

Huawei (HW-TSC) (Wang et al., 2021b) Authors submitted output of an unconstrained system to `En-Zh` language pair. They train a Transformer *big* architecture on both out-of-domain and in-domain (biomedical) data. Parallel data in biomedical domain is augmented using more resources from TAUS[6] and back-translation of monolingual in-domain data is also applied. For the terminology shared-task, authors applied the system created for the biomedical translation shared task (described in (Wang et al., 2021b)) without any specific adaptation except appending the terminology dictionary to the end of training data. No separate paper was submitted for the terminology task.

Kakao Enterprises (KEP) (Bak et al., 2021) Authors submitted to `En-Fr`, `En-Zh`, `En-Kr`, `Cz-De`. A detailed data cleaning is performed, removing between 6% and 14% of the data. In-domain data is back-translated (only for `En-Fr` and `En-Kr`) and is selected by a a combination of keywords spotting and domain similarity, measured as perplexity of an in-domain language model. A first model is obtained by adding to that synthetic language pairs obtained by verbalizing the terminology database. The only language pair were this verbalization does not yield improvement is `Cz-De`, whose terminology was automatically constructed. Models obtained in this manner were submitted for `En-Zh`, `En-Kr`, `Cz-De`.

For `En-Fr` additional techniques are used: as those obtained the highest COMET score we detail them there. The final system for that language pair is trained inspired by techniques from (Bergmanis and Pinnis, 2021a; Dinu et al., 2019), but without modifying the model architecture. The source data is modified by adding immediately after a source term the corresponding target *lemma*, separated by special tokens. The model is pre-trained on randomly selected verbs and nouns, and fine-tuned using the terminology ontology. Interestingly, the pre-trained model - while improving Exact Match with respect to the baselines - degrades all other metrics. That degradation is however recovered and even improved when fine-tuning. For `En-Ko` and `Cs-De` ensemble models were used.

Lingua Custodia (LC) (Ailem et al., 2021a) The team participated in `En-Fr`, `En-Ru` and `En-Zh` tasks. They build on top of (Ailem et al., 2021b) by inserting the terminology as constraints in the

[6] https://md.taus.net/corona

source sentence. Such constraints represent special tags around the detected source term followed by the target term from the terminology, the original source term is masked. Presence of such constraints at training encourages the model to copy the correct term translation. In case where multiple translations are proposed by the terminology, the one which is present in the target sentence is chosen at training time. At inference time the translation is selected at random. In order to enforce learning signal, the team enriched parallel data with back-translation of monolingual data that contains terminology. Authors show that the proposed method allows to improve significantly for standard MT evaluation metrics, as well as terminology oriented metrics (Alam et al., 2021) over the standard baseline without terminological constraints.

PROMT (Molchanov et al., 2021) The team submitted two systems (`En-Fr` and `En-Ru`), both of which are transformer models implemented on MarianMT (Junczys-Dowmunt et al., 2018). The first approach uses a rule-based system (SmartMT) to modify the neural system's output, which extracts rules only for noun phrases. If the desired output of a source term is not found in the NMT output, the rule-based system identifies the term's current translation and its morphological analysis (case and number) in order to substitute it with the terminology-provided translation in the desired inflection. The second approach is an adaptation of (Dinu et al., 2019) to MarianNMT toolkit. Each source terminological term is followed by its translation using special tokens to signal these terminological entries in the text (and impose a soft-constraint to the translation system). Model is retrained from such pre-processed data. Data augmentation is also performed to create more synthetic data with terminology markup. Both approaches are rather close in performance.

SPECTRANS (Ballier et al., 2021) This team sumbitted to `En-Fr` language pair. They experimented with 2 open source NMT toolkits JoyeNMT (Kreutzer et al., 2019) and OpenNMT (Klein et al., 2017). After the first experiments with Europarl they retained OpenNMT which gave better performance. Their best runs were trained on CommonCrawl augmented with terminological data. They provided qualitative analysis of terminology-related translations and discuss the limitations of the terminologies provided for the task.

SYSTRAN (Pham et al., 2021) This participant submitted to `En-Fr` language pair and proposed two methods to incorporate terminology. The first approach, based on (Michon et al., 2020), replaces source and target terminological terms by placeholders including a unique identifier plus morphological information (masculine/feminine and singular/plural). In a variant of this method, the source terminology word form is also incorporated in the source stream. At training time, NMT model is learnt on such pre-processed data and a post-processing step recovers the word tokens from the placeholders after inference. The second approach (which lead to better performance) consists in learning a copy behaviour for terminological tokens at training time: terminology translations are inserted in the source sentence either by appending the target term (its surface or lemma form) to its source version, or by directly replacing the original term with the target one. A NMT system is trained on such pre-processed data and no post-process for recovering terminology tokens is needed at inference as target side of parallel data remains untouched. For both approaches however, a grammatical error correction is applied to the MT hypotheses in order to limit morphology errors. The impact of such post-processing on BLEU is positive, although small.

TermMind (Wang et al., 2021a) The team submitted to `En-Zh` task. Similar to (Ailem et al., 2021a) they build on top of (Ailem et al., 2021b) by inserting terminological constraints in the training data. In the case where multiple translations are available they augment source sentence with all possible translations (which is different from (Ailem et al., 2021a) who kept only one translation). In order to strengthen the learning signal participants extend given terminologies with biphrases extracted from parallel data and integrate the constraints for those biphrases as well. Finally, they used backtranslation, fine tuning on pseudo in-domain data and ensembling to strengthen the baseline model. Ensembling methods seem to lead to the best results.

TILDE (Bergmanis and Pinnis, 2021c) The team participated to `En-Fr`, `En-Ru` and `Cz-De` language pairs. They focused primarily on terminology filtering, outlining several notable shortcomings of the Shared Task's terminologies, most of which are due to the use of terminologies intended

for human translators (as opposed to terminologies created specifically for integration with MT systems). They devise two strategies for selecting among multiple target candidates for a source term, finding that an alignment-based technique outperforms the option of always selecting the first terminology entry. The MT systems are transformer-based using MarianMT, also integrating the method of Bergmanis and Pinnis (2021b) for incorporating terminology constraints in a soft manner.

4 Results and Discussion

The results and rankings for English-French are listed in Table 2 and for English-Chinese in Table 3. The results for the surprise language pairs are in Table 4 for English-Russian and Table 5 for English-Korean and Czech-German.

In the English-French translation task, there are two winning submissions. Two ProMT submissions ranked first according to exact-match accuracy (along with a CUNI submission), but the ProMT.soft submission is statistically significantly better than the other two with respect to COMET, hence it is one of the winning submission. The second winning submission is the one by KEP, which ranks first according to COMET, but also according to 1-TER, which indicates that it might strike a good balance between general translation quality and term consistency.

In the English-Chinese translation task there is a single winning submission, the one by TermMind (system 2), which ranks first according to both metrics. We note that another submission (HW-TSC) is statistically significantly better than all submissions in all metrics except for 1-TERm, but this submission is an unconstrained one, and hence it is excluded from the rankings.

In English-Russian the ProMT submission ProMT.soft is the clear winner, ranking as the single best system according to exact-match accuracy, as well as one of the two best systems according to COMET. Interestingly, the other system that ranks first according to COMET (ProMT.smartnd.v2) ranks first according to 1-TERm score, but also *last* according to exact-match accuracy, denoting perhaps an orthogonality between the goals of terminological consistency and general translation quality, where prioritizing one over the other leads to performance drops along the other dimension.

Last, the submissions by KEP are the winning ones for English-Korean and Czech-German. For the former language pair it was the only submitted system (see discussion on potential reasons), while for Czech-German it ranked for best system according to exact match accuracy with the other submission (by TildeMT), but was significantly better according to COMET. Although TildeMT used a more sophisticated approach to the terminology translation, the KEP team had a stronger baseline and used ensembling which significantly increased both general translation quality and the term accuracy.

4.1 General Quality

It was pointed out by Bergmanis and Pinnis (2021c) that a majority of terms from the terminologies were represented in the training corpora, which could lead to an underestimation of the importance of terminology in the metrics. The results show that using terminology constrains leads to an improvement over the baselines trained without it, but the effect would be more substantial if the training corpora were filtered to exclude sentences with terms.

Perhaps a future iteration of the shared task could include an explicitly novel domain, although how well such a domain indeed exists or is even possible in the age of big data where our models can be trained on a large part of the Internet is debatable. An alternative is to carefully filter the training corpora to remove sentences with the terms, to create a truly challenging domain adaptation with terminologies setting.

4.2 Terminology Consistency

The discussion of the Shared Task taught us that narrow terminology with unambiguous translations is more suitable for terminology-focused machine translation than a broader and more universal terminology with several target options. Unlike human translators who naturally choose from translation alternatives, it is difficult for a MT system to filter out noisy or inappropriate word forms. While a narrow terminology can ensure a proper and exact translation of terms, e.g. when translating a lecture with several special terms known in advance, we believe that a broad terminology can serve for more general domain adaptation using existing lexical resources. We note that several participating teams highlighted this issue, e.g. Ballier et al. (2021); Bergmanis and Pinnis (2021c).

The TICO terminologies in a few cases included additional comments aimed at translators who are

directly looking at them, as opposed to the format that terminologies aimed at machines would use. We will take this into account in future iterations of the shared task – it is worth noting, though, that if most available terminologies are designed for human translators, it should probably be up to the

NLP/ML/MT practitioners to figure out how to best use the existing data, rather than demanding new, dedicated resources. Similarly, when compiling the Czech-German terminology, we aimed at creating a universal lexicon of medical terms with a wide coverage. Many terms have multiple translations and we used the Wikipedia redirection links as a proxy for synonyms. Unfortunately, they became a source of noise because not all redirects are synonyms and not all synonyms are appropriate in every context. We tackled the former by semi-automatic filtering and left the latter up to the candidate translation engine to select the version of the word appropriate for the given context. Unfortunately, some problematic terms remained even in the final version of the terminology, as pointed out by Bergmanis and Pinnis (2021c).

4.3 Development vs Surprise Language Pairs

The participants had significantly more time to develop systems for English-French and English-Chinese, as opposed to the other three surprise language pairs. This is reflected partly on the total submitted systems in each language pair, where English-Korean and Czech-German received only 1 and 2 submissions respectively. We hypothesize that another explanation for this lies in the much more low-resource setting of these two language pairs, which generally tend to lead to lower quality systems, which might in turn discourage the participants.

A second potential explanation could lie in the general cohort of participants, which is largely comprised of teams from industry (the only exception is the CUNI team that is an academic one). Perhaps the two low-resource language pairs are simply translation directions that the participating institutions are less interested in – which we take as an indication for the importance of including such less-researched, low-resource, under-served language pairs in future iterations of this shared task, to encourage research in languages and language pairs beyond those with the most obvious commercial value.

4.4 Czech-German Analysis

We believe that even with the automatically generated resources this task provided an important insight into translation of terms between two linguistically different and morphologically rich languages such as German and Czech.

When analyzing the results, we focused on the phenomenon of nominal compounding in German. A natural translation of terms into German often results in a compound of a term and a general word, e.g. *Hormonproduktion* (production of hormones), or two terms, e.g. *Plasmaprotein* (plasma protein). Compounding is an important aspect of terminology-based translation to German that the model should have the capacity to create compounds from terminology entries.

The automatic metrics favor translations into two separate words, even though a compound is often more natural. We analyzed how candidate translations handled concrete cases; see Table 6 for an example. Out of 262 sentences with this phenomenon in the reference, the correct compound word was generated in 112 and 133 cases by the TildeMT and KEP systems, respectively. Both systems generate compounds from terms, although the former was trained with terminology constraints and the latter only saw the terms during explicit training on the terminology entries.

5 Related Work

Phrase-based statistical MT systems (Koehn et al., 2003) allowed for fine-grained control over the system's output by design, e.g. by incorporating domain-specific dictionaries into the phrase table, or by forcing translation choices for certain words or phrases. On the other hand, the currently state-of-the-art approach of neural machine translation (NMT) does not inherently allow for such control over the system's output. Some approaches

SRC	Mozkové metastázy vykazovaly nekonsistentní nebo žádnou fluorescenci.	...krvácení do svalů nebo hematom.
TGT	Hirnmetastasen zeigten inkonsistente oder keine Fluoreszenz.	...Muskelblutung oder Hämatom.
TildeMT	Zerebrale Metastasen zeigten eine inkonsistente oder keine Fluoreszenz.	...Blutungen in den Muskeln oder Hämatom
KEP	Hirnmetastasen zeigten eine inkonsistente oder keine Fluoreszenz.	...Muskelblutung oder Hämatom.

Table 6: Examples of term compounding in German where candidates handle term translation differently.

incorporate dictionaries through interpolation of the decoder's probability with a lexical probability based on source-side attention matches (Arthur et al., 2016). Perhaps the most common paradigm is *constrained decoding* (Hokamp and Liu, 2017; Anderson et al., 2017; Post and Vilar, 2018, *inter alia*), where the terminology matches are presented as hard constraints that the beam search must satisfy.

Constrained decoding is not without disadvantages: it can be computationally expensive and it is often brittle when applied in realistic conditions (Dinu et al., 2019). To this end, some works (Dinu et al., 2019; Bergmanis and Pinnis, 2021b; Exel et al., 2020; Niehues, 2021) introduced approaches where the terminological constraints are provided as input to the NMT as additional annotations inline with the source sentence. As such, these can be considered as "soft" constraints, as there is no guarantee that the NMT system will indeed produce an output containing them.

In any case, the best practice for incorporating terminological constraints in NMT is both underresearched and still not settled yet, especially in the case of morphologically rich languages, underlying the need for this shared task.

6 Conclusion

We presented the results of the first edition of the WMT21 shared task on MT using Terminologies. For the purposes of the task we created new evaluation datasets, annotated by professional translators for their terminology consistency, based on the TICO-19 data for English to French, Chinese, Russian, and Korean, as well as a dataset for Czech-German based on the EMEA corpus.

The Shared Task received 43 submissions from 9 teams, 8 from industry and 1 from academia, underscoring the general applicability of our focus problem ('how best can we use a terminology in MT?') on real-world settings. Most submissions add soft or hard constraints on the source side that the MT learns to handle, as proposed in (Dinu et al., 2019), but other novel approaches include terminology filtering for selecting between multiple options provided by the terminology, or replacing terms with placeholders to be inserted after the MT has produced the output. We devised multiple terminology-targeted metrics and evaluated systems along both these metrics as well as general translation quality. In most cases we find that, encouragingly, one does not necessarily have to sacrifice general translation quality for terminology compliance, as long as the terminology is of adequate standards.

In future iterations of the Shared Task, we will take into account the distinction between terminologies created for humans (which are abundant) and terminologies created specifically for MT systems which need to be created, and have different requirements/specifications that the former. In addition, we will attempt to consider a new domain, rather than focusing again on the biomedical domain and specifically COVID-19 (although this is a great example of a "surge" domain that immediately required that translation providers and MT engines adapt in order to handle translations of large volumes of text in this novel domain).

Acknowledgements

The organizers want to first thank the participants for their submissions and their constructive feedback during and after the Shared Task, which made the evaluation more robust. In addition, we are thankful to NAVER for creating the English-Korean translations and to Appen for quality assurance on them. The Czech-German track was organized with the support of the grant 1050119 of the Charles University Grant Agency. Last, we are thankful to Amazon, Tanya Badeka and Margo Lynch for the creation of the terminology-compliant translations of the evaluation datasets. Anastasopoulos is generously supported by NSF grant IIS-2125466.

Abstract

In the sixth edition of the WMT Biomedical Task, we addressed a total of eight language pairs, namely English/German, English/French, English/Spanish, English/Portuguese, English/Chinese, English/Russian, English/Italian, and English/Basque. Further, our tests were composed of three types of textual test sets. New to this year, we released a test set of summaries of animal experiments, in addition to the test sets of scientific abstracts and terminologies. We received a total of 107 submissions from 15 teams from 6 countries.

1 Introduction

Machine translation (MT) is the automatic translation of textual resources from one language to another. It is an important component in many applications and natural language processing (NLP) pipelines in the clinical and biomedical domains. On the one hand, some resources, such as specific biomedical terminologies, are only available for a limited number of languages. English is especially well covered in the Unified Medical Language System (UMLS) (Lindberg et al., 1993) while other languages are not (Wilde, 2021). On the other hand, there are many publications written in languages other than English and are therefore inaccessible to researchers who cannot read those languages.

This context has been the overarching goal for the organization of the WMT Biomedical task. The first edition took place in 2016 and addressed scientific abstracts for English/French (both directions), English/Spanish (both directions), and En-

[*] The organization of the biomedical task is complex and relies on varied essential contributions from many individuals. Authors are listed randomly because we could not do justice to the contributors using a single ranking. We would like to acknowledge MN for dataset preparation and general task organization, CG for creating baselines, AN for compiling information on participants methods, AJY for conducting the automatic evaluation, LY, DW, MN, FV, AS, AN, GMDN, RR, PT, MVN, AJY for evaluating the alignment of the test sets, and LY, DW, MN, FV, AS, MO, NM, AN, RB, GMDN, RR, PT, MVN, AJY for conducting the manual evaluation. All authors approved the final version of the manuscript. E-mail for contact: mariana.lara-neves@bfr.bund.de

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 664–683

glish/Portuguese (both directions) (Bojar et al., 2016). The subsequent shared task included six new language pairs, namely, English into Czech, English into German, English into Hungarian, English into Polish, English into Romanian, and English into Swedish, in addition to a new type of document, viz., health information texts (Jimeno Yepes et al., 2017). In 2018, we started using MEDLINE® as the source for our scientific abstracts and addressed a new language pair, namely English/Chinese (both directions), in addition to some of the languages already considered in the previous year (Neves et al., 2018). In the subsequent year, we introduced the translation of biomedical terminologies (from English into Spanish), in addition to the MEDLINE abstracts for the five language pairs from the 2018 task (Bawden et al., 2019). In 2020, we added three new language pairs, namely English/Russian (both directions), English/Italian (both directions), and English into Basque (en2eu) (Bawden et al., 2020).

For this year's shared task[1], we address the same eight language pairs as last year (Bawden et al., 2020) on the same translations tasks (scientific abstracts and terminologies). The main novel feature this year is a new test set composed of summaries of planned animal experiments to be translated from German into English. The list below summarizes the language pairs addressed this year:

- English to Basque (en2eu)
- English to Chinese (en2zh) and Chinese to English (zh2en)
- English to French (en2fr) and French to English (fr2en)
- English to German (en2de) and German to English (de2en)
- English to Italian (en2it) and Italian to English (it2en)
- English to Portuguese (en2pt) and Portuguese to English (pt2en)
- English to Russian (en2ru) and Russian to English (ru2en)
- English to Spanish (en2es) and Spanish to English (es2en)

Finally, we highlight the new aspect that we introduced in the 2021 edition of our shared task, namely, a novel test set for the automatic translation of summaries of animal experiments from German into English (see Section 2.4).

2 Training and test data

No additional training data was released for any of the language pairs, with the exception of en2eu, where we provide last year's test set as new training data for abstracts and terminology. As for the tests sets, we released test sets for scientific abstracts, terminologies, and summaries of animal experiments as follows:

- Scientific abstracts:
  - English to Basque
  - Chinese/English (both directions)
  - French/English (both directions)
  - German/English (both directions)
  - Italian/English (both directions)
  - Portuguese/English (both directions)
  - Russian/English (both directions)
  - Spanish/English (both directions)
- Terms from biomedical terminologies:
  - English to Basque
- Summaries of animal experiments:
  - German to English

Table 1 shows the number of documents, sentences and terms (if applicable) for each test set. In this section, we give details on the construction of the test sets.

2.1 MEDLINE test sets

Similar to previous years, we retrieved recent MEDLINE abstracts that were available in both English and one of the seven other languages we evaluate on (namely Chinese, French, German, Italian, Portuguese, Russian, and Spanish). The abstracts in both languages were processed as follows:

- language detection with the Python `langdetect` library;[2]
- sentence splitting using the Python `syntok` library;[3]

[1] http://www.statmt.org/wmt21/biomedical-translation-task.html

[2] https://pypi.org/project/langdetect/

[3] https://github.com/fnl/syntok

Language pairs	Abstracts		Terminology	Summaries	
	Documents	Sentences	Terms	Documents	Sentences
en2eu	76	450	2,736	-	-
de2en	50	480/481	-	30	648
en2de	50	516/501	-	-	-
es2en	50	445/444	-	-	-
en2es	50	486/501	-		
fr2en	50	365/351	-	-	-
en2fr	50	384/394	-		
it2en	43	432/407	-	-	-
en2it	44	460/448	-		
pt2en	50	468/484	-	-	-
en2pt	50	494/486	-		
ru2en	50	428/436	-	-	-
en2ru	50	354/373	-		
zh2en	50	341/393	-	-	-
en2zh	50	425/375	-		

Table 1: Number of documents, sentences and terms in the test sets released for this shared task. Some abstracts had to be removed from the it2en and en2it during the evaluation phase.

- sentence alignment using the `GMA` tool[4] for all language pairs except for English/Chinese, for which the `Champollion` tool[5] was used;
- random retrieval of 100 abstracts for each language pair;
- and manual validation of the selected abstracts using the "quality checking" task in the Appraise tool (Federmann, 2010), of which the results are shown in Table 2.

Table 2 shows that the highest quality was obtained for the zh/en test sets, with up to 94.5% perfectly aligned sentences. This is actually not a surprise, since these were the only test sets where an expert manually discarded abstracts that are clearly non-parallel, e.g. when the entire English abstract corresponds to only the first half of the Chinese abstract. A high quality of over 80% was also obtained for four language pairs, namely pt/en (90.4%), es/en (88.4%), fr/en (86.0%), and it/en (80.3%).

For en/fr, the automatic alignment was manually reviewed. In this process, the overall corpus size increased from 630 sentences to 775 sentences, mainly through the addition of article titles that had not been collected in English, and did not have any equivalent in French. In terms of alignment quality, it is important to note that the problematic categories *Source>Target* and *Target>Source* are significantly reduced in the revised corpus. The de/en test set obtained a slightly lower quality of 77.7%, while only 54.2% of ru/en sentences were perfectly aligned. Similar to previous years, the automatic evaluation was carried out for all sentences as well as only for the perfectly aligned (hereafter referred to as "OK") ones.

2.2 Basque abstracts

As we mentioned in (Bawden et al., 2020), the presence of Basque in MEDLINE is almost non-existent. In this edition we have again used the abstracts from the journal Osagaiz[6] as part of the test set, but due to the low production of this journal written in Basque, we have added abstracts from the journal *Gaceta Médica de Bilbao*[7], which contains abstracts written in Spanish, English, and Basque. From the 76 documents and 450 sentences mentioned in table 1, 18 documents and 119 sentences are from the Osagaiz journal, and 50 documents and 331 sentences from *Gaceta Médica de Bilbao*. The sentences were manually aligned by human annotators.

2.3 Terminologies

In the WMT20 edition, on behalf of Osakidetza (Basque Public Health System), we released 27,900 terms of the Basque ICD-10-CM edition, 2,000 of

Language	OK	Source>Target	Target>Source	Overlap	No Align.	Total
de/en	710 (77.7%)	38 (4.2%)	40 (4.4%)	34 (3.7%)	92 (10.0%)	914
es/en	792 (88.4%)	55 (6.1%)	15 (1.7%)	7 (0.8%)	27 (3.0%)	896
fr/en	540 (85.7%)	68 (10.8%)	10 (1.6%)	1 (0.2%)	11 (1.7%)	630
fr/en §	666 (86.0%)	9 (1.2%)	1 (0.1%)	8 (1.0%)	91 (11.7%)	775
it/en	666 (80.3%)	51 (6.2%)	26 (3.1%)	13 (1.6%)	73 (8.8%)	829
pt/en	838 (90.4%)	54 (5.8%)	18 (2.0%)	15 (1.6%)	2 (0.2%)	927
ru/en	371 (54.2%)	79 (11.5%)	63 (9.2%)	25 (3.6%)	147 (21.5%)	685
zh/en	658 (94.5%)	16 (2.3%)	9 (1.3%)	1 (0.2%)	12 (1.7%)	696

Table 2: Statistics (number of sentences and percentages) of the quality of the automatic alignment for the MEDLINE test sets. For each language pair, the total number of sentences corresponds to the 100 documents that constitute the two test sets (one for each language direction). § Results after manual correction of sentence segmentation and/or alignment.

which were used for evaluation. This year, we updated some of the Basque translations for correctness and cohesion. The full set from last year was released for training and a new set of 2,736 terms was used as a test set.

2.4 Summaries of planned animal experiments

We released a test set of 30 summaries of planned animal experiments that were retrieved from the AnimalTestInfo database[8], which is maintained by the German Federal Institute for Risk Assessment (BfR). The summaries describe planned and approved animal experiments to be carried out in Germany, which are anonymously stored in this online database in a bid to improve transparency (Bert et al., 2017). The aim of considering these summaries in this shared task is to assess the quality of MT of these documents, which is relevant for a couple of projects currently being carried out in the BfR, such as mining for alternative methods to animal experiments. A previous larger training set and test set from this database has been previously used in another shared task for the assessment of the automatic assignment of ICD-10 codes (Neves et al., 2019). The summaries contain following information (see Figure 1 for an example):

- title;
- aim of the study (e.g., basic research);
- benefits of the experiments;
- species and number of animals to be used;
- comments regarding the compliance to the so-called 3R principle (replacement, reduction, refinement of animal experiments).

The summaries were selected from the database in a way that addressed various animal species, and they were then manually translated by an English native speaker with a high knowledge of German. Before releasing the data, we converted the summaries into a format that is suitable for the WMT shared task.

3 Baselines

This year we had more choices for the baselines. As before, one option was to use our own models, trained with Marian NMT (Junczys-Dowmunt et al., 2018) on biomedical texts. A new option was to use pre-trained models, not specialized on biomedical texts. We used our own models as baselines for the following language directions: en2de, en2es, en2fr, en2pt, de2en, es2en, fr2en, pt2en. For en2zh, en2ru, en2it, en2eu, zh2en, ru2en, it2en, we used the pre-trained generic Marian NMT models available in the HuggingFace "Transformers" library.[9] An interesting question was whether the specialized models were still better than the newest out-of-the-box pretrained models. To this end, for en2de and en2fr we also tested the recent T5-large[10] model (Raffel et al., 2019). For en2fr, it outperformed our own model (trained on biomedical data) by almost 3 BLEU points, whereas for en2de the two systems were fairly comparable. The performance of the systems submitted starts from close to baseline for some language directions (e.g. for en2fr, en2es, de2en), whereas for other languages all systems were much better than the baseline (e.g. es2en, pt2en and especially ru2en).

Titel Untersuchung der in Xenopus oocytes exprimierten Ionenkanälen

Zweck - Grundlagenforschung

Nutzen Ionenkanäle sind eine Proteinklasse, die die gesamten bioelektrischen Funktionen eines Organismus steuern (Tätigkeit von Hirn, Muskel, Herzmuskel) sowie an anderen wesentlichen Funktionen beteiligt sind. Das Verfahren der Expression von Ionenkanälen in Oozyten des Krallenfrosches ist ein Standardverfahren, das weltweit angewandt wird. Nach heterologer Expression der Ionenkanäle werden diese mit geeigneter elektrophysiologischer und mikroskopischer Technik bzw. einer Kombination aus beiden Techniken (konfokale Patch-Clamp-Fluorometrie) vermessen. Zur Zeit werden sogenannte CNG-Kanäle, HCN-Kanäle, Natrium-Kanäle und P2X-Kanäle untersucht. Teilweise werden auch mutierte Ionenkanäle untersucht, die spezifische Krankheiten auslösen. Von solchen Untersuchungen werden demzufolge wichtige Erkenntnisse über das Zustandekommen der jeweiligen Erkrankung erwartet. Insgesamt beschäftigt sich das Versuchsvorhaben überwiegend mit grundlagen-orientierter Forschung an medizinisch relevanten Ionenkanälen. Das Ziel ist das Verständnis der Funktion dieser Moleküle zu mehren, woraus sich dann Strategien für die Beeinflussung dysfunktionaler Kanäle bei Erkrankungen am Menschen ergeben können.

Schäden Die Versuchstiere (Xenopus laevis) dienen lediglich der Entnahme der Oozyten. Den Fröschen werden während einer OP (Bauchschnitt) unter Betäubung mit Tricain (MS222) Oozyten entnommen. Nach dem Aufwachen werden sie für 10 Tage in einem Quarantänebecken gehalten. Innerhalb dieser Zeit verheilt die Operationsnaht. Die Belastung wird insgesamt als gering-gradig eingestuft. Die Wiederverwendung des Frosches erfolgt nach frühestens 5 Monaten. Nach Durchführung von 3- 4 OPs wird der Frosch schmerzfrei getötet und für Aus- und Weiterbildungszwecke (Medizin- und Zahnmedizinstudenten) verwendet.

Tiere

Tierart	Anzahl	Freiwillige Ergänzungen (z.B. bei Auswahl „Andere ...„)
Krallenfrösche	500	

Anwendung der 3R:

Vermeidung/Replacement Die Gewinnung der Oozyten von Xenopus laevis sind die Grundvoraussetzung für die geplanten Untersuchungen an den isolierten Zellen. In diese Oozyten wird RNA injiziert, so dass die Zellen nach Inkubation die durch die RNA kodierten Ionenkanäle exprimieren. Alle bisherigen Versuche der Expression der oben genannten Ionenkanälen in alternativen Systemen, wie Zelllinien, sind gescheitert, da die Expression in der Membran dieser Zellen zu gering ist. Es gibt somit keine Alternative zur Expression der Ionenkanälen in diesem Expressionssystem.

Verminderung/Reduction Die Frösche werden 3 bis 4 Mal für die Oozytenentnahme verwendet. Durch diese Mehrfachverwendung der Tiere kann die Anzahl der benötigten Tiere auf ein Minimum beschränkt bleiben.

Verbesserung/Refinement Da der operativen Eingriffes nach einem standardisierten Verfahren mit geeigneten Narkoseverfahren und Narkosemitteln vorgenommen wird und eine jahrzehntelange Erfahrung damit an der Einrichtung vorliegt, kann die Belastung der Tiere auf ein notwendiges und gering gradiges Maß gesenkt werden. Nach der OP werden die Frösche in einem Quarantänebecken gehalten und täglich beobachtet. Für die Haltung der Frösche wurde eine eigens dafür entwickelte Haltungsanlage installiert (Aqua Schwarz GmbH).

4 Teams and systems

This year, we received a total of 107 runs from 15 teams from the following countries: China (8), Spain (2), France (1), Japan (1), Pakistan (1), and USA (2). Table 3 presents the list of teams. We can note four returning teams: Huawei_AGI (most team members were part of the Huawei United team in 2020), LISN (LIMSI in 2020), nrpu-fjwu and TMT.

Table 4 presents an overview of the runs submitted by each team for language directions translating *from* English. Table 5 presents an overview of the runs submitted by each team for language directions translating *into* English.

We did not receive any submission for en2pt, even though we did receive submissions from one team for the opposite direction of this language pair, i.e., pt2en. Unfortunately, we did not receive any submission for the new test set that we released this year, i.e., for the summaries of planned animal experiments. Nevertheless, the test set (including the reference translation) is available for the research community for further experiments.

Similarly to the WMT 2020 biomedical task edition, we asked participants to fill in a survey with key information regarding the specific material and methods used in their self-identified primary runs that were used for manual evaluation. The survey comprised 14 questions covering the translation methods and corpora used.

On average, the time spent by participants to supply information for one language pair was 6 minutes and 35 seconds (Median: 3 minutes and 27 seconds). This is consistent with the 2020 survey statistics and suggests that the time commitment for supplying this information is limited, even for teams addressing more than one language pair.

All teams used transformer-based neural MT (NMT) and largely relied on existing implementations: 7 teams submitted runs using available libraries while 5 teams submitted runs using their own NMT implementations. Teams often used the same setup for a range of language pairs. Table 6 shows details of the teams' methods.

For in-domain data, teams used the training data distributed as part of the task as well as many of the sources described in (Névéol et al., 2018). Additional corpus used for Chinese have been prepared by the teams but are not always available or described in details. We can also notice that the use or pre-processing of resources supplied by the task organizers can differ between teams as the size reported for seemingly similar data can differ sig-

Table 6: Overview of methods used by participating teams. Information is self-reported through the dedicated survey for each selected "best run" (information on the NVIDIA model is inferred from their system description (Subramanian et al., 2021)). BT indicates if backtranslation is used and LM if language models were used.

nificantly. Table 7 provide details of the in-domain data used by the teams.

For relevant language pairs, parallel data from other WMT tracks (e.g., News Task) was used. Out-of-domain data was also used in the form of pre-trained base models. Table 8 shows details of the out-of-domain data used by the teams.

We note that a number of the corpora used are referred to as "in house" corpus or data. This may indicate survey fatigue as this type of description is more frequently used for out of domain data, which appeared towards the end of the survey.

5 Automatic evaluation

For all the abstracts test sets, we evaluated system outputs using BLEU (Papineni et al., 2002) as provided by the Moses tool *mteval-v14.pl*[11]. We used this metric for the en2eu abstracts, summaries of animal experiments, and MEDLINE test sets. In en2zh, a modified version of the tool was used that removed white spaces and text is split in way that each character is a word.

The results for the en2eu abstract test sets are given in Table 9. There was a single team (Fujitsu DMATH) that submitted two runs, based on BPE dropout and sub-subword features with a Transformer (base) model. One of the runs (run2) included multilingual data from an English–Spanish terminology. The results are not as high as in the MEDLINE abstracts task, but they are above the baseline system, and they have improved from the best results from the 2020 challenge (0.1453 vs. 0.1279).

For the en2eu terminology test sets, we evaluated the translated concepts in terms of two metrics: (i) accuracy, by relying on strict matches (case insensitive) between the reference translation and predictions; and (ii) BLEU score, as measured by the Python NLTK module sentencebleu. The results are presented in Table 10. The same systems from FUJITSU DMATH participated in this task, and the BLEU score was higher than the score for abstracts, but there was a drop in performance from the results in 2020. This could have happened because the systems were tuned for abstracts and not terminologies. As is the case for abstracts, for the terminology set, run1 outperforms run2 again, showing that multilingual data seems to harm performance in this setting.

For the summaries of animal experiments, we only present the results obtained by our baseline system (Table 11).

Finally, for the Medline test sets, we performed evaluation based on all the sentences in the test set, including the poorly aligned ones, as well as an evaluation based on only the perfectly aligned ones (see Table 2). The results *from* English into the foreign languages are presented in Table 12, while the ones *into* English are presented in Table 13. The results calculated for all sentences, and not only the perfectly aligned ones, are published on the shared task's web site.[12]

For translation from English (cf. Table 12), the highest BLEU score of 0.5117 was obtained by the Transperfect team for en2es. Moreover, for all the language pairs for which the Huawei_TSC participated, i.e., en2de and en2zh, this team obtained the highest score, namely 0.3259 and 0.4650 respectively. For en2fr and en2it, the best performance was obtained by the Huawei_AGI team,

with 0.4531 and 0.0.4425 respectively. Finally, the NVIDIA NeMo team obtained the best score (0.4139) for en2ru.

For translation into English (cf. Table 13), the highest score over all teams and language pairs was 0.5685, which was obtained by the MT Learner team for pt2en. TMT obtained the best results for three of the language pairs, namely de2en, es2en, and fr2en, with the scores 0.4501, 0.5382, and 0.4928 respectively. For it2en and zh2en, slightly higher scores (0.4570 and 0.3943 respectively) were obtained by the Huawei_AGI team, when compared to the ones from the MT learner (0.4558) and Huawei_TSC (0.3904) respectively. Finally, the NVIDIA NeMo team obtained the top score (0.4918) for the only language pair (ru2en) and run that they submitted.

6 Manual evaluation

Similar to previous years, we manually validated a sample of the abstracts to compare the teams' primary submissions to each other and to the reference translation.

For the MEDLINE abstracts, we aimed for approximately 100 perfectly aligned sentences and retrieved the corresponding abstracts. The sentences were randomly retrieved, but we aimed to select abstracts with a higher percentage of perfectly aligned

sentences. This is the same strategy described in last year's publication (Bawden et al., 2020).

We only considered those teams which either submitted a publication to the workshop or filled in our survey with information about theirs runs. In some few cases, we could not considered some teams for the manual validation, e.g., MT learner for it2en, because the team filled in the survey when the manual validation was already been carried out.

For all teams, we considered the primary run (as indicated by the participants). The only exception was made for the Volctrans team, for which we considered the run with the highest BLEU score, according to the automatic evaluation. The primary runs that we considered in the manual validation are listed below:

- en2de (3 teams): Huawei_AGI (run3), Huawei_TSC (run3), TMT (run1)
- en2es (3 teams): talp_upc (run2), TMT (run1), Transperfect (run2)
- en2fr (3 teams): Huawei_AGI (run3), LISN (run1), TMT (run1)

- zh2en (6 teams): ECNU_PAHT (run3), Haozhiweizi (run1), Huawei_AGI (run3), Huawei_TSC (run3), Transperfect (run2), Volctrans (run2)

For each language pair, we generated pairwise combinations of either two teams' primary runs or one primary run and the reference translation. The evaluator first compared pairs of sentences, followed by whole abstracts; the exception was en2zh and zh2en, where only whole abstracts were compared due to the otherwise infeasible large amount of evaluation required. These pairs of translations were manually validated in the Appraise tool (Federmann, 2010) following the same procedure carried out in previous years. For each pair of sentence or abstracts, the aim of the evaluation was to decide whether the translations were of equivalent quality or whether one was better than the other. The results of the manual validation are presented in

- en2it and it2en: Table 18
- en2zh and zh2en: Table 19
- en2ru and ru2en: Table 20

We identified the item (a system or the reference translation) of each pairwise comparison that performed better (see respective tables) and ran a Wilcoxon Signed-Rank Test from the Python `scipy` library. We consider all comparisons for two particular items over all validated abstracts and sentences, except for skipped ones. The test was calculated for the abstracts and the sentences. We mark in bold in the respective tables the ones that were found to be significant (i.e., p-value< 0.05) and otherwise the systems are considered to be similar. We considered one item superior than the other when either the validation of the abstract of the sentences was statistically significant. For the language pairs validated by two experts (i.e., es2en and pt2en), we only considered one item to be superior than the other when at least two of the four comparisons (2x for the abstracts, 2x for the sentences) were statistically significant.

We ranked the system by assigning points to each item: 3 points if superior to the opponent, 1 point when they have similar quality, and no points if inferior to the opponent. Based on the sum of these points over all comparisons, we ranked the systems and the reference translations as shown be-

Abstracts for en2eu (Osagaiz + Gaceta) were manually validated following the same approach, but only at the sentence level. As there was one submission for this language pair, we only generated a pairwise combination of the participant's run and the reference. The run with the highest BLEU score was selected for validation:

- en2eu (1 team): FJDMATH (run1)

The translations were evaluated by three annotators using the Appraise tool, and the averaged results are presented in Table 21. The ranking based on the points is as follows:

- en2eu: FJDMATH (0) < reference (3)

7 Discussion

7.1 Quality of the MT evaluation process.

Marie et al. (2021) introduced guidelines for the evaluation of MT quality, based on four criteria:

Table 19: Manual validation for the en2zh and zh2en MEDLINE abstracts test set. Only the abstracts were validated. The better performing system (or reference translation) in each pairwise comparison is shown in bold, as well as the respective value that has been identified as superior.

(1) use of an evaluation method in addition to/in lieu of BLEU, (2) use of statistical significance testing to compare systems, (3) direct computation of scores instead of copying from previous experiments and (4) comparison of systems only if the same training, validation and test sets have been used, as well as the same pre-processing steps.

The evaluation carried out in this task is compliant with criteria (1-3). However, participants are free to use their choice of training corpus, validation corpus and pre-processing methods. This approach was selected to foster participant creativity and set a lower entry cost to the task. It is a limitation in the comparability of the systems submitted for this task. As a mitigation strategy, we encourage participants to also submit detailed descriptions of system particulars to provide transparency on the material and methods used.

A future edition of the task could introduce a "constrained" track where pre-processed training/validation sets would be supplied to be used exclusively (as in the WMT news translation task (Barrault et al., 2020)).

Table 21: Manual validation for the en2eu (Osagaiz and Gaceta) abstracts test set. The better performing system (or reference translation) in each pairwise comparison is shown in bold, as well as the respective value that has been identified as superior. The values show the validation performed by the Basque native speakers (averaged over three annotators).

7.2 Quality of the system translations

We report below some of the major observations collected throughout the manual validation of the selected runs and the reference translations.

7.2.1 MEDLINE test sets

de (from en) The perceived quality of translations was high, with a high proportion of perfect or near perfect translations. The translation quality between participating systems differ only by small nuances. For example, translations differ only by word order or use different synonyms for a specific medical term. All participating systems had problems translating abbreviations. For instance, "image quality (IQ)" becomes "Bildqualität (IQ)" instead of BQ. One participant could not generate umlauts (e.g., ä,ö,ß, ...) and another participant produced only lowercased text. Both problems lead to slightly reduced quality of translations.

en (from de) Overall, the translation quality was high. Most translated sentences were understandable, except in cases where the original German sentences were too long to translate correctly. In some cases, the translations captured the intended meaning, but took information from different sentences, or even used synonyms, which were not direct literal translations of words, such as "neurosensory retina" for "macular region". There were also some translations from the first person point of view, rather than the impersonal, for a more personal touch. If such examples represent MT outputs rather than the reference translations, the quality of translation is approaching native speaker level.

Some texts contained small errors, which should be easy to avoid, such as capitalization of the first word after "e.g.", the use of lower case letters for well-known abbreviations like "AR" for augmented reality, proper nouns ("Marburg heart score"), and gene names (PD-1). Also a repetition of words in common expressions like the German *wie z. B.* should not have been translated as "e.g. For example". Using the same word twice in a sentence could have been avoided: "Relapse is defined as the recurrence" instead of "Recurrence is defined as the recurrence". Interestingly, a translation actually corrected a capitalization error in the original German text, from *l. reuteri* to *L. reuteri*, for the genus *Lactobacillus* in the scientific name of the bacteria.

The correct translation of medical terms also

proved to be difficult in cases such as "centrum" instead of "ventrum", "neurology" instead of "urology", or "endourolgy" instead of "endourology". Medical terms pertaining to a specific field, were also difficult to translate properly, such as the German *Pluszeichen* to the English "plus disease" in the context of retinal disease and "fusion biopsy" to describe the method of using both magnetic resonance imaging and ultrasound to take prostate biopsies.

es (from en) Quality of translations is improving every year and in many cases it is difficult to identify which translations are machine made.

There have been cases in which abbreviations were not translated correctly (e.g. *HGS* vs *FPM* for *fuerza de prensión manual*) and some times specific terms were not translated, e.g. *receiver operating characteristic curve*. Only in a few cases word gender was different to the article one.

There are examples of words that are not translated properly for instance *adnexal* has been translated as *adnexiales* instead of *anexas* by one of the teams.

In addition to individual sentences, the manual evaluation included abstracts as well. Since translations were sentence based, there were cases in which there were misaligned information between the content of the sentences in the abstract, even if the translated sentences were perfectly fine in their own.

We identified that a team might have been missing accents on vowels and special letters such as *ñ*, which seemed to indicate that the translation was machine made.

fr (from en) The overall quality of translation was high. We noted that many of the sentences compared were identical or nearly identical. In many cases, the translations selected as superior were chosen based on small nuances, such as capitalization, typography, ordering of words or sentence structure that appeared more adequate to a native speaker, while causing no difference in the understanding of the text. A few terms or acronyms were sometimes untranslated but the resulting text could be understood (for example, *incidentaloma* was used instead of *incidentalome*). Erroneous disambiguation was observed in some translations for one abstract discussing pressure at the fingertips, where *numérique* was used instead of *digital*. At the abstract level, some vocabulary consistency issues could be evidenced. For example, one translation used the synonyms *sclérodermie systémique* and *sclérose systémique* alternatively as translation for "systemic sclerosis". While individual sentences were correctly translated, it created confusion at the abstract level, compared to the "reference" translation, which used the term *sclérodermie* throughout. Consistently with the 2020 edition, arbitration between sentences exhibiting a fluency or grammatical flaw vs. a semantic or clinical flaw was conducted as favoring the semantic or clinical correctness. However, the nature of the "reference" translation (which is often not produced by professional translators and does not necessarily provide straight forward sentence-by-sentence translations (Névéol et al., 2020)) introduces bias and difficulty in the evaluation: highly fluent text with some semantic distance with the "original" sentence to be translated can sometimes be easily identified as the reference text. It is difficult to arbitrate between this high quality text and the machine translation that will attempt to be semantically closer while exhibiting language flaws.

en (from fr) Translation quality was generally very high, with some variation in the quality depending on the topic of the abstract being translated (most systems struggled with the more literary text from a sociology abstract). This meant that many of the decisions were, as with the other language pairs, based on preferences and formatting rather than differences in meaning (punctuation, capitalisation, minor grammar mistakes).

The most serious errors observed were with the translation of specific terms, such as illnesses and drugs. They were particularly prevalent for acronyms, which were sometimes not translated and sometimes poorly translated (another more common acronym being used instead, e.g. *ADHD* instead of *ADPKD*). A few tricky sentences revealed the risk of major semantic errors resulting from seemingly small and localised errors. We give two such examples here. Firstly, concerning temporality, several systems translated French *puis* 'then' as English *and* in *un anticoagulant puis l'aspirine* 'an anti-coagulant then aspirine', a sentence for which the order in which drugs are given may be fundamental. Secondly, many systems stumbled on the translation of French *cela ne s'accompagne pas d'une attention égale au rôle de l'écoute* 'this is not accompanied by equal attention to the role of listening', inverting the order of the two underlined

words, resulted in the opposite meaning (i.e. listening receiving more rather than less attention).

As noted above for en2fr, despite very high MT quality, reference translations are often still easily identifiable due to them being less literal. This means that they are often characterized by better word choice and more natural syntax, but it can also mean that they are less adequate because of missing information or even additional details not present in the French text.

it (from en) The quality of the translation was on average high, probably higher than 2020. Some of the sentences compared were almost identical.

From a terminological viewpoint, it is possible to identify some inaccuracies in the choice of translating terms in the target language. For example, the term 'malignancies' was translated by one system with *tumori* (corresponding to the English 'tumors') having a broader meaning than *neoplasie maligne* ('malignant neoplasms'). Furthermore, cases of erroneous choices of the translating terms can be identified. The adjective 'unpreventable' was translated as *non prevedibile* ('unpredictable') instead of *non evitabile*, thus causing the transmission of an incorrect information in the target text.

Another error can be identified in the choice of the generic verb 'consider'. In the case of the sentence 'total laryngectomy should be considered [...]', the construction was wrongly translated as *la laringectomia dovrebbe essere considerata il trattamento di scelta*, that is the 'Laryngectomy should be considered the treatment of choice'. It is also possible to identify cases of non-translation in the Italian text (for example the name of the city 'Zurich' remained untranslated) and the presence of anglicisms as *imaging diagnostico* chosen as the translation of 'diagnostic imaging', although the Italian equivalent *diagnostica per immagini* is commonly used in the target language.

Moreover, the term 'livestock' was translated with *mandria* 'herd', *bestiame* 'livestock' or *allevamento* 'farm'. One interesting case was the term 'blacks', which was translated with *non bianchi* (non-whites) instead of the more frequently used *neri*.

Finally, from a syntactic point of view, there were a couple of examples where the syntactic tree was built erroneously: for example, the phrase 'incidental thyroid cancer rates' was translated as *i tassi di carcinoma tiroideo incidentale* ('rates of incidental thyroid cancer'); another example is '4 cm lobule contoured mass' translated as *massa sagomata di 4 cm del lobulo* ('4 cm contoured mass of the lobule').

zh (from en) The quality of translation was high overall. The primary reason for awkward translations was word order, since English and Chinese employ different word orders not only at the word level, but also at the phrase level. Consider this example, where the source text was *surveillance and early warning of infectious diseases in China*. A good translation first needed to adjust word order within *infectious diseases in China* to yield 中国传染病 (the order is *China* then *infectious diseases*). Then phrase order also needed to be adjusted to yield 中国传染病监测预警能力 (the order is *China infectious diseases* then *surveillance and early warning*). Some translations failed to make these necessary adjustments, such that the Chinese translation in the original English word order rendered the translation awkward or even unintelligible.

Another source of deficiency was translations that were too literal. For instance, *under-reporting* was most often translated as 报告不足 (*insufficient reporting*), though a more native, conventional wording would actually be 漏报 (*omitted reporting*). Consider another example, *appraised persons* in the context of a study of familial relationships. While the reference translation 被鉴定人 was the most fitting, some teams' translation 被评估者 (a person to be evaluated) was also a good fit. However, another translation such as 评估人员 (evaluation personnel) was outright incorrect, as the meaning went from "a passive person being evaluated" to "an active person evaluating someone else".

en (from zh) The quality of translation was also high and noticeably better than last year. Where some translations last year were unintelligible, such cases have disappeared this year. In addition, there was a range of translation qualities last year, but this year every team's translation quality was high.

This year, the aspects that distinguish a better translation from a worse one are more subtle. Firstly, Chinese sentences as delimited by the Chinese full stop "。" are often equivalent to short paragraphs in English. A good translation should therefore split a Chinese sentence where necessary into multiple English sentences. Secondly, a technical term may have synonyms (e.g. *acetabulum*

labrum and *acetabular lip*), and a better translation should use one synonym consistently within the same abstract instead of mixing different ones. Thirdly, a good translation should use the most fitting wording, a task that requires good understanding of sentence context as well as domain knowledge. Consider this example, where 夫妻婚姻关系 (*marital relationship of married couples*) and 双向关联性 (*bi-directional correlation*) occur within the same sentence. A good translation can tease out *relationship* and *correlation*, but a worse translation simply uses *relationship* for both occurrences. This year, the better translations achieved the above three aspects, though rarely all three at once in the same translation.

en (from pt) While there was no significant difference between the automatic translations from the MT Learner team and the reference translation, we highlight some situations in which one was considered better than the other. On one hand, some mistakes were very subtle, such as a typo in a word (e.g., "verage" instead of "average"), or an inappropriate capitalization of a word. On the other hand, there were some semantic mistakes related to the translation of the sentences. For instance, the passage "insuficiência do glúteo médio esteve presente em todos os sujeitos" was translated as "the gluteus medius was insufficient in all patients".

Overall Based on these comments, many language pairs would benefit from a visual feature highlighting differences in the translations in the interface to focus the analysts' attention on often small differences. It could also be relevant to focus manual evaluation on a number of targeted linguistic features that seem to remain difficult (based on 2020 and 2021 observations), such as (a) translation of acronyms (b) vocabulary/grammatical consistency throughout a document (c) translation of numerical data. This might help make the manual evaluation more comparable between language pairs. However, it raises the question of the method to use for the selection of sentences/passages exhibiting the desired phenomena.

7.2.2 Osagaiz/Gaceta abstract test sets (en2eu)

In general, despite the fact that in the manual evaluation FJDMATH ranked below the references, the translations generated by the system were good, containing sentences with high-level of fluency and high adequacy with respect to the source. Similar to what has been observed in other language pairs, the system sometimes struggled with the translation of acronyms. For example, "non-motor symptoms (NMS)" should be translated to "sintoma ez motor (SEM)" but the participant's system translated it as "sintoma ez-motor (NMS)"; or "amiotrophic lateral sclerosis (ALS)" should be "alboko esklerosi amiotrofikoa (AEA)".

On the other hand, sometimes the reference translation in Basque contained extra information that was not present in the source English sentence. In these cases the additional information is contained in the context (i.e. surrounding sentences in the abstract). This can penalize the BLEU score of a correct sentence-level translation. For example, the source sentence "*Important hormonal changes happen during pregnancy and lactation*" was correctly translated by the system to "*Hormona aldaketa garrantzitsuak gertatzen dira haurdunaldian eta laktazioan.*". However, the reference translation also mentions "physiological changes in the body" (i.e. "*Haurdunaldi eta edoskitzaroan zehar,* ***gorputzeko maila askotan aldaketa fisiologikoak eragingo dituzten*** *gorabehera hormonal nabariak gertatuko dira*"). Document or abstract level translation systems could potentially alleviate this problem by leveraging contextual information from surrounding sentences.

7.2.3 Terminology test sets (en2eu)

The participating team (FJDMATH) had more difficulty in the translation of ICD-10 code descriptions (16% accuracy), particularly if we compare them with the results obtained by many teams last year (∼70% accuracy). Note that ICD-10 codes included in the test sets every year are different, but the performance difference is big considering there was more in-domain training data available this year. Some of the common mistakes observed in the system are word repetition (e.g. *hortz-posizioko anomaliak, hortz edo hortz guztiz eruptatuen posizioa* - "tooth position anomalies, tooth and tooth"), not translating an English word (e.g. *tidal-wave* instead of *olatu erraldoi*) or low adequacy (i.e. *huts egin du jaioberrian irabaztean* / (en) *missed when winning the newborn* where it should be *jaioberriaren garapeneko atzerapen* / (en) *Failure to thrive in newborn*). It is possible that the system was not sufficiently fine-tuned for the technical and specific language employed in ICD-10 code descriptions.

8 Conclusions

Our sixth edition of the WMT Biomedical Translation addressed a total of eight language pairs and three types of documents. One more time, we could assess the performance of current MT technology for the translation of biomedical textual resources. Further, we could attract the attention of many teams and received submissions for most of our test sets.

Similar as in the more recent editions of the shared task, participating system could perform better than the reference translation for many of the language pairs. However, this is still a challenge for en2zh. In future editions of this challenge, we aim at releasing more resources, especially additional training data, adding new language pairs, and considering a variety of test sets.

Acknowledgements

We would like the thank the participants Virginia Adams (NVIDIA NeMo), Cao Jun (Volctrans/ByteDance), Wei Peng (Huawei_AGI), and multiple individuals in the Huawei_TSC team for supporting us in the manual validation. The Academy of Medical Sciences of Bilbao and the Gaceta Médica de Bilbao have collaborated in WMT 2021 by providing us with their documents.

Abstract

We report the results of the WMT 2021 shared task on Quality Estimation, where the challenge is to predict the quality of the output of neural machine translation systems at the word and sentence levels. This edition focused on two main novel additions: (i) prediction for unseen languages, i.e. zero-shot settings, and (ii) prediction of sentences with catastrophic errors. In addition, new data was released for a number of languages, especially post-edited data. Participating teams from 19 institutions submitted altogether 1263 systems to different task variants and language pairs.

1 Introduction

The 10th edition of the shared task on Quality Estimation (QE) builds on its previous editions to further benchmark methods for estimating the quality of neural machine translation (MT) output at runtime, without the use of reference translations. It includes the (sub)tasks of word-level and sentence-level estimation. The document-level task was removed from this edition, since it has not attracted many participants in previous editions. Important elements introduced this year are: a new sentence-level task where sentences are annotated with a binary label reflecting whether or not they contain a critical error that could lead to catastrophic consequences; new test data for languages that are not covered by any training set for zero-shot prediction (both direct assessment and post-editing based labels, at sentence and word levels. scores instead of labels based on post-editing; a new multilingual sentence-level dataset mainly from Wikipedia articles, where the source articles can be retrieved for document-wide context; the availability of NMT models to explore system-internal information for the task.

In addition to advancing the state-of-the-art at all prediction levels, our main goals are:

- To extend the MLQE-PE public benchmark datasets;
- To investigate new language independent approaches especially for zero-shot prediction;
- To study the feasibility of unsupervised approaches especially for zero-shot prediction; and
- To create a new task focusing on critical error detection.

We have three subtasks: Task 1 aims at predicting a variant of DA scores at sentence level (Section 2.1); Task 2 aims at predicting post-editing effort scores at both sentence and word levels, i.e. words that need editing, as well as missing words and incorrect source words (Section 2.2); Task 3 aims at predicting a binary label at sentence level to indicate whether the sentence contains one or more critical errors (Section 2.3).

Tasks make use of large datasets annotated by professional translators with either 0-100 DA scoring, post-edition, or critical error flagging. The text domains and languages vary for each subtask. Neural MT systems were built on freely available data using an open-source toolkits to produce translations. We provide new training and test datasets for Tasks 2 and 3, new test sets for Task 1, as well as new *zero-shot* test sets for Tasks 1 and 2. The datasets and models released are publicly available. Participants are also allowed to explore any additional data and resources deemed relevant.

Baseline systems were entered in the platform by the task organisers (Section 3). The shared task uses CodaLab as submission platform, where participants (Section 4) could submit up to 30 systems for each task and language pair, except for the multilingual track of Tasks 1 and 2 (up to 10 systems). Results for all tasks evaluated according to standard metrics are given in Section 5, which this year also included model size. A discussion on the main

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 684–725

goals and findings from this year's task is presented in Section 6.

2 Subtasks

In what follows, we give a brief description for each subtask, including the datasets provided for them.

2.1 Task 1: Predicting sentence-level DA

This task consists in scoring translation sentences according to their perceived quality score – which we refer to as direct assessment (DA). For that, we use the same training sets as last year's Task 1 (Specia et al., 2020), and provided new test sets for all low, medium and high-resource languages:

- English→German (En-De),
- English→Chinese (En-Zh),
- Russian→English (Ru-En),
- Romanian→English (Ro-En),
- Estonian→English (Et-En),
- Sinhala→English (Si-En), and
- Nepali→English (Ne-En).

This data was produced in the same way as the data for last year, with sentences sample from Wikipedia (or Wikipedia and Reddit for Ru-En) and translated by a fairseq Transformer (Ott et al., 2019) bilingual model.

In addition, we provide new test sets for four other languages, for which training data was not provided. The goal was to test the performance of QE models under zero-shot settings. The new test sets contain source Wikipedia sentences sampled in the same way as the previous data, but translated by the ML50 fairseq multilingual Transformer model (Tang et al., 2020),[1] which had been found to perform well especially for low-resource languages. The following languages were used:

- English→Czech (En-Cs),
- English→Japanese (En-Ja),
- Pashto→English (Ps-En), and
- Khmer→English (Km-En),

All translations were manually annotated for perceived quality, with a quality label ranging from 0 to 100, following the FLORES guidelines (Guzmán et al., 2019). According to the guidelines given to annotators, the 0-10 range represents an incorrect translation; 11-29, a translation with few correct keywords, but the overall meaning is different from the source; 30-50, a translation with major mistakes; 51-69, a translation which is understandable and conveys the overall meaning of the source but contains typos or grammatical errors; 70-90, a translation that closely preserves the semantics of the source sentence; and 91-100, a perfect translation. DA scores were standardised using the z-score by rater. Participating systems are required to score sentences according to z-standardised DA scores. Statistics on the dataset are shown in Table 1. This dataset part of the MLQE-PE dataset and more details are given in Fomicheva et al. (2020). The complete data can be downloaded from the public repository.[2]

Participation was encouraged for each language pair and also for the **multilingual variant** of the task, where submissions had to include predictions for all six Wikipedia-based language pairs (all except Ru-En). The latter aimed at fostering work on language-independent models, as well as models that can leverage data from multiple languages.

2.2 Task 2: Predicting post-editing effort

This task concerns scoring translations according to the proportion of the words that need to be edited to obtain a correct translation. The scores are generated using Human-mediated Translation Edit Rate (HTER) (Snover et al., 2006), i.e. calculating the minimum edit distance between the machine translation and its manually post-edited version, as well as detecting where errors are in the translation of source sentences. It comprises two sub-tasks, a sentence level one where the targets are the HTER scores per segment and a word level task where the targets are word level OK/BAD tags to signify the correctness of words and gaps in the source and translation sentences. Both sub-tasks use the same languages pairs and splits described for Task 1 in Table 1. Details on the data, such as label distributions, can be found in Fomicheva et al. (2020).

Sentence-level post-editing effort The label for this task is the percentage of edits that need to be fixed (HTER). The data used for this task is the PE annotations and corresponding HTER scores from the MLQE-PE dataset (Fomicheva et al., 2020). HTER labels are computed using TERCOM,[3] with

Table 1: Statistics of the data used for Task 1 (DA), Task 2 (PE) and Task 3 (CE) (last four rows). The number of tokens is computed based on the source sentences.

default settings (tokenised, case insensitive, exact matching only) with scores capped to 1.

Word-level errors This sub-task focuses on detecting word-level errors in the MT output. The goal in this case is to annotate each token with binary correctness (OK/BAD) tags. The token-level annotations include the annotation of gaps, which allows us to account for omission errors. All annotations are produced with respect to a post-edited sentence, which is treated as the ground truth reference. Similarly to the sentence-level tasks, the MLQE-PE data is used for all language pairs (see Table 1). The following types of labels are used:

- **Source side:** Each word in the source side is labelled as OK (correctly translated) or BAD (caused a translation error).
- **Target side:** Each word in the target side is labelled as OK (a correct translation) or BAD (should be replaced or deleted). Additionally, we consider gap 'tokens' at the beginning of the sentence, at the end and between each two words. They are labelled OK if no word should be inserted in that position (according to the post-edited version), and BAD otherwise.

2.3 Task 3: Predicting Catastrophic Errors

This is a new task introduced this year. It aims to predict a sentence-level binary score indicating whether a translation contains (at least one) critical error (CE). Translations with such errors are defined as translations that deviate in meaning as compared to the source sentence in such a way that they are misleading and may carry health, safety, legal, reputation, religious or financial implications. Meaning deviations from the source sentence can happen in three ways:

- **Mistranslation**: critical content is translated incorrectly into a different meaning, or not translated (i.e. it remains in the source language) or translated into gibberish.
- **Hallucination**: critical content that is not in the source is introduced in the translation, for example, profanity words are introduced that were not in the source.
- **Deletion**: critical content that is in the source sentence is not present in the translation. For example, the source sentence may contain a negation or hateful word that is removed in the translation.

We focus on the following set of critical error categories:

- **TOX.** Deviation in toxicity (hate, violence or profanity) be against an individual or a group (a religion, race, gender, etc.). This error can happen because toxicity is introduced in the translation when it is not in the source, deleted in the translation when it was in the source, or mistranslated into different (toxic or not) words, or not translated at all (i.e. the toxicity remains in the source language or it is transliterated).

- **SAF.** Deviation in health or safety risks, i.e. the translation contains errors that may bring a risk to the reader. This issue can happen because content is introduced in the translation when it is not in the source, deleted in the translation when it was in the source, or mistranslated into different words, or not translated at all (i.e. it remains in the source language).

- **NAM.** Deviation in named entities. A named entity (people, organisation, location, etc.) is deleted, mistranslated by either another incorrect named entity or a common word or gibberish, or left untranslated when it should be translated, or transliterated where the transliteration makes no sense in the target language (i.e. the reader cannot recover the actual named entity from it), or introduced when it was not in the source text. If the named entity is translated partially correctly but one can still understand that it refers to the same entity, it should not be an error.

- **SEN.** Deviation in sentiment polarity or negation. The MT either introduces or removes a negation (with or without an explicit negation word), or reverses the sentiment of the sentence (e.g. a negative sentence becomes positive or vice-versa). We note that SEN errors do not always involve a full negation, for example, replacing "possibly" with "with certainty" constitutes a SEN error.

- **NUM.** Deviation in units/time/date/numbers. The MT translated a number/date/time or unit incorrectly (or translated it as gibberish), or removed it, which could lead someone to miss an appointment, get lost, etc.

Data for this task was annotated at the word/span level by professional translators not only for the presence of an error, but also with the error category. Each instance was annotated by three professional translators using a modified version of MT-EQuAl.[4] We instructed the translators to ignore other translation errors, be them critical (there may be other types of critical errors outside these five categories) or non-critical, e.g. minor grammatical or typographical errors. We also instructed them to indicate source sentences that were unintelligible, or translation sentences that contained too many errors to be annotated. Figure 1 shows three examples of different error annotations for the translations.

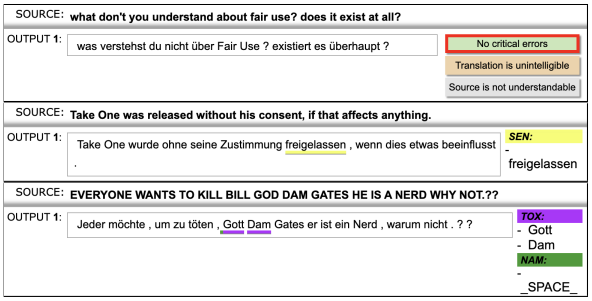

Figure 1: Example of fine-grained sentence annotation. Spans in the same colour belong to the same catastrophic error type. In the first case, the translation contains no critical error; in the second case, the translation contains only one SEN error; in the last case, the translation contains two errors: one TOX and one NAM (the space is annotated to indicate a missing named entity).

For this the first edition of this task, we aggregated these labels in two ways: First, for each of the three annotated versions of a sentence, we extrapolated the word-level labels into a sentence-level label: if the sentence contained at least one critical error, it was annotated as critical. Second: we took the majority sentence-level label from the three annotators to create a single sentence-level label for each sentence, resulting in the following binary labels:[5]

- ERR: the translated sentence contains at least one (any) token or whitespace (for deletion errors) annotated with a critical error in any categories, according to at least 2 out of 3 annotators, or otherwise

- NOT: the sentence does not contain any token with a critical error.

[4] https://mt4cat.fbk.eu/software/mt-equal

[5] We removed from the dataset sentences that had been annotated by the majority as having an unintelligible source or a translation with too many errors.

Thus, the task does not expect the errors to be categorised or to have their spans identified in the sentence, but rather to have a binary prediction on a sentence basis. For example, the first sample in Figure 1 would have resulted in the sentence labelled as NOT by that annotator, while the last two samples would have resulted in the sentence labelled as ERR.

An initial set of 10K English samples for training, development and test data was created from Wikipedia comments, extracted from two sources: the Jigsaw Toxic Comment Classification Challenge[6] and the Wikipedia Comments Corpus.[7] Machine translations were generated by the ML50 fairseq multilingual translation model for the following languages:

- English-Czech,
- English-Japanese,
- English-Chinese, and
- English-German.

After filtering for unintelligible source sentences and translations with too many errors, the statistics for the resulting splits are presented in Table 1. As expected, critical errors are rare. Give the nature of this dataset (user generated content with high chances of toxicity, named entities, etc.), we observed a fairly large proportion of sentences with such errors. Nevertheless, the distribution of labels is skewed towards the NOT class. The proportion of instances with NOT labels in the training set (similar for dev and test sets) is as follows: 83% for En-Cs, 72% for En-De, 91% or En-Ja, and 84% for En-Zh.

3 Baseline systems

Sentence-level baseline systems: For Tasks 1 and 2, both word and sentence-level, we used a multilingual transformer-based Predictor-Estimator approach (Kim et al., 2017), which is described in detail in (Fomicheva et al., 2020). Both baselines are implemented in OpenKiwi (Kepler et al., 2019) and trained using the concatenated train portions of the data for training (combining all 7 language pairs) and the concatenated development portions of the data for validation/early-stopping. In all cases, the XLM-RoBERTa transformer was used for the encoding (predictor) part of the architecture, using `xlm-roberta-base` for all experiments. The XLM-RoBERTa encoder is initially trained on the concatenated train and development segments using ULM fine-tuning (Howard and Ruder, 2018) and then this fine-tuned encoder is used in the full predictor-estimator model which is fine-tuned separately for each task scores (DA or HTER).

Word-level baseline systems: For Task 2, we used the same architecture and encoder as above, but it was trained to predict jointly word-level OK/BAD tags and sentence-level HTER scores.

Catastrophic error baseline system: The baseline model for Task 3 follows the MonoTransQuest architecture proposed by Ranasinghe et al. (2020) for sentence-level classification. As input, the model takes a sequence of tokens including the `[CLS]` token, and the source and translated sentence tokens, separated by a `[SEP]` token. This string is fed into a transformer encoder and the output of the encoder is given to a classification head where cross-entropy is adopted as the loss function. We use the pre-trained XLM-RoBERTa-base released by HuggingFace's model repository (**?**) for the implementation.

4 Participants

Table 2 lists all participating teams submitting systems to any of the tasks, and Table 3 report the number of successful submissions to each of the sub-tasks and language pairs. Each team was allowed up to two submissions for each task variant and language pair. In the descriptions below, participation in specific tasks is denoted by a task identifier (T1 = Task 1, T2 = Task 2, T3 = Task 3).

Bergamot (T1): Bergamot explores the use of a teacher-student knowledge distillation framework to transfer knowledge from a strong QE teacher model to a much smaller student model with a different, shallower architecture. Namely, the system distill a large and powerful QE model TransQuest [1] based on XLM-Roberta into a small BiRNN-based DeepQuest model [2]. The predictions from a teacher QE model trained on MLQE data [3] is used to train the lightweight student. Additionally, the system employs data augmentation through teacher predictions on monolingual data sampled from Wikipedia following

Table 3: Number of submissions to each sub-task and language-pair at the WMT21 Quality Estimation shared task.

the procedure described in [3]. Further details about the distillation framework used for submission can be found in [4].

Bergamot-UTartu (T1, T2): Bergamot-UTartu proposes CNN-models based on attention weights extracted from NMT systems. For Task 1, they explored three QE models: i) CNN-DA trained on human-labelled data; ii) CNN-BLEURT a "zero-shot" system that requires only synthetic data, for which they used BLEURT scores (Sellam et al., 2020) as training data; iii) CNN-BLEURT+ a fine-tuned version of CNN-BLEURT. For Task 2, CNN-HTER is a model similar to CNN-DA, but trained on the post-editing scores.

ENSBRT (T2): ENSBRT propose a system that is an ensemble of multilingual BERT (mBERT)-based regression models, which are generated by fine-tuning on different input settings. They adapted their system for the zero-shot setting by exploiting target language-relevant language pairs and pseudo-reference translations.

HW-TSC (T1, T2, T3): HW-TSC's submissions in the three sub tasks follow the framework of Predictor-Estimator (Kim et al., 2017), with a pre-trained XLM-Roberta as Predictor and task-specific classifier or regressor as Estimator. They further explore to incorporate additional high-quality translation sentences in the way of multitask learning or encoding it with the Predictor directly. For Task1, they enable the model to jointly learn to score translations with a regression task and to distinguish between translations and additional better translations (i.e. post-edits from Task2 dataset) with a classification task. They also exploit

a data augmentation strategy based on MC dropout to improve zero-shot performance. They ensemble multi results with MC dropout to keep a relatively small number of parameters and model size. For Task 2, they leverage additional translation sentence generated by a NMT system trained for WMT21 News shared task in the way of directly concatenating it with source and original translation. A unified model is trained under multi-task learning framework where losses of source word, translation token and gap, additional translation token and gap, HTER scores are all added up to train the model. For Task 3, they translate source sentences with Google and Baidu translation API. Each new translation is then concatenated to the corresponding source and translation pair, to get a sentence feature. They ensemble the results of three different models and take their majority voting as final result.

IST-Unbabel (T1, T2): For Task 1, IST-Unbabel's system is an ensemble of an XLM-R with stacked adapter layers and an mBART that incorporates different types of uncertainty (annotation uncertainty and MT uncertainty). For Task 2, the submitted system is an ensemble of two XLM-R with adapters (the difference being the XLM-R checkpoint, while one uses the xlm-roberta-large normal checkpoint the other uses an XLM-R checkpoint pertained on data from the metrics shared task). The ensembled checkpoints learn to predict both word level tags and sentence level HTER scores in a multi-task setting.

JHU-Microsoft (T2): The JHU-Microsoft submission focuses on the word-level subtask of Task 2, for which they adopt Levenshtein Transformer (Gu et al. 2019) as their model architecture. The training procedure starts with training a non-autoregressive translation model using a Levenshtein Transformer, with its encoder and decoder initialized with those from the M2M multilingual translation model (Fan et al. 2020). They then fine-tune the model to perform the word-level QE task on the human-annotated training set, or optionally also on automatically generated pseudo-post-editing translation triplets. The final submission is an ensemble of 4-8 best models on the 2020 test set for each language pair, and the ensemble is performed by linear interpolation of scores from each model, with the interpolation weights tuned by the Nelder-Meade method (Nelder and Meade, 1965).

LAMA-ICL (T3): LAMA-ICL's approach builds on cross-lingual pre-trained representations in a sequence classification model. We further improve the base classifier by (i) adding a weighted sampler to deal with unbalanced data and (ii) introducing feature engineering, where features related to toxicity, named-entities and sentiment, which are potentially indicative of critical errors, are extracted using existing tools and integrated to the model in different ways. We train models with one type of feature at a time and ensemble those models that improve over the base classifier on the development (dev) set.

NICT Kyoto (T3): NICT Kyoto submission for the Critical Error Detection task consists in large scale QE pretraining with synthetic data in a multilingual and multimetric setting. A total of six sentence- and word-level quality indicators were involved in continued training of an XLM-R checkpoint using QE oriented training objectives in a multi-task fashion, based on a corpus of 70 million sentence pairs including twelve languages. Fine-tuning on the official dataset was then performed and resulting models from different initializations were ensembled to constitute the final submission.

Papago (T1): Papago's submission is a multilingual Quality Estimation system that explores the combination of pre-trained language models and multi-task Learning architectures. They propose an iterative training pipeline based on pretraining with large amounts of in-domain synthetic data and fine-tuning with gold (labeled) data. They then compress our system via knowledge distillation in order to reduce parameters yet maintain strong performance.

POSTECH (T2): POSTECH's model uses two pre-trained monolingual encoders to first produce monolingual representations of the two input data separately and then exchanges the information of these representations through

two additional cross attention networks. The two pre-trained monolingual encoders are an English ELECTRA and a German ELECTRA, respectively. They fine-tuned their system in two stages: the QE pre-training stage and the QE fine-tuning stage. In the former, they used a large quantity of artificial training data, and the loss value equals to the sum of the losses for the estimated HTER (sentence-level QE), OK-BAD for the source tokens, OK-BAD for the MT tokens, and OK-BAD for the gap tokens in between two MT tokens. In the latter, they only used human labelled training data, and the loss value is one of the four above mentioned loss values, depending on the targeted subtask.

QEMind (T1, T3): QEMind propose novel glass-box QE features to estimate the uncertainty of machine translations and incorporate them into the transfer learning from the large-scale pre-trained model, XLM-Roberta. In addition, three important strategies are particularly utilized for improving the QE system's performance such as multilingual training, data augmentation and model ensemble.

RTM (T1, T2): Referential Translation Machines (RTMs) Superlearner results combine individual machine learning model results via cross-validation on the training set. The combined models guarantee lower error on the validation set than the model that minimises the overall error. A superlearner model improves the results over non-mixture results.

SMOB-ECEIIT (T1): SMOB-ECEIIT's participation is fully unsupervised, as created without using any annotated data or even parallel bilingual data. The system is composed of two novel different methods. The first method is based on soft alignment of multilingual contextual embeddings, generated by pre-trained mBert or XLM-R (depending on the specific language). The soft alignment is calculated by the Sinkhorn distance (Cuturi, 2013), which is an optimal transportation distance with an entropic regularization term. The second method is based on the assumption that word embedding spaces are approximately isometric (Vulić et al., 2020), and on an isometric-invariant method known as Persistent Homology (Edelsbrunner, 2013). Each sentence is represented by the distances between its own word embeddings (either static or contextual). The created distance matrices are compared using the Wasserstein distance between their persistence barcodes (the output of persistent homology computation). Finally, the two methods are linearly combined.

TUDa (T1): TUDa's submissions are produced with pre-trained multilingual language models which they extended to new languages and unseen scripts using recent adapter-based methods.

5 Results

5.1 Task 1

Submissions for Task 1 are **evaluated** against the true z-normalised direct assessment label using Pearson's r correlation score as primary metric. This is what was used for ranking system submissions. Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) were also computed as secondary metrics. Statistical significance on Pearson r was computed using William's test.[8]

Table 4 summarises the results for all language pairs, as well as the multilingual variant, in terms of Pearson's r correlation with direct assessments, ranking systems by their average performance for all language pairs (using 0 as Pearson score for other languages). In the Appendix, Tables 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19 and 20 provide the detailed results for all language pairs and the multilingual variant, ranking participants by their performance for each of these cases.

Best performers The best system varies slightly across language pairs, with QEMind winning the multilingual task, i.e. the average performance for all language pairs (including zero-shot). Overall, the three top performing systems, QEMind, HW-TSC and IST-Unbabel, perform very closely on average, and also for each given language. The three make use of the XML-R large pre-trained representations in a predictor-estimator fashion, and model ensembling. Another recurring theme is to explore data augmentation (QEMind and HW-TSC) and model uncertainty (QEMind and IST-Unbabel). While the baseline system also uses XLM-R as predictor, it uses its 'base' version, and only the provided 'train' part of the data to train the estimator. In addition, it does not resort to ensembling.

Table 4: Pearson correlation with direct assessments for the submissions to WMT21 Quality Estimation Task 1. For each language pair, results marked in bold correspond to the winning submissions, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey; ‡ indicates Codalab username of participants from whom we have not received further information.

To gain a better understanding in the performance of different QE approaches for different language pairs, Figure 2 shows the scatter plots for the baseline and the best performing system for each language pair.

The performance of all except four systems is substantially better than that of the baseline system for all languages. The systems below the baseline correspond to unsupervised systems (Bergamot, Bergamot-UTartu - using NMT glass-box features; and SMOB-ECEIIT, using alignment over XLM-R representations), as well as RTM, which does not rely on pre-trained representations altogether.

Zero-shot languages On the zero-shot languages, the performance was comparable to those of the average non-zero-shot language pairs, except for the En-Ja language pair, where it was substantially lower. Most systems achieved such good performance by relying on multilingual prediction models trained on cross-lingual representations from XLM-R. With En-Ja, we believe there may have been an issue with the segmentation of the Japanese data after translation, which led to annotation issues and/or issues of mapping of characters against the vocabulary of pre-trained language models. We will investigate this further.

High vs low-resource performance Similar to last year, MT quality for the high-resource language pairs, in particular En-De but also En-Zh, proved to be more challenging to predict. This could be an indication of less variability in the MT outputs for these language pairs, given that the NMT models are likely to perform overall well for these languages. This would lead to little variability in perceived MT quality by humans, and thus a harder data to learn from. Interestingly, this also seemed to be the case in the zero-shot QE setting for En-Cs, which is relatively higher resource than Ps-En and Km-En. We observe that these differences in correlation also happen with the HTER predictions for these language pairs (see the analysis of the sentence level task in §5.2 and Table 5).

All medium and low and medium-resource language pairs achieve high correlations, in particular in the supervised settings with Ro-En and Ne-En. This again is an indication of the potential of multilingual or cross-lingual pre-trained representations. It could also indicate that the models (and human annotators to some extent) rely heavily on the target language (English), which is well represented in the pre-trained representations.

High correlations Just like in WMT2020, the very high correlation for some language pairs, particularly for Ro-En (r = 0.91) but also for Ne-En (r = 0.87) could be explained by the fact that there is a number of very low-quality sentences that the QE systems are able to successfully detect. Esp. for Ro-En, we find that they correspond to 'hallucinated' outputs that do not have anything to do with the original sentences. Detecting such cases should be trivial for QE systems, which explains the particularly high correlation values for this language pair.

5.2 Task 2

Sentence-level post-editing effort For this task variant, **evaluation** was performed against the true HTER label using the same metrics as in Task 1, with Pearson's r correlation score as the primary metric. Table 5 summarises the results for all language pairs, including the multilingual performance. Systems are ranked by their averaged performance over all language pairs based on the Pearson r coefficient. Statistical significance on Pearson r was computed using the William's test. In the Appendix, Tables 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31 and 32 provide the detailed results for all language pairs and the multilingual variant, ranking participants by their performance for each of these cases. Note that for the *multilingual* track (Table 21 and 1st column of table 5) we present only the performance of systems that submitted multilingual models (HW-TSC and IST-Unbabel) for that specific track.

Best performers Both multilingual system submissions outperform the monolingual approaches in the individual language pairs, with HW-TSC ranking first for the majority of the 'supervised' language pairs (En-De, En-Zh, Ne-En, Si-En and Ru-En) as well as the multilingual track and IST-Unbabel leading the majority of the zero-shot language pairs (En-Cs, En-Ja, Ps-En). Apart from the multilingual aspect, the two top systems have more in common: they both use the Predictor-Estimator framework with XLM-Roberta encoders for the predictor and task-specific classifiers for the estimator. Additionally, they both address the sentence- and word-level task using a multi-task approach. HW-TSC enhances their approach using additional pseudo-references as input (generated by another NMT system), while IST-Unbabel system uses additional external data from the WMT Metrics shared task and incorporate adapters in their architecture.

Overall, submitted systems used a variety of approaches to improve performance and address the zero-shot tasks, which revolved around augmenting the training data either by including synthetic data (Bergamot-UTartu, POSTECH) and/or external data (IST-Unbabel) or by using pseudo-references generated by other MT systems (ENSBRT, HW-TSC, JHU-Microsoft). Additionally, ensembling approaches were used to boost performance (HW-TSC, ENSBRT, IST-Unbabel).

Figure 3 shows the scatter plots for the baseline and the best performing system for each language pair. We can see that in most language pairs (perhaps with the exception of En-Zh) the scatter plots for the 'Top' system are much narrower and closer to the identity line, compared to these for the corresponding baseline. More importantly, language pairs with a high proportion of HTER score values close to 0 (many segments without post edits) prove to be more challenging for the submitted models. For example, comparing En-Zh, Ru-En against En-De to Si-En, Ne-En and Et-En, we can see that the latter have narrower, better correlated scatter plots in Figure 3, which is reflected in higher performance in Table 5. This observation seemingly extends to the zero-shot languages, where we observe that performance for the Km-En language pair is consistently higher for all systems compared to the other zero-shot pairs.

Word-level errors For this task, the primary **evaluation** metric is Matthews correlation coefficient (MCC, Matthews, 1975). We also report the F_1-scores for the OK and BAD classes. Similarly to the previous editions, we evaluate separately the source and target side, and this year we also provide a separate evaluation for the target gap tag predictions. We also calculate the performance for combined gaps and words in MT, although it was not considered in the overall ranking process. Systems are primarily ranked by their MCC performance for the word tags on the target side (denoted as 'Words in MT' in the tables). The word-level results for Task 2 are summarised in Tables 6, ordered by the MCC metric, while in the Appendix, Tables 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43 and 44 provide the detailed results for all language pairs and the multilingual variant, ranking participants by their performance for each of these cases. Statistical significance was calculated based on the MCC metric for each language pair using randomization tests with Bonferroni correction (Yeh, 2000a).

Best performers For the multilingual track the picture is similar to the sentence level sub-task, with the HW-TSC system ranking first across all performance indicators, and also leading most of the individual language pairs. Apart from the two multilingual approaches, most of the systems participating in the sentence level sub-task did not submit predictions for the word-level task with the exception of POSTECH which submitted predictions for En-De. However, the JHU-Microsoft which

Table 7: Matthews correlation coefficient with the binary critical error labels for the submissions to WMT21 Quality Estimation Task 3. For each language pair, results marked in bold correspond to the winning submissions, as they are not significantly outperformed by any other system based on William's test. Baseline systems are highlighted in grey; ‡ indicates Codalab username of participants from whom we have not received further information.

was trained only for the target predictions of the word-level task, obtained the best performance in En-De. JHU-Microsoft also seemed to obtain competitive performance for the Et-En and Ro-En tasks, indicating a strength in languages closer to English.

Overall, the performance of the top two systems is closer for the high – and some of the medium – resource languages, both in the supervised and zero-shot tracks (En-De, En-Zh, En-Cs). Much like the WMT20 shared task, the performance for the target word tags is considerably higher compared to the source tags. This phenomenon is observed across language pairs with the exception of Ru-En where predictions for source and target words are close for all systems. This year we can also observe the performance on target gaps separately, which is consistently lower, even when compared to the source tags, across all language pairs and submitted systems.

It is important to note that when focusing on the combined target performance, i.e., the combination of word and gap quality predictions for the MT, the order and performance differences between the top scoring teams can vary compared to the MT word prediction ones. Overall, there are fewer language pairs where we have a clear winner (Ne-En, Si-En and Km-En for HW-TSC and Cs-En for IST-Unbabel) while for the rest there is no statistically significant difference between the top pairs. Still, HW-TSC is consistently among the top systems, with the exception of Cs-En.

5.3 Task 3

Table 7 summarises the results for all language pairs, ranked by their performance in terms of Matthews correlation coefficient (MCC, Matthews, 1975). In the Appendix, Tables 45, 46, 47 and 48 provide the detailed results for all language pairs, ranking participants by their performance for each of these cases. Statistical significance is calculated using the William's test.

This task attracted fewer participants than the others, most likely because it is new. All described systems perform better than the baseline for all language pairs. Across languages, the order of MCC scores roughly corresponds to the skewness of data distribution obtained for languages: For En-De, which achieved the highest MCC score, the NOT (no error class) accounted for 72% of the training instances, while for En-Ja, with the lowest MCC score, the NOT class accounted for 91% of the training instances.

Best performers NICT Kyoto ranked among the top systems for all language pairs. However, only for En-De it did significantly outperform all other systems. For the rest of the language pairs there could not be a clear winner based on statistical significance testing; HW-TSC was in the top-ranked systems for En-Zh and En-Cs, while for En-Ja no system managed to significantly outperform the others, but they all performed significantly better than the baseline.

In terms of the approaches applied by the best performing systems, they all use the baseline architecture as starting point, but HW-TSC also uses machine translations for the source sentences by top online systems. These are concatenated to the provided source and translation pair. NICT Kyoto also added synthetic data for multiple language pairs with multitask learning and model ensembling. LAMA-ICL used additional features to detect the presence/deviation of toxicity, sentiment and named entities, also followed by ensenbling of models with different individual features.

6 Discussion

In what follows, we discuss the main findings of this year's shared task based on the goals we had previously identified for it.

General progress. Participating systems achieved very promising results for most languages, with the best performing submissions showing moderate to strong correlation for sentence-level DA and HTER prediction tasks. One reason for high correlation levels is likely

to be that top performing systems are based on pre-trained representations. Even for zero-shot languages (see below), relatively high (above 0.5) correlation was achieved for most languages for sentence-level tasks. The same applies for the word-level tasks, where the performance was behind that of supervised prediction, but still high for Km-En and Ps-En.

A comparison to previous years submissions is possible for Task 1 on the non-zero shot languages. The training data is the same and the test sets (test20 and test21) were created at the same time, with data sampled and annotated in the same way. Comparing Pearson correlation scores from the 2020 official results to this year's official results, as we can see from Table 8, for the languages which had already achieved very strong correlations, it remained the same (Ro-En, Et-En, Ru-En) or improved (Ne-En), whereas for the languages with average correlation, it mostly improved substantially (En-De, En-Zh). The exception was Si-En, where the correlation was lower in 2021, which needs further investigation. Overall, we believe the numbers show steady progress over previous models, even though the core of most of the winning systems is the same for the 2020 and 2021 editions.

Model size. When interpreting the results for all tasks, it should be noted that most of the participants use extremely resource-heavy systems, ensembles of multiple models with more than 500M parameters, which could make them difficult to use in practice. In this year's edition of the Shared Task on QE we asked the participants to provide information on the size of their models. Figures 4 and 5 illustrate the performance-efficiency trade-off for the submitted systems. On the x-axis we plot the Pearson correlation with sentence-level DA judgements (Task 1), while the y-axis shows the number of model parameters, as reported by the participants. Pareto-optimal submissions are marked in blue. These plots give us a different view of the performance of the submitted systems. Thus, for the higher quality models, the best results are achieved by QEMind and HW-TSC, whereas Bergamot, Bergamot-UTartu and BASELINE are optimal in terms of model size.

Extending publicly available benchmarks. This year counted with substantial new data. One the one hand, we extended the MLQE-PE dataset with more DA test sets (for all seven previous language pairs and four new zero-shot language pairs), as well as post-editing training and test sets for five additional language pairs (which only had DA scores before), as well as the four zero-shot language pairs. On the other hand, we created sizeable data for the new Task 3, a unique set focusing on critical errors, based on three annotations by professional translators. We hope that others will also contribute by adding new languages to this dataset in the future.

Zero-shot prediction. For the first time, we introduced language pairs for which no training data was available. This challenge was addressed mainly in two ways: synthetic data creation with using parallel data for the relevant languages, and use of indicators coming from the NMT system for unsupervised prediction. Overall, the performance for these languages was surprisingly good (except for En-Ja, potentially for data segmentation issues), comparable to non-zero-shot languages in the dataset. We attribute this high performance mostly to the use of fine-tuning on synthetic data for the relevant languages. In future editions, we may consider blinder zero-shot settings where participants will not be informed of the actual languages the models will require to predict the quality for, to encourage the development of truly multilingual or language-agnostic models.

Critical error detection. We posit that the detection of critical errors is a very important problem for two main reasons: (i) high-quality NMT models may produce fluent translations that may appear very good, but contain localised errors which are not always obvious and may go unnoticed, even by human translators post-editing the translation; and (ii) certain types of content are particularly challenging for MT models, such as social media data posts containing named entities, and could lead to critical errors especially if translations are to be used without human editing. While in the past we have provided word-level QE tasks where errors were annotated not only with error categories, but also error severity (e.g. MQM data in last year's WMT QE Task 3), this was the first attempt to predict specifically (and only) critical errors. This seems a much harder problem, as we expect the QE model to be able not only to find errors, but to distinguish minor (and even major) errors from critical errors. That was the reasoning for our "simplification" of the task this year, i.e. for making

Shared task	En-De	En-Zh	Ro-En	Et-En	Ne-En	Si-En	Ru-En
WMT 2021	**0.58**	**0.60**	0.91	0.81	**0.87**	0.61	0.81
WMT 2020	0.55	0.54	0.91	0.82	0.82	**0.68**	0.81

Table 8: Pearson correlation with direct assessments - comparison between top submission in 2020 and 2021. While the test set is different, it was taken from the same distribution. The training set is the same.

Pareto optimal submissions are marked in blue, while the rest are shown in red.

it a sentence-level binary classification problem. This might be enough for filtering purposes, i.e. to avoid offering/using automatic translations that may contain critical errors. If the goal is to support human translators in the task of post-editing, more fine-grained prediction may be needed.

The overall results for this task in terms of MCC are promising, especially for En-Cs and En-De. Considering the detailed results for this task in Tables 45, 46, 47 and 48, we see that despite the skewed distribution between the two classes, the models achieve a high F1 score at detecting errors, around 0.9 or higher for all language pairs.

7 Conclusions

This year's edition of the QE Shared Task introduced a number of new elements: new data covering five more language pairs with post-edits for sentence and word-level prediction, new test sets for all tasks, including four new zero-shot language pairs, and a new task focusing on critical error detection. Our analysis also paid close attention to model size, an important aspect for deploying QE systems in realistic applications, such as real-time inference and devices with limited resources. The tasks attracted a steady number of participating teams and systems and we believe the overall results are a great reflection of the SotA in QE. Continuing from the effort we set forward last year, this edition the tasks in this edition, with its zero-shot variant, cover a broad range of challenges in QE, such as improving performance for languages with skewed distributions, addressing low (or zero) resource languages, predicting source words that lead to errors, multilingual models, etc.

We are making the gold labels and all submissions to all tasks available for those interested in further analysing the results, investigating approaches for prediction ensembling, among others.

Acknowledgments

Marina Fomicheva and Lucia Specia were supported by funding from the Bergamot project (EU H2020 Grant No. 825303). André Martins and Chrysoula Zerva were funded by the P2020 programs Unbabel4EU (contract 042671) and MAIA contract 045909), by the European Research Council (ERC StG DeepSPIN 758969), and by the Fundação para a Ciência e Tecnologia through contract UIDB/50008/2020. We would like to thank Erick Fonseca for answering questions about data preprocessing, and Marina Sánchez-Torrón and Camila Pohlman for monitoring the post-editing process for English-German, English-Chinese, and Russian-English for Task 2. We thank IQT Labs for providing the Russian-English dataset for Task 1. We thank Genze Jiang for helping with the baseline model for Task 3.

Table 28: Official results of the WMT21 Quality Estimation Task 2 for the **Russian-English** dataset. Teams marked with "•" are the winners, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey. "Rank" indicates the averaged ranking of participants with regards to all metrics (including memory print and number of parameters).

Findings of the WMT 2021 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT

Jindřich Libovický and **Alexander Fraser**
Center for Information and Language Processing
LMU Munich
{libovicky,fraser}@cis.lmu.de

Abstract

We present the findings of the WMT2021 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT. Within the task, the community studied very low resource translation between German and Upper Sorbian, unsupervised translation between German and Lower Sorbian and low resource translation between Russian and Chuvash, all minority languages with active language communities working on preserving the languages, who are partners in the evaluation. Thanks to this, we were able to obtain most digital data available for these languages and offer them to the task participants. In total, six teams participated in the shared task. The paper discusses the background, presents the tasks and results, and discusses best practices for the future.

1 Introduction

For some languages, machine translation (MT) reached such a high quality that allows a discussion of whether and under what circumstance human parity might have been reached (Popel et al., 2020; Läubli et al., 2020). This is the case, however, for only a small minority of the world's language. For most of the 7k languages spoken in the world only very limited resources exist. The goal of the WMT Shared Task on Unsupervised and Very Low Resource MT is to promote research on methods for MT that alleviate such data sparsity in a real-world setup.

A task on unsupervised MT was already held at WMT in 2018 (Bojar et al., 2018) and 2019 (Barrault et al., 2019), where the lack of parallel data was simulated on high-resource language pairs: English–German in 2018 and German–Czech in 2019.

Starting from last year, we cooperate with local communities working on preserving their languages. In cooperation with the Sorbian Institute[1] and the Witaj Sprachzentrum[2], we offered a shared task in translation between German and Upper Sorbian in low-resource and unsupervised tracks (Fraser, 2020). For this year, we kept the low-resource track for Upper Sorbian and added unsupervised translation between German and Lower Sorbian. Upper and Lower Sorbian are minority languages spoken in the east part of Germany in the federal states of Saxony and Brandenburg. Having only 30k and 7k native speakers, processing of the languages is an inherently low-resource problem, without any chance that the size of available resources would ever get close to the size of resources available for languages with millions of speakers. On the other hand, being western Slavic languages, the Sorbian languages can take advantage of existing resources for Czech and Polish.

Additionally, in cooperation with the Chuvash Language Laboratory[3], we added another low-resource task, translation between Russian and Chuvash. Chuvash is a minority Turkic language spoken by approximately one million people in the Volga region in the southwest of Russia. There is a larger amount of training data available for Chuvash, but the language is rather isolated in the Turkic language family, so unlike Sorbian, it cannot benefit that much from the existence of closely related languages.

Five teams participated in the German-Upper Sorbian task, six teams in the German-Lower Sorbian task, and two teams in the Russian-Chuvash task.

2 Tasks and Evaluation

This year, there were three tasks for very low resource and unsupervised translation were:

[1] https://www.serbski-institut.de
[2] https://www.witaj-sprachzentrum.de/
[3] https://en.corpus.chv.su/content/about.html

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 726–732
November 10–11, 2021.

- Very Low Resource Supervised Machine Translation: *German ↔ Upper Sorbian.*
- Unsupervised Machine Translation: *German ↔ Lower Sorbian.*
- Low Resource Supervised Machine Translation: *Russian ↔ Chuvash*.

To make the submissions better comparable with each other, we only allowed using resources released for the task (see Section 3) and resources for related languages commonly used in other WMT tasks. The use of large models pre-trained on large datasets was not allowed. By this decision, we wanted to motivate the participants to find better use of limited language resources.

German↔Upper Sorbian. There is only a very limited amount of parallel data between Upper Sorbian and German. However, because Upper Sorbian is closely related to Czech and Polish, we encouraged the use of all German, Czech and Polish data released for WMT. Other parallel data released from the WMT News Task were also allowed, but the participants were recommended not to use them. Unlike last year, there was no unsupervised task for Upper Sorbian.

German↔Lower Sorbian. For this task, no parallel training data were available, as the only available Lower Sorbian data were monolingual. Lower Sorbian is closely related to other Western Slavic languages, so the same related language data as for the Upper Sorbian task was allowed.

Russian↔Chuvash. The Chuvash language is not that critically low-resource as the Sorbian languages, but it is still affected by being a minority language. The participants were provided with parallel and monolingual data that we released for the task. Additional data that might be used: Chuvash-Russian part of the JW300 corpus (Agić and Vulić, 2019). In addition, the participants were encouraged to use the Kazakh–Russian corpus and monolingual Kazakh data from WMT19 (Barrault et al., 2019) and monolingual Russian data made available for the WMT News tasks.

Evaluation. Following the recent literature on MT evaluation (Mathur et al., 2020; Marie et al., 2021; Kocmi et al., 2021), we evaluate the systems using multiple evaluation measures, both string-based and model-based, and perform statistical testing to decide the ranking of the systems. In particular, we use the BLEU Score (Papineni et al., 2002), chrF score (Popović, 2015) as implemented in SacreBLEU (Post, 2018).[5] Further, we evaluate the models using BERTScore (Zhang et al., 2020)[6] with XLM-RoBERTa Large (Conneau et al., 2020) as an underlying model for German and Russian

Dataset	# lines	# chars.
German↔Upper Sorbian		
WMT20 parallel data	60k	11M
Parallel data provided by the Witaj Sprachzentrum, collected for the development of its own tranlator SoTra[4].		
Additional parallel data	87k	17M
Additional parallel Witaj Sprachzentrum collected since the last year.		
Sorbian Institute mono	340k	39M
Upper Sorbian monolingual data provided by the Sorbian Institute. This contains a high quality corpus and some medium quality data which were mixed together.		
Witaj mono	222k	19M
Upper Sorbian monolingual data provided by the Witaj Sprachzentrum (high quality).		
Web monolingual	134k	12M
Upper Sorbian monolingual data scraped from the web by CIS, LMU. This should be used with caution, it is probably noisy, it might erroneously contain some data from related languages.		
German↔Lower Sorbian		
Sorbian Institute mono	145k	14M
The sentences come from the Lower Sorbian reference corpus and were provided by the Sorbian Institute.		
Russian↔Chuvash		
Parallel corpus	714k	181M
A parallel corpus being collected by the Chuvash Language Laboratory since 2016 with the goal of promoting automatic processing of Chuvash.		
Bilingual dictionary	74k	182k
Monolingual Chuvash	5.6M	749M
The dataset contains monolingual sentences from various publicly available sources including Wikipedia, web crawl and fiction.

Table 2: Overview of the method used by the task participants. SP stands for SentencePiece, BT for backtranslation.

and mBERT (Devlin et al., 2019) for Chuvash. We conduct the significance test using bootstrap resampling (Koehn, 2004) at a significance level of 0.95.

The final ranking is determined by the number of points each system gets. The systems get one point for each system that is significantly worse in each of the metrics. This means that if a system is significantly better than 1 system in the BLEU score, 2 systems in the chrF score, and 3 systems in the BERTScore, it gets 6 points in total.

3 Data

Upper Sorbian. The data for this task was provided by the Sorbian Institute (monolingual data) and The Witaj Sprachzentrum (Witaj Language Center) (both parallel and monolingual data).

The development and test data for Upper Sorbian are the same as the last year. There was a different blind test set than the last year.

Lower Sorbian. As far as we know, there is no parallel data for Lower Sorbian except for the development and test data provided for this task.

Chuvash. The validation data are sampled from the training set. The development test data and blind test data were also sampled from the parallel corpus and manually filtered by a native speaker.

In addition to the described data, the use of other parallel and monolingual data available for WMT News Tasks was allowed (see Section 2).

4 Submitted systems

Six teams participated in the shared task, five teams in Upper Sorbian-German, slightly different five in Lower Sorbian-German, and two in the Russian-Chuvash direction. An overview of the systems is in Table 2, a brief description of the systems follows. For detailed information, we refer the reader to the respective system description papers.

NoahNMT (Zhang et al., 2021b). NoahNMT submitted their systems into the supervised tasks. The NoahNMT submission is a standard Transformer model equipped with our recent technique of dual transfer (Zhang et al., 2021a). Compared to other systems, these submissions used a significantly larger amount of monolingual data.

NRC-CNRC (Knowles and Larkin, 2021). The Upper Sorbian-German system is an ensemble of eight systems with 25k BPE vocabulary, incorporating transfer learning (from cs–de) with continued training, monolingual data filtering, back-translation (Sennrich et al., 2016), BPE-dropout (Provilkov et al., 2020), and multilingual models.

Upper Sorbian → German

Team	BLEU	chrF	BERTScore	Points

LMU	20.9 0	50.1 0	.856 0	0

Table 3: The main results of the task. Points awarded in the particular metrics are in gray.

In the opposite direction, the submission is an ensemble of 7 systems. The Lower Sorbian-German and German-Lower Sorbian systems are ensembles of 2 and 4 systems, respectively, with 20k BPE vocabulary, incorporating transfer learning from hsb–de and de-hsb systems along with iterative backtranslation.

IICT-Yverdon (Atrio et al., 2021). The system used the Transformer architecture with back-translation of large German corpora and parent-language initialization using Czech-German data. The final submission is an ensemble of different models with some changes in their training setups to maximize the diversity among the models.

CFILT. The submitted systems cover four language pairs: German↔Upper Sorbian German↔Lower Sorbian. For de↔hsb, the system pre-trained using the MASS objective (Song et al., 2019) and finetuned using iterative back-translation. Final finetuning is performed using the provided parallel data for translation objective. For de↔dsb, no parallel data is provided in the task. The final de↔hsb model is used for initialization of the de↔dsb model, which is further trained using iterative back-translation, using the same vocabulary as used in the de↔hsb model.

CL_RUG (Edman et al., 2021). CL_RUG's submission uses the MASS model, focusing pre-training on 2 languages at a time, from least to most related to Lower Sorbian. The largest improvement comes from a novel method for initializing the Lower Sorbian word embeddings from Upper Sorbian, using a bilingual dictionary created in an unsupervised fashion.

LMU Munich (Libovický and Fraser, 2021). The LMU submissions for all tasks are Transformer models first pre-trained on related languages and then finetuned on the low-resource languages. For the Sorbian languages, the systems are pre-trained on German–Czech translation. The system is fine-tuned using the authentic German–Upper Sorbian data, which is the starting point for four iterations of tagged back-translation. The unsupervised German–Lower Sorbian translation is trained by iterative backtranslation using the monolingual data only. The Upper Sorbian–German system is used to generate the first translation of Lower Sorbian. The Russian–Chuvash systems were pretrained on Russian–Kazakh translation and finetuned using the provided parallel data.

5 Results

The results are presented in Table 3. The most successful teams were NRC-CNRC, which was the best or on par with the best systems in all Sorbian

tasks, and NoahNMT which were the best in the Chuvash tasks, on par with the best systems in German-Upper Sorbian translation and the second in the Upper Sorbian-German direction.

In German-Upper Sorbian translation, the best two system, NRC-CNRC and NoahNMT reach very similar results although they use significantly different sizes of monolingual data for backtranslation. NRC-CNRC manage to compensate for the smaller data size by accumulating minor tricks including monolingual data selection (Moore and Lewis, 2010), tagged backtranslation (Caswell et al., 2019), BPE dropout (Provilkov et al., 2020), and language tags in multilingual training. LMU, which used data of a similar size to NRC-CNRC but did not use most of the further tricks, ranked below these two.

In Upper Sorbian-German translation, all teams used German-Czech parallel data for pre-training, except for CFILT who only used monolingual data for pre-training and scored 0 points in both directions.

In the unsupervised German-Lower Sorbian task, CL_RUG ranked on par with NRC-CNRC in translation into German (despite not using ensembling), but at third place in the opposite direction. This suggests that CL_RUG's innovative vocabulary transfer method works better on the encoder side than on the decoder side.

In the Russian-Chuvash translation, NoahNMT outperformed LMU Munich by using larger datasets and a more advanced transfer learning technique.

6 Conclusions

In WMT 2021 shard task on Unsupervised and Very Low Resource MT, we created realistic benchmarks for low-resource minority language which reflect the needs of the language communities trying to preserve their languages. In the task, we provided the participants with comprehensive resource for translation between German and Upper and Lower Sorbian and for translation between Russian and Chuvash. We hope that this will increase the interest of the community in these languages.

The six teams that participated in the task used state-of-the-art MT techniques to develop high quality systems. The main technical takeaway from the results are that pre-training on parallel data in related language is important and that carefully applying known tricks can to a large extent compensate for using smaller datasets.

Acknowledgments

This work was also supported by the European Research Council under the European Union's Horizon 2020 research and innovation program (grant agreement #640550) and by the DFG (grant FR 2829/4-1). Thanks very much to coorganizers: Hauke Bartels – Sorbian Institute, Olaf Langner – Witaj Sprachzentrum, Marcin Szczepanski – Sorbian Institute, Alexander Antonov – Chuvash Language Laboratory. Many thanks also to Tom Kocmi and Christian Federmann from Microsoft for providing an instance of Ocelot for the system submissions.

Abstract

This paper presents the results of the WMT21 Metrics Shared Task. Participants were asked to score the outputs of the translation systems competing in the WMT21 News Translation Task with automatic metrics on two different domains: news and TED talks. All metrics were evaluated on how well they correlate at the system- and segment-level with human ratings. Contrary to previous years' editions, this year we acquired our own human ratings based on expert-based human evaluation via Multidimensional Quality Metrics (MQM). This setup had several advantages: (i) expert-based evaluation has been shown to be more reliable, (ii) we were able to evaluate all metrics on two different domains using translations of the same MT systems, (iii) we added 5 additional translations coming from the same system during system development. In addition, we designed three challenge sets that evaluate the robustness of all automatic metrics. We present an extensive analysis on how well metrics perform on three language pairs: English→German, English→Russian and Chinese→English. We further show the impact of different reference translations on reference-based metrics and compare our expert-based MQM annotation with the DA scores acquired by WMT.

1 Introduction

The metrics shared task[1] has been a key component of WMT since 2008, serving as a way to validate the use of automatic MT evaluation metrics and driving the development of new metrics. We evaluate reference-based automatic metrics that score MT output by comparing the MT with a reference translation generated by human translators, who are instructed to translate "from scratch" without post-editing from MT. In addition, we also invited submissions of reference-free metrics (quality estimation metrics or QE metrics) that compare MT outputs directly with the source segments. All metrics are evaluated based on their agreement with human rating when scoring MT systems and human translations at the system or sentence level. This year, we implemented several changes to the methodology that was followed in previous years editions of the task:

- **Expert-based human evaluation** This year, we collected our own human ratings for selected language pairs (en→de, en→ru, zh→en) from professional translators via MQM (Lommel et al., 2014). As shown before (Freitag et al., 2021), this produces more reliable[2] scores when compared to the DA-based human ratings acquired by the WMT News-Translation task. This step was necessary as Freitag et al. (2021) suggested that some automatic metrics already outperform (taking MQM as the golden standard) the DA-based human ratings that were usually used in the past for the metrics task and thus the DA-based ground-truth may be of lower quality than some of our submissions.

- **Additional Training Data** We encouraged the participants to further fine tune or test their metrics on the already existing MQM annotations for newstest2020 (Freitag et al., 2021)[3].

- **Additional domain** Since we collected our own human ratings, we were also able to expand the domain of the test sets beyond news and evaluate the performance of the metrics on translations of the same MT systems on TED talks, in order to test the generalization power of metrics.

[1] http://www.statmt.org/wmt21/metrics-task.html

[2] DA is unreliable for high-quality MT output; ranks human translations lower than MT; correlates poorly with metrics. Expert-based MQM ranks human translations higher than MT and correlates generally much better with automatic metrics.

[3] https://github.com/google/wmt-mqm-human-evaluation

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 733–774
November 10–11, 2021.

- **Additional MT systems** One use case for automatic metrics is choosing the better among different model versions of the same MT system during system development. To address this scenario, in addition to the WMT submissions and online systems, we added extra development systems to the set of MT systems on which we evaluated the metrics.

- **Additional challenge sets** We generated three challenge sets containing specific translation errors that are believed to be challenging for automatic MT evaluation metrics to identify. These challenge sets test metrics robustness on several different phenomena such as sentiment polarity, antonym replacement, named entities, among others.

- **Designated primary metrics** Participants had to designate a single metric as their primary submission for each track (reference-free and unconstrained). Other submissions were permitted, but only the primary metric is included in the official main results.

- **Accuracy for ranking system pairs** We calculate a joint score across all language pairs and adopt the pairwise accuracy score for ranking system pairs to generate the final metric ranking (Kocmi et al., 2021).

Our main findings are:

- WMT direct assessment (DA) scores generally correlate poorly with MQM scores, and exhibit weaker preference for human translations compared to machine output. In particular for English→German and Chinese→English, the two human evaluations methodologies produce very different rankings (Tables 16 and 18). In both language pairs, DA ranks the human translations below many MT systems, demonstrating again that expert-based evaluation is needed to generate a reliable ground truth for metric development for high quality language pairs.

- The majority of automatic metrics correlate better with MQM than the DA scores from WMT. This confirms the findings of Freitag et al. (2021) that automatic metrics are already more reliable than non-expert human evaluations. A metrics task with ground truth ratings acquired by non-experts would consequently not be very helpful.

- The performance of many metrics largely varies depending on the underlying domain (being either news or TED talks), resulting in distinct clusters of winning metrics for these two domains. All metrics of the winning cluster on the news domain show lower correlation with human ratings when switching to the TED talks domain (Table 8). Lower ranked metrics are more robust and can sometimes even improve the correlation to humans on the TED domain.

- Trainable embedding-based metrics are typically better at rating and correctly ranking (with respect to MQM golden truth) human-generated translations. (Table 8).

- Reference-free metrics, in particular COMET-QE and OpenKiwi perform very well when human translations are included in the setup. Nevertheless, once we focus on MT output only, reference-free metrics perform worse compared to reference-based metrics (Table 8).

- Reference-based metrics performance is significantly worse when reference translations contain major errors (Table 13).

- Some metrics are more robust than others when presented with alternate reference translations (Table 14). It is unclear so far what characterizes a good reference translation in addition to the clear requirement of fidelity of the translation to the source.

- When counting top performances across different language pairs, granularities, and test conditions (Table 12), three embedding-based metrics—C-SPECPN, BLEURT-20[4], and COMET-MQM_2021— emerge as distinctly better than the others, especially at the segment level and when rating human translations. Reference-free metrics are also relatively good at rating human translations, but under-perform at segment-level. Metric performance is distributed more evenly on

[4]BLEURT-20 denotes the new retrained version of BLEURT which is different from last years BLEURT submission (Sellam et al., 2020)

system-level tasks, especially when the test set is out-of-domain.

- Most metrics struggle to accurately penalize translations with errors in reversing negation or sentiment polarity (Table 9).
- Of the 14 linguistically motivated categories represented in the challenge sets, high-performing metrics have lower correlations for *Subordination* and *Named Entities and Terminology* (Tables 10 and 11).
- MQM annotations on TED data, both between annotation setups (Google and Unbabel) and between annotators themselves, show relatively low levels of agreement. However, we note that many of the system rankings remain relatively consistent; critically we note that the human reference comes out on top in both setups and that resulting metrics ranking is not significantly affected. This indicates that whilst MQM is an attractive framework for evaluation, the annotation task itself is still subject to human disagreement, especially on challenging content. TED talks in particular are highly specialized and ambiguous, presenting a unique challenge for annotators and evaluation.

2 Data

Similar to the previous years' editions, the source, reference texts, and MT system outputs for the metrics task are mainly derived from the WMT21 News Translation Task. This year, we expand the domain and evaluate the same MT systems on an additional out-of-domain data – TED talks, for our three primary language pairs: English→German, English→Russian and Chinese→English. In addition to the MT system outputs from the WMT evaluation campaign, we added translations from five additional MT systems that represent different versions of the same system during system development.

2.1 WMT Test Sets

The Newstest2021 set contains between 1000 and 2000 segments for each translation direction. All test sets are from the news domain. The reference translations provided for Newstest2021 were created in the same translation direction as the MT systems. We have two reference translations for English→Russian and Chinese→English and four reference translations for English→German. For more details regarding the news test sets, we refer the reader to the WMT21 news translation task findings paper.

2.2 TED Talks Test Suite

A long standing question about automated MT evaluation metrics has been whether metrics *generalize and perform well across domains*. In the past, metrics were mostly tested on news translation evaluation. The WMT2016 metrics shared task (Bojar et al., 2016) experimented on the IT and medical domains but the number of MT systems involved were small (2-10 in each translation direction). Thus, there was insufficient statistical evidence collected for a detailed analysis on how well metrics perform in different domains.

In an attempt to conduct a detailed analysis on the robustness of metrics when evaluating translations in a domain other than news, we generated and provided an additional test suite for translation by the MT systems participating in the news translation task, consisting of transcriptions of TED talks. The TED domain is quite different from the news domain, particularly in its more informal and disfluent language style, yet it covers a wide variety of topics and vocabularies.

The TED talk transcripts translation test set was extracted from OPUS[5] based on the corpus released by Reimers and Gurevych (2020). The English TED talk transcripts were translated by volunteers into multiple languages. To minimize the problem of translationese as the source for the Chinese→English part of the test suite, we had a first-language Chinese speaker select talks with Chinese translations that were judged to be natural-sounding in Chinese. (Unfortunately, there are still some problems in the translation quality for the Chinese→English part of the test suite which we will further discuss in Section 8.1.1.) Then, the same talks were extracted from the corpus to create the English→German and English→Russian parts of the test suite, where the translation was already available in the corpus and the quality of the translation was approved by professional translators. Table 1 shows the basic statistics of the TED talks test suite.

2.3 Additional MT Output

One major use case for automatic metrics is choosing among different versions of the same system during system development. We translated all test sets for all language pairs with five different versions of the same system which we call *metricsystem{1,..,5}*. The underlying NMT models are trained on unconstrained training data and the model variations include baseline models, fine-tuned models and models considering document context. As we will see, the quality performance of these systems and their relative rankings can be quite different depending on the language pair, as these were not trained to yield the highest performance on the news or TED domain.

3 MQM Human Evaluation

Automatic metrics are usually evaluated by measuring correlations with human ratings. The quality of the underlying human ratings is critical and recent findings (Freitag et al., 2021) have shown that crowd-sourced human ratings are not reliable for high quality MT output. Furthermore, an evaluation schema based on MQM (Lommel et al., 2014) which requires explicit error annotation is preferable to an evaluation schema that only asks raters for a single scalar value per translation. Contrarily to the previous versions of the WMT metrics task, for our primary evaluation this year, we decided not to use the crowd-sourced DA human ratings from the WMT News Translation task, and conducted our own MQM-based human evaluation on a subset of submissions and a subset of language pairs that are most interesting for evaluating current metrics. This not only had the advantage of more reliable ratings for a subset of language pairs, but also gave us the opportunity to run the same human evaluation on a different domain (TED talks) on output generated by the same MT systems, in order to test the generalization capabilities of the metrics.

MQM is a general framework that provides a hierarchy of translation errors which can be tailored to specific applications. Google and Unbabel sponsored the human evaluation for this year's metrics task for a subset of language pairs using either professional translators (English→German, Chinese→English) or trusted and trained raters (English→Russian). The error annotation typology and guidelines used by Google's and Unbabel's annotators differs slightly and is described in the following two sections.

3.1 English→German and Chinese→English

Annotations for English→German and Chinese→English were sponsored and executed by Google, using 23 professional translators (14 for English→German, 9 for Chinese→English) with access to the full document context. Instead of assign a scalar value to each translation, annotators were instructed to "just" label error spans within each segment in a document, paying particular attention to document context. Each error was highlighted in the text, and labeled with an error category and a severity. To temper the effect of long segments, we imposed a maximum of five errors per segment, instructing raters to choose the five most severe errors for segments containing more errors. Segments that are too badly garbled to permit reliable identification of individual errors are assigned a special *Non-translation* error. Error severities are assigned independent of category, and consist of *Major*, *Minor*, and *Neutral* levels, corresponding respectively to actual translation or grammatical errors, smaller imperfections, and purely subjective opinions about the translation. Since we are ultimately interested in scoring segments, we adopt the weighting scheme shown in Table 2, in which segment-level scores can range from 0 (perfect) to 25 (worst). The final segment-level score is an average over scores from all annotators. For more details, exact annotator instructions and a list of error categories, we refer the reader to Freitag et al. (2021) as the exact same setup was used for the WMT21 metrics task.

Severity	Category	Weight
Major	Non-translation	25
	all others	5
Minor	Fluency/Punctuation	0.1
	all others	1
Neutral	all	0

Table 2: Google's MQM error weighting.

3.2 English→Russian

Annotation for English→Russian was performed by Unbabel who used a single professional native language annotator with several years of translation error experience based on variations of the MQM framework (Lommel et al., 2014). For this task, Unbabel provided a proprietary variant of MQM, specifically tailored for Russian language annotation. In a manner similar to the Google annotation, the annotator was given full document context and instructed to highlight spans of errors according to the categories specified in the typology. As with the Google annotation, the annotator was also instructed to indicate error severity. The Unbabel severity options differ slightly from that of Google in that we also specify a 'critical' error severity and do not specify a 'neutral' category. Additionally, in the Unbabel typology, all error categories are weighted equally within each severity level.

MQM scores at a segment level are calculated by summing the number of errors in the segment in each severity and applying a severity weight as described in Table 3. In contrast to the Google scheme, Unbabel does not impose a limit on the number of errors in a segment. We do, however, apply a normalization of the score by segment length. The full score calculation is shown in Equation 1 below:

$$\text{MQM} = 100 \cdot (1 - \frac{10 \cdot \#critical + 5 \cdot \#major + \#minor}{\#tokens}) \quad (1)$$

The same type of MQM annotations were previously used in the WMT QE shared tasks for the document-level subtask (Fonseca et al., 2019; Specia et al., 2020a) also sponsored by Unbabel.

Severity	Category	Weight
Critical	all	10
Major	all	5
Minor	all	1

Table 3: Unbabel's MQM error weighting.

3.3 Human Evaluation Results

As discussed in Section 1, we decided to run our own human evaluation in order to generate our golden-truth ratings and come to stronger conclusions about the quality of each automatic metric across two domains. Unfortunately, this also meant that we were only able to evaluate a subset of documents of newstest2021 and TED talks. In Table 4, you can see the number of segments for each language pair and test set that we used for human evaluation.

language	news	TED
en→de	527/1002	529/606
en→ru	527/1003	512/684
zh→en	650/1948	529/843

Table 4: Numbers of MQM-annotated segments for each test set.

The results of the MQM human evaluation can be seen in Table 5. Most of the reference translations are ranked first, surpassing all MT systems, except for *ref-B* for zh→en TED talks and *ref-A* for en→de newstest2021. This confirms the findings in Freitag et al. (2021) that when human evaluation is conducted by professional translators and MQM, high-quality human translations typically still outperform MT. We will discuss the impact of the identified low-quality reference translations in Section 8.1.1 in more detail. We wish to highlight one more important observation: the ranking of the MT systems is sharply different when switching from the commonly used Newstest2021 test sets to TED talks. This is particularly interesting for the metrics task, as metrics need to assess MT quality purely on the basis of the translations themselves and cannot rely on features that are specific to any particular MT system. We will analyse the differences between Google's and Unbabel's MQM approach in Section 8.2 and compare our MQM human evaluation with the DA assessment from WMT in more detail in Section 8.3.

4 Metric Submissions and Baselines

4.1 Baselines

SacreBLEU baselines We use the following metrics from the SacreBLEU *v1.5.0* (Post, 2018) as baselines, with the default parameters:

- BLEU (Papineni et al., 2002) is the precision of n-grams of the MT output compared to the reference, weighted by a brevity penalty to Using SacreBLEU we obtained sentence-BLEU values using the `sentence_bleu` python function and for corpus-level BLEU we used `corpus_bleu`. Both functions were used with the default arguments.[6]

Table 5: MQM human evaluations for Newstest2021 and TED. Lower average error counts represent higher MT quality for En→De and Zh→En (using Google's formulation of MQM), while higher scores represent higher quality for En→Ru (using Unbabel's MQM definition).

- TER (Snover et al., 2006) measures the number of edits (insertions, deletions, shifts and substitutions) required to transform the MT output to the reference. As in BLEU, for TER we used SacreBLEU `sentence_ter` and `corpus_ter` functions (with default arguments[7]) to obtain segment-level and system-level scores.

- CHRF (Popović, 2015) uses character n-grams instead of word n-grams to compare the MT output with the reference. For CHRF we used the SacreBLEU `sentence_chrf` function (with default arguments[8]) for segment-level scores and we average those scores to obtain a corpus-level score.

BERTscore BERTSCORE (Zhang et al., 2020) leverages contextual embeddings from pre-trained transformers to create soft-alignments between words in candidate and reference sentences using a cosine similarity. Based on the alignment matrix, BERTSCORE returns a precision, recall and F1 score. We used F1 without TF-IDF weighting.

Prism PRISM (Thompson and Post, 2020) is an automatic MT metric which uses a sequence-to-sequence paraphraser to score MT system outputs conditioned on their respective human references. We used the default parameters with version 0.1 and model *m39v1*.

4.2 Submissions

The rest of this section summarizes participating metrics.

COMET All COMET* metrics (Rei et al., 2021) were built using the Estimator architecture presented in Rei et al. (2020a,b). The difference between all the submitted metrics stem from: the data used for training, the size of the encoder model and whether or not they take advantage of the reference translation.

- COMET-DA_2020 is the same model submitted for last year's shared task (Rei et al., 2020b; Mathur et al., 2020b) while COMET-DA_2021 is a retrained version of the previous model that includes the DA udgements collected in 2020.

- COMET-MQM_2021 is an MQM adaptation of the COMET-DA_2021 model that further trains for 1 additional epoch on MQM z-scores extracted from the MQM ratings for newstest2020 provided for the task this year.

- COMETINHO-MQM and COMETINHO-DA are lightweight versions of COMET-MQM_2021 and COMET-DA_2021 respectively, which use a distilled version of XLM-RoBERTa as the encoder.

Table 6: Baseline metrics and participants of WMT21 Metrics Shared Task.

- Finally, COMET-QE-MQM_2021 and COMET-QE-DA_2021 are the reference-free versions of COMET-MQM_2021 and COMET-DA_2021 respectively.

From all the submitted models, the authors identified COMET-MQM_2021 and COMET-QE-MQM_2021 as their primary submissions to this years shared task edition.

OPENKIWI-MQM OPENKIWI-MQM (Kepler et al., 2019; Rei et al., 2021) is a multitask model that estimates a sentence-level MQM score along with word-level OK/BAD tags. The model is trained on top of XLM-RoBERTa using proprietary MQM data from several customer support domains. While word-level QE typically tags each word with an OK/BAD tag depending on post-edition information (Specia et al., 2020a), the OK/BAD tags used in OPENKIWI-MQM are derived directly from MQM annotation spans ignoring error types and/or severities.

YISI YISI (Lo, 2019) is a unified semantic MT quality evaluation and estimation metric for languages with different levels of available resources.

- YISI-1 is a reference-based MT evaluation metric. It measures the semantic similarity between a machine translation and human references by aggregating the idf-weighted lexical semantic similarities based on the contextual embeddings extracted from pretrained language models (e.g. BERT, CamemBERT, RoBERTa, XLM, XLM-RoBERTa, etc.).

- YISI-2 is the bilingual, reference-less version for MT quality estimation. It uses bilingual mappings of the contextual embeddings extracted from multilingual pretrained language models (e.g. XLM-RoBERTa) to evaluate the crosslingual lexical semantic similarity between the input and MT output.

YISI is an untrained metric and the submissions this year are the same as those in WMT20. The metric settings are described in Lo (2020) and Lo and Larkin (2020).

MTEQA MTEQA (Krubiński et al., 2021a,b) is an MT evaluation metric that leverages automatically generated questions and answers to assess the quality of MT systems. It builds upon the assumption that a good translation should preserve all of the key information that one can extract from the reference. Based on syntactic structure and NER system, they extract potential answers from the reference, and for each of them generate a human readable question. They then use a question-answering system to provide a new (test) answer given the question and the MT output as the context. The test answer is then compared to the reference answer to obtain the numerical score.

REGEMT REGEMT (Stefanik et al., 2021) is a family of ensemble metrics trained on MQM labels.

- {SRC, TGT}-REGEMT: This ensemble combine selected metrics of surface-, syntactic- and semantic-level similarity as input features to a regression model that estimates a quality assessment. Some of these features are newly introduced and some are based on related work. The reference-free ensemble uses as input features: Source length, Target length, Contextual SCM, Contextual WMD, BERTScore, Prism and Compositionality the reference-base ensemble uses: COMET, BLEURT, BLEU, METEOR, Non-contextual SCM and WMD.

- REGEMT-BASELINE: This ensemble uses only Source length and Target length of the given texts, in characters

The authors identified {SRC, TGT}-REGEMT as their primary submissions.

ROBLEURT ROBLEURT (Wan et al., 2021), short for Robustly Optimizing the training of BLEURT, is a model-based metric based on powerful language model XLM-RoBERTa. The ROBLEURT metric is constructed by the following steps: 1) jointly leveraging the advantages of source-included and reference-only metric models, 2) continuously pre-training the model with massive synthetic data produced by the real-world machine translation engines, and 3) fine-tuning the model with a data denoising strategy.

BLEURT BLEURT-20 and BLEURT-21-BETA are obtained by fine-tuning Rebalanced mBERT (Chung et al., 2021) (a multilingual variant of BERT) on a combination of two datasets: previous ratings from the WMT shared, task and generated data. The generated data consists of "perfect" sentence pairs, obtained by copying the reference into the hypothesis, as

well as “catastrophic" sentence pairs, obtained by randomly sampling tokens for each language pair. The fine-tuning methodology is similar to (Sellam et al., 2020). BLEURT-20 was trained on human ratings from WMT metrics 2015 to 2019 (z-scores) using WMT20 for test, and BLEURT-21-BETA was trained on WMT 2015 to 2020. The suffixes “-20” and “-21” denote the year of the WMT Metrics ratings that were used to build the test sets. The authors identified BLEURT-20 as their primary submission.

hLEPOR and cushLEPOR

- HLEPOR (Han et al., 2013) is an augmented metric with factors including enhanced sentence length penalty, precision, recall, and positional difference penalty which captures word order.

- CUSHLEPOR(LM) (Han et al., 2021) is a customized hLEPOR metric that uses LABSE pre-trained language model to automatically optimise hLEPOR parameters towards better correlation to human judgement and lower cost.

- CUSHLEPOR(PSQM) (Han et al., 2021) is trained and validated on the MQM and pSQM annotations from human professionals (Freitag et al., 2021). The tuned cushLEPOR achieves very high agreement to LABSE pre-trained language model in performance but uses much less computational cost as a distilled model.

The authors identified CUSHLEPOR(LM) as their primary submission.

C-SPEC C-SPEC (Takahashi et al., 2021) is designed for both segment-level and system-level translation evaluation. The authors' objective was to design a better metric by detecting significant translation errors that would not be ignored in real instances of human evaluation. Thus, pseudo-negative examples are generated in which selected words in the translation are replaced with alternatives based on a Word Attribute Transfer, and a metric model is built to handle such serious translation errors (denoted as C-SPECPN). A multilingual large pretrained model is fine-tuned on the provided corpus of past years' metrics task and fine-tuned again further on the synthetic negative samples that is derived from the same fine-tuned corpus. The authors identified C-SPECPN as their primary submission.

MEE

- MEE (Mukherjee et al., 2020) is an automatic evaluation metric that leverages the similarity between embeddings of words in candidate and reference sentences to assess translation quality focusing mainly on adequacy. Unigrams are matched based on their surface forms, root forms and meanings which aids to capture lexical, morphological and semantic equivalence. Semantic evaluation is achieved by using pretrained fasttext embeddings provided by Facebook to calculate the word similarity score between the candidate and the reference words. MEE computes evaluation scores using three modules namely exact match, root match and synonym match. In each module, fmean-score is calculated using harmonic mean of precision and recall by assigning more weight to recall. A final translation score is obtained by taking the average of fmean-scores from the individual modules.

- MEE2 is an improved version of MEE, focusing on computing contextual and syntactic equivalences along with lexical, morphological and semantic similarity. The intent of MEE2 is to capture fluency and context of the MT outputs along with their adequacy. Fluency is captured using syntactic similarity and context is captured using sentence similarity leveraging sentence embeddings. The final sentence translation score is the weighted combination of three similarity scores: a) Syntactic Similarity achieved by modified BLEU score; b) Lexical, Morphological and Semantic Similarity: measured by explicit unigram matching similar to MEE score; c) Contextual Similarity: Sentence similarity scores are calculated by leveraging sentence embeddings of *Language-Agnostic BERT* models.

The authors identified MEE2 as their primary submission.

5 Main Results

Currently, the main use case of automatic metrics is to rank systems either during system development or by comparing your own output with the one

from other research institutes or competitors. Consequently, we present system-level correlations as our main metric in this year's WMT21 metrics task. To be in line with the main use case, we present *pairwise accuracy* numbers for each metric that calculate the accuracy scores on binary comparison of system outputs for each language pair. We refer the reader to Section 7 for language pair specific results on both the segment and system level with more traditional correlation metrics.

5.1 System-Level

The system-level metric scores submitted by the participants pertained to the complete WMT test set, but we collected human MQM scores for only a subset of documents, as shown in Table 4. To correct for this discrepancy, we re-computed system-level scores as averages over the segments for which MQM scores were available, after first verifying with all participants that their system-level scores were computed in the same fashion.

To generate a single score combining the data from all 3 language pairs, we calculate *pairwise accuracy* (Kocmi et al., 2021) as our primary scoring metric. Pairwise accuracy is defined as follows: For each language pair and system pair, we calculate the difference of the metric scores (metricΔ) and the difference in average human judgements (humanΔ) for each system pair. We calculate accuracy for a given metric as the number of rank agreements between the metric and human deltas, divided by the total number of comparisons:

$$\text{Pairwise accuracy} = \frac{|\text{sign}(\text{metric}\Delta) = \text{sign}(\text{human}\Delta)|}{|\text{all system pairs}|} \quad (2)$$

We present results for three different settings: Looking at the news domain with and without human translations (HT) as additional systems: (a) *Newstest2021 w/o HT*, (b) *Newstest2021 w/ HT*, and (c) looking at *TED talks w/o HT*. In this section, we consider only the primary submissions of each metric team and the baseline metrics. We have multiple reference translations for some settings. Instead of reporting results with respect to all reference translations, we use here for reference-based metrics only the single reference that was judged best by the MQM raters for each language pair. The remaining reference translations are used in the role of participating MT systems in the "w/ HT" evaluations. Table 7 summarizes the use of reference translations for different language pairs and domains. We will analyse the impact of using different reference translations in Section 8.1 in more detail.

language	news		TED
	best ref	scored refs	best ref
en→de	C	A, D	A
en→ru	A	B	A
zh→en	B	A	B

Table 7: Use of reference translations.

Metric rankings based on pairwise accuracy can be found in Table 8. The top significance cluster (bolded in the table) consists of primary or baseline metrics that are not significantly outperformed by any other primary or baseline metrics nor outperformed by a primary or baseline metric not in the top cluster.[9]

Metric	newstest21 w/o HT	newstest21 w/ HT	TED w/o HT
tgt-regEMT	**0.773** (1)	0.694 (5)	0.636 (15)

src-regEMT	0.494 (18)	0.415 (18)	0.405 (18)

Table 8: Pairwise accuracy for Chinese→English, English→German, and English→Russian using the MQM annotations. Correlations for metrics in the top significance cluster are bolded. All submissions labelled with * participated only in 1 or 2 language pairs and are not considered during significance testing. Metrics not using reference translation (QE-metrics) are indicated by italics.

- **Newstest2021 w/o HT** This setting is most similar to previous years' settings. Metrics are required to score all MT outputs without considering human translations (HT). This setup investigates how metrics evaluate current SOTA MT

[9]Note that this definition is different from the metric clustering used in previous metrics tasks, in which every metric in a cluster must be significantly better than all metrics in lower clusters.

models. Looking at the ranking in Table 8, we can see that in total 8 metrics fall into the first significance cluster. The cluster includes a variety of embedding-based metrics and surface metrics. None of the QE metrics (i.e. reference-less metrics) are part of the first cluster.

- **Newstest2021 w/ HT** When considering the additional reference translations as system outputs (ref-A for zh→en, ref-B for en→ru, ref-A and ref-D for en→de), the ranking of the metrics is sharply revised. The QE metric *COMET-QE-MQM_2021* and the reference-based metric *C-SPECpn* are the winners in this setup. Overall, the embedding-based metrics that also rely on fine-tuning are much better in rating human translation higher than MT output and thus dominate this setting.

- **TED talks w/o HT** This year, we also measured the domain robustness of each metric on the TED talks domain. In Table 8, we can see that *COMET-MQM_2021* and *YiSi-1* show the highest correlation with human ratings on the TED domain. Interestingly, both metrics did not fall into the first significance cluster in the previous two settings of the news domain, leading to very different conclusion about the quality of metrics.

5.2 Significance Testing

We run PERM-BOTH hypothesis test (Deutsch et al., 2021) on the pairwise system-level accuracy of Table 8 to measure significance between metrics' performance.[10] Results can be seen in Figure 1. By looking at the heat map of Newstest2021 without human translations (*Newstest2021 w/o HT*), we observe that the top performing metrics are not significantly different. This observation changes when we add human translations to the setup (*Newstest2021 w/ HT*). The top 2 performing metrics, although different ones, are significantly better than all other metrics. This setup gives us the clearest result of all our 3 different setups and highlights that embedding-based metrics that are fine-tuned on previous years' human ratings rate human translations much better than all the other metrics and are good at distinguishing human-produced text. Another different situation can be seen when looking at the TED talk setting (*TED talks w/o HT*). Even though we see more significant differences compared to *Newstest2021 w/o HT*, most pairs of metrics are not significantly different.

[10]Previous editions of the metrics task used the Williams test (Williams, 1959), but we adopted PERM-BOTH because it is more general, and because Deutsch et al (2021) demonstrate that it has higher power.

6 Challenge Sets

While the correlation analysis is testing the evaluation metrics on their ability to rank MT systems according to translation quality, we are also interested in understanding metrics' performance on identifying certain types of translation errors. We created three challenge sets containing translation errors that are believed to be challenging for automatic MT evaluation metrics to identify. A good metric should not only rank candidate translations by their quality but also be sufficiently sensitive to these types of errors.

Each challenge set consists of two MT outputs (and the corresponding source and reference) where one of them contains the type of translation error of interest and the other does not. Metrics are expected to give a lower score to the MT output containing the error.

We use Kendall's tau-like correlation, typically used for DARR (Bojar et al., 2017; Ma et al., 2018, 2019; Mathur et al., 2020b), for evaluating the primary submissions on the challenge sets. Kendall's tau-like correlation is defined as follows:

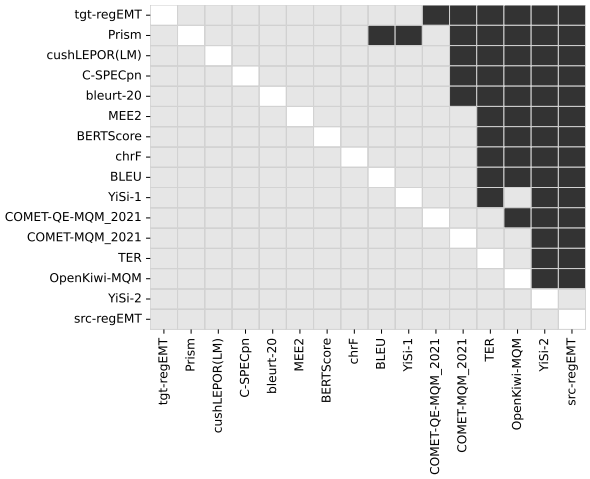
$$\tau = \frac{Concordant - Discordant}{Concordant + Discordant} \quad (3)$$

where *Concordant* is the number of times a metric assigns a higher score to the MT output without the error and *Discordant* is the number of times a metric assigns a higher score to the MT output containing the error of interest.

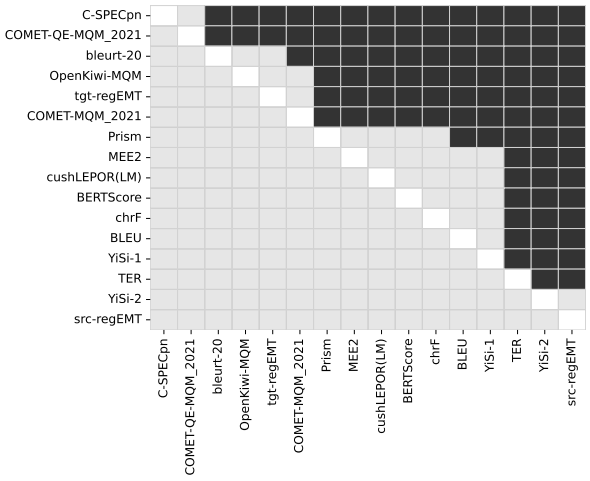
6.1 Negation and Sentiment Polarity Challenge Set

The goal of this challenge set is to test metrics' ability to penalize translations when there is a catastrophic error in reversing of a negation or of sentiment polarity. It is a common phenomenon that MT systems may either introduce or remove a negation (with or without an explicit negation word), or may reverse the sentiment polarity of the sentence (e.g. a negative sentence becomes positive or vice-versa). These types of errors could result in serious consequences of misleading users of MT.

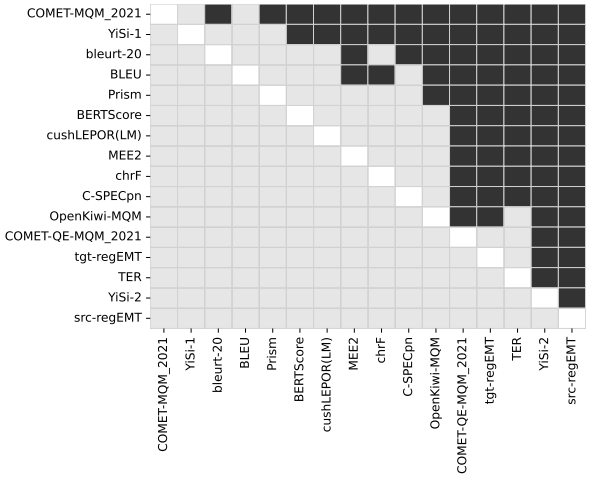
The WMT2020 MT Robustness shared task (Specia et al., 2020b) collected Wikipedia Edit comments with toxic content that could lead to possible



(a) newstest2021 w/o HT



(b) newstest2021 w/ HT



(c) TED talks w/o HT

Figure 1: The results of running PERM-BOTH hypothesis test to find a significant difference between metrics' pairwise system-level accuracy. Dark squares mean the row metric correlates significantly better than the column metric at $\alpha = 0.05$.

catastrophic errors in the MT output. After selecting segments of interest they created reference translations for the entire test set using professional translators. Finally, they collected annotations of catastrophic errors on the translations performed by participating systems[11].

To test metrics on sentiment polarity we looked for source sentences from the English→German data portion where we can find an MT output annotated with a sentiment polarity error and another MT output without the polarity error. The resulting challenge set contains 177 source sentences (not necessarily distinct), each equipped with two MT outputs, one with a catastrophic error and one without it. We note that most of the sentences in this challenge set contain toxic language.

Table 9 shows the results for this challenge set. We also show the actual number of concordant pairs here because this challenge set is rather small. Despite the high severity of the translation error in reversing the sentiment polarity or negation, we see that both the baselines and the submissions struggle to accurately discriminate between translations with and without such errors. TER and BERTSCORE are the only two metrics that are able to achieve a medium correlation (i.e. greater than 0.4) with human annotators on ranking the translation with the catastrophic error as lower in translation quality. Perhaps more importantly, embedding-based and semantic-oriented metrics, such as BERTSCORE, YISI-1, etc., do not significantly outperform surface-form matching metrics, such as TER, CHRF and SENT-BLEU. This may indicate that the pretrained language models used by the embedding-based metrics are weak at learning language representations that explicitly reflect differences in negation and sentiment polarity.

6.2 Corrupted Reference Challenge Set

The goal of this challenge set is to sanity check the behaviour of the submitted metrics and possibly identify some weaknesses in detecting specific anomalies in a corrupted reference translation. In order to do this we used this years' Chinese→English Newstest corpus, which contains two human systems (referenceA and referenceB) and we perturb one of these human systems while using the other as reference. Given that, our final corpus is composed of $14,080$ tuples with

[11] Professional translators with access to the original source sentence, the reference and the system output were used during this evaluation.

Metric	*Concordant*	τ
TER	132	0.492
BERTSCORE	124	0.401
CHRF	123	0.390
YISI-1	122	0.379
MEE2	120	0.356
BLEURT-20	119	0.345
SENT-BLEU	118	0.333
C-SPECPN	118	0.333
COMET-MQM_2021	117	0.322
TGT-REGEMT	115	0.299
SRC-REGEMT	112	0.266
CUSHLEPOR(LM)	108	0.220
OPENKIWI-MQM	108	0.220
PRISM	107	0.209
MTEQA	106	0.198
COMET-QE-MQM_2021	106	0.198
YISI-2	104	0.175

Table 9: Results for the Negation and Sentiment Polarity Challenge Set. (Out of 177 hypothesis pairs)

(source, referenceBpert, referenceB, referenceA) where referenceBpert denotes the perturbed reference.

The perturbations used are: *antonym replacement*, *word omission*, *tokenization*, *sentence omission*,[12] *punctuation removal*, *number swapping*, *lowercasing*, *word addition* and addition of *spelling errors*. Table 22 in Appendix A shows examples for each perturbation.

From Table 10 we can observe that for most embedding based metrics (YISI, BERTSCORE, BLEURT-21-BETA, ROBLEURT, PRISM) correlations are close to 1.0 for all perturbation types. The only exceptions are COMET-MQM_2021 and C-SPECPN that seem to struggle with *sentence omission* and *punctuation removal*. This behaviour is even more unexpected if we take into consideration that they seem to be sensitive to *word omission*. Regarding punctuation removal, since both metrics are fine-tuned on Google MQM annotations (see Section 3.1) we hypothesize that they learn to be less sensitive to punctuation errors. Regarding the lexical metrics, we can observe that SENT-BLEU, CHRF and CUSHLEPOR(LM) are not sensitive to tokenized text. This is an expected behaviour for lexical metrics since they typically ignore whitespaces. Also, CUSHLEPOR(LM) scores -1.0 in lowercased text. This seems to indicate that this metric does not encode casing information.

6.3 German→English Challenge Set

The challenge set is based on the test suite by Macketanz et al. (2018a). It is a test suite for German-English that consists of around 5,500 German test sentences covering 107 linguistically motivated phenomena (listed in Avramidis et al. (2020)), organized in 14 categories. These phenomena do not follow a linguistic theory but rather cover various grammatical aspects which are relevant for MT. Each phenomenon is represented by at least 20 test sentences to guarantee a balanced test set. The test suite is used to evaluate MT systems with regard to their performance on the test sentences. The evaluation operates semi-automatically and is based on a set of handwritten rules which contain regular expressions and fixed strings.

The test suite has been used to evaluate the outputs of 40 German-English systems submitted at the translation task of the Conference of Machine Translation (WMT) for three consecutive years (Macketanz et al., 2018b; Avramidis et al., 2019, 2020) and also this year (Macketanz et al., 2021). Across the past three years, this amounts to 40 system outputs. We use these outputs to construct the challenge items for the metrics task, since the test suite contains only source sentences and handwritten rules for the outputs but no reference translations. For every source sentence of the test suite we separate MT outputs into "correct" and "incorrect" ones using the handwritten rules of the test suite and create a tuple including; (1) a set of "correct" MT outputs, to be given to the metrics as supposedly correct reference translations and, (2) a pair of one "incorrect" and one "correct" translation randomly sampled from the respective set. Note that the "correct" candidate does appear among the references (1). The goal of the metric is to score the "incorrect" translation worse than the "correct" one.

The same source sentence may be appear more than once, if there is more than one WMT translation marked as wrong by the rules for this item. The above process resulted in a metrics challenge set with 1,819 items with source, wrong hypothesis, correct hypothesis, and a pseudo-reference (another MT that was deemed correct for that phenomenon).

[12]Note that after experimenting with paragraph-level translation in WMT20, WMT21 moved back to segments again corresponding to individual sentences. In Chinese→English corpus, paragraph boundaries are not apparent (all documents consist of one paragraph). For the purposes of this experiment, we used *nltk.sentence_tokenizer* and looked for all the references B with more than 1 sentence and randomly delete 1 of those sentences to create referenceBpert. Note that since we do not have entire paragraph, the size of this challenge is 88 samples only.

Metric	Antonym	W. Omission	Tokenized	Sent. Omission	Punct.	Numbers	Lower.	W. Add.	Spell.

SRC-REGEMT	0.637	0.512	0.357	0.341	0.209	0.333	0.365	0.342	0.300

Table 10: Kendall's tau-like correlation results for the Corrupted References Challenge set (Section 6.2). The horizontal lines delimit baseline metrics (top), participating reference-based metrics (middle) and participating reference-free metrics (bottom).

The covered phenomena are: *Function Words (FW), Non-verbal Agreement (NVA), Verb Tense/Aspect/Mood (VT), Composition (Comp.), Multi-Word Expressions Negation (MWE N.), Punctuation (Punct.), Verb Valency (VV), Subordination (Sub.), Coordination and Ellipsis (CE), Named Entities and Terminology and Long Distance Dependencies and Interrogative (LDD).*

Overall, from Table 11 we observe that embedding-based metrics such as BLEURT-20 and COMET-MQM_2021 seem to be less sensitive to *Subordination*, *Named Entities and Terminology*, and to *Punctuation*. We can also observe a clear performance difference between reference-free and reference-based metrics. Nonetheless most metrics have positive correlations in all covered phenomena. Note that this corpus is composed of "pseudo-references" which can have a negative impact on metrics' performance (see Section 8.1).

7 Results per Language Pair

We computed individual correlation results for each focus language pair (English→German, English→Russian, Chinese→English) at both the system and segment level. The system-level metric scores submitted by the participants pertained to the complete WMT test set, but we collected human MQM scores for only a subset of documents, as shown in Table 4. To correct for this discrepancy, we re-computed system-level scores as averages over the segments for which MQM scores were available, after first verifying with all participants that their system-level scores were computed in the same fashion.[13] Exceptions to this pattern are the baseline metrics BLEU and TER: the system-level versions of these metrics are not averages over segment-level scores, and we computed them only over the MQM segments.

Since we have multiple reference translations for the focus language pairs, we required participants to submit versions of their (reference-based) metrics for each reference. We used only the scores corresponding to the reference that was judged best by the MQM raters for each language pair. For the news domain, we evaluated metric performance both when using only MT outputs and using MT outputs augmented by human references, adding all remaining references in the latter condition except for English→German, where we excluded reference B since it was very similar to the best reference C. Table 7 summarizes the use of reference translations for different language pairs and domains.

We measure correlation using the Pearson-r statistic at the system level and the Kendall-tau statistic at the segment level. Pearson correlation is complementary to the pairwise accuracy used for our global results as discussed in Section 5: it tests linear fit with MQM scores, a stringent but

[13] In contrast to the standard practice with WMT DA scores, where scored segments for each system are sampled independently, the segments for which we have MQM scores comprise a fixed set, independent of the MT system being scored.

Table 12: Summary of language-specific results. Numbers give the count of times each primary metric occurred in the top cluster for the specified condition. Metrics not being among the winners in any competition are not listed. Reference-free metrics are indicated by italics. All submissions labelled with * participated only in 1 or 2 language pairs.

reasonable criterion since we expect these scores to conform to a linear scale (for example, a translation with two minor errors is twice as bad as one with only a single error). Pearson has well-known drawbacks (Mathur et al., 2020a), notably sensitivity to outliers, which we avoided by choosing only relatively high-performing systems. In preliminary tests, Pearson also yielded a larger number of pairwise significant differences among metrics than Kendall, an important property since our fairly small number of systems makes it difficult to reliably distinguish metrics at the system level.

Segment-level scores—metric or human—are naturally arranged as a system × segment matrix (rows × columns). There are several ways to extract vectors for input to correlation statistics. Comparing metric and human row vectors corresponds to a use case of judging the relative quality of different segments output by a given MT system ("where is my system making mistakes on this test set?"); comparing column vectors corresponds to judging the relative quality of outputs for a given source

segment across different MT systems ("which systems performed better or worse than mine on this segment?"). To avoid emphasizing either of these scenarios at the expense of the other, we flattened the metric and human score matrices into single vectors (row1, row2, ...) before comparing them. This measures the metrics' ability to assign independent scores to MT segments, abstracting away from system or source segment, and provides a large number of comparisons to boost statistical significance. We used Kendall rather than Pearson correlation for robustness to segment-level noise.[14]

The results for each language pair and granularity are shown in Tables 23 to 28, with corresponding pairwise significance plots derived using the PERM-BOTH test in Figures 2 to 7. The tables contain results for all metrics; the significance plots include only primary and baseline metrics. In the tables, primary submissions are in bold, baseline metrics are underlined, and metrics that used only the source have "-src" appended to their name. For each condition (news without human translations, news with human translations, or TED), the *scores* of primary and baseline metrics in the top cluster are in bold. The top cluster consists of primary or baseline metrics that are not significantly outperformed by other primary or baseline metrics nor outperformed by a primary or baseline metric not in the top cluster.[15] In the significance plots, this corresponds to the leftmost block of columns containing no dark squares.

Table 12 summarizes all results in this section by counting the number of times each metric occurs in the top cluster (it got a "win"), summed across different ways of partitioning the results. This synthesis is fairly crude, since it treats all conditions as equally important. Also, membership in the top cluster is likely to be subject to high statistical variance, and metrics that fall outside this cluster are not accounted for; in particular, those that sometimes perform very poorly are not penalized. Nevertheless, the counts permit some general observations.

In terms of total "wins", three metrics stand out clearly: C-SPECPN, BLEURT-20, and COMET-MQM_2021. These have fairly evenly-distributed performance across languages, granularities, and data conditions, with the exception of BLEURT-20, which does relatively poorly on Chinese→English. Their advantage over other metrics is most pronounced at the segment level and when human translations are included among the systems to be judged (*w/ HT*)—both of which are more challenging tasks. In contrast, the distribution of metrics that achieve top-level performance is much broader for system-level granularity, the out-of-domain TED setting, and to a lesser extent the news *w/o HT* setting. Two metrics that do not use a reference translation—COMET-QE-MQM_2021-src and OpenKiwi-MQM-src—do surprisingly well overall, particularly in the *w/ HT* condition, but perform poorly at the segment level. This could be explained by these metrics benefiting from their ability to distinguish human vs. machine produced text. Finally, the surface-level baselines—BLEU, TER, and chrF—join the winners exclusively at the system level and almost exclusively in the out-of-domain TED condition.

8 Additional Results

8.1 Impact of Reference Translation

The quality of the reference translation can have a higher impact on the correlation to human ratings than the actual choice of metric (Freitag et al., 2020). For all our different test sets and language pairs, we consequently included all reference translations in our human evaluation to (a) assure that we have reference translation with high quality and (b) to choose the best reference translation for our main results. In this section, we present two interesting observations by looking into the Chinese→English TED talks and the English→German news setups.

8.1.1 zh→en TED

We started by having only one reference translation for all TED talks. Unfortunately, the MQM evaluation revealed that the reference translation *ref-A* for Chinese→English was ranked last – lower than all the MT systems – and that it contained on average more than one major error (= 5 MQM points) per segment. We spot checked the errors and agreed that the reference translation indeed contained many errors. We then decided to acquire

[14] Our use of Kendall differs in two major aspects from the "Kendall-like" statistic used for segment-level correlations in previous editions of the WMT metrics task: we do not threshold MQM score differences, as we consider them to be more reliable than DA scores; and we compare all pairs of scores over complete flattened matrices rather than comparing pairs of scores in each column, and micro-averaging results across columns.

[15] Note that this definition is different from the metric clustering used in previous metrics tasks, in which every metric in a cluster must be significantly better than all metrics in lower clusters.

a new reference translation (*ref-B*) which turned out to be better than all MT systems after running a human evaluation. The impact of using an excellent versus an inaccurate human reference translation can be seen in Table 13. All metrics achieve an accuracy score lower than 0.5 when using ref-A to calculate their scores. This means that the metrics would perform worse than by chance. By switching to ref-B, all but one metric (*tgt-regEMT*) greatly improve their correlation score. This demonstrates once again that metrics become unreliable when they are provided with inaccurate reference translations.

8.1.2 en→de Newstest2021

For English→German Newstest2021, we started with two reference translations (*ref-A* and *ref-B*). Both reference translations had issues: ref-A was ranked lower than two MT systems (see Table 5) and we agreed with that assessment after spot checking the errors. ref-B had high-levels of overlap with the Online-W MT system and is most likely a post-edited translation of Online-W. Therefore, Microsoft and Google sponsored two new reference translations (*ref-C* and *ref-D*) which turned out to be the best translations based on MQM. In Table 14, you can see the pairwise accuracy scores from all reference-based primary and baseline metrics. Despite the good (low) MQM scores of both ref-C and ref-D, the ranking of the metrics when using these two references is quite different. Some metrics are more robust when switching the reference translation (e.g. *Prism*, *YiSi-1*, or *C-SPECpn*, but others yield very different correlation scores (e.g. *BERTScore*, *tgt-refEMT*, or *BLEU*). Something else in addition to quality makes *ref-C* more appealing for metrics than *ref-D*. We do not have an explanation why the quality of some metrics is so different when switching the reference translation and leave this as an open challenge for the community to better understand why this is happening.

8.2 Google vs. Unbabel MQM

Given that annotations were undertaken for English→Russian using a different setup and MQM scheme than those for English→German and English→Chinese we sought to provide some insight into the compatibility of the two schemes by repeating the annotation for English→German using Unbabel's scheme and annotator pool: For a subset of 5056 segments of the TED talk data for English→German from 10 MT systems, Unbabel had another expert annotator trained on MQM provide annotations using their proprietary typology. MQM was calculated for each set of annotations (using their respective scoring) and the latter were then converted to a sequence of OK/BAD tags as a means of evaluating the level of agreement between the two annotations at a token level.

The Pearson's r correlation score between the two sets of MQM annotations was found to be 0.212, significant to p<0.05. Given the levels of correlation of metrics with Google's MQM scores on the full set of English→German, this is surprisingly low. Similarly, Cohen's Kappa on the

annotated tags was found to be 0.165. Not only do scores correlate poorly but agreement at the tag level is also fairly weak. Equally, Cohen's Kappa on the subset of annotations on which both sets of annotators found some error was found to be improved but still low (0.2). This indicates that even when limited to erroneous sentences, the annotators struggled to agree on where the errors were.

We note that the Google annotators left 59.5% of the sample untouched (i.e. error free), whereas the Unbabel annotator left only 46.9% untouched. It appears that the Unbabel annotator was on average more aggressive in their annotation which might partially explain low levels of agreement.

A number of the MT systems often produced the same translation of the same source text. With this in mind, and given that Google used a pool of annotators, we were able to also compare annotations within the Google set. For every source/target pair with more than two annotations we calculated and averaged the pairwise Cohen's Kappa. The mean Kappa across all of these segments was 0.21, which suggests equally low levels of agreement between Google annotators.

Despite low segment level agreement we note that the ranking of systems remains fairly consistent between annotation schemes with a few outlying exceptions. Table 15 details the rankings for our sample across annotation schemes. In particular it is encouraging to note that the human reference (albeit one of the worse ones, see Section 8.1.2) is ranked first in both cases; at a high level both schemes are making meaningful quality judgements. For the sake of completeness, we similarly examined the rankings of metrics at segment level (measuring Pearson's r correlation score and ranking the result) against both sets of MQM scores for our sample. Rankings in both cases were found to be sufficiently similar to official results reported in this paper and no metric moved more than three positions.

To rationalize these low segment-level agreement numbers, we asked an independent native language German speaker to look at a subset of annotations where we noticed the worst levels of segment-level agreement. The independent rater provided some rudimentary annotation of the most obvious errors and some qualitative analysis of the segments themselves. From this independent analysis, we were able to conclude at a high-level that the nature of TED talk text broken into segments is highly complex, context dependent and ambiguous even in the original language which resulted in equally ambiguous translation errors. This serves as a harsh reminder of the complexity of the annotation task and that inevitably even human annotation using highly granular schemes like MQM is only as reliable as the simplicity of the underlying text. The same reminder extends to human-generated references where highly specialized content will inevitably require specialized translators to ensure the most accurate translation.

Table 15: System-level MQM scores for Unbabel and Google annotation schemes

We note that whilst we do not have human direct assessment (DA) scores on TED data in order to provide a direct comparison of the two annotation schemes in this setting, we observe in the following section that MQM appears to provide a more stable basis for evaluation in general.

8.3 Comparison to WMT Scoring

The WMT evaluation campaign (Akhbardeh et al., 2021) ran a human direct assessment (DA) evaluation for the primary submissions in the news domain for all language pairs. Segment-level ratings with document context (SR+DC) on a 0-100 scale were collected either using source-based evaluation with a mix of researchers/translators (for translations out of English) or reference-based evaluation with crowd-workers (for translations into English). In general, for each MT system, only a subset of documents receive ratings, with the rated subset differing across systems. System-level DA scores are averages over the available segment-level scores. Both raw scores and per-rater z-normalized versions of the scores are provided.

Appendix C contains correlations to WMT Newstest DA scores for all metrics, at both segment and system level, for all 16 language pairs. There is significant variation in metric performance and

ranking across languages, although a general pattern is that correlations are substantially higher for out-of-English pairs than into-English. Although the WMT correlations are not strictly comparable to the MQM results in previous sections, MQM scores tend to correlate somewhat better with metric scores for two of our three focus languages (English→German and Chinese→English), and somewhat worse for English→Russian.

Table 18: MQM versus DA for Chinese→English.

Tables 16 to 18 compare MQM and DA scores for our focus language pairs, on all systems where both sets of scores were available. Notably, MQM scores rank human translations at or near the top more consistently than do DA scores. The only reference ranked worse than MT by MQM is ref-A for English→German, which as discussed above is a low-quality translation. In contrast, DA z-normalized scores rank all references below at least one MT system except for ref-A in English→Russian, which is ranked first, in agreement with MQM. For English→German and English→Russian, MQM correlates better with raw DA scores than with z-normalized scores; Pearson correlations are 0.508 versus 0.243 for the former and 0.911 versus 0.898 for the latter. For Chinese→English the pattern reverses, with correlations of 0.216 versus 0.729.

Table 19: System-level Pearson correlations, including WMT DA z-normalized scores as a metric, for English→German.

The correlations between MQM and WMT DA scores in the previous section motivated us to investigate how DA scores would fare in comparison to automatic metric scores when using MQM as gold scores. We computed system-level Pearson correlations using z-normalized DA scores for MT outputs only and MT outputs augmented with human references for which DA, MQM, and metric scores were all available.[16] Tables 19 to 21 compare these to the performance of primary and baseline metrics using the references from Table 7.[17] The performance of DA varies across languages: for English→German and English→Russian it ranks roughly among the

[16] ref-A for en→de, ref-B for en→ru, and ref-A for zh→en.

[17] These numbers do not match others in the paper due to the use of a reduced set of MT systems, and, for the *w/ HT* condition, a reduced set of human outputs.

bottom half of the automatic metrics; while for Chinese→English it ranks third. DA scores tend to perform better when judging human output, ranking 7th, 3rd, and 3rd for English→German, English→Russian, and Chinese→English, respectively.

9 Conclusion

This paper summarized the results of the WMT21 shared task on automated machine translation evaluation, the Metrics Shared Task. This year, we collected our own human ratings for selected language pairs (En→De, En→Ru, and Zh→En) from professional translators via MQM to generate a reliable ground truth across two domains. WMT direct assessment (DA) scores generally correlate poorly with MQM scores, and exhibit weaker preference for human translations compared to machine output. For En→De and Zh→En, DA ranks the human translations below many MT systems, demonstrating that expert-based evaluation is needed to generate a reliable ground truth for the Metrics Shared Task. The majority of metrics correlate better with MQM than with WMT DA, confirming previous findings that the best automatic metrics are already more reliable than crowd worker human evaluations. The performance of each metric varies depending on the underlying domain (being either TED talks or news) demonstrating that most metrics are not domain robust. Further, the challenge sets revealed that most metrics struggle to penalize translations with errors in reversing negation or sentiment polarity, and show lower correlations for Subordination, Named Entities and Terminology.

Overall, metrics perform very differently based on domain, language pair or setting (with or without human translations among candidate systems) making it hard to declare a clear winner. When counting top performances across all test conditions, three embedding-based metrics—C-SPECPN, BLEURT-20, and COMET-MQM_2021— emerge as distinctly better than the others, especially at the segment level and when rating human translations. Nevertheless, it is unclear which test scenario and correlation metric is best to yield reliable results. We would encourage the community to investigate different ways of how to evaluate automatic metrics. We are very open to apply new suggestions in the next round of the Metrics Shared Task.

Another challenge is to define the overall ground truth (i.e. the human ratings). Even though, we are convinced that expert-based ratings via MQM are more reliable, we also found that the two MQM methodologies of Unbabel and Google disagree for some systems. We would encourage the community to further work on establishing a reliable human evaluation setup. The field would benefit from a reliable human evaluation standard that could be used by everyone.

10 Ethical considerations

MQM annotations and additional reference translations in this paper are done by professional translators. They are all paid at professional rates.

Our TED talks test suite is created based on TED transcripts and translations under CC BY–NC–ND 4.0 International. Additional translations done for this shared task follow the TED Talks Usage Policy.

Organizers from the National Research Council Canada and Unbabel have submitted to this task the frozen stable versions of their metrics (YiSi and COMET) dated before they joined the organizing committee. Newer versions of COMET were developed without using any of the test set, test suite or challenge sets.

11 Acknowledgments

Results for this shared task would not be possible without tight collaboration with the organizers of the WMT News Translation Task. We are grateful to Google and Unbabel for sponsoring and overseeing the human evaluation. We would also like to thank the organizers of the WMT20 Robustness Task, especially Lucia Specia, for providing the pre-release version of the MT critical error annotations. We are grateful to Roman Grundkiewicz for his help in deciphering raw scores exported from Appraise and André Martins, Thibault Sellam, Qijun Tan and Macduff Hughes for their valuable review. Finally, we would like to thank Eleftherios Avramidis and Vivien Macketanz for providing us the German→English Challenge set (Section 6.3).

Nitika Mathur is supported by the Australian Research Council. Ricardo Rei is supported by the P2020 programs MAIA (contract 045909) and Unbabel4EU (contract 042671). Ondřej Bojar would like to acknowledge the support from the Czech Science Foundation (grant n. 19-26934X, NEUREM3).

A Challenge Set Perturbation Examples

Perturbation	Description	Example
Antonym	Randomly replaces as word with it's antonym.	Orig.: *Fire in French chemical plant extinguished* New: *Fire in French chemical plant ignite*
Word omission	Randomly drops a word from a sentence	Orig.: *Fire in French chemical plant extinguished* New: *Fire in French␣ plant extinguished*
Tokenized	Applies tokenization to the sentence.	Orig.: *Spain: It is safe here.* New: *Spain␣: It is safe here␣.*
Sentence Omission	Removes a sentence from a paragraph.	Orig.: *The No.3 flood of the Yangtze River in 2020 was formed. The Ministry of Water Resources has refined and implemented countermeasures - www.chinanews.com* New: *The No.3 flood of the Yangtze River in 2020 was formed. ␣*
Punctuation	Removes punctuation from the input.	Orig.: *Spain: It is safe here.* New: *Spain␣ It is safe here␣.*
Numbers	Replaces a number by another randomly generated number.	Orig.: *Around 65 people work at the plant.* New: *Around 400 people work at the plant.*
Lowercasing	Applies lowercasing to the entire input.	Orig.: *Fire in French chemical plant extinguished* New: *fire in french chemical plant extinguished*
Word Addition	Adds a word in the middle of a sentence using `distilbert-base-uncased`. This perturbation is applied on top of lowercase perturbation.	Orig.: *fire in french chemical plant extinguished* New: *fire in french underground chemical plant extinguished*
Spelling	Adds spelling errors to the input.	Orig.: *Fire in French chemical plant extinguished* New: *Fire in French chemical pants extinguished*

Table 22: List of all perturbations used to construct the Challenge Set described in Section 6.2. The right column provides for each perturbation an example with the original sentence and the corresponding new corrupted sentence.

B Language-Specific Results Tables

Language-specific results are given on the following pages. Each page contains results for a single language pair and granularity (system or segment). Correlation results in tables are followed by pairwise significance plots for each condition (news without human outputs, news with human outputs, TED talks) considering only primary and baseline metrics.

Metric	news w/o HT	news w/ HT	TED

C WMT Direct Assessment Results

Correlations with WMT Direct Assessment scores for the news and FLORES test sets are given in the following tables, with results for news to-English language pairs followed by to-non-English pairs, followed by FLORES. Since most language pairs contained only a single reference, we used reference A for all pairs, and report results only for scoring MT output (omitting additional scored references for language pairs where these were available). System-level correlations use Pearson over z-normalized rater scores. Segment-level correlations use the traditional Kendall-like formula over raw rater scores, discarding segment pairs whose scores differ by less than 25.[18]

Abstract

We participated in all tracks of the WMT 2021 efficient machine translation task: single-core CPU, multi-core CPU, and GPU hardware with throughput and latency conditions. Our submissions combine several efficiency strategies: knowledge distillation, a simpler simple recurrent unit (SSRU) decoder with one or two layers, lexical shortlists, smaller numerical formats, and pruning. For the CPU track, we used quantized 8-bit models. For the GPU track, we experimented with FP16 and 8-bit integers in tensorcores. Some of our submissions optimize for size via 4-bit log quantization and omitting a lexical shortlist. We have extended pruning to more parts of the network, emphasizing component- and block-level pruning that actually improves speed unlike coefficient-wise pruning.

1 Introduction

This paper describes the University of Edinburgh's submission to Sixth Conference on Machine Translation (WMT2021) Efficiency Task[1], which measures performance on latency and throughput on both CPU and GPU, in addition to translation quality. Our submission focused on the trade-off between these metrics and quality.

Our submission builds upon the work of last year's submission (Bogoychev et al., 2020). We trained our models in a teacher-student setting (Kim and Rush, 2016), using Edinburgh's En-De system submitted to the WMT2021 news translation task as the teacher model. For the students, we used a Simpler Simple Recurrent Unit (SSRU) (Kim et al., 2019) decoder, used a target vocabulary shortlist, and experimented with pruning the student models by removing component- and block-level parameters to improve speed. We further experimented with quantizing into smaller numerical formats, including fixed point 8-bit quantization on the CPU, and both 8-bit and log based 4-bit quantization on the GPU, as well as post-quantization fine-tuning of 4-bit quantized models.

For running our experiments, we improved upon the Marian (Junczys-Dowmunt et al., 2018) machine translation framework by incorporating speed ups for 8-bit matrix multiplication operations, optimizations for pruning neural network parameters on Intel CPUs, and exploring tensorcores on the GPU.

1.1 Efficiency Shared Task

The WMT21 efficiency shared task consists of two sub-tasks: throughput and latency. Systems should translate English to German under the constrained conditions of the WMT21 news task. For each task, systems are provided 1 million lines of raw English input with at most 150 space-separated words. The throughput task receives this input directly. The latency task, introduced this year, is fed input one sentence at a time, waiting for the translation output before providing the next sentence.

Throughput is measured on multi-core CPU or GPU system, and latency is measured on single-core CPU or GPU systems. The CPU-based evaluations use an Intel Ice Lake system via Oracle Cloud BM.Optimized3.36, while the GPU-based use a single A100 via Oracle Cloud BM.GPU4.8.

Entries to both tasks are measured on quality, approximated via BLEU score (Papineni et al., 2002), speed, model size, Docker image size, and memory consumption. We did not optimise specifically for the latency task beyond configuring the relevant batch sizes to one. We used Ubuntu 20.04 based images for our systems, with standard Ubuntu for CPU-only systems and NVIDIA's Ubuntu-based CUDA-11.4 docker for GPU-capable systems. Docker images were created using multi-stage builds, with model disk size reduced by compression with xzip.

2 Training teacher models

We used Edinburgh's En↔De systems submitted to the WMT 2021 news translation task as teacher models (Chen et al., 2021). We trained transformer-big models (Vaswani et al., 2017), using a shared 32K SentencePiece (Kudo and Richardson, 2018) vocabulary, built in three stages: corpus filtering, back-translation and fine-tuning. The models achieved 29.90 and 51.78 BLEU on En→De and De→En WMT 2021 test respectively (scored by the task organizers, with multiple references).

We used sequence-level knowledge distillation (Kim and Rush, 2016) to synthesize forward, backward, and backward-forward translations using the teachers. We filtered the synthesized parallel data using handcrafted rules[2], followed by removing bottom 5% according to cross-entropy per word on the generated side using KenLM (Heafield et al., 2013).

3 Knowledge distillation

We ran experiments using different combinations of teacher-synthesized corpora. One variant included all of the synthesized data: parallel, monolingual backward and forward as well as backward-forward (Aji and Heafield, 2020b). Another variant excludes only the fully-synthetic monolingual backward-forward data, while the final variant used parallel data only. All student models were trained using a validation set consisting of the subset of sentences in the English-German WMT test sets from 2015–2019 that were originally in English. Training concluded after reaching 20 consecutive validations without an improvement in BLEU score. The student models used the same shared vocabulary as the teacher ensemble. During decoding, we used a lexical shortlist (Schwenk et al., 2007; Le et al., 2012; Devlin et al., 2014) of the top 50 most probable alignments, combined through a union with the top 50 most frequent vocabulary items. Other than this, we used the default training hyperparameters from Marian for the transformer-base model.

Each of the student models used transformer encoders (Vaswani et al., 2017) and RNN-based decoders with Simpler Simple Recurrent Unit (SSRU) (Kim et al., 2019). Several different architectures were explored; these differ in the number of encoder and decoder blocks as well as in the sizes of the embedding and FFN layers. Further to this, some of our transformer architectures use a modified attention matrix of shape $(d_{\text{emb}}, n_{\text{head}} \times d_{\text{head}})$ rather than the typical $(d_{\text{emb}}, d_{\text{emb}})$. In all cases we use 8 transformer heads per layer, and set $d_{\text{head}} = 32$ across all modified attention models.

The student architectures are summarized in Table 1. A baseline comparison of student models trained on all synthesized data can be seen in Table 1.

3.1 Pruning

Attention is a crucial part of the transformer architecture, but it is also computationally expensive. Research has shown that many heads can be pruned after training; with further work suggesting that pruning during training can be less damaging to quality. Feedforward layers are also expensive and could be reduced.

Among many experiments, we applied group lasso regularisation to sparsify and prune 12–1.tiny and 12–1.micro architectures. We follow the directions set by Behnke and Heafield (2021). We tried two pruning settings: *rowcol-lasso* and *head-lasso*. Both prune feedforward and attention layers in the encoder. *rowcol-lasso* regularised individual connections (rows and columns) and removed an entire attention head if at least half of its connections are dead. *head-lasso* applied lasso to a whole head submatrix. Due to the scale of the task, we had no opportunity to grid-search for the best pruning hyperparameters, thus the experiments are as close to 'out-of-the-box' usage as they can be. We control pruning with $\lambda = 0.5$ for both methods. The models were pretrained for 50k updates and regularised for 150k, after which the models were sliced and trained until convergence. The results are presented in Tab. 2.

head-lasso left attention layers almost completely unpruned, focusing on removing connections from feedforward layers instead. *rowcol-lasso* was much more aggressive in both layers at the cost of quality. Behnke and Heafield (2021) have shown that group lasso pruning results in a better quality model than training the same exact architecture from scratch. To further optimise the models, they were quantised to work within 8bit representation. However, we observe that the smaller a model is, the larger the quality drop after its quantisation. Additional finetuning allows us to recover at least partially from the quantisation

Table 1: Architectures for the different student models. The number of encoder/decoder layers are reported with the size of the embedding, attention and FFN layers, the total number of parameters, the model size on disk, quality in both BLEU and COMET as well as speed on WMT21 testset. The first and second groups use a modified attention matrix shape, with second group consisting of tied models. The third group uses the typical shape attention matrices.

damage. Evaluating on the latest testset WMT21, our pruned models are 1.2–1.7× faster at the cost of 0.6–1.3 BLEU. With quantisation, those models are 1.9–2.7× faster losing 0.9–1.7 BLEU in comparison to the unpruned and unquantised baselines.

3.2 Fixed Point 8-bit Quantization

Quantizing fp32 models into 8-bit integers is a known strategy to reduce decoding time, specifically on CPU, with a minimal impact on quality (Kim et al., 2019; Bhandare et al., 2019; Rodriguez et al., 2018). This year's submission closely follows the quantization scheme of last year's work (Bogoychev et al., 2020).

Quantization entails computing a scaling factor to collapse the range of values to $[-127, 127]$. For parameters, this scaling factor is computed offline using the maximum absolute value but activation tensors change at runtime. This year, we changed from computing a dynamic scaling factor on the fly for activations to computing a static scaling factor offline. We decoded the WMT16-20 datasets and recorded the scaling factor $\alpha(A_i) = 127/max(|A_i|)$ for each instance A_i of an activation tensor A. Then, for production, we fixed the scaling factor for activation tensor A to the mean scaling factor plus 1.1 standard deviation: $\alpha(A) = \mu(\{\alpha(A_i)\}) + 1.1 * \sigma(\{\alpha(A_i)\})$. These scaling factors were baked into the model file so that statistics were not computed at runtime.

Quantization does not extend to the attention layer, which is still computed in fp32. The reason being is that in the attention layer, both the A and B matrices of the GEMM operation would need to be quantized at runtime, which makes the quantization too expensive. We note that we only perform the GEMM operations in 8-bit integers.

3.3 Log 4-bit Quantization

We further quantize the models with log based 4-bit quantization (Aji and Heafield, 2020a). In this case, model weights are represented in a 16 unique quantization centers in a form of $S * 2^k$. S is a scaling factor that is optimized to minimize the MSE of the quantized weight to the actual weight. Following Aji and Heafield (2020a), we only perform 4-bit quantization on non-bias layers.

Unfortunately, the hardware used is not designed to perform native 4-bit operations. Therefore, our 4-bit quantization experiment is used solely for model compression purposes, in which we can reduce the model size to be 8x smaller. To perform inference, we de-quantize the 4-bit model back to fp32 representation, therefore does not achieve any speed up over the vanilla fp32 models.

3.4 Quantization fine-tuning

Quantizing models degrades the quality, especially on smaller architectures. Therefore, after applying quantization, we fine-tune the model under the quantized weight. We find that lowering the learning rate to 0.0001 yields better model quality. Moreover, for 4-bit models, we also find that doubling the warm-up duration helps.

Our 8-bit quantization models mainly aim for speed improvement. Therefore, we apply 8-bit quantization to pruned models to further boost the speed. As shown in Table 2, 8-bit inference achieves significant speedup. However, fine-tuning is necessary to restore the quality degradation.

	BLEU		COMET		Sparsity		
	WMT20	WMT21	WMT20	WMT21	Att.	FFN	Speed (s)
12-1.tiny	36.1	27.6	48.2	41.9	0%	0%	19.2
+ head-lasso pruning	34.7	27.0	42.9	38.8	3%	75%	14.5
+ 8bit quantisation	33.9	26.2	38.8	33.6	3%	75%	9.3
+ finetuning	34.1	26.7	39.8	33.0	3%	75%	9.3
+ rowcol-lasso pruning	33.8	26.3	39.3	34.2	68%	73%	11.6
+ 8bit quantisation	32.9	25.6	33.7	28.7	68%	73%	6.9
+ finetuning	32.9	26.0	35.7	31.3	68%	73%	7.1
12-1.micro	35.4	27.6	46.2	40.2	0%	0%	17.1
+ head-lasso pruning	34.6	26.7	43.0	35.4	3%	72%	14.1
+ 8bit quantisation	33.4	26.0	36.7	31.2	3%	72%	9.2
+ finetuning	33.7	26.5	38.3	33.3	3%	72%	9.2
+ rowcol-lasso pruning	34.3	26.4	40.7	35.1	60%	59%	12.0
+ 8bit quantisation	32.7	25.5	34.2	29.1	60%	59%	7.5
+ finetuning	33.3	25.9	35.2	30.5	60%	59%	7.5

Table 2: 8-bit model performance. BLEU score is calculated from WMT20. Speed is measured on a single core CPU with a mini-batch of 32. We experimented with two types of pruning. Head pruning removes entire heads. Row and column pruning removes entire rows or columns of matrices, resulting in a smaller matrix.

	BLEU		COMET		
	WMT20	WMT21	WMT20	WMT21	Size
12-1.base	37.1	28.3	51.5	45.1	195MB
+ 4bit	36.3	27.7	50.0	43.2	25MB
12-1.tiny	36.0	28.0	47.5	42.5	85MB
+ 4bit	35.0	27.6	42.4	38.3	11MB
8-4.tied.tiny	35.7	27.5	49.4	43.6	69MB
+ 4bit	34.2	26.4	44.4	38.2	9MB

Table 3: 4-bit model performance. BLEU score is calculated from WMT20. All the quantized models include fine-tuning. The inference is done in 32fp, therefore their speed are comparable.

We apply 4-bit quantization solely for size efficiency. Therefore, we quantize non-pruned models since they give better size to quality trade-off, compared to pruned models. The performance of 4-bit models can be seen in Table 3.

4 Software improvements

4.1 CPU

We built our work using the Marian machine translation framework, making some improvements on top of the submission from last year: We used predominantly *intgemm*[3] for our 8-bit GEMM operations, including for the shortlisted output layer. All parameter matrices are quantized to 8-bit offline and the activations get quantized dynamically before a GEMM operation. We only perform the GEMM operation and the following activation in 8-bit integer mode. Right after a GEMM operation, the output is de-quantized back to fp32. More formally we perform $dequantize(\sigma(A * B + bias))$, where the addition of the $bias$, the activation function[4] σ, and the de-quantization are applied in a streaming fashion to prevent a round trip to memory.

Furthermore we make use of Intel's *DNNL*[5] for our pruned models, as it performs better than *intgemm* for irregular sized matrices. Unfortunately, *DNNL* doesn't support streaming de-quantization, bias addition or activation function application.

For the CPU_ALL throughput track, we swept configurations of multiple processes and threads on the platform, settling on 4 processes with 9 threads each. The input text is simply split into 4 pieces and parallelized (Tange, 2011) over processes. The mini-batch sizes did not impact performance substantially and 32 was chosen as the mini-batch size. The Hyperthreads available on the platform were not put into use as the compute on each was saturated by the efficient threads. Each process is bound to 9 cores assigned sequentially and to the memory domain corresponding to the socket with those cores using numactl. Output from the data parallel run is then stitched together to produce the final translation.

Table 4: Comparison between the **master** branch of marian-dev, **our** branch and **our** best 8-bit integer tensorcore work for GPU decoding. For grid search we used last year's submission model and tested on 1 million sentences from last year's WNGT competition (Heafield et al., 2020).

4.2 GPU

For our GPU submission we built up on top of last year's submission, applying experimental GPU optimisations on top of the marian-dev master tree[6] and exploring tensorcore[7] applicability using CUTLASS.[8]

Tensorcores can in theory drastically increase the performance of our computations and were enabled for all of our fp16 experiments. Tensorcores can also improve speed when doing 8-bit integer operations, so we implemented 8-bit integer GPU decoding similar to our CPU scheme. We found that shortlisting doesn't improve the performance, so we didn't use it.

We found that while fp16 decoding works fairly well and delivers good performance improvements for decoding, especially when using a really large mini-batch size. We performed a large parameter sweep on a RTX 3090, as shown on Table 4. Unfortunately, we found no setting in which tensorcore 8-bit integer decoding outperforms the fp16 baseline, likely due to the overhead of quantisating the activations beforehand.

5 Conclusion

We participated in all tracks of the WMT 2021 efficiency tracks and we submitted multiple systems that have different trade-offs between speed and translation quality. We performed ample hyperparameter tuning and exploration in order to take advantage of GPU tensorcores for decoding, but unfortunately we couldn't beat our optimised fp16 baseline. For the CPU submission we used 8bit integer decoding and a combination of pruned and non-pruned system, together with a lexical shortlist in order to reduce the computational cost of the largest GEMM in decoding – the output layer.

Abstract

This paper presents the submission of Huawei Translation Services Center (HW-TSC) to WMT 2021 Efficiency Shared Task. We explore the sentence-level teacher-student distillation technique and train several small-size models that find a balance between efficiency and quality. Our models feature deep encoder, shallow decoder and light-weight RNN with SSRU layer. We use Huawei Noah's Bolt[1], an efficient and light-weight library for on-device inference. Leveraging INT8 quantization, self-defined General Matrix Multiplication (GEMM) operator, shortlist, greedy search and caching, we submit four small-size and efficient translation models with high translation quality for the one CPU core latency track.

1 Introduction

Transformer and its variants (Vaswani et al., 2017; Shaw et al., 2018; So et al., 2019; Dehghani et al., 2019) have become benchmark models in the domain of machine translation. A lot of innovations and engineering optimizations (Tay et al., 2020) in this area are based on Transformer. In general, to train a high-quality translation model, a large amount of data is required. Expensive training and deployment costs pose great challenges to scenarios where hardware are limited or the deployment environment is complex. This task aims to explore a solution that balances efficient decoding and high-quality translation. We focus on the one CPU latency track, which can better demonstrate the capability of our model and inference framework. We explore a balance between speed and quality, and ensure efficient memory usage and light-weight inference framework capability at the same time. We finally submit four models of different sizes.

We use knowledge distillation (Hinton et al., 2015) to train small models. The teacher models come from our WMT 2021 News Shared Task. For the sake of efficient decoding, our models have only 1-layer decoder. However, the number of encoding layers vary. Such settings lead to a great increase of inference efficiency while ensuring the translation quality (Wang et al., 2019).

All of our experiments are conducted based on fariseq (Ott et al., 2019), including the training of teacher and student models, as well as the generation of distillation data.

We use Huawei Noah's Bolt as the inference library. Bolt is a universal deep learning library featuring light weight and high speed. For the CPU task, we realize INT8 quantization inference and efficient GEMM operator, which is faster than Intel oneDNN[2]. With other engineering optimization strategies, we achieve a significant improvement in terms of inference efficiency.

Section 2 describes the teacher-student knowledge distillation process. Section 3 introduces how we optimize inference for this task. Section 4 presents the final result of our submissions.

2 Teacher to Student Knowledge Distillation

Sentence-level distillation (Kim and Rush, 2016; Freitag et al., 2017) have been demonstrated effective for machine translation tasks. First of all, we train a large teacher model that emphasizes translation quality. Then, we translate the source side of the training data and generate a synthetic parallel corpus, as synthetic data is easier for model fitting than real parallel data. Finally, we train student models using the synthetic data, hoping to minimize model sizes while ensuring equal translation quality as the teacher model. We use KD refer to knowledge distillation.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 781–786
November 10–11, 2021.

2.1 Teacher Model

As suggested in the task description, we select four iteration models for the third round and also the models before the final round of fine-tuning. All the models adopt back translation (Edunov et al., 2018) and forward translation (Wu et al., 2019) techniques. Our final ensembled model gained 39.7 BLEU on the WMT 2020 test set. The settings of the four models vary. We make sure that the model sizes are similar by adjusting hyperparameters such size of embedding, encoder layers, decoder layers, ffn size, etc. For more details about our teacher model, please refer to our system report for WMT 2021 News Shared Task.

2.2 Traning data

We comply with the constrained condition and use only data from the WMT 2021 En-De News Task. The size of parallel data after filtering is around 80M. In terms of monolingual data, we only use the news-crawl corpus with 230M sentences. So the size of English data we obtained is around 310M. In our teacher-student distillation experiment, we translate all English sentences from the parallel corpus and only 80M sentences sampled from the English monolingual data. Thus, the ratio of real parallel data to synthetic parallel data is 1:2.

When translating English sentences from the parallel corpus, we generate four candidates using the teacher model. Then we calculate the TER scores between those candidates and the corresponding German reference from the parallel corpus and select the candidate with the lowest TER score as the translation result. When translating monolingual data, the beam size is set to 4. For all translation results, we conduct data filtering with language identification using FastText (Joulin et al., 2017). We also delete sentences of which the source side has less than 5 tokens and those with repeated translated segments. The final sizes of our training data are as follow: 79M real parallel data, 73M synthetic data generated from the source side of parallel data, and 76M synthetic data generated from monolingual sentences. Table 1 summarizes the details of data we use.

Type	Corpora	Size
Parallel	Europarl v10	1.8M
	News Commentary v16	0.4M
	Tilde Rapid corpus	1.6M
	Wiki Titles v3	1.4M
	Common Crawl	2.4M
	ParaCrawl v7.1	82.6M
	WikiMatrix	6.2M
	Totle	96.5M
	Filtered	79.4M
Mono	news-crawl	230M
	For KD Translate	80M
KD	Parallel	79.4M
	Parallel En Translated	73.8M
	Mono En Translated	76.8M
	Total	230M

Table 1: Our training data details. The training data consists of three parts: filtered Parallel corpus, Parallel En translated then filtered and part of news-crawl En translated then filtered.

2.3 Vocabulary

We build a joint subword segmentation model from the synthesized parallel data using SentencePiece (Kudo and Richardson, 2018). The vocabulary size is set to 25,000 tokens. We employ SentencePiece regularization (Kudo, 2018) during data processing. We integrate SentencePiece into the training code and perform subword segmentation on the source side via sampling. Such strategy can improve model quality and robustness.

2.4 Student Model

The standard Transformer with self-attention in decoder has a drawback: decoding complexity increase as the decoding length increases. To address this issue, we refer to some light-weight RNNs, such as SRU (Lei et al., 2018) and SSRU (Kim et al., 2019). Based on our previous experiments and experience, we find that under the teacher-student distillation setting, SSRU models cam basically satisfies the translation quality requirements. As a result, all our student models replace the self-attention layer with SSRU layer on the decoder side. The encoder is still the standard Transformer architecture (Vaswani et al., 2017). We train three sizes of model during our experiment: base, small, and tiny, with different hidden sizes and filter sizes. They all have deep encoders/shallow decoders an architecture capable of increasing speed and maintain quality (Kasai et al., 2021; Wang et al., 2019). All models share the source and target word embeddings and softmax weights.

2.5 Traning

Our distillation experiments are based on fairseq. We also integrate SentencePiece into training. The sampling size is set to 64 and smoothing parameter to 0.1 for subword regularization. All our models are trained using 8 Nvidia Tesla V100 for two days with a batch size of 4096. Because the student models have relatively small capacities, regularization techniques such as dropout and label smoothing are not used. The other parameters use the default fairseq parameters. We save models every 1000 steps and average the last 10 checkpoints to produce the final models.

2.6 Evaluation

We use WMT 2019 and 2020 News Task test sets to measure our models with SacreBLEU (Post, 2018). We use the 12-1 base configuration model as our baseline model, which achieves 38.02 BLEU on 2020 test set, 1.7 BLEU lower than our teacher model. In general, more parameters means better translation quality. The BLEU score of the small.12 model is about 2-2.5 lower than that of the base.12 model, and the BLEU score of the tiny.2 model is also about 2-2.5 lower than that of the small.6 model. For details about parameter settings and BLEU results, see Table 2.

3 Inference Optimizations

For CPU optimization, we use Bolt v1.3.0. Bolt is a standalone open-source deep learning acceleration library. v1.3.0 will be available in September 2021.

3.1 Bolt technical overview

As a universal deployment tool for neural networks, Bolt aims to be faster and lighter. Key features of Bolt include extremely high performance, low-bit inference, widely compatible model converter and low memory usage. Bolt has a standalone C++ runtime, therefore Bolt can perform fast inference without any third-party dependencies. Bolt supports most of the NLP and CV models inference on x86 and ARM CPU as well as MALI GPU. We apply assembly-level optimizations to ensure computing performance and memory accessing efficiency. The operators of Bolt are capable of achieving high throughput near the peak of hardware.

3.2 8-bit Quantization

To accelerate translation tasks on Intel CPU and reduce the model size, Bolt uses linear symmetric quantization (Bhandare et al., 2019) to quantize the weights and part of the activations to 8-bit signed integers. Then Bolt converts the activations to 8-bit unsigned integers by adding 128 because of the limitation of Intel SIMD instructions. To ensure the correctness of matrix multiplication, Bolt applies extra integer offsets which can be obtained offline to the results.

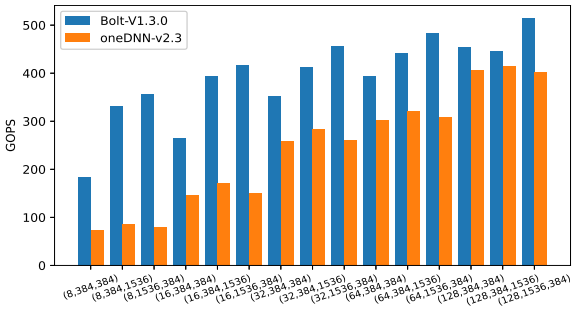

Figure 1: single thread u8s8s32 gemm performance of Bolt v1.3.0 and oneDNN-v2.3 tested on Intel Xeon Gold 6266C CPU, the reported sizes are frequently used in translation task.

The most time-consuming operation of translation tasks is GEMM, Bolt has implemented u8s8s32 gemm kernel, which is faster than Intel oneDNN (MKL-DNN). The u8s8s32 gemm performance of Bolt and oneDNN are shown in Figure 1. We present two key-points of the implementation:

Weights Offline Packing. Assuming the layout of GEMM weights is [N, K], Bolt chunks the weights in the K direction first, and then rearranges the data as NKNxK4 layout, where x is the chunk-size of N direction, x is in {8, 16, 32, 48}. The one that can divide N will be selected.

Highly Efficient Computation. Bolt quantizes bias to 32-bit signed integers, and then adds the offset value obtained offline to bias as the new bias, which is used to initialize the accumulation register of computation for saving addition operations. Bolt uses AVX512 VNNI instructions to perform u8s8s32 matrix multiplication. We have highly optimized the assembly to well utilize the register sources and ensure the instruction efficiency, and we also use memory optimization techniques such as cache-blocking, prefetching and memory alignment. All elements of the product of matrices are 32-bit signed integers. These intermediate data could be efficiently quantized to 8-bit unsigned integers or de-quantized to floating point numbers in registers for the next layer.

Model	Emb.	FFN	Head	Depth	Params(M)	Size(MB)	wmt19	wmt20
Teacher*4	1024	4096	16	25/6	514	2000	46.71	39.70
Base.12	512	2048	8	12/1	53	210	44.65	38.02
Small.12	384	1536	6	12/1	33	132	42.56	35.77
Small.9	384	1536	6	9/1	28	112	42.17	35.73
Small.6	384	1536	6	6/1	22	88	41.15	34.49
Tiny.2	256	1024	4	6/2	13	52	38.92	31.93
Tiny	256	1024	4	6/1	12	48	37.22	30.54

Table 2: Results of Distillation Training. The translation quality deteriorates as the model size decreases: the BLEU score of small model is 2-2.5 lower than that of the base model, and the BLEU score of the tiny model is also about 2-2.5 lower than that of the small model.

3.3 Greedy decoding and Caching

To maximize speed and reduce memory usage, we use greedy search instead of beam search. During decoding, we also skip the final softmax layer and simply get the maximum from the output logits.

Due to the autoregressive model, we also cache the linear transformations for keys and values before the self-attention and cross attention layers.

3.4 Shortlist and Online Quantification

When decoding, we also use the mapping relationship between source and target tokens, a.k.a shortlist, which finds the best matched target token via the source input. Such strategy decreases the dimensions of softmax_weight, which can significantly improve the decoding efficiency while ensuring that the quality is only slightly influenced.

We use fastalign[3] (Dyer et al., 2013) to construct the mapping relationship. During inference, a small target token set is obtained via querying the mapping dynamically, which conflicts with our offline quantization matrix technique. As a result, we try two schemes: a) abandon shortlist and use offline quantification instead; b) keep shortlist and quantify the reduced matrix online. In our experiments, we find that the efficiency of the two versions depends on the size of the target tokens. Because the larger the matrix, the greater the cost of online quantization, and the multiplicative benefits of dimension reduction are offset. For example, on a model we tested, when the input is fixed to 47 tokens, the time cost of a) is 46 ms; the time cost of b) is 68 ms when the size is set to 25000; and the time cost is 48 ms when the size is set to 2000.

Since we focus on the one CPU core latency track, the model processes only one input at a time, and the maximum size of target tokens is less than 2000, so we choose b).

3.5 Submitted Docker images

We choose the base image of ubuntu:18.04. Following the task requirements, our startup script is /run.sh. We use C++ to encapsulate our calls to Bolt and models, SentencePiece, as well as our simple pre- and post-processing. Our model is stored in the /model directory, which contains the converted Bolt model, vocabulary, and shortlist files. The compressed file is provided. Due to the simple runtime environment of Bolt, the final SO package is about 2 MB without any third-party dependency. After quantization, the maximum size of our model is less than 60 MB and the minimum size is about 13 MB. Therefore, the final submitted image is about 100 MB.

4 Optimization results

The latency track we participated in is defined as providing one sentence on standard input and flushing then waiting for your system to provide a translation on its standard output (and flush) before providing the next sentence. So we don't use techniques such as batch. We believe such strategy can better demonstrate the capability our model and inference framework.

After the preceding optimizations, the inference speed is significantly improved. Table 3 lists the results. In general, INT8 inference greatly improves performance. Especially, when the model is relatively large, INT8 improves performance by about three times when comparing with FP32. As the model size becomes smaller, the speed improvement becomes less obvious. But our smallest model also has at least a 2x or above speed improvement. Comparing with that of FP32, the average transla-

[3]http://github.com/clab/fast align

Model	Precious	Size	WPS	BLEU
Base.12	FP32	212	237	38.26
	INT8	53	815	38.02
Small.12	FP32	133	411	36.15
	INT8	33	1158	35.77
Small.9	FP32	112	473	35.90
	INT8	28	1295	35.73
Small.6	FP32	88	550	34.53
	INT8	22	1467	34.49
Tiny.2	FP32	52	759	32.06
	INT8	13	1515	31.93
Tiny	FP32	48	1000	31.01
	INT8	12	2096	30.54

Table 3: Optimization results. The test set is WMT 2020 News Task. The unit of size is MB. WPS refers to the source side. The test environment is Intel(R) Xeon(R) Gold 6278C CPU @ 2.60GH. We submit four models: Base.12, Small.9, Small.6 and Tiny.

tion quality of INT8 models decreases less than 0.1 BLEU.

In our small model setting, the translation quality of the 12-1 model is not significantly improved compared with the 9-1 model, but the inference speed decreases by about 25%. Perhaps under the small model setting, the addition of three encoding layers does not bring significant changes to the model quality. Compared with the Tiny.2 model, the size of our Small.6 model doubles, resulting in an increase of 2.5 BLEU. However, the inference speed are almost the same. In addition, the speed of our Tiny model is 30% faster than our Tiny.2 model by dropping a decoder layer. Our result demonstrates that the number of decoding layers has greater impacts on decoding efficiency. As a result, we submit four models: Base.12, Small.9, Small.6 and Tiny.

The above tests on inference speed are performed with Intel(R) Xeon(R) Gold 6278C CPU @ 2.60GHz.

5 Conclusion

In order to produce a translation system with high inference efficiency, we explore sentence-level distillation techniques and train student models with a trade-off between speed and quality by leveraging Deep-Encoder and Shallow-Decoder models. In terms of inference, we use Huawei Noah's Bolt library. Using a series of optimization techniques, such as INT8 inference and custom efficient GEMM operators, we accelerate inference speed by 2 to 3 times. By using shortlist, greedy search and caching, we submit four models with different settings to the efficiency one CPU core latency task, realizing efficiency improvement under different circumstances.

Abstract

This paper describes the NiuTrans system for the WMT21 translation efficiency task[1]. Following last year's work, we explore various techniques to improve the efficiency while maintaining translation quality. We investigate the combinations of lightweight Transformer architectures and knowledge distillation strategies. Also, we improve the translation efficiency with graph optimization, low precision, dynamic batching, and parallel pre/post-processing. Putting these together, our system can translate 247,000 words per second on an NVIDIA A100, being 3× faster than our last year's system. Our system is the fastest and has the lowest memory consumption on the GPU-throughput track. The code, model, and pipeline will be available at NiuTrans.NMT[2].

1 Introduction

Large and deep Transformer models have dominated machine translation (MT) tasks in recent years (Vaswani et al., 2017; Edunov et al., 2018; Wang et al., 2019; Raffel et al., 2020). Despite their high accuracy, these models are inefficient and difficult to deploy (Wang et al., 2020a; Hu et al., 2021; Lin et al., 2021b). Many efforts have been made to improve the translation efficiency, including efficient architectures (Li et al., 2021a,b), quantization (Bhandare et al., 2019; Lin et al., 2020), and knowledge distillation (Li et al., 2020; Lin et al., 2021a).

This work investigates efficient Transformers architectures and optimizations specialized for different hardware platforms. In particular, we study deep encoder and shallow decoder Transformer models and optimize them for both GPUs and CPUs. Starting from an ensemble of three deep Transformer teacher models, we train various student models via sequence-level knowledge distillation (SKD) (Hinton et al., 2015; Li et al., 2021a; Kim and Rush, 2016) and data augmentation (Shen et al., 2020). We find that using a deep encoder (6 layers) and a shallow decoder (1 layer) gives reasonable improvements in speed while maintaining high translation quality. We improve the student model's efficiency by removing unimportant components, including the FFN sub-layers and multi-head mechanism. We also explore other model-agnostic optimizations, including graph optimization, dynamic batching, parallel pre/post-processing, 8-bit matrix multiplication on CPUs, and 16-bit computation on GPUs.

Section 2 describes the training procedures of the deep teacher models. Then, Section 3 presents various optimizations for reducing the model size, improving model performance and efficiency. Finally, Section 4 details the accuracy and efficiency results of our submissions for the shared efficiency task.

2 Model Overview

Following Hu et al. (2020), Li et al. (2021a) and Lin et al. (2021a), we use the SKD method to train our models. Our experiments also show that the SKD method can obtain better performance than the word-level knowledge distillation (WKD) method, similar to Kim and Rush (2016). Therefore, all of student models are optimized by using the interpolated SKD method (Kim and Rush, 2016), and trained on data generated from the teacher models.

2.1 Deep Transformer Teacher Models

Recently, researchers have explored deeper models to improve the translation quality (Wang et al., 2019; Li et al., 2020; Dehghani et al., 2019; Wang et al., 2020b). Inspired by them, we employ deep Transformers as the teacher models. More specifically, we train three teachers with different configurations, including *Deep-30*, *Deep-12-768*, and *Skipping Sublayer-40*. We also utilize Li et al. (2019)'s

Student Model	Param.	BLEU
Student-6-6-8	96M	33.2
Student-6-1-8	42M	33.0
Student-6-1-1	42M	32.9

Table 1: Reference BLEU scores for the student models on *newstest20*. 6-6-8 means that the model contains 6 encoder layers and 6 decoder layers with 8 attention heads. Other hyper-parameters are the same as the vanilla Transformer.

ensemble strategy to boost the teachers.

Deep-30 Transformer Model: We set the number of encoder layers to 30 in the Transformer model. Other hyper-parameters are identical to the vanilla Transformer.

Deep-12-768 Transformer Model: This model modifies the number of encoder layers, hidden sizes and embedding sizes to 12, 3072 and 768. Such a setting makes the Transformer model deeper and wider. Other hyper-parameters are the same as vanilla Transformer.

Skipping Sublayer-40 Transformer Model: This model uses a simple training procedure that samples one streaming configuration in each iteration (Li et al., 2021a). The number of encoder layers is 40 and model's other setups are same as Li et al. (2021a).

We adopt the relative position representation (RPR) (Shaw et al., 2018) to further improve the teacher models and set the key's relative length to 8.

2.2 Lightweight Transformer Student Models

Although the ensemble teacher model delivers excellent performance, our goal is to learn lightweight models. The natural idea is to compress knowledge from an ensemble into the lightweight model using knowledge distillation (Hinton et al., 2015). We employ sequence-level knowledge distillation on the ensemble teacher model described in Section 2.1.

Seqence-level Knowledge Distillation The SKD will make a student model mimic the teacher's behaviors at the sequence level. Moreover, the method considers the sequence-level distribution specified by the model over all possible sequences $\mathbf{t} \in T$. Following Kim and Rush (2016), the loss function of SKD method for training students is

$$\mathcal{L}_{\text{SKD}} \approx -\sum_{\mathbf{t}\in\mathcal{T}} \mathbf{1}\{\mathbf{t}=\hat{\mathbf{y}}\}\log p(\mathbf{t}\mid\mathbf{s}) \quad (1)$$

$$= -\log p(\mathbf{t}=\hat{\mathbf{y}}\mid\mathbf{s}) \quad (2)$$

where $\mathbf{1}\{\cdot\}$is the indicator function, $\hat{\mathbf{y}}$ is the output of teacher model using beam search, $\mathbf{s}$ symbolizes the source sentence and $p(\cdot|\cdot)$ denotes the conditional probability. We use the ensemble teacher model to generate multiple translations of the raw English sentences. In particular, we collect the 5-best list for each sentence against the original target to create the synthetic training data. However, we select only 12 million synthetic data to train our student models to reduce training costs. We find that student models will not have better performance when increasing the number of training data.

Fast Student Models As suggested in Hu et al. (2020), the bottleneck of translation efficiency is the decoder part. Hence, we accelerate the decoding by reducing the number of decoder layers and removing multi-head mechanism[3]. Inspired by Hu et al. (2021), we design the lightweight Transformer student model with one decoder layer. We further remove the multi-head mechanism in the decoder's attention modules. Table 1 shows that the Transformer student model with one decoder layer and one decoder attention head can achieve similar translation quality to the baseline. Therefore, we train four different student models based on the Transformer architecture with one decoder layer and one decoder attention head. Those student models are described in detail in the Table 2. Besides, experiments show that adding more encoder layers cannot improve the performance when the student model has 12 encoder layers. Therefore, our submissions have 12 encoder layers at most.

2.3 Data and Training Details

Our data is constrained by the condition of the WMT 2021 English-German news translation task[4], and we use the same data filtering method as Zhang et al. (2020). We select 20 million pairs to train our teacher models after filtering all official released parallel datasets (without official synthetic datasets). The data is tokenized with Moses tokenizer (Koehn et al., 2007), and jointly Byte-Pair

[3] Although the multi-head mechanism does not increase the parameter of the model, it brings non-negligible computational costs.

[4] https://www.statmt.org/wmt21/translation-task.html

Student Model	N-Enc	Dim-FFN	Param.	Speedup	newstest18	newstest19	newstest20
Student-12-1-512	12	512	56M	2.0×	45.3	41.7	33.2
Student-6-1-512	6	512	38M	2.3×	44.5	41.0	32.7
Student-6-1-0	6	0	37M	2.4×	43.9	40.6	32.4
Student-3-1-512	3	512	28M	2.6×	42.8	40.0	31.5

Table 2: N-Enc is the number of encoder layers and Dim-FFN denotes the feed-forward network (FFN) size. The Speedup and BLEU results are measured on a TITAN V GPU. The Speedup is calculated comparing with our ensemble teacher model. The student model has not FFN component in the decoder when the Dim-FFN is 0. Evaluation is performed without inference optimizations and with a beam size of 1.

Teacher Model	Param.	BLEU
Deep-30	138M	32.8
Deep-12-768	170M	33.3
Skipping Sublayer-40	171M	33.1
Ensemble	479M	33.4

Table 3: Results on *newstest20*-Teacher Models. We train our teacher models with the RPR and back-translation.

Encoded (BPE) (Sennrich et al., 2016) with 32K merge operations using a shared vocabulary. After decoding, we remove the BPE separators and detokenize all tokens with Moses detokenizer (Koehn et al., 2007).

Teacher Models Training We train three teacher models using *newstest19* as the development set with `Fairseq` (Ott et al., 2019). We share the source-side and target-side embeddings with the decoder output weights. We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.997$ and $\epsilon = 10^{-8}$ as well as gradient accumulation due to the high GPU memory footprints. Each model is trained on 8 TITAN V GPUs for up to 11 epochs. The learning rate is decayed based on the inverse square root of the update number after 1,6000 warm-up steps, and the maximum learning rate is 0.002. After training, we average the last five checkpoints in the training process for all models. Similar to Zhang et al. (2020), we train our teacher models with a round of back-translation with 12 million monolingual data selected from the News crawl and News Commentary. We train three De→En models with the same method and model setup to generate pseudo-data. Table 3 shows the results of all teacher models and their ensemble, where we report SacreBLEU (Post, 2018) and the model size. Our final ensemble teacher model can achieve a BLEU score of 33.4 on *newstest20*.

Student Models Training The training settings for student models are the same for the teacher models, except its learning rate is 0.0007 and warmup-updates is 8000. In addition, we also use the cutoff method (Shen et al., 2020) to boost our student models[5] and we train our student model with 21 epochs. Table 2 shows the results of all student models. Our student model yields a significant speedup (2×-2.6×) with modest sacrifice in terms of BLEU (0.2-0.9 on *newstest20*).

2.4 Interpretation of Results

After training the final student models, we evaluate their BLEU scores on the English-German *newstest20*, *newstest19*, and *newstest18* before any inference optimization. Results show that the student models can achieve very similar performance to the teachers. For instance, the *Student-12-1-512* model delivers a loss of 0.2 BLEU score compared to the ensemble of teacher models.

3 Optimizations for Decoding

Our optimizations for decoding are implemented with NiuTensor [6]. The optimizations can be divided into three parts, including optimizations for CPUs, GPUs, and device-independent techniques.

3.1 Optimizations for GPUs

For the GPU-based decoding, we mainly explore dynamic batching and FP16 inference.

Dynamic Batching Unlike the CPU version, the easiest way to reduce the translation time on GPUs is to increase the batch size within a specific range. We implement a dynamic batching scheme that maximizes the number of sentences in the batch while limiting the number of tokens. This strategy

[5] https://github.com/stevezheng23/fairseq_extension/tree/master/examples/translation/augmentation

[6] https://github.com/NiuTrans/NiuTensor

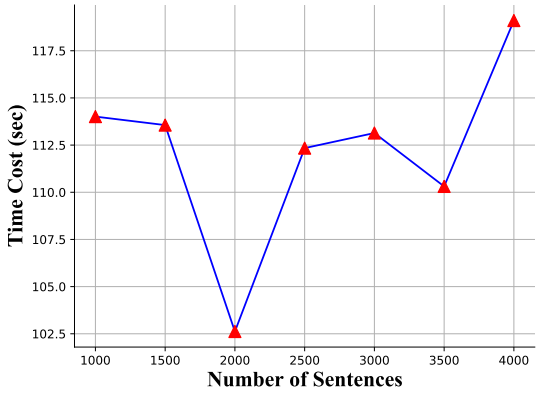

Figure 1: Results on Student-6-1-512 model. The time cost is measured on an Intel Xeon Gold 6240 CPU with 100,000 lines of raw English sentences with an averaged length of 18 words.

significantly accelerates the inference compared to a fixed batch size when the sequence length is short.

FP16 Inference Since the Tesla A100 GPU supports calculations under FP16, our systems execute almost all operations in 16-bit floating-point. To escape overflow, we convert the data type before and after the softmax operation in the attention modules. We also reorder some operations for numerical stability. For instance, we apply the scaling operation (dived by $\sqrt{d_k}$) to the query instead of the attention weights. To accelerate our systems further, we replace the vanilla layer normalization with the L1-norm (Lin et al., 2020). Also, we find that removing the multi-head mechanism (by setting the head to 1) in the student models significantly improves the throughput without performance loss.

3.2 Optimizations for CPUs

We employ the *Student-6-1-512* and *Student-3-1-512* models as our CPU submissions. Two methods are discussed to speed up the decoding for our CPU systems.

The Use of MKL We use the Intel Math Kernel Library (Wang et al., 2014) to optimize our NiuTensor framework, which helps our systems to make the full use of the Intel architecture and to extract the maximum performance.

8-bit Matrix Multiplication with Packing We implement 8-bit matrix multiplication using the open-source library FBGEMM (Khudia et al., 2021). Following Kim et al. (2019), we quantize each column of the weight matrix separately with different scales and offsets. Scale and offsets for weight matrix are calculated by:

$$b_{scale}[j] = \frac{14\sigma_j}{255} \tag{3}$$

$$b_{zeropoint}[j] = \frac{127 - (\bar{x}_j + 7\sigma_j)}{b_{scale}[j]} \tag{4}$$

where σ_j and $\bar{x}_j$ refers to average and standard deviation for the j-th column. The quantization parameters for the input matrix is calculated by:

$$a_{scale} = \frac{x_{max} - x_{min}}{255} \tag{5}$$

$$a_{zeropoint} = \frac{255 - x_{max}}{a_{scale}} \tag{6}$$

where x_{max} and x_{min} are the maximum and minimum values of the matrix respectively. With FBGEMM API, we also execute the packing operation to change the layout of the matrices into a form that uses the CPU more efficiently. We pre-quantize and pre-pack all the weight matrices to avoid repeated operation during inference.

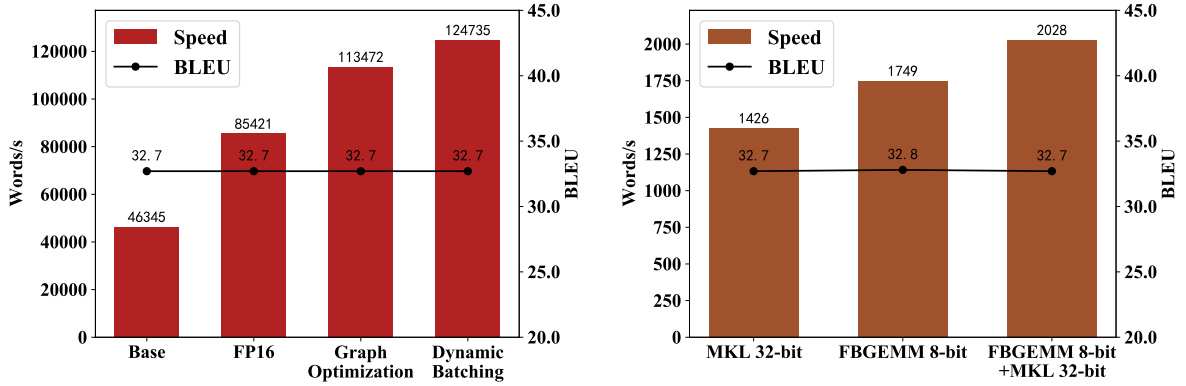
where x_{max} and x_{min} are the maximum and minimum values of the matrix, respectively. We also execute the packing operation to change the layout of the matrices into a form that uses the CPU more efficiently. We pre-quantize and pre-pack all the weight matrices to avoid repeated operation during inference.

3.3 Other Optimizations

Furthermore, we explore other device-independent methods to optimize our systems. Those methods help our systems to achieve obvious speed-up without translation precision loss.

Graph Optimization A neural net can be represented by a directed acyclic graph (DAG), where the nodes represent tensors and the connections represent operations. We optimize our system by simplifying the computational graph of the models. The optimizations for the graph are detailed as follows:

- Computation optimization. We prune all redundant operations and reorder some operations in the computational graph. For instance, we remove the *log-softmax* operation in the output layer when using greedy search. We also extract the *transpose* operations from matrix multiplications to the begin of decoding.



(a) Performance of our GPU system

(b) Performance of our CPU system

Figure 2: BLEU on *newstest20* versus words per second (Words/s) with different optimizations on a TITAN V GPU and Intel Xeon Gold 5118 CPUs. Result of decoding speed is measured with 0.1 M sentences (average length is 18). When the GPU system is running, it will use all free CPUs on the device.

- Memory optimization. We reuse all possible nodes to minimize the memory consumption. We also reduce the memory allocation or movement with an efficient memory pool. Moreover, we sort the source sentences in descending order of length and detect the peak memory footprint before decoding.

Parallel Execution We use the GNU Parallel (Tange, 2011) for our systems to perform tasks in parallel. More specifically, we split the standard input into several lines and deliver them via the pipeline. The method is used to accelerate pre-processing, post-processing, and decoding on CPUs. We also find that the system decoding speed/memory is strongly correlated with the number of lines per task. To find the best number of lines for each run, we measure the time cost in different setups against the number of lines. Figure 1 shows that 2000 is a relatively good choice, and the *Student-6-1-512* model can translate 100,000 sentences in 102.6s on CPUs under this setup.

Better Decoding Configurations As aforementioned, our GPU versions use a large batch size, but the batch size on the CPU is much smaller. To be more clear, there is sentence batch (*sbatch*) and word batch (*wbatch*) in our systems, and they restrict the number of sentences and number of words in a mini-batch to not be greater than *sbatch* and *wbatch*, respectively. In our GPU systems, we set the *sbatch*/*wbatch* to 3072/64000. For our CPU systems, the number of processes is managed by the Parallel tool, which is more efficient and accurate. Moreover, We use one MKL thread for each process and set the *sbatch*/*wbatch* to 128/2048.

Greedy Search In the practice of knowledge distillation, we find that our systems are insensitive to the beam size. It means that the translation quality is good enough even using greedy search in all submissions.

Fast Data Preparation We use the fastBPE[7], a faster C++ version of subword-nmt[8], to speed the BPE process. Moreover, we also use the fast-mosestokenizer[9] for tokenization.

3.4 Results after Optimizations

Figure 2 plots the *Student-6-1-512* model's performance with different decoding optimizations. All results show that our optimizations can significantly speed up our system without losing BLEU. What is interesting about the BLEU is that we can achieve additional improvements of 0.4/0.1 BLEU points on the GPU/CPU through decoding optimizations in all our experiments. We also measure other models after decoding optimizations and find their performance is similar to the *Student-6-1-512* model.

4 Submissions and Results

4.1 Submissions

For the GPU track submissions, our GPU systems are compiled with CUDA 11.2. We set the num-

[9] https://github.com/mingruimingrui/fast-mosestokenizer

ber of decoder layers and the number of our decoder attention head to 1 as described in Section 2.2 for all our GPU systems. We see a speedup of more than 6× on the GPU system created by *Student-12-1-512* model and a slight decrease of only 0.2 BLEU on the *newstest20* compared to the deep ensemble model. The system is named as ***Base-GPU-System*** in following part. We continue to reduce the number of encoder layers for more accelerations, and the GPU system with *Student-6-1-512* model reduces the translation time by one-four with only six encoder layers compared to the *Base-GPU-System*. Our fastest GPU system consists of three encoder layers and one decoder layer, which achieves 31.5 BLEU on the *newstest20* with GPU and 1.6× speedup compared to the *Base-GPU-System*. We also employ the *Student-6-1-0* model to create a GPU system that can achieve the 1.3× speedup compared to *Base-GPU-System*. Our systems are compiled in the 11.2.1-devel-centos7 docker image, an NVIDIA open-source image[10]. We copy the executables, dependence tools, and model files to the 11.2.1-base-centos7 docker image (final submission). In this way, we ensure all of our system docker images can be executed by the organizers successfully and reduce the docker images size.

For the CPU track submissions, we use the test machine, which has 18 virtual cores. Our CPU version is compiled with MKL static library, and the executable file is 23MiB. Also, we use the 8-bit matrix multiplication with packing to speed the matrix multiplication in the network. We use the *Student-3-1-512* and *Student-6-1-512* models in our CPU systems, and they respectively achieve 31.5 and 32.8 BLEU on *newstest20*. For our CPU docker images, we use the base-centos7 docker image[11] to deploy our CPU MT systems.

Furthermore, all submissions are tested with different cases, including dirty data, empty input, and very long sentences. The test results show that our systems can run successfully with exceptional inputs.

4.2 Results

Our systems for the GPU-throughput track are the fastest overall submissions. Specifically, the *Student-3-1-512* system can translate about 250 thousand words per second and achieve 25.5 BLEU on *newstest21*. We attribute this to the comparison of the performance of our teacher model on WMT21. In the CPU track, our system also has competitive performance. Our fastest CPU system created by *Student-3-1-512* model can translate about 48 thousand words per real second via 36 CPU cores and can achieve 25.5 BLEU. We find that reducing the number of encoder layers for student model achieves lower BLEU scores at a similar speed for our CPU systems. Moreover, we compare the cost-effective of GPU and CPU decoding in terms of millions of words translated per dollar according to the official evaluation results. We find that highly-effective GPU decoding is about to out-compete CPU-bound decoding in terms of cost-effective. Noteworthy, our GPU system with *Student-3-1-512* model can translate 300M words per dollar with acceptable quality. Also, all of our GPU systems have the lowest RAM consumption (about 4 GB) to official test compared with the submissions of other participants.

5 Conclusion

We have described our systems for the WMT21 shared efficiency task. We have explored various efficient Transformer architectures and optimizations specialized for both CPUs and GPUs. We have shown that a lightweight decoder and proper optimizations for different hardware can significantly accelerate the translation process with slight or no loss of translation quality. Our fastest GPU system with three encoder layers and one decoder layer is 11× faster than the deep ensemble model and lose 1.9 BLEU points.

TenTrans High-Performance Inference Toolkit for WMT2021 Efficiency Task

Kaixin Wu, Bojie Hu, Qi Ju*
TencentMT Oteam
{danielkxwu, bojiehu, damonju}@tencent.com

Abstract

The paper describes the TenTrans's submissions to the WMT 2021 Efficiency Shared Task. We explore training a variety of smaller compact transformer models using the teacher-student setup. Our model is trained by our self-developed open-source multilingual training platform TenTrans-Py[1]. We also release an open-source high-performance inference toolkit[2] for transformer models and the code is written in C++ completely. All additional optimizations are built on top of the inference engine including attention caching, kernel fusion, early-stop, and several other optimizations. In our submissions, the fastest system can translate more than 22,000 tokens per second with a single Tesla P4 while maintaining 38.36 BLEU on En-De *newstest2019*. Our trained models and more details are available in TenTrans-Decoding competition examples[3].

1 Introduction

We participate in the GPU throughput track of the Workshop on Machine Translation (WMT) 2021 Efficiency Shared Task. The efficiency task aims at exploring the different techniques for training and optimizing GPU models for high throughput while preserving the highest possible accuracy. While we do not pay more attention to training techniques, we apply a variety of optimizations to improve the computation efficiency of our GPU models in the inference phase.

In terms of the training phase, we trained a variety of smaller compact student models using the common teacher-student training approach (Hinton et al., 2015; Kim and Rush, 2016) on our open-source multilingual training platform TenTrans-Py. All of them are based on the deep transformer which has proven more effective and has lower training costs than the wide transformer models (Wang et al., 2019). For the inference phase, our strategy for the shared task includes attention caching, kernel fusion, early-stop, and several other optimizations. All of these optimizations are employed in a high-optimized and C++-based inference engine TenTrans-Decoding.

The paper is structured as follows: Section 2 describes the data preparation and the training details, then Section 3 presents the variety of ours optimizations to improve decoding efficiency. The detailed accuracy and efficiency results are shown in Section 4. Finally, we conclude our work in Section 5.

2 Teacher-student Training

To train smaller compact student models, the teacher-student training approach (Hinton et al., 2015; Kim and Rush, 2016) is adopted. First, a large model (the teacher) is trained on all available bilingual data, included synthetic data generated by the back-translation (Sennrich et al., 2015a) method. Multiple model ensembles are also typically used to build stronger teacher systems. Then, all our small optimized models (the student) are created using sequence-level knowledge distillation (Kim and Rush, 2016) and trained on data generated from the teacher model. The sequence-level knowledge distillation is a common technique that has proven successful for reducing the size of neural models, especially in NMT tasks.

2.1 Deep Transformer

Transformer networks (Vaswani et al., 2017) are the current state-of-the-art in many machine translation tasks, and the deep transformer (Wang et al., 2019) which simply stacks more encoder layers has been proved to further enhance the accuracy of the model. To stabilize the training of the deep

Table 1: Transformer model configurations and SacreBLEU (Post, 2018) scores on *newstest2019*.

model, we use the Pre-Norm strategy (Wang et al., 2019). The layer normalization (Ba et al., 2016) is applied to the input of every sub-layer which the computation sequence could be expressed as: layer normalization $\longrightarrow$ multi-head attention / feed-forward $\longrightarrow$ residual-add. All of our models are based on deep transformer architecture.

2.2 Teacher & Student Models

The different model configurations for both teacher and student models are presented in Table 1. We train a teacher model and three student model variant with a different number of encoder layers N_{enc}, decoder layers N_{dec}, hidden size d_{model}, and feed-forward network size d_{ff}. We adopt a deep encoder and a shallow decoder architecture of all student models, and the number of decoder layers is set to 1 by default. All of our models tie source embedding, target embedding, and softmax weights.

2.3 Data and Training Details

Dataset Following the shared task setup, we limit our training data to the WMT 2021 English-German translation task. The bilingual data used in the English-German task includes all the available corpora provided by WMT 2021: Europarl v10, ParaCrawl v7.1, News Commentary, Wiki Titles v3, Tilde Rapid corpus and WikiMatrix. For monolingual data, we only use NewsCrawl2020, Europarl v10, and News Commentary for back-translation.

Data preprocessing Then, we normalize punctuation and tokenize all data with the Moses tokenizer (Koehn et al., 2007). For the bitext datasets, we remain sentences no longer than 200 words as well as sentence pairs with a source / target length ratio between 0.3 and 2.0. The fast-align tools (Dyer et al., 2013) are applied to further obtain a cleaned and high-quality parallel corpus. For the monolingual dataset, the sentences with words between 4 and 200 are remained. See Table 2 for details on the bitext and monolingual dataset sizes. After that, we use joint byte pair encodings (BPE) with 32K split operations for subword segmentation (Sennrich et al., 2015b).

	En-De	De (**mono.**)
No filter	49.2M	57.0M
+ length filter	46.9M	55.2M
+ fast-align	41.2M	-

Table 2: Number of sentences in bitext and monolingual datasets for different filtering schemes.

Student training First, we train the teacher model on all available bilingual data, including synthetic data through the back-translation method, and we use English-German *newstest2019* as the development set. We ensemble four best models for building a stronger teacher. Then, the English part of the bilingual data is translated by the teacher model and the resulting synthesized parallel data is used to train the student models. Table 1 shows their evaluation scores on *newstest2019* of different models. The results correlate well with the expectation that more model parameters lead to better performance. Our distillation student models show strong competitiveness even when the number of parameters is greatly reduced.

3 GPU Inference Optimizations

3.1 Implementation: TenTrans-Decoding

TenTrans-Decoding is an open-source high-optimized inference engine for transformer models and the code is written in C++. TenTrans-Decoding's goal is to offer a lightweight and rapid deployment of high-performance service solutions for executing models. All additional optimizations are built on top of the inference engine.

3.2 Attention Caching

We apply the common technique of caching linear projections in Transformer decoder layers. More specifically, we cache the linear transformations for keys and values before cross-attention layers and each step of decoder self-attention layers.

3.3 Kernel Fusion

To reduce kernel launching overhead and enhance the GPU computation efficiency, we implement many kernel fusion techniques for our Transformer models.

- ***Add_bias_residual_layerNormalization*** For the layer normalization between two General Matrix Multiplications (GEMMs), we reorganize the *AddBias* kernel, residual network, and *LayerNormalization* kernel into a single one.
- ***Add_bias_ReLU*** In the Feed-Forward network layers of the Transformer model, the *AddBias* kernel and *ReLU* kernel are fused into one.
- ***Add_bias_residual*** For the output of every encoder or decoder layer, we fuse the *AddBias* kernel and residual network.
- ***Fused_multihead_attention*** In addition to the fusion techniques above, we also fuse the attention layer by packing GEMMs and bias to further improve the computation efficiency.

Figure 1 details the kernel fusion techniques of a transformer decoder layer. The computation graph of a transformer can be reorganized into a more compact graph by fusing all the kernels between two GEMMs into a single one.

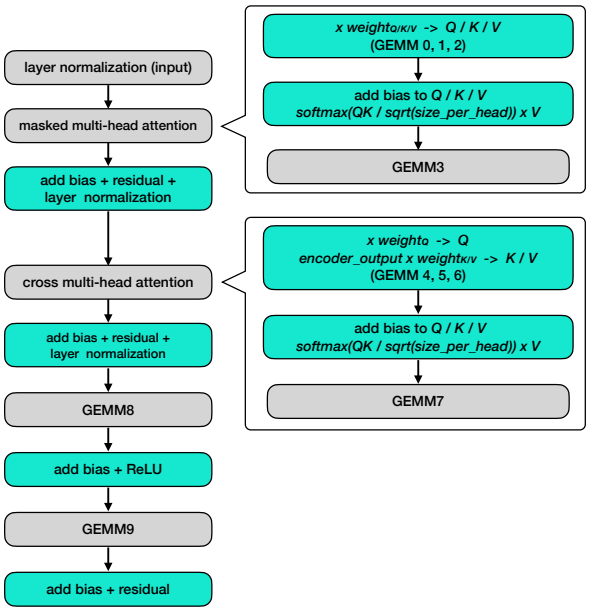

Figure 1: Kernel fusion of a transformer decoder layer. The part in darker color represent using the kernel fusion technique.

	Speed	Ratio	BLEU
TenTrans-Py	696.5	1.00x	38.91
TenTrans-Decoding	1822.4	2.62x	38.91
+ kernel fusion	2565.4	3.68x	38.82
+ early-stop	2682.5	3.85x	38.82
+ sorted batch	5034.8	7.23x	38.98

Table 3: The decoding speed (source tokens per second) and SacreBLEU scores on *newstest2019* for student-tiny-20_1. The speed is measured by a single Tesla P4 GPU and the beam size is 4.

3.4 Early-stop

In batch decoding, the number of decoding ending steps between sentences is different. The early-stop strategy which optimizes kernel function is adopted to avoid redundant computation. For sentences that have been decoded in batch, there is no additional computation for these sentences until the whole batch has been decoded.

3.5 Sorted Batch & Greedy Search

In addition to the methods above, we sort all input sentences from shortest to longest, and the batch size is 128 in our settings. The sorting makes the batches contain sentences of similar sizes which reduces the amount of padding and increases the computation efficiency. During decoding, we use greedy search instead of beam search since we find the distillation model are insensitive to the beam size. We skip the final softmax layer and simply get the maximum from the output logits.

4 Optimization Results

Table 3 shows the impact of different inference optimizations when decoding the Student-tiny-20_1 student transformer model. TenTrans-Decoding leads to a 2.62x speedup than the TenTrans-Py baseline without any inference optimizations. Combine all the inference optimizations mentioned above, it can achieve a 7.23x speedup with no accuracy loss over the baseline.

Table 4 presents all of our submissions and we only participate in the GPU-throughput track. As details in Table 4, we report our model configuration, model size, and metric for translation, including SacreBLEU scores on *newstest2019* and the real translation time cost. All of our systems are tested on a single Tesla P4 GPU. All student models follow a deep encoder and a shallow decoder architecture, the number of decoder lay-

transformer	Model size	Speed (tokens/s)	Ratio	Time Cost (s)	BLEU
Teacher-base-20_6 (2xFFN)	642MB	6274.0	1.00x	9.80	39.97
Student-base-20_1	354MB	12128.1	1.93x	5.07	39.93
Student-base-10_1	234MB	15900.3	2.53x	3.87	39.30
Student-tiny-20_1	113MB	22481.8	3.58x	2.74	38.36

Table 4: Results of all submissions. Time Cost in seconds to translate *newstest2019* and BLEU scores are reported using SacreBLEU. The *newstest2019* contains 1997 sentences. All systems were executed on a single Tesla P4 GPU with greedy search.

ers is 1 by default. All student models training with sequence-level distillation show a competitive performance. The Student-base-20_1 transformer achieves a 1.93x speedup over the teacher baseline with almost no accuracy loss, and the amount of parameters is greatly reduced. Compared with the teacher baseline, the Student-base-10_1 transformer has a speedup of 2.53x times and a slight decrease of only 0.67 BLEU. The Student-tiny-20_1 transformer, our fastest system, which has one-sixth parameters of the teacher model, achieves 38.36 BLEU on *newstest2019* and speeds up the teacher baseline by 3.58x.

In this version, we do not pay more attention to the model size, memory footprint, and low precision inference (e.g., FP16). All operations on the model are based on FP32 floating-point numbers. In the future version, we plan to optimize these points mentioned above.

5 Conclusion

This work presents the TenTrans's submissions to the 2021 Efficiency Shared Task of WMT. We show the deep encoder and shallow decoder student models that training with sequence-level distillation can achieve a competitive performance both in speed and accuracy compared with the teacher baseline. To further improve computation efficiency, we combine several optimizations including attention caching, kernel fusion, early-stop and sorted batch. Finally, our fastest student model achieves a speedup of 3.58x times, while only has one-sixth parameters of the teacher baseline.

In the future, we will apply low-precision inference (e.g., FP16) and more kernel fusion techniques to improve the computation efficiency of our GPU systems. Furthermore, we will continue to explore a more efficient teacher-student training approach to obtain compact student models with competitive performance both in quality and speed.

Lingua Custodia's participation at the WMT 2021 Machine Translation using Terminologies shared task

Melissa Ailem, Jinghsu Liu and Raheel Qader
Lingua Custodia, France
{melissa.ailem,jingshu.liu,raheel.qader}@linguacustodia.com

Abstract

This paper describes Lingua Custodia's submission to the WMT21 shared task on machine translation using terminologies. We consider three directions, namely English to French, Russian, and Chinese. We rely on a Transformer-based architecture as a building block, and we explore a method which introduces two main changes to the standard procedure to handle terminologies. The first one consists in augmenting the training data in such a way as to encourage the model to learn a copy behavior when it encounters terminology constraint terms. The second change is constraint token masking, whose purpose is to ease copy behavior learning and to improve model generalization. Empirical results show that our method satisfies most terminology constraints while maintaining high translation quality.

1 Introduction

Neural-based architectures have become standard for Machine Translation (MT), they are efficient and offer state-of-the-art performance in many scenarios (Vaswani et al., 2017). However, these models often trained on very large corpora turn out to be less adequate in domains that require very careful use of terminology. For instance, consider the following English sentence from a biomedical corpus ***"now for the fever you can take a tachipirina sweet"*** . The term ***"tachipirina sweet"*** refers to ***"paracétamol"*** in French. Unfortunately, a generic English-French Neural MT (NMT) model would translate the above sentence as: ***"maintenant pour la fièvre tu peux prendre un tachipirina bonbon"***, where the term ***"tachipirina sweet"*** is translated ***"tachipirina bonbon"***.

The goal of the WMT21 shared task on machine translation using terminology constraints is to explore methods that can take into account terminology constraints, in order to improve MT models' accuracy and consistency on specific domains. In the literature there are two main families of methods to take into account specific terminologies. One family incorporates terminology constraints at inference (Post and Vilar, 2018; Susanto et al., 2020). Members of this category can guarantee strict enforcement of constraints, however this often comes at the cost of higher decoding time and decreased accuracy (Hokamp and Liu, 2017; Post and Vilar, 2018). The other family of method integrates terminologies at training time (Dinu et al., 2019; Ailem et al., 2021), and they have the benefit of not changing the NMT model as well as of not incurring additional computational overheads at inference time (Crego et al., 2016; Song et al., 2019; Dinu et al., 2019).

We participate in the following three directions: English to French, Russian, and Chinese, and the system we submit falls into the second family of method incorporating terminologies at training time. More precisely, we explore a variant of the models proposed in (Ailem et al., 2021), which we train for each language pair. Following this work, we first annotate our training data with the constraints using tags to distinguish constraints terms from other tokens in the sentences. Second, we further perform constraint-token masking, which improves model robustness/generalization as supported by our experiments.

The rest of the paper is organized as follows: section 2 reviews the details of our system, section 3 describes the training data selection, the development and test sets, as well as the terminologies used for each language pair, and section 4 presents the different experimental settings and results.

2 Method

Our objective is to encourage neural machine translation to satisfy lexical constraints. To this end, we rely on the approch proposed in (Ailem et al., 2021), which introduces two changes to the standard procedure, namely training data augmentation

Figure 1: Illustration of TrAining Data Augmentation (TADA) and MASK.

and token masking. In the following we describe these two operations, which are also depicted in Figures 1 and 2.

TrAining Data Augmentation (TADA). The purpose of this step is to encourage the NMT model to exhibit a copy behavior when it encounters constraint terms whose translation should be consistent with some terminology. This step, illustrated in Figures 1 and 2, consists in using tags to annotate our training data with the terminology constraints, i.e., indicate the constraints (if any) in a given source sentence. Note that in the literature, there are other variants that use additional information such as source factors (Dinu et al., 2019). We do not use such information, and we specify terminologies using tags only.

Token MASKing (MASK). We further consider masking the source part of the constraint – tokens in blue – as illustrated in Figure 1 last row. As suggested in (Ailem et al., 2021), this masking strategy provides a more general pattern for the model to learn to perform the copy operation every time it encounters the tag $< S >$ followed by the MASK token. Moreover, this can make the model more apt to support conflicting constraints, i.e., constraints sharing the same source part but which have different target parts. This may be useful in situation in which some tokens must be translated into different targets for some specific documents and contexts at test time.

3 Data

This section provides information and some statistics regarding the datasets for the three language pairs we consider.

Training Data Selection. We consider three language pairs, namely English to French, Russian, and Chinese. Since our method acts at training time, we first perform a training data selection in order to obtain a reasonable number of sentences containing at least one term from the provided terminologies. To do so, we consider both bilingual and monolingual data, provided as part of the shared task. In fact, we observe that bilingual data do not contain many sentences with terminology terms. Thus, we rely on back-translation of monolingual data, which contains more recent news on COVID-19, to obtain more sentence pairs with terminologies. We rely on OpusMT[1] to back translate the Russian monolingual to English. For Chinese and French we use in-house translation engines. Note that we further convert the Chinese data into simplified Chinese using OpenCC. Following previous work on terminology control (Dinu et al., 2019; Ailem et al., 2021), only 10% of the training sentences are annotated in order to maintain the model's performance in terminology free cases. The details about training data selection for the different language pairs are summarized in tables 1, 2 and 3.

Development and Test Sets. For all language pairs, a development and test sets are provided. Note that for the test sets we have access to the source part only. For the dev sets, the terminology constraints associated with each sentence are available, for the test sets this information is not available, and we leverage the terminology files to find constraint terms in these sets. Just like the training data, both test and dev sets are augmented with the terminology constraints as presented in figures 1 and 2. The dev/test sets of the different language pairs share the same English source file containing 971/2100 sentences respectively.

Terminologies. For each language pair, we use the provided terminologies to annotate our train, dev and test sets. The terminologies consist of respectively 670, 925 and 710 unique source-target terms for English → French, Russian and Chinese. We also observe that one source term might be associated with one or more target terms. In that

case, when annotating the train and dev sets we choose the target term used in the ground truth translation. For the test set, we select one of the possible terms at random.

4 Experimental results

4.1 Settings

For English to French and Russian pairs, we first tokenize the terminology files and the train/test/dev sets before annotating them with the terminology constrains. We use the Moses tokenizer (Koehn et al., 2007) for this step. We then rely on BPE encoding (Sennrich et al., 2015) with 40k merge operations to segment words into subword-units, which results in a joint vocabulary size of 42588 words for English->French, and vocabulary sizes of (44644, 47532) for the (English, Russian) pair. For English->Chinese we rely on sentence piece (Kudo and

Richardson, 2018) for tokenization, which also performs BPE encoding simultaneously and results in a vocabulary size of 52172 for Chinese and 39996 for english. We then annotate the train/test/dev sets with the terminology constraints.

As a building block for our system, we use the transformer architecture (Vaswani et al., 2017) with 6 stacked encoders/decoders and 8 attention heads. For English-French, the source and target embeddings are tied with the softmax layer. We use 512-dimensional embeddings, 2048-dimensional inner layers for the fully connected feed-forward network and a dropout rate of 0.3. The models are trained for a minimum of 50 epochs and a maximum of 100 epochs with a batch size of 2000 tokens per iteration and an initial learning rate of 5×10^{-4}. For each language pair, the validation set is used to compute the stopping criterion. We use a beam size of 5 during inference for all models.

4.2 Results

For all language pairs, the models are evaluated using the standard MT evaluation metrics (BLEU and COMET scores) as well as other terminology-targeted metrics (Anastasopoulos et al., 2021). The latter include the "Exact-Match Accuracy" measure, which simply compute the percentage of constraint terms present in the predicted translations. Although this measure provides an indication of terminology satisfaction, it can only assess whether a term is present in the hypotheses without evaluating whether this target term is correctly placed. To overcome this issue, the authors in (Anastasopoulos et al., 2021) proposed an additional measure, namely "Window Overlap", which computes the percentage of similar tokens surrounding the constraint terms – within a defined window – in the ground truth and the generated hypotheses. Finally, the models are also evaluated in terms of "Terminology-biased TER" score, which is an edit distance based metric (Snover et al., 2006; Anastasopoulos et al., 2021).

We compare the our model TAG+MASK with the traditional transformer baseline (Vaswani et al., 2017) and the constrained decoder approach (Post and Vilar, 2018), which integrates the constraints during inference time. Results on English → French data are presented in table 4. We observe that the TAG+MASK approach significantly improves over baselines in terms of all measures.

Table 5 depicts the results that the submitted system reaches across all the language pairs in terms of different metrics.

5 Conclusion

In this paper, we describe our submission to the WMT21 shared task on machine translation using terminologies. We participate in three language pairs, namely English → French, Russian and Chinese. Our system integrates terminology constraints during training by augmenting the data with terminological terms. Due to the lack of parallel training data containing the terminology terms, we rely on monolingual data for all language pairs to augment the number of sentences containing terminology terms. Empirical results comparing our approach with terminology grounded as well as terminology free baselines show the effectiveness

of the investigated method.

Abstract

This paper describes Kakao Enterprise's submission to the WMT21 shared Machine Translation using Terminologies task. We integrate terminology constraints by pre-training with target lemma annotations and fine-tuning with exact target annotations utilizing the given terminology dataset. This approach yields a model that achieves outstanding results in terms of both translation quality and term consistency, ranking first based on COMET in the En→Fr language direction. Furthermore, we explore various methods such as back-translation, explicitly training terminologies as additional parallel data, and in-domain data selection.

1 Introduction

We participate in the WMT21 Machine Translation using Terminologies Task in four language directions, English→French (En→Fr), English→Chinese (En→Zh), English→Korean (En→Ko) and Czech→German (Cs→De).

1.1 Task description

The recent COVID-19 pandemic has raised the urgency to translate and distribute the latest medical information worldwide. However, despite recent advances in neural machine translation (NMT), translation in such emerging domains remains a challenge, as it is unaffordable to collect fair amounts of quality in-domain parallel data in a short time. As an alternative, word- or phrase-level dictionaries of key terms are relatively easier to obtain. These dictionaries are prevalent in commercial settings, where customers specify domain-specific jargon that human translators can attend to. However, incorporating pre-specified dictionaries effectively into NMT models is a non-trivial problem, as NMT is inherently trained without explicit constraints compared to statistical approaches.

In this context, the shared task of Machine Translation using Terminologies is held in five language directions at WMT21. The task assumes a realistic scenario where parallel and monolingual data are abundant in generic domains (e.g., news, web crawl), but only hundreds of word- or phrase-level term dictionaries are available in the domain of interest — COVID-19. Technically, this poses a challenge as we must impose terminology constraints without hurting general translation quality, while only 1.5% of parallel data contain the provided terminologies. Additional issues such as the $1:N$ mapping of term translations further complicate the problem.

Evaluating MT systems in specialized domains diverge from general MT evaluation in that overall translation quality may not ensure the translation accuracy of domain-specific terms. This potential gap calls the need for evaluation metrics that directly assess the consistent use of terms. Concretely, three metrics proposed in Alam et al. (2021) are employed in this task – Exact-Match Accuracy, Window Overlap, and Terminology-biased Translation Edit Rate (TERm). The suggested metrics complement general translation accuracy measured by standard MT metrics (BLEU, chrF, BERTscore, COMET) by validating whether terms are translated faithfully according to the dictionary.

Specifically, human-labeled COVID-19 related term dictionaries are released in four language directions (En→Fr, En→Zh, En→Ko, En→Ru), with around 600 terms for each direction. Exceptionally, the dictionary for Cs→De is constructed automatically and consists of 5,601 parallel terms.

1.2 Related work

Word- or phrase-level constraints have often been introduced to NMT via constrained decoding to reinforce specific tokens in the output sequence.

*Work done during the author's internship at Kakao Enterprise.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 804–812

Combined with terminology dictionaries, constrained decoding integrates the target side terms as decoding-time constraints (Hokamp and Liu, 2017; Anderson et al., 2017; Post and Vilar, 2018).

Subsequent work has shown that adding inline annotations to the source sentence as soft constraints can improve performance and time complexity when employed with additional source factor streams (Dinu et al., 2019; Bergmanis and Pinnis, 2021). Similarly, a merging approach by adding markers without modifying the model has also proven to be effective (Wang et al., 2019).

2 Data

2.1 Cleaning

Both monolingual and parallel corpora of all languages are preprocessed according to the following pipeline. First, we remove non-utf8 or non-printable characters. Second, we unescape HTML characters such as `>`. Finally, we normalize variations in spaces and punctuation marks. All cleaning steps are done with Moses scripts (Koehn et al., 2007). We also use the Moses tokenizer, but only for European languages (En, Fr, Cs, De) since Asian languages (Zh, Ko) require language-specific tokenizers that consider the characteristics of each language.

2.2 Filtering

Web-crawled data are notorious for being noisy. To prevent defective data from undermining performance, we filter both parallel and monolingual data with diverse methods.

Bi-text We filter the provided parallel data with several heuristics. We first eliminate pairs that contain empty lines or identical content in both source and the target side. We filter pairs that contain overly long sentences (250 words) or excessively long words (50 characters). The pairs that have a word count ratio larger than four are also omitted. We refer to previous literature to set statistical thresholds of each rule. Lastly, we only use pairs of which both sides are identified as the correct language with a language identification tool. Specifically, we use fastText (Joulin et al., 2016, 2017).

In addition, for En→Ko, we filter out mislabeled bi-text which we found manually, that seemed as byproducts of web-crawl in the source or target side. For instance, the pattern "*YYYY년 MM월 DD일에 확인함*", which means "*Confirmed in YYYY/MM/DD*", was found instead of the correct labels in 20,909 samples. The final dataset sizes are shown in Table 1.

	En-Fr	En-Zh	En-Ko	Cs-De
Parallel	158M	62M	13M	15M
+ Filter	149M	-	12M	13M

Table 1: Dataset sizes of parallel corpora before and after filtering in each language pair. For En-Zh, we did not apply rule-based filtering.

Mono-text We used monolingual text for two language pairs (En→Ko, En→Fr) to augment existing parallel corpora via back-translation (Sennrich et al., 2016a). The back-translation procedure is described in Section 3.2.

For En→Ko, we do not apply any filtering schemes as the size of the Korean monolingual corpus is small (14M sentences).

On the contrary, for En→Fr, using the entire French monolingual corpora (8.5B) for back-translation is unwieldy, considering the time and computation required to infer all samples. Hence, we filter the corpus and select in-domain, COVID-19 related data to maintain a reasonable size for inference and training.

We filter French monolingual data in three steps. First, we roughly filter the data with rule-based methods that are similar to those of bi-text filtering. Second, we choose sentences that contain terms in the terminology dictionary (8.5B → 725M). Lastly, we use the Moore and Lewis (Moore and Lewis, 2010) method to find samples that are more similar to the term-related samples. Specifically, we train an in-domain language model with sentences that contain terminologies from the En-Fr parallel corpus. A general-domain language model is also trained with samples chosen randomly from the En-Fr parallel corpus. For both models, we use KenLM (Heafield, 2011) to train 5-gram language models with modified Kneser-Ney smoothing. Finally, top-k sentences with the highest scores are chosen (725M → 160M).

3 Approaches

3.1 Baseline

We explore two baseline approaches that differ by their training data. First, models are trained with

solely the parallel data described in 2.2. This baseline does not utilize the terminology dictionary.

Second, we take a naïve approach to leverage the term dictionary – including the provided terms as additional parallel data to train the model. For $1:N$ mappings of term translations, we flatten them into N distinct pairs. We refer to this approach as the "explicit" model in the following sections as we "explicitly" augment the training dataset with terminology dictionaries.

3.2 Back-translation

We incorporate back-translated monolingual data for two language directions: En→Fr and En→Ko.[1] We train reverse translation models (Fr→En, Ko→En) with the same parallel corpora and training configuration used to train our baseline models covered in Section 4.2. Back-translated samples are inferred with beam search of beam size 4, and a length penalty of 0.6.

For En→Fr, we use back-translated corpora for Exact Target Annotation fine-tune. We revisit the details of this procedure in Section 3.4.

For En→Ko, we train the back-translation model from scratch using both parallel and back-translated text. During training, we upsample the parallel corpus twice as frequently as the back-translated text.

3.3 Target Lemma Annotation

To integrate terminology constraints, we employ Target Lemma Annotation (**TLA**) of Bergmanis and Pinnis (2021), which helps the model learn how to copy-and-inflect inline annotations. At training time, we randomly select target lemmas and inject them into the source sentence behind the corresponding source word(s).

Specifically, we adopt a simple approach where we modify the input data but not the model. This differs from the method described in Bergmanis and Pinnis (2021), which uses additional input streams to denote the annotated tokens. In detail, we introduce three special tokens **<b>**, **<t>**, and **</t>** which respectively indicate the start of annotated source tokens, the start of target lemma tokens and the end of target lemma tokens. An example is shown in Table 2.

Following the training data annotation procedure of Bergmanis and Pinnis (2021), we first lemmatize and mark part-of-speech tags of the target sentences, using spaCy (Honnibal et al., 2020) instead of the pre-trained Stanza model (Qi et al., 2020) due to the time complexity. We then obtain word alignments using fast_align (Dyer et al., 2013) and randomly annotate verbs or nouns with their corresponding target lemma. To set annotation thresholds, we refer to Bergmanis and Pinnis (2021) – [0.6, 1.0) for sentence-level and [0.0, 1.0) for word-level. The annotated and original data are fed into the model with a proportion of 1:1.

At test time, we provide soft terminology constraints by annotating source terms with their corresponding target terms retrieved from the terminology dataset. Terminology entries are identified with the longest word-sequence match in the source sentence. If there exist several target terms for one source term, we randomly select one candidate.

Original Source	EN	and are you having any of the following **symptoms** with your chest pain?
Annotated Source	EN	and are you having any of the following **<b> symptoms <t> symptômes </t>** with your chest pain?
Target	FR	et avez-vous l'un de **symptômes** suivants en plus de vos douleurs thoraciques ?

Table 2: An example of using special tokens for inline annotations. Inline annotations are marked in bold. **<b>**, **<t>**, **</t>** denote the start of the annotated source tokens, the start of the target lemma tokens, and the end of the target lemma tokens.

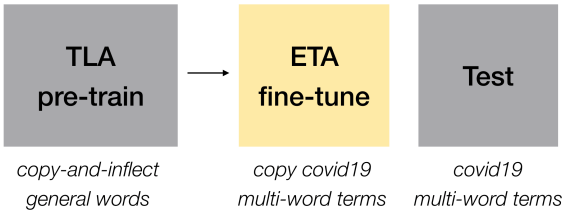

Figure 1: The steps in our TLA pre-train → ETA fine-tune approach and the objective of each phase.

3.4 Exact Target Annotation (Fine-tune)

We adopt Exact Target Annotation (ETA) designed by Dinu et al. (2019) to fine-tune the TLA model pre-trained as in Section 3.3. ETA injects the exact target-side translation of a terminology entry into the source sentence using inline annotations. Note that we utilized the whole terminology dataset during training, unlike Dinu et al. (2019), since the task allows the use of the terminology dataset at

[1] We do not incorporate back-translated corpora of Cs-De and En-Zh due to time constraints.

training time.

While TLA learns to copy-and-inflect general words, our terminology dataset is domain-specific. We aim to fill the domain gap by constructing fine-tuning data in which terminology entries are present on both the source and target sides. As a result, 750K samples from the parallel data and 10M samples from the back-translated data are selected. We upsample the parallel corpus by eight times.

Another discrepancy between training and test time annotation in TLA is that TLA engages a single target word to the corresponding source word(s), whereas many of the actual terms are multi-word expressions in both source and target sides. We expect ETA fine-tune to alleviate the problem since ETA annotates target terms in verbatim. The pretrain-finetune phases are outlined with their motivation in Figure 1.

Specifically, we follow the annotation strategy of Dinu et al. (2019), where we annotate only when both the source side term t_s and the target side term t_t are present. When a sentence contains multiple matches overlapping each other, we keep the longest match.

The difference between Dinu et al. (2019) and our method is that we annotate with three special tokens as described in Section 3.3. Instead of randomly deciding whether to annotate or not, we annotate all matches. We then combine the annotated data with its original data and use it for training with a proportion of 1:1. The annotation procedure at test time is also equivalent to Section 3.3.

4 Experiments

4.1 Evaluation setting

Evaluation of the models is done using the evaluation script [2] and the development dataset, both provided by the task organizers. We select the best models by considering all metrics provided by the evaluation script.

For evaluation, we tokenize our outputs so that they resemble the tokenization setup of the development dataset. For En→Fr and Cs→De, we use the Moses toolkit (Koehn et al., 2007). For En→Zh, we apply the Jieba tokenizer.[3]

Before submitting the test set translations, we handle rare target-side tokens decoded as <unk> by simple substitutions, which we found to work well during evaluation even without incorporating external methods such as word alignments. When the number of <unk> tokens are equal on both sides, we copy the original source-side tokens to the target slots in the same order. After replacing rare tokens, outputs are detokenized using the Moses toolkit (Koehn et al., 2007).

4.2 Experimental details

For En→Fr and Cs→De, we pre-tokenize the data using the Moses toolkit (Koehn et al., 2007). We use sentencepiece (Kudo and Richardson, 2018) to learn a joint byte pair encoding (BPE) with vocabulary size 40K (En→Fr) and 32K (Cs→De). For En→Ko, We pre-tokenize Korean sentences with Mecab (Kudo, 2005) without space tokens as suggested in Park et al. (2021) and use sentencepiece to learn a BPE model with vocabulary size 32K for each language side. For En→Zh, we first convert characters possibly in traditional Chinese to simplified Chinese text using hanziconv [4] and. Then, we pre-tokenize the data using the Jieba tokenizer [3]. We then use subword-nmt (Sennrich et al., 2016b) to train BPE on combined Chinese and English corpus and build separated vocabularies. The final vocabulary size is 44K for Chinese and 32K for English.

For all language directions, we employ the Transformer architecture (Vaswani et al., 2017) implemented in fairseq (Ott et al., 2019). The specific training and generation configurations can be found in Appendix A.

Since TLA relies on the word-aligner's performance, we did not apply TLA pre-training and ETA fine-tuning for En→Ko and En→Zh. Given that both are linguistically distant language pairs, we assumed that the word-aligner's performance would not be sufficient enough to guarantee improvements from TLA.

We start ETA fine-tuning from the TLA checkpoint saved at 750,000 steps for En→Fr and 200,000 steps for Cs→De, chosen based on BLEU scores and Exact Match Accuracy. To evaluate the TLA and ETA fine-tuned models, we run annotation using the terminology tags provided with the development dataset, which is different from the test annotations described in 3.3.

For En→Ko and Cs→De, we use an ensemble of models that utilize back-translation, explicit training, and data augmentation. The exact ensemble

configurations are detailed in Appendix B.

5 Results

Table 3 reports the evaluation results of the four language pairs that we participated in.

5.1 English→French

The TLA model improves Exact Match Accuracy but shows deteriorated performance on all other metrics compared to the baseline. Notably, the degradation stems from the test-annotation method – test scores are comparable to the baseline when tested with raw text (without test-annotation) on the same TLA model.

On the other hand, under the same test-annotation condition, the ETA fine-tuned model recovers the performance loss and even boosts the BLEU score, Exact Match Accuracy, and the 1-TERm score compared to both the baseline and the TLA model. TLA + ETA fine-tune outperforms the baseline by 0.33 points, 4.65%, and 0.24% on BLEU, Exact Match, and 1-TERm, respectively.

In addition, we run a simple ablation experiment by using only bi-text data during ETA fine-tuning: TLA + ETA fine-tune (bi-text only). The results are indistinguishable from the original TLA + ETA fine-tune, which is fine-tuned with data from both bi-text and mono-text. This result supports that the performance gain stems not only from the use of monolingual data, which was unseen during TLA pre-training.

5.2 English→Chinese

We compare two approaches – baseline and explicit, and observe that adding the term pairs explicitly to training improves both general translation performance (+0.73 BLEU) and term consistency (+2.29% 1-TERm) compared to the baseline.

5.3 English→Korean

Back-translation yields performance gains across all metrics with considerable improvements, particularly in BLEU and 1-TERm. The explicit model also brings modest improvements to Exact Match

Language	COMET			Exact Match Accuracy			Number of
	Ours	Best	Rank	Ours	Best	Rank	Submissions
En-Fr	**0.781**	-	1	0.95	0.974	4-6	22
En-Zh	0.229	0.716	8	0.645	0.886	7-8	8
En-Ko	**0.581**	-	1	**0.569**	-	1	1
Cs-De	**0.694**	-	1	0.866	0.871	1-2	2

Table 4: Official task results of our submitted systems. Scores, where our system ranked 1st, are bold-faced. In other cases, the best scores from other submissions are shown for comparison.

Accuracy and 1-TERm. Finally, our ensemble model that combines these approaches demonstrates the best performance across all metrics, raising the BLEU score by 2.52 points, Exact Match Accuracy by 4.2%, Window Overlap by 0.43% and 0.54% for windows 2 and 3 respectively, and 1-TERm by 4.88 points.

5.4 Czech→German

We discover that the explicit model does not bring significant gains compared to the baseline model. This trend contradicts other language directions, where we observed at least modest improvements over their respective baselines. We suspect the differences lie in how the terminologies are generated; Cs→De terminologies are constructed automatically, whereas, for other language directions, the terminologies were annotated manually.

Our ensemble model improves upon the baseline model by 1.5 BLEU points, 1.6% Exact Match Accuracy, 1.84% and 1.74% Window Overlap for window sizes 2 and 3, and 1.1 points in 1-TERm.

We also attempted to apply TLA pre-training + ETA fine-tuning to Cs→De as done in En→Fr. In our preliminary experiments, while some metrics improved, we observed Exact Match Accuracy deteriorate after 1,000 steps of TLA training, unlike En→Fr, possibly due to the automatic creation pipeline of Cs→De terminologies. Therefore, we did not further explore this direction during our task participation. However, subsequent experiments after the deadline revealed that TLA, when followed by ETA fine-tuning, has its advantages in finding a balance between BLEU and Exact Match Accuracy, supporting our findings in En→Fr.

5.5 Official task results

We present our official submission results in Table 4. Despite the trade-off between general translation quality (COMET) and term consistency (Exact Match Accuracy), our approach strikes at the right balance between the two criteria for En→Fr. Out of 22 submissions in this direction, our system ranks 1st in COMET. According to Exact Match Accuracy, our system performs roughly comparable to the best system, ranking 4-6th. For En→Zh, our system ranks 8th in both metrics out of 8 submissions. For En→Ko, our submission is the only submission. For Cs→De, our submission ranks 1st in terms of COMET and 1st-2nd for Exact Match Accuracy out of 2 submissions.

6 Conclusion

We participate in four language directions for the shared task WMT21 Machine Translation Terminologies. To this end, we explore various techniques, including back-translation, explicitly training with term pairs along with other parallel data, and in-domain data selection to improve translation performance in the COVID-19 domain.

In particular, for En→Fr and Cs→De, we find that TLA outperforms the baseline in terms of Exact Match Accuracy by leveraging terminology constraints. However, all other metric scores (BLEU, 1-TERm) plummeted, implying that the overall translation quality was compromised. We recover this performance loss by introducing a new technique – fine-tuning with ETA, and achieve significant improvements in both general translation quality and terminology consistency. We leave it to future work to validate our approach in other languages and reveal the factors behind the benefits of ETA fine-tuning precisely, hopefully, to discover a more suitable design to impose terminology constraints.

A Training configuration

```
fairseq-train
  task : translation
  arch : transformer_wmt_en_de_big
  lr : 0.0005
  lr-scheduler : inverse_sqrt
  warmup-updates : 4000
  warmup-init-lr : 1e-07
  optimizer : adam
  adam-betas : (0.9, 0.98)
  update-freq : 8
  dropout : 0.1
  weight-decay : 0
  criterion : label_smoothed_cross_entropy
  label-smoothing : 0.1
  fp16 : True

fairseq-train (ETA fine-tune)
  lr : 1e-06
  lr-scheduler : fixed
  warmup-updates : 0

fairseq-generate
  beam : 4
  lenpen : 0.6
```

B Ensemble Configuration

For En→Ko, we use an ensemble of four models trained with different configurations:

- Baseline + Back-translation
- Baseline + Back-translation + Rule-based filtering
- Baseline + Back-translation + Explicit
- Baseline + Back-translation + Explicit (Parallel corpus upsampling with ratio 2)

For Cs→De, we use an ensemble of four models trained with different configurations. The third model concatenates the previous and next sentence for additional context with probability of 0.1:

- Baseline
- Baseline + Rule-based filtering
- Baseline + Two sentences concatenation (0.1)
- Baseline + Explicit

Abstract

This paper discusses the WMT 2021 terminology shared task from a "meta" perspective. We present the results of our experiments using the terminology dataset and the OpenNMT (Klein et al., 2017) and JoeyNMT (Kreutzer et al., 2019) toolkits for the language direction English to French. Our experiment 1 compares the predictions of the two toolkits. Experiment 2 uses OpenNMT to fine-tune the model. We report our results for the task with the evaluation script but mostly discuss the linguistic properties of the terminology dataset provided for the task. We provide evidence of the importance of text genres across scores, having replicated the evaluation scripts.

1 Introduction

In our (traditional) sense, terminological databases are the collection of specialised lexical resources that are generally compiled from corpora, in collaboration with experts from the field, then analysed and structured according to the type of information recorded in term records: terms, equivalents, definitions, synonyms, contexts of use, and related terms (hyperonyms, hyponyms, meronyms, holonyms, etc.). The data thus created are empirical and provide knowledge-based representations of the domain (especially in the case of an ontological approach), underlining conceptual links between terms that can be observed (like meronomy: "X is a part of Y") and potentially represented in conceptual graphs.

For instance, the ARTES database (Pecman and Kübler, 2011), used at Université de Paris in Masters studies for teaching terminology management to translation students (Kübler et al., 2018), adopts such a comprehensive approach to terminology, with specific attention to emerging terminology and complex noun phrases (CNPs) (Kübler et al., 2021). In recent works combining studies on terminology, specialised translation and corpus linguistics, attention has been drawn to CNPs in English which have been demonstrated to cause major difficulties during translation, both human and machine (Kübler et al., 2021; Maniez, 2017). Moreover, studies have demonstrated an increase of complex compounding in specialised texts in English over the last few decades, with, for instance, an overwhelming use of patterns with adjectival and participial compound pre-modifiers (e.g. *receptor-binding activity, electron-dense aggregates*) (Mestivier-Volanschi, 2015).

For this WMT21 Terminology workshop, we focused on the linguistic properties of the terminological dataset provided. We selected what we believe to be the two best models we produced for the EN-FR track with two different neural toolkits but we mostly took the opportunity to discuss the addition of terminology to neural machine translation. The rest of the paper is organised as follows: section 2 summarises our approaches to the task, section 3 presents the tools we used and how we used the constrained data. Section 4 presents our experiments and the best models we used for the translation challenge. Section 5 discusses our results.

2 Our Approaches to the Task

This section presents our various strategies for the terminology task.

2.1 Toolkit Comparison

We compared the predictions of two toolkits. We trained two systems, JoeyNMT (Kreutzer et al., 2019) and OpennMT (Klein et al., 2017) with comparable parameters, using Europarl as baseline, later supplemented with the terminology resource provided for the task.

2.2 Model selection and fine-tuning

With OpenNMT only, we selected the training data, comparing the performance with and without the

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 813–820

terminological data for CommonCrawl and Europarl and applied fine-tuning to the model based on Europarl enriched with the terminological data.

2.3 Comparing with pre-trained models

We were curious to see how pre-trained models fared on this tasK. We produced two translations, one based on `mBART-50` (Tang et al., 2020) and the other one on the `Hugging Face` (Wolf et al., 2019) baseline. We finalised them after the evaluation deadline, so that we report our findings on the sacreBLEU score we calculated with the Systran translation used as reference. Debatable as it may sound to use an MT-generated reference translation, this enabled us to run comparisons.

2.4 A linguistic analysis of the terminology resource and evaluation script

We focused our analysis on the linguistic properties of the terminology provided and tested. We also tried to test other models we produced after the competition deadline, which is why we detail the evaluation script we tried to replicate and the terminology in the next section.

3 Data and Tools Used

This section presents the datasets used to build our system as well as our replication of the evaluation script to analyse the models we did not have the time to submit.

3.1 Training Data

The first challenge lies in the data selection for the training corpora among the possibilities of the challenge. We did not resort to specific texts such as the TICO-19 data (Anastasopoulos et al., 2020) but used the Europarl corpus as baseline.

3.2 Terminological Data

This subsection provides a linguistic qualitative approach to the provided terminology dataset.

A potential problem with the terminology dataset is variation. While some variants are probably interchangeable in most texts (e.g. 220 *hand sanitizer: gel hydroalcoolique* | *désinfectant pour les mains*), others present different degrees of specialization (e.g. 345 *multi-organ failure: défaillance multi-viscérale* | *défaillance de plusieurs organes*). For yet other variants, both forms are possible, but not within the same text for coherence (e.g. 286 *SARS-CoV-2: SRAS-CoV-2* | *SARS-CoV-2*, where the first variant is the translated acronym and stands for *syndrome respiratoire aigu sévère*).

The French-English terminological resource included 595 "terms" out of which only 181 were tested in the script so that the achievement rate as testd by the evaluation scripts only relies on 30.42% of the resource provided. Many entries in the dataset are not actually terms, but rather out-of-context strings or keyword combinations that are impossible to translate since, in translation, context truly is everything. Strings such as (154) *covid-19 WHO* and (158) *covid19 CDC* are not actual NPs and are rarely found as such, on their own, in real texts. In context, these n-grams are always followed by additional information that needs to be taken into account in their translation (e.g. *Covid-19 WHO Situation Report* or *Covid-19 CDC Info*). [1] Therefore, the proposed translations (respectively, *OMS et covid-19* and *CDC et covid19*), where the different elements are simply linked with the conjuntion *et* cannot work in context since the components of the actual NP would need to be reorganized in translation when unpacking the informational content in these CNPs. Other examples of out-of-context keyword combinations in the dataset are entries 112 *covid-19 dangerous*, 113 *covid-19 deadly*, 116 *covid19 domestic travel*, and 128 *covid19 international travel*. The role of Complex Noun Phrases seems to be underestimated in the terminology resource, as well as collocations. Nouns are more frequent than adjectives and verbs in the provided resource. 143 adjective + noun collocations are proposed (such as *deadly virus*) for 13 adjectives. Only 19 verbal collocations are proposed for eight verbs.

Beyond the immediate textual context, lack of real-world context is also a potential source for incorrect translation. For entries 245 *n95*, 246 *n95 mask*, and 247 *n95 respirator*, the proposed translations all use the N95 classification, which is the US NIOSH standard. For real texts, functionally adequate translation might require, for instance, using the equivalent European classification (*FFP2*). Dataset entry 246 presents an additional real-word related issue: *N95 respirators* should not be referred to as "masks", as their airborne-particle filtration capacity is far superior to those of surgical

[1] With hindsight, setting values at n=2 or n=3 for Window Overlap Accuracy was consistent with "truncated" sequences such as *covid-19 WHO* but *Covid-19 WHO Situation Report* and similar embedding structures would only be captured by the Window Overlap Accuracy metric when n=4 or more.

masks which serve a different purpose (reducing outward particle emission).

3.3 Data for Fine-Tuning

We re-trained our generic model by selecting the presumed best candidates for training sets. To specialize the model and make it more efficient, after having trained it on Europarl, we chose a method to select texts that are closer to the terminological data. Several similarity measurement methods are possible. In this case we worked with cosine similarity, which is more sensitive to the number of occurrences of terms in each corpus. After having carried out the similarity measurement of all the texts with the test data, we retained 1/4 of the files, corresponding to 22,741,561 sentences. These selected texts served as a corpus of re-training of our model for its specialization. Compared to the constrained corpora proposed for training, our optimised selection of texts based on the cosine similarity with the testing set corresponded to the following subsampling of the proposed corpora: 1 % of News Commentary v16 and 99 % of 10^9 French-English Corpus. From a purely machine learning perspective, using testing sets to figure out training sets may sound unusual, but it should be borne in mind that we do not aim here at generalisability but at performing a specific task (translating biomedical texts).

3.4 Replicating the evaluation script

We did not have the time to submit our translations based on fine-tuning and pre-trained systems, so that we tried to replicate the evaluation script[2]. Our script[3] is a modification of the procedure described in (ibn Alam et al., 2021) that includes 1-TER but not COMET. It allows the calculation of the following scores: Exact-Match accuracy, Window Overlap (2), Window Overlap (3), sacreBLEU, TER and TERm. The calculation, unlike the evaluation made by the competition, is done here segment by segment and the average of the set of results makes it possible to detail scores per segments. The preprocessing is the same as on the reference script (tokenization and lemmatization) and the removal of parentheses on the corpus is necessary to run it. It is limited to 1,371 segments, for which the term to be translated was identified with certainty. As a result, one section of the testing data was not considered (the email sent to the wikipedia collaborators, referred to as "email" in our text genre analysis).

4 Experiments and Results

4.1 Training with JoeyNMT

For comparison purposes, we used the baseline of JoeyNMT which is based on TRANSFORMER (Vaswani et al., 2017) and requires lighter implementations. It took the `Europarl 7` parallel corpus as data set, split as follows: training (341,554 sentences), dev (50,000 sentences) and test (100,000). The data set has been preprocessed with a two-level tokenization: standard tokenization (Spacy) segments data into words and BPE tokenization (*SentencePiece* (Kudo, 2018)) into sub-words. Our model was trained with the following parameters: vocabulary size: 32, 000, maximum sentence length: 50, maximum output length: 100, training optimizer: `ADAM`, normalization: tokens, training model initializer: `XAVIER`, encoder embedding dimension: 512, decoder embedding dimension: 512, hidden size: 512. The best BLEU score from English to French (Figure 1) was achieved at 32.04 at step 41 000 with a training rate of 18 seconds per 100 steps, whereas the best French to English BLEU score was 31.35. By comparing JoeyNMT translation with OpenNMT translation, we notice that JoeyNMT had poor results in translating dates, numbers, proper nouns, acronyms and symbols. Sentences which have several of those may have been translated into a string of characters of repeated sub-words. The translation submitted could not be scored but for BLEU (5.29). The result came as a surprise to us since JoeyNMT has the same model architecture as OpenNMT (Transformer). Because of these issues, we only conducted the other experiments with OpenNMT.

4.2 Training and Fine-tuning with OpenNMT

We used the baseline of OpenNMT-tf 2.20.1 based on `TRANSFORMER` (Vaswani et al., 2017). The parallel data Europarl v10 (Koehn et al., 2005) containing 1,911,202 aligned sentences pairs was used as a dataset, which was divided into two subsets: training set (1,906,202 sentences) and evaluation set (5,000 sentences). The dataset was preprocessed with a BPE tokenization using SentencePiece into subword units (32,000 subword units as training vo-

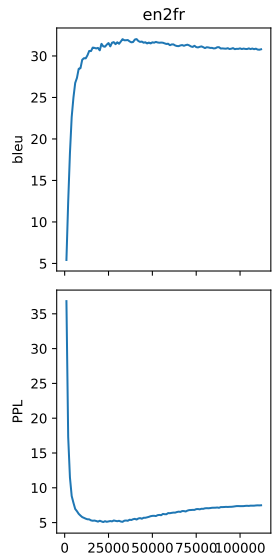

Figure 1: JoeyNMT : BLEU score and PPL score (en-fr)

cabulary). The model was trained with the following parameters: vocabulary size: 31,000, learning optimizer: LazyAdam. The best BLEU score from English to French was 43.90 after 70,000 steps with a training rate of 1.18 steps per second.

We then produced a model with Europarl adding the terminology to the training data with the same evaluation data. As a comparison, we also tried to produce a model with Common Crawl corpus [4] using the same parameters of SentencePiece and training. The dataset consists of 3,244,152 aligned sentences pairs split into training set (3,239,152 sentences) and evaluation set (5,000 sentences). This model produced the best scores in among our submissions (0.871 for Exact-Match Accuracy).

For fine-tuning, we used the Europarl model enriched with the terminological data. We were not able to use the onmt-update-vocab command, so that instead we directly replaced the dictionary file in the configuration with the dictionary based on the files described in section 3.3. Contrary to our expectations, the fine-tuning did less well for scores, according to our estimations (see Table 1). Not being able to update the dictionary in fine-tuning might be responsible for worsening the quality of our results.

4.3 Pre-trained Systems

For a point of comparison, we considered two Transformer-based models available in the Hugging Face library (Wolf et al., 2019). The first one is the standard *pipeline*[5] for English to French translation. The second one is based on the multilingual language model `mBART-50` (Tang et al., 2020), fine-tuned for multilingual machine translation as described in (Tang et al., 2020). The two models were applied on the raw sentences extracted from the SGM files of the test data. The sole preprocessing that was applied consisted in replacing XML entities by their corresponding characters and applying the tokenizer considered by the model. While the translation for the PUBMED section is satisfactory, the translation of the CMU section revealed issues in the use of subjunctive (ie segment 20). It should be noted that, according to our homemade evaluations, these models did much better for sacreBLEU scores (+3.7) and Hugging Face is slightly higher than the Corpus Crawl data trained with the terminology resources (the two models are superimposed on Figure 3.

4.4 Replicating the scoring system with the different translations

Because we could not submit all our translations in time, we resorted to a proxy for evaluation by adapting the available scripts to produce our own evaluation scripts. Our sacreBLEU (Post, 2018) score was based on the SYSTRAN translation used as a reference text. We used the SYSTRAN generic Pure Neural Server (Crego et al., 2016). We show how our scoring system (dots) compares to the official evaluation system (crosses) in Figure 2. We tend to be less generous for Exact-Match Accuracy and more optimistic for Window Overlap Accuracy (with n=3). It should be noted that our reference translation, although mostly accurate, also presents some problems. These occur mainly in the incomplete out-of-context segments related to patient symptom descriptions, many of which are also ungrammatical (ie segment 4). Table 1 recaps the scores we obtained for all the models we produced. For the models we submitted in time, as could be expected, the model trained with Common Crawl and the terminological resources (+ Term in our table) got better scores than Europarl supplemented with the terminological resources. For our in-house evaluation, we tested the translations produced by these models as well, so that we could

[4] https://commoncrawl.org/

[5] Pipelines are Hugging Face abstractions for NLP tasks that automatically select the 'correct' model architecture and all the related components (such as the tokenizer) required to make a prediction

submitted model	BLEU (truecased)	Exact-Match Accuracy	Window Overlap Accuracy (n=2)	Window Overlap Accuracy (n=3)	1-TERm Score	COMET
Common Crawl + Term	40.02	0.871	0.296	0.296	0.507	0.596
Europarl + Term	34.93	0.795	0.275	0.267	0.495	0.296
Europarl (baseline)	33.59	0.640	0.248	0.241	0.480	0.212
in-house scores	**sacreBLEU**	**Exact-Match Accuracy**	**Window Overlap Accuracy (n=2)**	**Window Overlap Accuracy (n=3)**	**1-TERm Score**	**1-TER score**
Hugging Face	**32.21**	0.73	0.32	**0.324**	0.36	0.37
mBART	30.46	0.707	0.296	0.294	0.35	0.36
Common Crawl + Term	28.50	**0.77**	0.299	0.306	0.30	0.308
Europarl + Term	23.74	0.68	0.258	0.256	0.293	0.303
Europarl (baseline)	17.98	0.53	0.18	0.17	0.24	0.25
Europarl (fine-tuning)	26.19	0.68	0.279	0.278	0.278	0.287
joeyNMT (Europarl)	4.67	0.16	0.039	0.034	0.045	0.064

Table 1: Summary of our official and home-made scores for our models

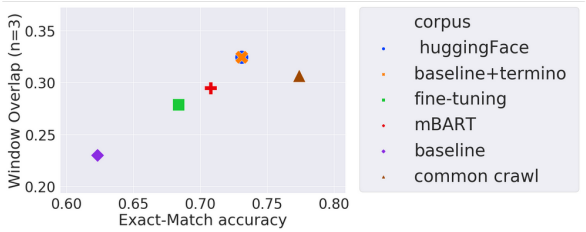

Figure 2: Comparison of the scores for the three SPECTRANS models submitted)

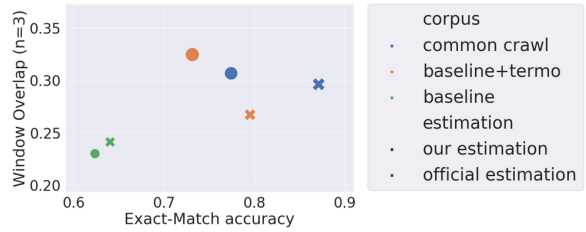

Figure 3: Comparison of the best models acccording to our scores)

compare them to the translations produced by the pre-trained models (`Hugging Face` and `mBART`. The latter did better for sacreBLEU and Window Overlap Accuracy (n=3) but probably having seen the terminological resources in the training data gave an edge for Exact-Match Accuracy to our model trained with Common Crawl and the terminological resources.

5 Discussion

5.1 Variability Across Text Genres

The benefit of our recreation of the evaluation script is that it allowed us to compute the terminology scores for 1,430 segments. We grouped the different sections of the test data according to text genres, in fashion similar to (Anastasopoulos et al., 2020). We distinguished 5 groups of texts and the variability of the BLEU scores across these text genres can be seen on Figure 4. This variability across text genres can also be seen for some other metrics, such as Window Overlap accuracy (with n=3) (see Figure 5).

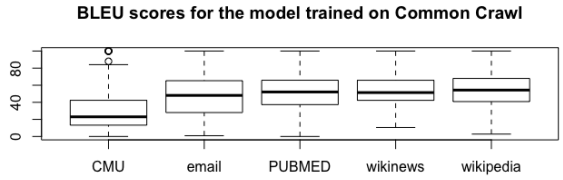

Figure 4: BLEU scores and text genres (Common Crawl training)

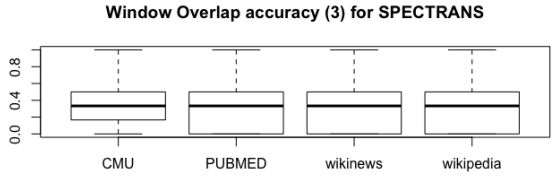

Figure 5: Variability of Window Overlap accuracy (n=3) across text genres

Overall, it is likely that our results could have been better if we had used alternative testing sets rather than using part of the reference corpora as testing sets.

5.2 Alternative qualitative terminological analysis

This subsection discusses the error analysis in terminology from a qualitative point of view.

For CNPs not included in the terminology dataset such as *chest pain*, the system deploys various avoidance strategies ranging from anatomic approximations (segment 20: *mal de coeur*) to omission (segment 8: *Et cette douleur est-elle bien réelle?*) to unlucky guesses (segment 2: *maux de mer*) to idiomatic expressions (segment 18: *C'est bien là que le bât blesse*). For less formal descriptions of similar symptoms where the actual term does not appear in the source text, the output

type	segments	acronyms	terms	acronym/segment	terms/segment
CMU	104	0	71	0.000	0.683
PUBMED	676	465	622	0.688	0.920
wikinews	67	11	25	0.164	0.373
email	98	7	7	0.071	0.071
wikipedia	1,155	315	929	0.273	0.804

Table 2: Distribution of acronyms in the text data

ranges from gibberish and hallucinations (segment 25: *c'est comme si la grenna est écrasée* to soaring lyricism (segment 97: *C'est la peine que j'ai sur le cœur*). When confronted with an unorganized list of terms such as the one in segment 30 (*anyone in the family have a heart problem heart disease heart attack high cholesterol high blood pressure*), most of which are not included in the dataset, the system valiantly tries to make sense of it by turning it into a complete sentence: *Quiconque au sein de la famille est confronté à un problème cardiaque, s'attaque à la pression sanguine élevée en raison de la forte pression sanguine*.

For key terminology around Covid-19, the preferred option in the output is the masculine form (*le/du/au Covid*: 127 occurrences) that is also massively present in the terminology dataset, whereas the feminine *la Covid* only appears 9 times in the output. Interestingly, in only one of these occurrences (segment 2124) does the feminine form appear within the CNP recorded in the dataset (*virus de la COVID-19*). In the other segments, it appears as a translation for the simple term COVID-19, which is in the dataset invariably associated with the masculine form when the gender is specified.

For the compound key term (56) *coronavirus disease*, different solutions appear in the output alongside the proposed translation from the dataset (*maladie du coronavirus*). One erroneous solution in our output is *maladie des coronavirus*. The plural form is problematic, as several coronaviruses exist indeed and most of them are linked with the common cold, with presents a very different picture from the illness provoked by the new coronavirus having emerged in 2019. An interesting solution appears in our output for segment 186:

[EN] The outbreak of Coronavirus disease 2019 (COVID-19), caused by severe acute respiratory syndrome (SARS) coronavirus 2 (SARS-CoV-2)

[FR] L'apparition de la maladie liée au coronavirus 2019 (COVID-19), causée par les syndromes respiratoires aigus sévères (SARS) Le coronavirus 2 (SARS-CoV-2)

The proposed translation, i.e. *la maladie liée au coronavirus 2019 (COVID-19)*, is actually a better choice than the one included in the dataset. The system seems to have achieved this translation by linking *disease* and *illness*, as the translation for *coronavirus disease* appears to draw from that given for *covid19 illness* in the terminology dataset. For the second CNP in this segment, *severe acute respiratory syndrome (SARS) coronavirus 2 (SARS-CoV-2)*, however, the proposed translation is less accurate, specifically in terms of syntax. This example also contains one of the few occurrences of the short form *SARS-CoV-2* in our output (16 in total, most with no article). The preferred option in our output is the translated acronym *SRAS-CoV-2*, with 153 occurrences, of which 143 also have a definite article (*le/du/au*).

5.3 Presence of acronyms in the terminological data

Medical terms in each segment involve two forms: acronyms and fully spelled form. The semantic fields covered by these terms include medical products ("face masks," "vaccine"), biochemical elements ("virus"), diseases ("COVID", "SARS"), as well as public health practices ("quarantine"), organizations ("WHO") and phenomena ("outbreak"). For any segment that contains at least one medical term of either form, the term count of the corresponding form is set to 1 for the segment. Counts and ratios per segment for each of the five types of documents are calculated. It can be observed from the above table that type PUBMED has the highest ratio per segment for either form of medical terms (0.688 for acronym and 0.920 for normal form), while type EMAIL has very low ratios especially for normally spelled form (0.071). In terms of medical term density, differences among these types of documents are therefore distinct. Table 2 sums up our findings in terms of the presence of acronyms

5.4 Terminology better at inference time?

We entered the challenge following the track for using the terminological resources at training time. We nevertheless did a background check on the possibilities of using the provided dataset at inference time. We plan to experiment the SYSTRAN Model studio functionalities to test the performance of using the terminology resource at inference time.

5.5 A Case for Onto-terminology?

The terminology provided for this task was unstructured, contrary to existing ontologies for medical English. Taking advantage of ontology-oriented programming in Python as implemented in Owlready (Lamy, 2017), it is tempting to consider potential implementations of onto-terminology in python-based neural translation toolkits. Biomedical ontologies have a record of established terminologies. One of the added benefits of this line of investigation is that we could not only test the gains of a structured ontology at training time but we could try to implement sanity checks at inference time to ensure the quality of the terminology by making sure the position of the terms in the output is consistent with the hierarchy in the ontology.

6 Conclusion

This paper presents the SPECTRANS system description for the WMT21 Terminology Shared Task. We participated in the English-to-French task, using the terminology resources at training time. Though English–French is a language-pair with many linguistic resources, we only used the data provided by the organisers. Given the novel evaluation of terminology provided for this task, we not only aimed to build a translation system for the competition, but also to provide a critical angle on the task and on its evaluation. For the MT system, we applied a variety of strategies, toolkit comparison, data augmentation and fine-tuning. Though we did not experience catastrophic forgetting, our fine-tuning did less well in the terminology metrics, probably because we were not able to update the dictionary. We obtained the best scores for the models we submitted with a model trained with Common Crawl supplemented with the terminology resource. The translations produced with pretrained models competed in terms of terminology scores, did better for sacreBLEU, especially for the translation of PUBMED, but proved less robust for the translation of the patient-doctor interactions of the CMU section of the testing data.

For the analysis of the terminology, we discussed the role of complex noun phrases and initialisms. Our contribution mostly lies in the critical analysis of the terminological input and of the evaluation script. This allowed us to raise the issue of the role of acronyms in the terminology, the importance of complex NPs (and the correlative interest of the Window Overlap Accuracy with n=3, more likely to capture complex NPs than Window Overlap Accuracy when n= 2) as well as the importance of text genres.

Abstract

The majority of language domains require prudent use of terminology to ensure clarity and adequacy of information conveyed. While the correct use of terminology for some languages and domains can be achieved by adapting general-purpose MT systems on large volumes of in-domain parallel data, such quantities of domain-specific data are seldom available for less-resourced languages and niche domains. Furthermore, as exemplified by COVID-19 recently, no domain-specific parallel data is readily available for emerging domains. However, the gravity of this recent calamity created a high demand for reliable translation of critical information regarding pandemic and infection prevention. This work is part of WMT2021 Shared Task: *Machine Translation using Terminologies*, where we describe Tilde MT systems that are capable of dynamic terminology integration at the time of translation. Our systems achieve up to 94% COVID-19 term use accuracy on the test set of the EN-FR language pair without having access to any form of in-domain information during system training. We conclude our work with a broader discussion considering the Shared Task itself and terminology translation in MT.

1 Introduction

This work is part of WMT2021 Shared Task: *Machine Translation using Terminologies*, which is concerned with improving machine translation (MT) accuracy and consistency on *newly developed domains* by utilising word and phrase-level terms. We describe Tilde MT systems that are capable of dynamic terminology integration at inference time. Our submissions consist of translations by terminology-enabled general-purpose MT systems for EN-RU, EN-FR, and CS-DE translation directions. Our systems are deliberately trained without consideration for the test domain to follow the spirit of the Shared Task—MT for emerging domains. Despite term collections being noisy, our MT systems with dynamic terminology integration improve term translation accuracy proving their usefulness in dynamic adaptation for novel domains, where training-time domain adaptation methods are not feasible.

The remainder of this work describes the methods used for dynamic terminology integration (Section 2) by describing the tasks of terminology filtering, term recognition, and dynamic terminology integration in the translation process. The bulk of Section 2 describes problems due to the low-quality term collections and terminology mismanagement and our solutions to them. We hope that the examples provided will not only illustrate the self-imposed problems by the Shared Task but also will motive reconsidering the purpose and the desired qualities of a term collection in the context of MT. We then briefly describe the experimental setting and results in Section 3 and Section 4 respectively. We conclude our work with a broader discussion considering the Shared Task and terminology translation in MT in Section 5.

2 Methods

This section describes the three tasks necessary for successful MT with terminology: terminology filtering, term recognition, and finally, integration of terminology constraints in the translation process.

2.1 Terminology Filtering

To guarantee terminology translation correctness and consistency, which are two quality aspects of terminology translation, term collections must provide unambiguous information about the preferred translation equivalent for each source term's type (full form, short form, or acronym) when listing multiple possible translation equivalents in a tar-

Table 1: Examples of noisy term entries in the provided term collections. Inflected forms are blue, wrong translations of the source term are red, alternative spelling variants are *italic*, other possible translations are **bold**, other terms within one term entry are underlined.

get language. Typically preparing such term collections that are useful for MT (or the translation process in general) is the task of a professional translator or a terminologist. In this Shared Task, however, term collections sometimes contain entries that do not feature reciprocal translations of terms (e.g., see examples 1, 3, 7, and 8 in Table 1), have multiple translations per term (example 8 in Table 1), have multiple different terms merged into a single term entry (examples 2 and 9 in Table 1), have different spelling forms listed on the target side (examples 4 and 9 in Table 1), and have different inflections or spelling variants of source terms separated in different term entries (examples 5 and 6 in Table 1). Besides, unlike the common custom of providing terms and their translations in their dictionary forms (e.g., see examples of terms in EuroTermBank[1], the InterActive Terminology for Europe[2], the United Nations Terminology Database[3], and other authoritative term banks), the terminologies provided for the Shared Task often contain entries where the source or the target language form is already inflected (examples 1, 2, and 6 in Table 1).

To reduce the noise present in the provided term collections, we performed filtering by discarding:

1. Term pairs that feature terms consisting of symbols other than digits, letters, apostrophes, white-spaces, and hyphen symbols. This filter allows to identify and discard expressions that do not represent terminology (e.g., full sentences, complete clauses, formulas, expressions consisting of terms and their acronyms within one term entry, etc.; see examples 1-6 and 8 in Table 2).

2. Term pairs where the source term is longer than the target term and the source term contains the target term as a sub-string (or vice versa). This filter is intended to discard term entries representing named entities that are written identically in both source and target languages, but for which one of the sides is incomplete (see examples 7 and 9 in Table 2).

3. Term pairs that represent general language (i.e., are too common). General language phrases are typically ambiguous and may require different translations based on surrounding context as well as external knowledge, which may not be available when translating. Therefore, it may be safer to allow the NMT model to handle the translation of general language phrases. We also do not want to burden the MT model too much with excessively annotated input data since longer segments are typically handled worse by NMT models than shorter segments (Neishi and Yoshinaga, 2019). To identify term entries that are too general, we apply an inverse document frequency (IDF) (Jones, 1972) filter (Pinnis, 2015a). As an example, this filter discarded from the term collections all term entries of the English term "spread" as it is a highly ambiguous word and according to the Collins EN-FR dictionary[4] it may have at least 20 distinct translations . Since the term collection

[1] https://eurotermbank.com/
[2] https://iate.europa.eu/
[3] https://unterm.un.org/
[4] https://www.collinsdictionary.com/dictionary/EN-FR/spread

features just one possible translation without any added meta-data, it is safer to not use such terms (considering also the limitations of term recognition when working with emerging domains with scarce or no parallel data).

Besides filtering out the noisy term entries, the type and the quality of the term collections provided in the Shared Task also require selecting one among potentially many term translation equivalents. As noted before, this is typically done by a human, possibly, a domain expert. Nevertheless, we opt for two different strategies. If more than one translation equivalent is provided, it is fair to assume that they are all equally applicable. Thus we propose to select the first translation equivalent in the list. We refer to it as **1st Trg Term** term selection strategy. After analyzing the term collections, however, we conclude that it is not the case that all translation equivalents provided in the Shared Task are of equal quality. Therefore, we employ a statistical word alignment-based strategy to select the translation equivalent with the highest alignment score. To compute word alignments we use *eflomal*[5] (Östling and Tiedemann, 2016). We refer to it as **Alignment-based** term selection strategy.

Table 3 gives examples of terms selected by either of the term selection strategy. Examples illustrate that some translation equivalents are of equal quality (examples 1, 3, 6, and 7). However, selecting the first translation equivalent can sometimes give long (examples 6 and 8) or inadequate (example 4) translation equivalents. The Alignment-based term selection strategy also tends to select translation equivalents that are dictionary forms (example 2) instead of inflections.

2.2 Term Recognition

Having a term collection, the next task in the MT workflow is term recognition in a running text. Term recognition depending on the morphological typology of the source language and the nature of the domain can prove to be a complex task. Recognition involves term identification in its surface form, which for morphologically complex languages may be hindered by many surface forms a single word can take or by the level of form ambiguity in the case of morphologically impoverished languages (Bergmanis and Goldwater, 2018). To overcome issues posed by the morphology of the natural language, one can use one of the many off-the-shelf morphological taggers to obtain contextually correct part-of-speech and lemma pairs for each token and perform term recognition on lemmatized collections and texts. We, however, opt for an alternative, a more rudimentary method utilizing language-specific stemmers to normalise the surface forms and do the term recognition on stemmed running text and term collections (Pinnis, 2015a,b). We opt for the stemmer-based approach because, in the production setting, stemming is faster than morphological tagging and has broader coverage for low-resource languages. Besides, to take full advantage of the morpho-syntactic information provided by morphological taggers, similar information must be provided by the term collection. However, as term collections of this Shared Task exemplify, expecting any meta-data is naive.

Last but not least, recognised forms must be word-sense disambiguated if more than one translation sense (i.e., term entry per source-side lexical form) is available. Word-sense disambiguation tools typically are lexicalized classifiers that are trained using large amounts of parallel data. However, the spirit of this Shared Task is MT using terminology for emerging domains where "*parallel data are hard to come by*"[6]. Thus we skip word-sense disambiguation and use just one word-sense per word form.

2.3 Integration of Terminology Constraints

In the day-to-day work of professional translators, terminologies are glossaries containing source language terms and their corresponding target language translations in their dictionary forms. Some of the previous work on terminology translation assumes that term entries are given in forms already inflected as required by the target morpho-syntactic context. Thus, such work focuses either on morphologically impoverished languages or is concerned with terminology translation in unrealistic scenarios. Either way, such methods are not relevant for the languages of the Shared Task because all of the target languages, with the exception of Chinese, are to some degree inflective languages.

There is, however, another body of work that addresses translation with terminology while accounting for morphological complexity of the target language (Exel et al., 2020; Niehues, 2021;

Table 2: Examples of terms removed by basic filtering.

Bergmanis and Pinnis, 2021). We base our submission on Bergmanis and Pinnis (2021) and employ target lemma annotations (TLA) to augment MT training data. An example of a sentence fragment annotated with TLA is "*infections*|**s** инфекция|**t** *result*|w *in*|**w** *mild*|**w** *symptoms*|**w**", where |**s**, |**t**, |**w** are factors indicating whether token is a source language term, a lemma (the dictionary form) of a target language term, or an ordinary source language word respectively. Systems trained on such data are equipped with a mechanism for passing soft terminology constraints at inference time. An essential property of MT systems trained using TLA is that they learn not just to copy but also to inflect the provided terminology constraints according to the target morphosyntactic context. Therefore, the translation of the sentence above, for example, "инфекций приводят к легким симптомам", contains the plural noun "инфекций" and not just the annotated singular form "инфекция".

3 Experiments

Data. We use all parallel data provided for the Shared Task for training, except for development data which we use to choose the best model for final submission. Although back-translated monolingual data could, in theory, improve the overall translation quality, we do not use it to train our systems because typically, the monolingual target data is selected based on its similarity with the target domain data. However, the scenario proposed for the Shared Task assumes that the domain is novel; thus, we aim to explore the merits of terminology translation and do not look for extra synthetic target domain data.

MT Model and Training. For system training, we use the *Marian toolkit* (Junczys-Dowmunt et al., 2018) because of its factored model functionality developed within the scope of the *User-Focused Marian project* [7][8]. In this Shared Task, we train standard MT systems that mostly follow the Transformer (Vaswani et al., 2017) *base* model configuration. The only deviations from the standard configuration are 1) the use of source-side factors (we use factor embeddings of dimensionality 8 and concatenate them with word embeddings), 2) increased *–optimizer-dealy* (from 16 to 24), and 3) an increased maximum sequence length (from 128 to 196 tokens). These changes are necessary purely for TLA support during training and inference: increased sequence length accounts for longer input sequences due to TLA and terminology constraints, while increased optimizer delay compensates for fewer sentences fitting in workspace memory-based batch due to their increased maximum length.

4 Results

We trained one NMT system per translation direction and evaluated translation quality on the development sets using the terminology translation evaluation tool provided by the Shared Task[9] (ibn Alam et al., 2021). We compare the baseline translation scenario where no terms are annotated in the source text with improved scenarios where terms are annotated using term collections acquired using the different filtering and term translation equivalent selection strategies.

When analysing the lemmatized exact match accuracy, we must bear in mind that the evaluation data similarly to the term collections feature term

Table 4: Development set results for baseline MT systems and systems using terminology integration. MT systems using terminology integration are named after the method used for terminology filtering. The numerically highest scores according the Lemmatized Exact-Match Accuracy (Accuracy) in data setting are **bold**. For detailed description of other metrics consult (ibn Alam et al., 2021).

entries 1) with more than one allowed synonymous translation equivalent (not counting different inflected forms), and 2) where different terms are merged into one entry (see examples in Section 2.1). This consequently means that the evaluation procedure 1) allows terminological ambiguity on the target side, 2) does not allow analysing terminology translation consistency, and 3) may depict a rough estimate of terminology translation accuracy. Therefore, we believe that the lemmatized exact match accuracy results should be analysed with a grain of salt.

That being said, the results in Table 4 show that the metric improves when using a term collection in all but one experiment. The fact that in overall the Alignment-based term collections show better overall translation results (in terms of BLEU) and also allow reaching the highest terminology translation accuracy results shows that relying on the first translation equivalent in a term entry is not a good idea.

We also see that the overall terminology translation quality is already relatively high for the baseline systems ranging from 76% for EN-RU till 88.5% for EN-FR. This makes us wonder whether the evaluated domain can be considered emerging as it features few novel terms and the majority are well handled by the baseline systems. To investigate further, we analysed whether the bilingual terminology that can be found in the development sets is also present in the training data of the NMT systems. We found that for CS-DE, 97.9% and 92.5% of such (unique) bilingual terms are featured at least once or 10 times in the training data respectively. The numbers are even higher if we analyse running terms (tokens) – 99.8% and 98.7% respectively. Since the terminology for EN-RU was human-created and not extracted from parallel data, it shows slightly lower results when analysing unique terms – 93.5% and 88.3% respectively. However, the situation is similar to CS-DE when analysing running terms – 99.1% and 97.8% of bilingual terms found in the EN-RU development data are also found in the training data at least once and 10 times respectively. Based on these findings, we believe that the validation data does not depict an emerging domain and does not help analysing terminology translation quality for emerging domains.

When analysing the overall translation quality (in terms of BLEU), we see that term filtering using the IDF-based filter is crucial when relying on very noisy and automatically acquired term collections (as was the case with the CS-DE term collection). The results show that translation quality drops by 3 BLEU points when using the unfiltered term collections. This shows that too general (and ambiguous) terminology can be harmful and lower translation quality. The overall translation quality change is marginal for the translation directions that featured human-created term collections (EN-FR and EN-RU), however we do see an increase in terminology translation accuracy.

Our **final submission** consists of machine translations of Shared Task test sets provided by general-purpose MT systems that use dynamic terminology integration using TLA (Bergmanis and Pinnis, 2021). To translate our final submissions, term collections are filtered by basic filters (see Section 2.1) for EN-FR and EN-RU language pairs, while for CS-DE language pair, we also use IDF>5 filtering. We use the statistical word alignment term selection strategy for term entries with multiple translation equivalents for all language pairs. The development set results for the corresponding systems are marked bold in Table 4.

5 Discussion

Shared Task. Results of automatic metrics show that our baseline systems are already well equipped to translate the development and test sets regardless of their seemingly novel domain. Indeed – we found no statistically significant differences in scores measuring general translation quality between the baseline systems and systems with terminology integration. Preliminary test results suggest a similar pattern in other submissions (c.f. results of submissions by Prompt). The only seemingly meaningful differences are in metrics specifically targeting terminology integration. These results are in stark contrast with previous work (Exel et al., 2020; Niehues, 2021; Bergmanis and Pinnis, 2021) which report significant improvements not only on terminology use targeted metrics but also on metrics measuring general translation quality. This disparity suggests that test data is *not* from an emerging or novel domain (at least as far MT systems trained on the training data provided are concerned). Considering this shortcoming, together with the visibility of WMT Shared Tasks, these results pose a risk of misrepresenting the problem the Shared Task was set out to research. The outcome might be

unintended downplaying of the role of terminology translation for technical domains, which could lead to diminishing interest in terminology translation from the MT research community.

Term Collections in MT. Tables 1, 2, and 3 of Section 2 provide numerous examples of problems present in the provided term collections. We believe that these examples illustrate the understanding of the purpose and desired qualities of a term collection not just of those individuals involved in preparing term collections for the Shared Task but also to a broader community of translation professionals. Many of the problematic examples suggest that the shift from human-readable to machine-readable term collections is not there yet, or that it has happened rather formally by merely reformatting the for-human-made term collections into neater TSV-formatted files. While having TSV-formatted files helps for the file to be machine-readable, it does not make the content machine-usable. The standards for-machine-made term collections have to be higher than those made for humans. At least as long as there is no sophisticated intelligence in the MT workflow that is on par with humans to recover from the irregularities and noise present in the term collections typically made for humans. Likewise, the encyclopedia-style entries explaining a concisely coined concept of the source language using a whole sentence to define it in the target language are still present in for-human-made term collections, but they are of no use for current MT systems.

If translation with terminology is supposed to improve MT for novel domains, the term collections, being the supposed source of the expected improvement, have to be of a higher quality than the MT systems they are intended to improve.

Abstract

This paper describes Charles University submission for Terminology translation Shared Task at WMT21. The objective of this task is to design a system which translates certain terms based on a provided terminology database, while preserving high overall translation quality. We competed in English-French language pair. Our approach is based on providing the desired translations alongside the input sentence and training the model to use these provided terms. We lemmatize the terms both during the training and inference, to allow the model to learn how to produce correct surface forms of the words, when they differ from the forms provided in the terminology database. Our submission ranked second in Exact Match metric which evaluates the ability of the model to produce desired terms in the translation.

1 Introduction

Terminology integration, or, more generally, constrained translation in NMT was extensively studied in recent years. Lexically constrained translation means that aside from the source sentence, we have available some additional knowledge of what tokens or expressions should appear in the translation and we want to force the system to include them in the generated output. Three main ways of enforcing these constraints have been studied.

First, replacing the source part of the constraint that is found in the source sentence with a placeholder which is then copied by the model into the output. There it gets replaced by the target part of the constraint (Luong et al. (2015); Crego et al. (2016)).

Second way is to modify the decoding search algorithm in a way that only allows hypotheses containing the constraints to be marked as finished (Anderson et al. (2017); Hasler et al. (2018); Chatterjee et al. (2017); Hokamp and Liu (2017); Post and Vilar (2018); Hu et al. (2019))

Finally, some works focus on providing the constraints directly to the model as part of the input sequence. The model is trained to incorporate these constraints into the output, for example Dinu et al. (2019); Chen et al. (2020); Song et al. (2019) or Bergmanis and Pinnis (2021).

As apparent from previous paragraphs, the problem of integrating lexical constraints into NMT is well studied, but one issue was largely ignored. In inflected languages, the surface form of the constraint in the output cannot be known beforehand, as there are usually many possible ways to translate a sentence and many of them need different surface forms of the constraint to be fluent and grammatically correct. For example, let's say we have a terminology database containing term pair *influenza -> grippe* and this source sentence:

During the 2018-2019 **influenza** season.

Possible correct translation is:

Pendant la saison **grippale** 2018-2019.

Where the term base noun form *grippe* is inflected into adjective *grippale*. Traditional constraint integration methods will try to enforce the term DB form *grippe* instead.

We have studied this problem in our recent work (Jon et al., 2021) concurrently with Bergmanis and Pinnis (2021), who used a very similar approach. Both works use different languages and evaluation pipelines and both show that the proposed approach is feasible.

2 Method

NMT models are known to produce fluent, consistent and grammatically correct outputs (Popel et al., 2020). Thus, it makes sense to utilize this ability of the model to inflect the constraint into correct form, instead of trying to disambiguate the form externally. Our approach is based on annotating

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 828–834
November 10–11, 2021.

source sentences with the desired target constraints and training the model to incorporate these constraints into the output. We publish our preprocessing scripts at https://github.com/ufal/bergamot/wmt21-terminology

2.1 Term annotation

There are multiple possibilities in how to exactly annotate the source sentence. For example, let's say the terminology database contains entries:

runny nose -> nez qui coule
fever -> fièvre

and we have a sentence:

*And are you having a **runny nose** or **fever**?*

One way is to replace the part of the source sentence containing the source constraint with the target part of the constraint:

*And are you having a **nez qui coule** or **fièvre**?*

Another option is to insert the translation tokens after the source part of the constraint and use factors to mark which tokens of a sentence belong to source constraint, which tokens are part of the target constraint and which are neither. For example, if factor with value 2 denotes that the token is part of the translation, value 1 means that the token is part of a source constraint and 0 means that it is just ordinary token, we get:

And_0 are_0 you_0 $having_0$ a_0 ***runny***$_1$ ***nose***$_1$ ***nez***$_2$ ***qui***$_2$ ***coule***$_2$ or_0 ***fever***$_1$ ***fièvre***$_2$ $?_0$

We use simpler method to integrate the constraints in our systems: we append them to the source sentence as a suffix, separated by a special token (<sep>) and in case of multiple constraints for a single sentence, we separate them by a different token (<c>):

*And are you having a **runny nose** or **fever**? <sep> **nez qui coule** <c> **fièvre***

For more details about the possible modifications of our method, comparisons with other approaches and detailed evaluation and analysis, we refer the reader to our previous work (Jon et al., 2021).

2.2 Training data generation

We prepare synthetic constraints for parallel training data by sampling random token subsequences from the target sentence. These subsequences are used as a suffix for the source sentence as described earlier. There is a number of parameters guiding this process. Every token in a sentence can become a start of a constraint with probability s. Unless stated otherwise, we set $s = 0.1$. Any subsequent token in an open constraint can end the constraint with probability $e = 0.75$. We permit multiple non-overlapping constraints for a sentence. We skip the sentence for constraint generation (i.e. leave it without any constraints) with probability $n = 0.1$. In pseudocode:

```
s=0.1
e=0.75
n=0.1
for sent in text:
  r=random()
  constraints=[]
  if r > n:
    open=False
    constraint=""
    for t in tokens(sent):
      r=random()
      if open:
        if r < e:
          constraints.append(constraint)
          open=False
        else:
          constraint+=t
      else:
        if r < s:
          constraint+=t
          open=True
  print(sent, constraints)
```

Since the task allows for multiple target variants for a single source term, we have to account for such possibility in our training data generation. We assume that each generated constraint can have a variant with probability $v = 0.1$. This variant is sampled randomly (with no relation to the source sentence) from n-grams extracted from the target training corpus (so it is not a part of a current target sentence, but it is still a plausible subsequence in the target language). The variant has the same number of tokens as the original constraint with probability $l = 0.9$, otherwise the length of the variant is taken from triangular distribution between 1 and 9 with mode 2. The variants of a single constraint are delimeted with another special token <v>. None of the probabilities were tuned for improving results, we chose them based on manual inspection of the generated data. We use values that produced similar counts and lengths of the constraints as in

the validation set.

2.3 Lemmatization

The training data generation method described above works, but suffers from the issues described in the introduction – the system learns to generate only the exact tokens supplied as constraints in the suffix, but doesn't account for different possible inflections of the constraints in different contexts. To overcome this issue, we lemmatize the constraints both during the training and during test time. This way, the model learns to not only generate the correct words in the output, but also to correctly inflect them.

2.4 Source-side terminology matching

To find term pairs from terminology database in the input text, we lemmatize both the database source side and input sentences and search for the terms that appear either on lemma or surface form level. Since our lemmatizer works with context, we lemmatize both the text and the database word by word to ensure consistent lemmas. For the models trained with lemmatized constraints, we lemmatize also the target side of the terminology database and anntote the source sentence with lemmas of the target terms, instead of the surface forms.

3 Experiments

3.1 Data

We used all English-French corpora allowed by the organizers, aside from Paracrawl (with the exception of one model, which is marked). Namely this means Europarl v10, Common Crawl, UN Parallel Corpus v1.0, News Commentary v16 and Gigaword. We used WMT15 news test set as our validation set. After deduplication and filtering, the resulting training set consists of 24.6M sentences without Paracrawl and 125.9M including Paracrawl.

3.2 Tools

We use MarianNMT (Junczys-Dowmunt et al., 2018) to train Transformer-big models with standard parameters (Vaswani et al., 2017). The corpora are filtered using Moses cleaning script[1] and `fasttext` langid (Joulin et al., 2016). We split the text into subwords using FactoredSegmenter[2] based on SentencePiece (Kudo and Richardson, 2018) and lemmatize using UDPipe (Straka and Straková, 2017). BLEU scores are computed using SacreBLEU (Post, 2018), other metric are obtained by an evaluation script provided by the organizers[3](ibn Alam et al., 2021).

3.3 Evaluation

The script provided by the task organizers computes multiple metrics: BLEU, (Lemmatized) Exact Match, Window overlap and 1-TERm.

Exact match is a fraction of constraints which were produced in the outputs (the output sentences are lemmatized and the search is performed on both lemma and surface form level). This metric can be cheated in two ways – first, the system can place the target constraint at arbitrary place in the output, e.g. we can just translate with a non-constrained MT model, append the constraints at the end and obtain a perfect score. Second way is related to lemmatization – the system can produce any valid surface form of the constraint and even though this form is not grammatically correct in context of the output sentence, it still gets counted as matching. On the other hand, without lemmatization, only the word forms listed in the terminology database would get accepted, which would not cover all the possible correct forms.

Window overlap aims to overcome the first shortcoming of EM by evaluating placement of the constraint in the output. For each constraint in the translation and in the reference, windows of n tokens are extracted and compared with each other to see if the system places the constraint in similar context as in the reference. 2 and 3 token windows are used.

TERm metric is weighted TER which uses higher weights for tokens which are part of a term from terminology database to increase sensitivity to differences in the terminology. In the experiments, we observed that 1-TERm score is influenced mainly by the overall translation quality and less so by the term integration. We believe that this metric alone is also not sufficient for comparing ability to integrate constraints in different models, as the results seem to rely mainly on the "baseline" model performance, i.e. big general NMT model, trained on more data, which provides better overall translation quality, but does not explicitly

Constraints	Corpus	Variants	BLEU	EM	window 2	window 3	1-TERm
None	Base	-	43.976	0.862	0.289	0.283	0.584
None	Base+paracrawl	-	45.084	0.851	0.283	0.279	0.587
None	Base+bt	-	42.319	0.834	0.282	0.275	0.575
SF	Base	no	43.771	0.953	0.297	0.290	0.581
SF	Base	yes	41.656	0.982	0.253	0.255	0.555
Lemm	Base	yes	42.317	0.919	0.278	0.274	0.552
Lemm	Base	no	44.959	0.961	0.302	0.296	0.591
Lemm*	Base	no	44.623	0.909	0.292	0.288	0.588
Final combined	-	-	45.590	0.989	0.309	0.304	0.600

Table 1: Results of our models on official validation set. The first column specifies whether the constraint were lemmatized (*Lemm*) or not SF (*SF*), second one shows which part of copora we used. Base means all parallel data allowed by the organizers with exception of Paracrawl. Third column says whether we provided all possible variants of the target term from terminology database to the model, on we only the first one. Asterisk in *Constraints* column means that the model was trained with these form of constraints, but no constraints were provided during the test time.

integrate constraints, may obtain higher scores than a smaller constrained model with perfect constraint integration ability.

3.4 Results

We trained our models by techniques described earlier and we present metrics computed by the official evaluation script in Table 1. Due to time and computing constraints, most of the models were trained without Paracrawl corpus and we only trained one baseline on dataset including Paracrawl for comparison. We compared integrating constraints in the surface form (so the model needs to produce exactly the same token as provided in the input) and constraints in lemmatized form (the model can produce different inflection of the provided constraint). We also compared providing all possible variants of the target constraint from terminology database (delimeted by <v>, as described earlier), or just the first possible translation.

We see that in most metrics, the model which is trained with lemmatized constraints and uses only one variant performs the best. Systems trained with multiple variants of the target term show large degradation in BLEU scores. We suppose one of the problems in our method is that during training, only the true constraint variant from the target is plausible translation of the source, others are n-grams sampled randomly from the whole corpus. Thus, the negative samples are very easy to distinguish during the training, but during the test time, the variants are provided by the term base and they are all plausible in the context. We will analyse these results further in the future.

Our final primary submission is a combination of all the models. They are ranked by their respective BLEU scores on validation set and we check if the produced translation contains the desired term either at lemma level. We use the best ranking systems' translation that does, or, in case none of the systems produced the term, we use the translation of baseline system.

The task organizers provide test set results.[4] Two metrics were considered for the ranking. First, COMET (Rei et al., 2020), which evaluates general translation quality without special regard for specific terminology. Secondly, exact match, which measures how many of the desired constraints were actually produced in the output, but suffers from the issues described earlier. Our primary submission was ranked on joint 6th-10th place out of 21 systems according to COMET and 1st-3rd according to exact match.

3.5 Error analysis

Our submitted system did not cover 10 out of 872 term occurrences in the validation set. We analyse these ten errors manually. Six of these errors are related to casing, notably by translating *SARS-CoV* as *Sars-CoV*, instead of keeping the original casing (five occurrences). This is caused by our lemmatization pipeline, which produces *Sars* as lemma of *SARS*. We confirmed that after manually fixing the input and restoring the original casing, the system produces correct output. Other five examples classified as errors are presented in Table 2.

i	Source	Target terms	MT output
1	Many human **Coronavirus** have their origin in bats.	coronavirus	Beaucoup de **Coronavirus** humains ont leur origine dans les chauves-souris .
2	Data from these practices are reported online in a weekly return, which includes monitoring weekly rates of influenza-like illness (ILI) and other communicable and **respiratory diseases** in England.	maladies respiratoires / maladies communes des voies respiratoires / maladie respiratoire	Les données relatives à ces pratiques sont communiquées en ligne dans une déclaration hebdomadaire, qui comprend le suivi des taux hebdomadaires de maladies grippales(SG) et d'autres **maladies** transmissibles et **respiratoires** en Angleterre.
3-4	We will share the protocol with UK colleagues and the I-MOVE consortium who have recently obtained EU Horizon 2020 funding from the stream "Advancing knowledge for the clinical and public health response to the **novel coronavirus epidemic**"	coronavirus nouveau; epidémie / épidémies / épidémique	Nous partagerons le protocole avec nos collègues du Royaume-Uni et le consortium I-MOVE , qui ont récemment obtenu un financement de l'OMS horizon 2020 dans le cadre du projet «Advancing knowledge for the clinical and public health response to the **novel coronavirus epidemic**»
5	The statistical methodology is in support of a policy approach to widespread disease **outbreak**, where so-called nonpharmaceutical interventions (NPIs) are used to respond to an emerging pandemic to produce disease suppression.	épidémie / épidémies / épidémique	La méthodologie statistique est à l'appui d'une approche politique face à l'apparition de **maladies à grande échelle**, où les interventions dites non pharmaceutiques (ISP) sont utilisées pour répondre à une pandémie émergente afin d'éliminer les maladies.

Table 2: Rest of the examples with uncovered terms. *Target terms* column shows possible translations of the source terms (bold) as provided in the terminology database.

Another casing error occurs in translation of the sentence (1) in the table. The model keeps the original source casing, but the evaluation script only checks for lower-case *coronavirus*. This sentence is also actually part of unsplit and wrongly tokenized source line *The large number of host bat and avian species, and their global range, has enabled extensive evolution and dissemination of coronaviruses.Many human coronavirus have their origin in bats.* This may be a source of further confusion for the model.

In example (2), the related terminology DB pair is *respiratory diseases -> maladies respiratoires*. In the model output, the adjective *transmissibles* is interjected between the terms, which is probably not an error from human point of view, but is hard to evaluate automatically.

In example (3-4), the model does not translate the name of the project in quotes, thus it does not produce the desired translations of both *epidemic -> épidemie* and *novel coronavirus -> coronavirus nouveau* .

Finally, (5) is a true failure of the model to use the provided term. The sentence produced by the model is a plausible and semantically correct translation, but it is not using the desired term. For further analysis, we manually replaced the produced translation of the term (*maladies à grande échelle*) with the term from the terminology database (*épidémie*). We computed cross-entropy scores for the modified sentence both with and without providing the constraint to the model. We saw that when provided with the constraint, the modified translation is more probable than without the constraint (but still slightly less probable than the translation that was actually produced.) This shows that the method still partially works in this case, but the bias towards producing the term in the output needs to be stronger – we plan to explore this further using contrastive learning.

4 Conclusion

We describe our submission to Terminology translation Shared Task at WMT21. We show our method can effectively incorporate the terminology without negative effects on overall translation quality. We analysed all ten examples in the validation set where our model did not cover the desired term constraint and we show that most of them can be explained by preprocessing issues.

Abstract

This paper describes the PROMT submissions for the WMT21 Terminology Translation Task. We participate in two directions: English to French and English to Russian. Our final submissions are MarianNMT-based neural systems. We present two technologies for terminology translation: a modification of the Dinu et al. (2019) soft-constrained approach and our own approach called PROMT Smart Neural Dictionary (SmartND). We achieve good results in both directions.

1 Introduction

The currently state-of-the-art approach of neural machine translation (NMT) does not inherently allow for explicit control over the system's output. That is why terminology translation has always been a problem for NMT systems. There are several approaches to solving this problem. One common paradigm is constrained decoding (Hokamp and Liu, 2017; Anderson et al., 2017; Post and Vilar, 2018), where the terminology matches are presented as hard constraints that the beam search must satisfy. Constrained decoding has its disadvantages: it is computationally expensive and can deteriorate the translation quality (Dinu et al., 2019). Another common approach is the one introduced by (Dinu et al., 2019): the terminological constraints are provided as input to the NMT as additional annotations inline with the source sentence. These can be considered 'soft' constraints, as there is no guarantee that the NMT system will indeed produce an output containing them.

In this paper we describe two approaches to terminology translation. First, we propose a modification of the (Dinu et al., 2019) approach. Second, we introduce our own technology PROMT Smart Neural Dictionary (SmartND) aimed at handling terminology translation.

The paper is organized as follows: in Section 2 we describe the systems built for the Task and the data we used. In Section 3 we describe our technologies for terminology translation. In Section 4 we present and discuss the results. We conclude the paper with discussion for possible future work in Section 5.

2 Systems overview

We submitted two single baseline transformer-based (Vaswani et al., 2017) systems trained with the `MarianNMT` (Junczys-Dowmunt et al., 2018) toolkit: English-Russian and English-French. We use all parallel data allowed by the organizers. The final systems have the same architecture: we use a shared vocabulary of sizes 16k and 32k for the English-French and English-Russian systems respectively. We use the `OpenNMT` toolkit (Klein et al., 2017) version of byte pair encoding (BPE) (Sennrich et al., 2016b) for subword segmentation. We use the devsets provided by the organizers as our development sets.

We build intermediate models to obtain back-translations (Sennrich et al., 2016a) for our final systems. We use iterative back-translation for the English-Russian system. The intermediate models are trained using SentencePiece (Kudo and Richardson, 2018) for subword segmentation as we noticed that SentencePiece-based models are more robust in low and middle-resource

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 835–841

conditions. We also tag all our synthetic data with special tokens at the beginning of the source sentences as described in (Caswell et al., 2019). Our final models use three types of synthetic data for training: back-translations, data with terminology and special data with placeholders for processing named entities during translation (see Molchanov, 2019 for details). The models are trained with guided alignment which is used at translation time by our SmartND technology. We obtain alignments using the `fast-align` (Dyer et al., 2013) tool. Both final models were trained for approximately 1.2M steps on two RTX 2080 GPUs.

We also perform fine-tuning for our final systems. There are two reasons for that. First, due to time constraints the initial final systems were trained with only one term in each sentence with terminology markup. After testing these systems we realized that they couldn't handle sentences containing multiple terms. The second reason is that we only processed parallel data and not back-translations for the initial final systems, whereas the 2020 news contain a lot of information about COVID etc. For fine-tuning we processed both the back-translated news and parallel data only using the glossary provided by organizers. This data was mixed with general parallel data.

2.1 Data preparation

There are several stages in our data preparation pipeline. These are mostly common filtering techniques. The statistics for the training data are shown in Table 1. The main stages of the pipeline are:

- Basic filtering
  This includes some simple length-based and source-target length ratio-based heuristics, removing tags, lines with low amount of alphabetic symbols etc. We also remove lines which appear to be emails or web-addresses and duplicates.

- Language identification
  The algorithm is a fairly simple ensemble of three tools: `pycld2` [1], `langid` (Lui and Baldwin, 2012), `langdetect` [2]. We only use pycld2 for large monolingual corpora.

- Bicleaner filtering
  We use the bicleaner (Ramírez-Sánchez et al., 2020) tool to filter parallel data. We discard all sentence pairs with the score threshold <= 0.3.

- Scoring with NMT models
  We finally score all parallel data and back-translations with our intermediate models to discard non-parallel sentence pairs and bad synthetic translations.

2.2 English-French

Due to time constraints and relatively large amounts of training data for the English-French pair we only build one intermediate model. We use all parallel data that we suppose to be of good quality (i.e. all data except the paracrawl, commoncrawl and giga corpora; we also randomly select only 2.5M sentence pairs from the United Nations corpus) and build a joint system trained to translate both from English into French and back. Basic filtering is applied to this data. We use a shared vocabulary of size 8k obtained with SentencePiece. We also tag the source side of the training data with language tokens. The model is trained for approximately 1M steps on two RTX 2080 GPUs. We then use this system to 1) score all parallel data in both directions; 2) translate the monolingual French news corpora into English. We translate the 2020, 2019 and 2018 news corpora. The final model is built using all allowed filtered parallel data, back-translated news and additional synthetic data for terminology markup (see Section 3 for details).

2.3 English-Russian

The English-Russian was a surprise pair announced roughly three weeks before the submission deadline. That is why despite the relatively small amounts of parallel data we only make two iterations of training intermediate systems. We first build an English-Russian system using all parallel data (except commoncrawl which we believe to be of bad quality; basic filtering is applied) including the Edinborough corpus of Russian news translated into English and separate SentencePiece-based vocabularies of

[1] https://pypi.org/project/pycld2/

[2] https://pypi.org/project/langdetect/

size 16k each. As there are approximately 25M parallel sentences pairs, we randomly select 25.5M from the back-translated Russian news corpus. We then use this model to translate the English monolingual 2020 news corpus into Russian. Then we build a Russian-English system with the same vocabularies using all completely filtered parallel data and the obtained English-Russian translations. After that we translate the Russian monolingual news (2020, 2019 and 2018) into English. The final English-Russian model is trained on all filtered parallel data (also scored with the two intermediate systems) and the back-translations of the Russian monolingual news. Despite the fact that it is better to use separate vocabularies for models with different alphabets we use a shared vocabulary because this is necessary for our terminology handling approach.

3 Terminology translation

In this section we describe our two approaches to terminology handling in detail.

3.1 SmartND

Our SmartND systems work on the backbone of the PROMT RBMT technology. The technology doesn't need any specific pretraining or fine-tuning. The entire process can be divided into three steps: dictionary creation, terminology search and output modification.

First off we create a PROMT dictionary in specific format based on the provided glossary. The dictionary is highly optimized for speed and

Table 1: Statistics for the initial and filtered parallel data in sentences (#sent) and tokens (#tok); 'clean' stands for the final filtered versions of the corpora.

contains POS information for each lexeme along with the complete inflectional paradigm. If a term is present in any of our existing dictionaries, we copy the information from there. In other cases, we try to guess the POS and possible paradigm based on how the term ends. Currently, this system only works with nouns, so we omitted any verbs and adjectives present in the provided terminology glossary, as well as any ambiguous terms that could belong to different parts of speech (like 'quarantine'). If a term has multiple translations we either choose one (if the translations are interchangeable, like 'World Health Organization' – 'Organisation mondiale de la Santé' or 'Organisation Mondiale de la Santé') or omit the term entirely. We also drop any common terms that would likely be translated correctly by our NMT models (like 'coronavirus') or, in case of the English-Russian language pair, terms with translations that are incorrect ('Coronavirus crisis' – 'коронавирус кризис'). This ensures that SmartND will not interfere with a perfectly valid NMT output. We remove 30 entries from the original glossary.

The translation process is organized as follows. If a term is present in the input text, we search the NMT output for the expected term translation. If that translation is not present in the NMT output, our RBMT systems analyze it and determine the grammatical information (case and number) of the word which our NMT model used to translate the term. We use the word-level alignment provided by the NMT model to find the term-translation pair. Then we can substitute that word for the correct translation taken from the RBMT dictionary using the same case and number. The entire process depends of the NMT model providing good quality word-level alignment. We do not substitute the term translation if the alignment is incomplete in that part of the segment.

3.2 Soft-constrained Terminology Translation

Our second approach is based on (Dinu et al., 2019) with slight modifications. The general idea is quite simple: terminology is identified and tagged on the source side, and each term is appended by its translation (also tagged). The work of (Dinu et al., 2019) and (Bergmanis and Pinnis, 2021) is based on the `Sockeye` (Hieber et al., 2017) toolkit. Each part of the term and its translation is marked with a special source feature. Whereas `MarianNMT` doesn't support source features (and our systems are `MarianNMT`-based), we propose a 'trick' similar to the one described in (Tamchyna et al., 2017). We add special tokens after the term and its translation in the input string. In the first version of our systems we added special tokens after each part of the term and each part of its translation to 'mimic' a source feature behavior. But we noticed that the resulting strings are often too long, especially if the source line contains several multi-word terms. So we decided to simplify the algorithm and mark each term with three special tokens which indicate the beginning and end of the term itself and the end of its translation: <term_start>, <term_end> and <term_trans>.

We use the glossary provided for the Task to tag our parallel data. We also use the parallel WikiTitles corpora to create more synthetic data with terminology markup. For the English-Russian pair we use the provided WikiTitles corpus. For the English-French pair we use the `wikipedia-parallel-titles`[3] tool to extract the English-French Wikipedia titles. Note that we only use this corpus to indentify and tag terms in the provided constrained data. We apply the basic filtering to the titles corpora and then randomly select 10k parallel entries for data markup. The English-French glossary remains as is, whereas we generate all possible forms for the translations of the English-Russian glossary using our parser to be able to find them in the parallel data and process more sentences for training.

The data preprocessing is simple: we go through the parallel data line by line and identify the terms (either from the provided glossary or from the WikiTitles) on the source side. If a term is found, we look for any of its translations on the target side. If a translation is found, we tag the term and append the found translation as described above. We obtain about 2.1M sentence pairs for the initial system training and around 0.8M pairs for fine-tuning (using only the provided glossary) for the English-Russian pair, For the English-French pair we have around 0.8 sentence pairs for the initial system and 0.2M pairs for tuning.

[3] https://github.com/clab/wikipedia-parallel-titles

At translation time both glossaries remain as is because we don't use the lemmatized approach, so each term is appended by the initial form of the translation. The motivation for this is that we think that having seen different forms of words and expressions at training time the model can 'guess' that it should transform the initial form to the one necessary in this context (i.e. copy and inflect).

4 Results and discussion

In this Section we present the results on the dev and test sets both in terms of automatic and human evaluation and discuss advantages and drawbacks of our approaches. The results of automatic evaluation on the dev sets according to the tool (Mahfuz ibn Alam et al., 2021) provided by the organizers are presented in Table 2. We can see that both our approaches clearly outperform the baseline according to the terminology-related metrics. As for the BLEU (Papineni et al., 2002) scores, they slightly rise for both approaches which indicates positive results of the application of our approaches. We also present the final results for our submitted systems on the test sets in Table 3. They are generally consistent with the results we obtained on the dev sets.

4.1 Tuned models with SmartND

We observe minor decrease in the exact match scores for the tuned models with the SmartND technology. Surprisingly, our final English-Russian tuned system was ranked last on the test set according to the Exact Match and Window Overlap metrics. We performed human evaluation for these translations. The results show that the exact match scores decrease because of the translation of the term *COVID-19* which is translated as *Covid-19* by the tuned model. This is a perfectly fine translation, but the evaluation metric handles all term translations in case-sensitive mode. The tuned model outperforms the baseline model in all other aspects. This is probably a reason to 1) slightly modify our SmartND algorithm; 2) make the scoring metrics more robust regarding the case aspects.

4.2 SmartND and Soft-constrained translation

We compared the two approaches to handling terminology during our experiments. They both have advantages and drawbacks originating from their architecture.

The SmartND technology is more reliable as it almost always produces the right translation given the input from the glossary. However, a noisy glossary is a great problem for SmartND as in this case it needs to be carefully handled and filtered by linguists. The second problem with SmartND is that it sometimes (rarely) produces incorrect translations putting words in the wrong form in the output. This concerns morphologically rich languages, and the reason for it is that it is sometimes hard to parse the output and define the correct form for the term translation.

The soft-constrained approach is more robust to noise in terminology glossaries. The NMT output is more fluent as the system tends to put the terms in the right forms or generate its own translation. However, as we noticed, this technology cannot handle very noisy glossaries or entries either. The soft-constrained systems also require specific training and fine-tuning and data for it, which can be costly.

4.3 General translation quality

We also observe the fact that better baseline models receive better scores according to all metrics. We paid more attention to the English-Russian direction in this task and contributed more work to it. As a result, we obtain generally higher scores on the English-Russian direction compared to the English-French direction according to all metrics.

5 Conclusions and future work

In this paper we presented our submissions for the WMT21 Shared Terminology Translation Task. We show good results in both directions we participate (English-French and English-Russian). We are planning to make more thorough analysis of the results of our work on both the dev and test sets. We are also planning to try the lemmatized approach as described in (Bergmanis and Pinnis, 2021).

Abstract

This paper describes SYSTRAN submissions to the WMT 2021 terminology shared task. We participate in the English-to-French translation direction with a standard Transformer neural machine translation network that we enhance with the ability to dynamically include terminology constraints, a very common industrial practice. Two state-of-the-art terminology insertion methods are evaluated based (i) on the use of placeholders complemented with morphosyntactic annotation and (ii) on the use of target constraints injected in the source stream. Results show the suitability of the presented approaches in the evaluated scenario where terminology is used in a system trained on generic data only.

1 Introduction

The high quality obtained by out-of-the-box neural machine translation (NMT) systems (Bojar et al., 2016) has boosted the adoption of automatic translation by the industry and invigorated the research and development on domain adaption and integration of technology in human translation workflows. For instance, combination with translation memories (Bulte and Tezcan, 2019; Xu et al., 2020; Pham et al., 2020), terminology handling (Hasler et al., 2018; Dinu et al., 2019; Michon et al., 2020; Bergmanis and Pinnis, 2021), interactive translation (Peris and Casacuberta, 2019), post-editing modelling (Chatterjee et al., 2020) or dynamic adaptation (Farajian et al., 2017) are all different techniques to make machine translation part of real-life localization workflow.

Terminology resources with all their sophistication have been the core building bricks and a continuous challenge to acquire in volume (Senellart et al., 2003) for rule-based engines. At the other extreme, they have been reduced to corpus or aligned "phrase pairs" (Schwenk et al., 2008) for Statistical Machine Translation approaches, missing most of their intrinsic linguistic properties. In contrast, neural machine translation operates on word and sentence representations in a continuous space so, on the one hand, it has access to deep actual linguistic knowledge (Conneau et al., 2018) and demonstrates a huge ability to generalize. But on the other hand, results are more difficult to interpret (Koehn and Knowles, 2017), and subsequently the translation process is far more complicated to control. Therefore, as for several other linguistic annotations, the challenge is how terminological information can be "passed" to the model. From a human perspective, even though presentation and usage of dictionaries have evolved from ontology (as found in paper dictionary) to corpus-based presentation, looking up terms in a dictionary is the ultimate point of reference for validating the correct term for a specific domain and context.

Inline with the conditions of the WMT 2021 terminology shared task, we present English-to-French NMT engines built from abundant generic (out-of-domain) training data. We evaluate several methods to enhance translation engines with the ability to integrate terminology as a quick way to dynamically specialize a translation to a particular domain, which in this case considers the new COVID-19 domain and the large efforts for translation of critical information regarding pandemic handling and infection prevention strategies. In-domain resources are limited to word- and phrase-level terminology entries created to guide professional translators to ensure both accuracy and consistency in translations. Our generic systems make only use of terminologies at inference time.

The remainder of the paper is organized as follows: Section 2 gives details of several terminology injection approaches considered in this work. In addition, we outline a grammatical error correction network that is applied over French translation hypotheses. The experimental framework is presented in Section 3. Results are discussed in Section 4. Finally, we draw conclusions in Section 5.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 842–850
November 10–11, 2021.

2 Terminology Injection

Terminology is typically defined as the technical or special terms used in a business, art, science, or special subject. A high quality asset maintained by language specialists as part of a translation project. It allows to guarantee language consistency, certify translation accuracy and define constraints to human translation.

In recent years there has been significant work proposing methods to integrate such external specialized terminologies into NMT models, each showing different levels of performance when facing terminology injection issues, mainly inference overhead and generalization power.

In this section we describe the two main methods employed for this shared task and illustrate the particularities of each on a common scenario using two English-French terminology entries: *Coronavirus* ⇝ *Coronavirus* and *pneumonia* ⇝ *pneumonie*, in the following translation:

Coronavirus can cause pneumonia
Les coronavirus peuvent causer des pneumonies

Table 1 illustrates training examples of each terminology injection methods evaluated in this work. First row shows the ***base*** configuration where no terminology is employed.

2.1 Placeholders

Our first method incorporates non-terminal tokens into NMT systems, which require modifying the pre-and post-processing of the data, and training the system with data that contains the same placeholders which occur in the test sets (Crego et al., 2016; Michon et al., 2020). Following our example, source and translation terms appearing in the sentence pair are replaced by placeholders adapted to cover a wider variety of cases, and to control morphology to allow generalization power.

The method presented in Michon et al. (2020) allows handling very challenging cases concerning homographs. This is, words (or phrases) that sharing the same form (*i.e. spread*) can occur with multiple meanings or different grammatical functions (*verb* or *noun*). The method predicts the part-of-speech of the target placeholder. Thus, solving the source homograph.

Given that the vast majority of the terminology released for this shared task consists of nouns (single words or phrases) we decided to use a simplified version of the method that only considers using noun placeholders.

Row ***mrk*** in Table 1 illustrates the use of placeholders for our previous training example. Each word form detected as terminology is replaced by two placeholders: The first indicates the part-of-speech of the terminology (in this work always a noun 'N') followed by a unique identifier; the second indicates the set of features conveying the morphology of the noun (masc/fem and sing/plur).

To predict the target morphology of the each term, the NMT model may find it useful to have access to the source word form. Thus, in a second version of the method we incorporate the terminology word form (*Coronaviruses* and *pneumonia*) in the source stream. We denote this version ***mrk+***. It is worth to notice that this second version only improves on the previous when the incorporated source term has sufficiently occurred in training.

Note also that Michon et al. (2020) do not require linguistic information in inference since ambiguities are not resolved in the source placeholders. In contrast, our implementation uses `SpaCy`[1] to obtain part-of-speeches and morphology features of input streams.

Target-side streams of methods *mrk* and *mrk+*, require post-processing to replace target-side placeholders by the final word forms. In practice, for each source-target term pair we encode all possible inflections of the source and target word labelled with the corresponding inflection type (placeholders). Not only does this analysis enable to lexically match any inflected form of the source term, but it can also produce any inflected form of the translation term, ensuring full flexibility in the inflection choice made by the neural network. Table 2 illustrates target word forms for the terminology *pneumonia* ⇝ *pneumonie*.

2.2 Learning to apply constraints

This approach tackles the same problem by learning a copy behaviour of terminology at training time (Song et al., 2019; Dinu et al., 2019; Bergmanis and Pinnis, 2021). The NMT model is trained to incorporate terminology translations when they are provided as additional input in the source sentence. Terminology translations are inserted as inline annotations, expecting the model to learn that such additional words must be copied in the target hypothesis. The authors insert terminology translations in the source sentence either by *appending* the target term to its source version, or by

[1] `https://spacy.io/`

Placeholders (tgt)	Word form
<N> <fem_sing>	pneumonie
<N> <fem_plur>	pneumonies

Table 2: Target word forms and associated placeholders for the term entry *pneumonia* ⇝ *pneumonie*.

directly *replacing* the original term with the target one. Example in row ***app*** of Table 1 illustrates the *append* alternative presented in Dinu et al. (2019).

The approach uses a generic NMT architecture which learns to use an external terminology provided at run-time, thus, showing no inference overhead. However, similarly to the preceding approach, it lacks generalization power as it simply "copies" the term found in the terminology base injected in the source sentence, irrespective of the target hypothesis context. Dinu et al. (2019) argue that in some cases the approach exhibits the ability to inflect translation terms.

Finally, a second version of the method is also illustrated in Table 1, denoted as ***app+***. The target term is injected using its lemma form. Thus, forcing the NMT model to produce the right inflection of the term observed in the source stream. In the example, *pneumonie* must be inflected in its plural form, *pneumonies*. Tokens <b>, <i> and <e> are used to inform the model of the source and target terminology boundaries. Note that, in contrast to placeholder methods, no additional post-processing is required.

2.3 Grammatical Error Correction

As previously stated, placeholder methods allow larger generalization power thanks to the flexibility of the inflection mechanism employed in the translation workflow. However, morphology choices made by the network do not take into account the actual word forms, which was observed to result in a higher number of inflection errors (Michon et al., 2020). To alleviate this problem we add a correction module that performs over the resulting translation hypotheses.

We use a correction module based on Gector (Omelianchuk et al., 2020) with a pretrained multilingual BERT to correct grammatically incorrect French words. The model predicts grammatical features for each word in the translated sentence, allowing only for 3 types of edits:

- Transformation of gender/number

  le [Fem] → la
  le [Plur] → les

- transformation of tense/person of verbs

  avez [3_Plur] → avons
  avez [Ind_Imp] → aviez

- Elision

  le [ELISION] → l'

Table 9 in Appendix B illustrates the vocabulary of tags considered by the model. Once the model predicts whether a word needs to be corrected (and which correction), the final word form is found using a dictionary and the predicted tag. Table 3 illustrates examples of translation hypotheses produced by the NMT model (Hyp) predicted tags for each word (Pred) and corrected hypotheses (Corr). Tag ✓ is used to indicate that no transformation is required.

base	Coronaviruses can cause pneumonia Les coronavirus peuvent causer des pneumonies
mrk	*<N#1> <masc_plur> can cause <N#2> <fem_sing>* *Les <N#1> <masc_plur> peuvent causer des <N#2> <fem_plur>*
mrk+	*<N#1> Coronaviruses <masc_plur> can cause <N#2> pneumonia <fem_sing>* *Les <N#1> <masc_plur> peuvent causer des <N#2> <fem_plur>*
app	*<b> Coronaviruses <i> coronavirus <e> can cause <b> pneumonia <i> pneumonies <e>* *Les coronavirus peuvent causer des pneumonies*
app+	*<b> Coronaviruses <i> coronavirus <e> can cause <b> pneumonia <i> pneumonie <e>* *Les coronavirus peuvent causer des pneumonies*

3 Experimental Framework

3.1 Corpora

Table 7 in Appendix A provides some statistics on the parallel corpora employed for training our models. It is important to note that all corpora used are out-of-domain. We first filtered out longer sentences and sentences with a significant difference in the number of words between the source and the corresponding translation. All data is pre-processed using the OpenNMT tokenizer[2].

In order to train our correction (GeC) model with additional data, we also use the monolingual (French) corpora made available for the shared task. See Table 8 in Appendix A for detailed statistics of monolingual data.

3.2 Terminology

Table 4 illustrates some examples of the terminology entries released by the organisers of the shared task.

English	French
contagious	contagieux
active cases	cas actifs
confirmed cases	cas confirmés

Table 4: English-French terminology examples.

We note that most terminology entries are composed of several words. Indeed 54.8% of terms are groups of two words, 22.3% contains more than three words and only 22.9% are single words as measured in the source side.

3.3 NMT Engines

All our NMT engines follow the Transformer architecture (Vaswani et al., 2017) implemented by the `OpenNMT-tf`[3] toolkit (Klein et al., 2017). More precisely, we use: Word embedding size: 1024; Number of layers: 6; Number of heads in multi-head self-attention layer: 16; Inner dimension of feedforward layer: 4096; Dropout rate: 0.1; In addition, we use shared embeddings for both the input and output layers. The encoder and decoder use the same BPE units (Sennrich et al., 2016) learned from source and target corpora. We train our MT models using Noam schedule (Vaswani et al., 2017) with 4000 warm-up iterations. To balance between the domains of the training corpora, we use the following sampling distribution over the training corpora:

$$\lambda_\alpha(d) = \frac{q_d^\alpha}{\sum_{d=1}^{n_d} q_d^\alpha}, \quad (1)$$

where q_d is the size of d^{th} corpora, the scalar $\alpha \in [0, +\infty]$ changes the sampling distribution as low α upsamples small corpora and downsamples large corpora while high α favors large corpora over small corpora. In the training of our MT systems, we use $\alpha = 0.5$. Learning is performed over 8 GPUs during $300K$ steps with a batch size of $32K$ tokens per step. During training, we filtered out sentences larger than 250 tokens. We applied label smoothing to the cross-entropy loss with a rate of 0.1. Resulting models are built after averaging the last ten checkpoints of the training process. In inference, we apply a length penalty rate of 0.6.

3.4 Training NMT

Terminology injection approaches implemented for this evaluation rely on NMT models with the ability to translate input streams with target terms (*app* and *app+*) and using placeholders (*mrk* and *mrk+*). Thus, a key step for our models is the availability of training data with such annotations.

To identify terminology pairs in our training database we :

- Analyse English and French using `SpaCy` to produce part-of-speeches, morphology features, noun phrases and lemmas. Only NPs (single words or phrases) are considered.
- Word align English and French parallel corpora using the `fast_align`[4] toolkit (Dyer et al., 2013).

Terminology pairs are only considered when English and French sides consist of noun phrases and when words in a term are only aligned to words in its counterpart.

Words of the terminology entries identified are replaced by the corresponding tokens (depending on the approach). See Table 1 for examples of sentence pairs with terminology entries. We make sure that a given sentence pair does not exceed 5 terminology entries.

3.5 Training GeC

We used all available French corpora to train our GeC network. To include errors in the French streams we replace some words by any inflection of its base form (lemma). The resulting corpora is then tokenized using wordpiece and passed to the BERT language model for embedding. Error detection and tagging are then performed by the network from subword embeddings. Grammatical features, part-of-speeches and lemmas are performed by the `SpaCy` toolkit. Table 3 illustrates examples of word error correction by our model.

3.6 Terms with Multiple Translations

Note that terms released by the shared task organisers may have multiple translation options (*i.e. quarantine ⇝ quarantaine/mise en quarantaine*). Thus, the right translation must be predicted and injected in the translation hypothesis.

The translation workflow implemented for this evaluation considers the injection of each translation option into the input sentence. This is, when a matched term is built with n different translation options, the original input sentence is copied n times and each translation is injected into one copy. Once all copies have been translated, the one showing the lowest perplexity is selected as measured by the pretrained BERT French language model detailed in section 2.3.

4 Results

Table 5 indicates BLEU[5] (Post, 2018) accuracy results of our NMT systems implementing different terminology injection methods before (second column) and after (third column) grammatical error correction.

System	NMT	`+corr`
`base`	**44.9**	44.8
`mrk`	42.3	**42.7**
`mrk+`	44.9	**45.1**
`app`	45.9	**46.0**
`app+`	**45.9**	**45.9**

Table 5: BLEU score of our NMT systems before (NMT) and after the correction model (`+corr`) measured over the development set.

As it can be seen, the methods that learn to apply constraints (*app* and *app+*) obtain the best performance. Overall, the GeC model succeeds in fixing grammatically incorrect French words. However, a benefit barely reflected by BLEU.

We now evaluate the performance of matching terminology entries over the development input sentences. Note that the same matching method is always applied, detailed in Section 2.1, where input sentences are matched against all possible inflections of source terms. Table 6 illustrates the accuracy of recognized terms. 73 percent of the unrecognized terms are verbs which we choose to not process. We recognized also 234 terms that are not highlighted in the development set (FP), most of them do not interfere with translations.

Accuracy	FN	FP
0.97	0.03	0.21

Table 6: Matching rates of terminology entries measured over the development set. FN and FP scores stand respectively for false negatives (terms not identified) and false positives (wrong terminology identifications).

5 Conclusions

We presented SYSTRAN English-to-French submissions to WMT 2021 terminology shared task. All our systems follow the Transformer network architecture enhanced with the ability to dynamically include terminology constraints. Several terminology injection methods were evaluated, showing their ability to effectively injecting terms while producing highly accurate translations.

A Corpora Statistics

We experiment with English-French corpora made available via the shared task organisers[6] (Tiedemann, 2012), corresponding to texts from: News commentaries (*news*), European Parliament proceedings (*epps*), United Nations official records and documents (*unpc*), web crawling (*ccrawl*, *pcrawl* and *giga*), In addition we also used the next monolingual French data sets: News Commentary 2019 (*news.19*) and News Commentary 2020 (*news.20*).

Table 7 shows statistics of the parallel corpora used for learning NMT models. Statistics computed after a lightly tokenization (to split-off punctuation). Data sets were previously filtered to discard very long sentences (> 80 words) and with very different number of tokens on either side (fertility > 6 words).

Corpus	Sents (M)	Words (M)		Vocab (K)	
		En	Fr	En	Fr
news	0.2	4.4	5.5	70	75

Abstract

This paper describes our work in the WMT 2021 Machine Translation using Terminologies Shared Task. We participate in the shared translation terminologies task in English to Chinese language pair. To satisfy terminology constraints on translation, we use a terminology data augmentation strategy based on Transformer model. We used tags to mark and add the term translations into the matched sentences. We created synthetic terms using phrase tables extracted from bilingual corpus to increase the proportion of term translations in training data. Detailed pre-processing and filtering on data, in-domain finetuning and ensemble method are used in our system. Our submission obtains competitive results in the terminology-targeted evaluation.

1 Introduction

Terminology is important for domain-specific machine translation. Each domain has its own terminology, which represents the important and core concepts in the domain. In the workflow of human translation, terminology is an effective method to integrate the knowledge of human translator into machine translations (Wuebker et al., 2016; Cheng et al., 2016; Álvaro Peris et al., 2017).

One line of approach is "hard constraint". The terminology is ensured to appear in the translation by adding constraints in beam search decoding (Hokamp and Liu, 2017; Post and Vilar, 2018). However, the enforcement of terminology constraints tends to reduce the fluency of translation (Hasler et al., 2018), especially when there are multiple constraints or the constraint is noisy (Susanto et al., 2020). Another line of approach is "soft constraint". Training data is augmented with placeholders or additional terminology translations (Arthur et al., 2016; Song et al., 2019; Dinu et al., 2019; Chen et al., 2020; Ailem et al., 2021a).

The above methods assume that the terminology translations are good ones. However, in industry or real world the terminology translations may be noisy (Li et al., 2020). And in the human translation workflows the terminology constraints usually need to be applied hierarchically according to priority. In these scenarios one source term will have more than one translation. Therefore, we are happy to participate in this task and develop the method to deal with 1-to-many term translations in neural machine translation systems.

The structure of the paper is as follows. Section 2 describes the dataset, data pre-processing and selection. We introduce details of our system in Section 3. The experiment settings, terminologies used in training and main results are introduced in Section 4. Finally, we conclude our work in Section 5.

2 Data

2.1 Data Source

For this task, we utilize parallel data from English to Chinese language provided in WMT2021: ParaCrawl v7.1, News Commentary v16, Wiki Titles v3, UN Parallel Corpus V1.0, CCMT Corpus and WikiMatrix. In addition, we also require Chinese monolingual data from News crawl and News Commentary corpora for back translation.

2.2 Data Pre-processing

For all datasets, we tokenize English text with Moses[1] and the Chinese text with Jieba[2] tokenizer. We create a joint source and target BPE vocab (Sennrich et al., 2016) with 40k merge operations using filtered bilingual dataset as described in Section 2.3, resulting in a vocabulary with size of 63K words.

2.3 Data Selection

According to the previous works (Li et al., 2019; Sun et al., 2019), we selected data for training with

the following schemes:

- Remove the texts of over 120 tokens.
- Remove bitexts with length ratios greater than 3.
- Remove texts with special HTML tags.
- Remove duplicate bitexts.
- Remove texts with fastText-langid (Joulin et al., 2016b,a), which is an open-source tool for text-based language identification.
- Remove Chinese sentences when the proportion of Chinese tokens is less than 0.8.

3 System Overview

In this section, we will describe the details about the model and techniques of our work. First, we will introduce the terminology data augmentation strategy to improve terminology translation accuracy. Then, different transformer model architectures we adopted in the paper will be depicted. Finally, we will introduce several strategies to train our models for performance improvement.

3.1 Terminology Learning

We use a terminology data augmentation strategy to encourage neural machine translation (NMT) to satisfy terminology constraints. The key point of term translation idea is that when multiple possible terms are encountered, the NMT model is preferred copying the correct terms, and the terms are correctly placed in the output sentence. Encouraged by the work (Chen et al., 2020; Ailem et al., 2021b), we use tags to specify the term constraints in the source sentence. We have given an example in the Table 1. A **Source** sentence could have more than one terms. Each term could have multiple **Constraint**. The source term is indicated as tag <S>, and the pair <C> </C> is used to label target term. Tag [SEP] is used to separate multiple possible target terminologies, when there are 1-m term constraints. Following the work (Ailem et al., 2021b) we mask the source tokens of a term to strengthen the learning of target term tokens. In table 1, term source tokens are marked in red, and the term target tokens are in blue. **Tag & Mask** shows an example. <S> indicates term constraint "infection", but the token "infection" is masked with [MASK]. "infection" 's translations " 传染病" and " 感染" are enclosed by <C> and </C>, separated by [SEP].

The official term table is small. We extract a phrase table from the bilingual training data and filter it as synthetic terms. More details are described in Section 4.2.

3.2 Model Architecture

In our systems, we adopt three different model architectures with Transformer (Vaswani et al., 2017):

- **BIG** Transformer is the Transformer-Base model (Vaswani et al., 2017) with 4096 feed-forward network (FFN) width and 16 attention heads.

- **DEEP** Transformer (Sun et al., 2019) is Transformer-Base model with 20 encoder layers.

- **LARGE** Transformer (Ng et al., 2019) is Transformer-Base model with 8192 FNN inner width.

We use 6 decoder layers for all models. Our models are implemented with open-source toolkit Fairseq (Ott et al., 2019).

3.3 Optimization Strategies

To further improve the translation performance, several common strategies are used to train our models such as Back Translation, Finetuning and Ensemble. The strategies are performed basically sequentially. We use the terminology data augmentation on back translation and fine-tuning datasets to train models.

3.3.1 Back Translation

Back translation is a data augmentation technique to incorporate monolingual data into NMT model. Similar to previous work (Edunov et al., 2018), we use back translation to improve the model performance. We first train a Chinese-to-English Transformer-Deep NMT model based on bilingual training dataset. The NMT model is applied to translate Chinese monolingual corpus to English. The pseudo parallel corpus is used to train models together with the bilingual training dataset.

3.3.2 Finetuning

Previous study (Sun et al., 2019) demonstrate that fine-tuning a model on in-domain data effectively improve the model performance. For the term translation task, two fine-tuning datasets are used in our works. We use two kinds of finetuning datasets to train the model sequentially.

Base FT We use all the previous English $\rightarrow$ Chinese development and test dataset as fine tuning corpus, including WMT2017 development data, WMT2017 test data, WMT2018 test data, WMT2019 test data and WMT2020 test data.

In-domain FT To use in-domain dataset to fine tune the model, we perform data selection on out-of-domain corpus based on in-domain n-gram match. The key idea is to select sentence pairs from the large out-of-domain corpus that are similar to the in-domain data. We use the bilingual training data as the out-of-domain corpus and WMT2021 term development dataset as the in-domain corpus. We extract 1-3grams from the in-domain and out-of-domain dataset. After exclude the ngrams from the out-of-domain data, the left in-domain ngrams are applied to match relevant sentence from the bilingual training.

In our work, we use source and target to select in-domain dataset respectively and finally the two sets are combined to train the model.

3.3.3 Ensemble

Model ensemble is an effective strategy widely used in real-world tasks. At each step of translation prediction, it combines the predicted probabilities of different models. We use the log-avg strategy to ensemble the different NMT models. The model diversity is an important factor for ensemble. We have trained three Transformer models with different architectures including the variants of Transformer-BIG, Transformer-DEEP and Transformer-LARGE.

4 Experiments

4.1 Setups

Our models are implemented in Fairseq Library[3]. All the single models are trained based on 4 NVIDIA P100-PCIe GPUs, each with 16 GB memory. The models are optimized with Adam algorithm (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. We set max learning rate to 0.001 when training a single model from scratch and 0.0007 when fine-tuning the model. The batch size is set to 2048 tokens per GPU. The 'update-freq' parameter in Fairseq is set to 16 when training a single model from scratch and 4 when fine-tuning the model. The dropout (Gal and Ghahramani, 2016) probabilities are set to 0.1 in all experiments. We select the checkpoint with the best BLEU score on development set as the final checkpoint in each training. Evaluation of results focus on translation accuracy and term translation consistency. We evaluate translation accuracy with SacreBLEU (Post, 2018), which is a

Table 2: Evaluation results on the WMT2021 English → Chinese development set.

case-sensitive detokenized BLEU. Terminology-targeted metrics (Anastasopoulos et al., 2021) is used to term translation consistency, including exact-match accuracy, window overlap metric and terminology-biased Translation Edit Rate (TERm)[4]. The exact-match accuracy is defined as the ratio between the number of matched source terms and the total number of source terms. The window overlap metric is to evaluate the position accuracy of each target term in translation. The TERm, a metric based on TER (Snover et al., 2006), focuses on penalizing errors related to terminology tokens.

4.2 Terminologies

In order to increase the proportion of term translations in training data, we extract phrase tables from bilingual training corpus to create synthetic term translations. First, we use FastAlign (Dyer et al., 2013) to generate word alignments. Second, based on the word alignments we extract a phrase table by using moses (Koehn et al., 2007) with default settings. We use count-based pruning (Zens et al., 2012) and fastText-langid (Joulin et al., 2016b,a) to filter the phrase table. The count threshold is set to 200. Finally, the term table for the terminology data augmentation is obtained by combining the English → Chinese term table from WMT2021 and the filtered phrase table. The target terms corresponding to the same source term are separated by '|'. The term table contains 1-to-1 and 1-to-many term pairs. The term information with tags will be added into source sentences when they match, as shown in Table 1. 15.4% of the training sentences with the term information. We have used only the official terms from WMT 2021 for the test and dev datasets.

4.3 Results

Table 2 shows the English → Chinese translation results on WMT2021 terminologies development dataset, including BLEU, exact-match accuracy, window overlap accuracy (2/3) and 1-TERm Score. We train multiple single models in each settings and report the best BLEU scores in Table 2. The baseline is the LARGE transformer model using the bilingual training data. Our models using terminology data augmentation are called Term model. Ensemble models of each step consist of 3 single models: BIG, DEEP and LARGE models. As shown in Table 2, the LARGE Term model using the bilingual dataset boosts the exact-match

[4]https://github.com/mahfuzibnalam/terminology_evaluation

accuracy from 65.89 to 69.23. Under each setting, the performance of the ensemble Term models is higher than that of the best single Term model by a BLEU score of 0.46 to 2.05. After adding back translation, we improved the BLEU score to 39.39 and the exact-match accuracy to 75.6 on ensemble models. The base FT can achieve 2 BLEU and 4.3 1-TERm score improvements on ensemble models. After applying In-domain FT, We achieve 0.96 exact-match accuracy and 0.88 1-TERm score improvements on ensemble models.

Considering the effectiveness of fine-tuning, we use WMT2021 development data to fine tune the model after completing 100 steps. In our final submission, we selected sentences with the higher probability from the translations of the ensemble Term model and the ensemble NMT model.

5 Conclusion

This paper presents the submissions by Alibaba for WMT 2021 English to Chinese translation terminologies task. We have applied a terminology data augmentation method to integrate term translations into NMT systems. We also used a series of data filtering strategies, fine-tuning and ensemble methods to improve the system performance. Experimental results show the method can improve terminologies translation performance.

Abstract

In this paper we present the FJWU's system submitted to the biomedical shared task at WMT21. We prepared state-of-the-art multilingual neural machine translation systems for three languages (i.e. German, Spanish and French) with English as target language. Our NMT systems based on Transformer architecture, were trained on combination of in-domain and out-domain parallel corpora developed using Information Retrieval (IR) and domain adaptation techniques.

1 Introduction

Due to vast availability of multilingual information, Neural Machine Translation (NMT) systems have achieved remarkable growth over Statistical Machine Translation (SMT) systems. Although the amount of training resources has significantly increased in the past few years but availability of large in-domain parallel data is still a challenging task. Performance of NMT system may quickly degrade as soon as the application domain deviates from training domain. Domain adaptation (Koehn and Schroeder, 2007) is a promising active research topic to enhance the translation quality when faced with data scarcity issues. In domain adaptation, initially large amount of parallel out-of-domain corpora is utilized for training NMT models and then fine-tuning is performed on small in-domain data for adapting to novel domains (Freitag and Al-Onaizan, 2016; Luong and Manning, 2015). Fine-tuning does not require building system from scratch, instead it is fast and efficient method of integrating in-domain data. An NMT model already trained on general domain data is further fine-tuned on in-domain data with less time and effort (Chu et al., 2017; Hira et al., 2019). Training MT systems on back-translated data is a proven domain adaptation method (Abdul Rauf et al., 2020; Sennrich et al., 2015), where synthetic parallel data is combined with original data to generate large in-domain training corpus. In addition, information retrieval (IR) technique to extract relevant sentences from out-of-domain corpus has shown promising results to overcome data scarcity (Naz et al., 2020).

NMT system incorporating multiple languages into single model is known as multilingual NMT (MNMT) (Dabre et al., 2020). Multilingual NMT systems are gaining popularity due to effective use of available resources and boosting translation quality with Translation Knowledge Transfer (Pan and Yang, 2009).

In this paper, we present study on adapting MNMT systems (Multiway many-to-one) for translating English (EN) language from French (FR), German (DE) and Spanish (ES) using fairseq (Ott et al., 2019) implementation of Transformer model. Our main focus is to investigate the effect on EN translation in Biomedical domain using multilingual NMT systems. We have also explored the domain adaptation for fine-tuning of bilingual NMT models into multilingual NMT models using out-domain and in-domain corpora. Furthermore, we show the effectiveness of utilizing in-domain data generated through IR techniques (Naz et al., 2020) by training a NMT system on combined parallel in-domain data. We also compare in-domain multilingual and bilingual models.

The remainder of this paper is organized as follows. Section 2 introduces the literature review followed by corpus processing in Section 3. Section 4 presents experiments and results. In Section 5, we conclude the findings of our work.

2 Literature Review

MNMT models tend to acquire knowledge from more than one language which helps in generalization and in building systems for low resource languages. MNMT models may help in miti-

Table 1: Sentence Pairs Used for Training, Development and Testing of MNMT models (K stands for "Thousand" and M stands for "Million")

gating the problem for resource poor languages (Dabre et al., 2020), where limited training data is available. Tubay and Costa-jussÃ (2018) submitted their NMT systems for English translation with multi-source similar languages including Portuguese, French and Spanish showing improvement of 6 BLEU points over single source NMT system. Soares and Krallinger (2019) also built NMT systems using two of the Romance languages, Spanish and Portuguese for translating into English language. For domain adaptation in NMT, fine-tuning models on in-domain parallel text is a common and effective approach (Peng et al., 2020). We assume that, the same can be used for training multilingual (many-to-one) NMT models. Chu and Dabre (2019) focused on fine-tuning MNMT models for domain adaptation, they initially trained different MNMT models using single domain and then further fine-tune on multi-domain corpora with mixed (combination of out-domain and in-domain) corpora.

3 Corpus Pre-processing

This section describes parallel corpora used in training and evaluation of our models. Statistics of train, development and test data are presented in Table 1. Main sources of data were provided by WMT21 Biomedical Translation Task. Data sources include:

- Medline abstracts and titles in-domain corpora consists of scientific publications (Bawden et al., 2019). We used datasets available for DE/EN, ES/EN and FR/EN provided by WMT. These datasets are aligned through Bilingual Sentence Aligner[1] (Moore, 2002).
- EDP are the in-domain texts of scientific publications available for FR/EN language pair only (Neves et al., 2018).
- EMEA provides in-domain biomedical parallel corpus of documents related to medicinal products (Tiedemann, 2012). We used corpora provided for DE/EN, ES/EN and FR/EN language pairs.
- Scielo in-domain corpus provided by WMT comprises of abstracts and titles in biological and health sciences domain (Neves et al., 2016). We used datasets provided for FR/EN and ES/EN language pairs.

  We also used Scielo full text corpus of scientific articles as general domain data set provided for ES/EN language pair (Soares et al., 2018).
- UFAL Medical Corpus provides various in-domain medical texts and out-domain corpus sources including dictionaries (Jimeno Yepes et al., 2017). We included corpora provided for DE/EN, ES/EN and FR/EN language pairs.
- United Nations (UN) parallel corpus comprises of official records in general domain (Ziemski et al., 2016) . We used sources provided for ES/EN and FR/EN language pairs.

News Commentary[2] and WikiPedia[3] in-domain IR corpora are used. These corpora are extracted using data selection based on IR approach (Abdul-Rauf et al., 2016) by using Medline titles as queries

		M6	M5⇒Medline	26.40	38.74	**34.73**
Bilingual	System III	M7	In-domain	**27.40**	**41.60**	30.20

Table 2: Bilingual and Multilingual DE/ES/FR → EN Transformer models and their BLEU scores for Medline20 test-sets for three language directions (DE→EN, ES→EN and FR→EN. (M here stands for 'Model'). Superscripts denote the runs submitted.

for retrieving related biomedical domain sentences. From experiments conducted by (Naz et al., 2020), corpora with top-2 best sentences gave good results in training NMT models for biomedical domain.

Medline18 and 19 testsets are used as development set. We used Medline20 testset provided by WMT20 (Bawden et al., 2020) as initial test sets to determine quality of our translation models. Preprocessing of data include tokenization and learning joint Byte Pair Encoding (BPE) (Sennrich et al., 2016) using sentencepiece[4] with a vocabulary size of 32K over in-domain corpus and encoding all available corpora with learned BPE.

4 Experiments and Results

In this section we present details of experimentation along with training configurations.

4.1 Training and Parameters

We employed Fairseq toolkit to train MNMT systems for (German, Spanish, French) → English translation. We used Transformer architecture and followed similar configuration parameters for out systems as reported in original paper (Vaswani et al., 2017). Batch size of 4K words and Adam optimizer was used in all experiments. Training was done till convergence and stopped if no improvement was noted in BLEU scores on development sets for 2-3 consecutive checkpoints. Fine-tuned models were trained for 150K steps unless early stopping is employed based on bleu score convergence.

[4] https://github.com/google/sentencepiece

4.2 NMT Models

We have categorized our experiments into 3 classes based on the corpora and training technique used. I) Multilingual models trained using all in-domain corpus and fine-tuned on Medline and IR. II) Multilingual models trained on all out-domain corpus and fine-tuned on all in-domain and Medline corpus. III) Bilingual models trained on all in-domain corpus. Results of all experiments are depicted in Table 2. BLEU score for all models is calculated using Sacrebleu (Post, 2018) on Medline20 test-set for German-English, Spanish-English and French-English.

For System I:

- $M1$: this is trained on all in-domain parallel corpus with a total size of 3.71M (DE-EN), 2.77M (ES-EN), 1.78M (FR-EN) sentences. Best BLEU score of 39.12 on Medline20 test-set was achieved for ES→EN as it has high rate of Medline sentences (66K) as compared to FR→EN (46K) and DE→EN (18K).
- $M2$: this model derived from $M1$ by further tuning it on Medline corpus for domain adaptation which resulted in significant increase in BLEU score of +3.56 for FR→EN as compared to previous model ($M1$). An increase of +0.26 BLEU for DE→EN and +0.28 BLEU for ES→EN is achieved.
- $M3$: $M2$ was further fine-tuned on IR corpus for FR→EN language pair but we observe no significant improvements in term of BLEU score on out test-set for all combinations of languages. IR corpus was extracted

from News commentary and Wikipedia parallel corpora. Apparently these corpora are far in language jargon from the traditional Medline tests, so we see no apparent gain. It is pertinent to note that IR data was only available for FR-EN thus the in-domain training corpus was used for other language pairs.

For System II:

- $M4$: this model is trained on all out-domain parallel corpus with a total size of 3.82M (DE-EN), 10.6M (ES-EN) 8.33M (FR-EN) sentences. Highest BLEU score of 29.75 is achieved with ES→EN test set. As the model is mainly trained on out-domain corpora, the huge difference in score is visible as compared to previous models. When compared with models trained on in-domain we see significant loss in BLEU scores for our current model.

- $M5$: previous model is fine tuned on in-domain corpus that shows substantial improvements over baseline model. A gain of +5.43 points for DE→EN, +9.12 points for ES→EN and +6.08 points for FR→EN was achieved. This clearly indicates that fine-tuning is an effective method for improving quality of multilingual NMT.

- $M6$: $M5$ is further fine tuned on Medline corpus yielding an improvement of +3.79 points for FR→EN giving best score of **34.73** among all models . No significant improvement in DE→EN and ES→EN is observed.

For System III:

- $M7$: Represents the bilingual models trained on all in-domain corpus. Comparing with the multilingual models; ES→EN achieved the best score of `41.60` BLEU points in bilingual mode. Bilingual DE→EN results are comparable to the multilingual systems whereas for FR→EN multilingual systems majorly outperformed the bilingual systems. Interestingly, ES→EN had more medline corpus as compared to other two. The three language pairs that we work on are not similar and thus do not have too much to gain from each other. Introducing other romance languages in the systems might lead to better performance for French and Spanish. The factor of training corpus imbalance is also playing it's part, we intend to employ better sampling strategies for multilingual systems in future.

5 Conclusion

In this paper we have described our system submissions at WMT21 biomedical shared translation task under FJWU's submission. For our submission we trained multilingual NMT systems for German, Spanish and French languages with English as target language. We focused on utilizing in-domain and out-domain parallel corpora and domain adaptation techniques for training multilingual NMT systems. We showed that, domain adaptation using fine-tuning of multilingual NMT model can be a reasonable alternative to achieve good translation quality for novel domains.

High frequent in-domain word segmentation and forward translation for the WMT21 Biomedical task

Bardia Rafieian and Marta R. Costa-jussà
TALP Research Center, Universitat Politècnica de Catalunya, Barcelona
{bardia.rafieian,marta.ruiz}@upc.edu

Abstract

This paper reports the optimization of using the out-of-domain data in the Biomedical translation task. We firstly optimized our parallel training dataset using the BabelNet in-domain terminology words. Afterward, to increase the training set, we studied the effects of the out-of-domain data on biomedical translation tasks, and we created a mixture of in-domain and out-of-domain training sets and added more in-domain data using forward translation in the English-Spanish task. Finally, with a simple bpe optimization method, we increased the number of in-domain subwords in our mixed training set and trained the Transformer model on the generated data. Results show improvements using our proposed method.

1 Introduction

Domain adaptation is one of the known challenges in Machine Translation since NMT(neural machine translation) models are susceptible to the training data (Koehn and Knowles, 2017). To say, NMT models perform poorly for domain-specific translation when trained on large out-resource data (Chu and Wang, 2018). As a result, due to the limitations of specific domain data, domain adaptation strategies help NMT models by increasing the parallel corpora. There have been several tasks to address domain adaptation which recently, in (Sato et al., 2020) they proposed a vocabulary adaptation to fine-tune the embedding layers of the NMT model by projecting general word embeddings induced from monolingual data in a target domain onto a source-domain embedding space to improve translation score. On the other hand, augmenting bilingual training data with forwarding and backward translation improves the in-domain translation quality (Nayak et al., 2020). Inspired by mentioned ideas, in this work, we implemented our strategy by two essential steps: 1) collecting and augmenting data by forwarding translation and then tuning it using Babelnet to include biomedical sentences 2) Implementing subwords bpe optimization on the train set to study the adaptation of out-of-domain data in the biomedical task. After that, We selected the transformer model (Vaswani et al., 2017) to train our system in different experimental settings. The remainder of the paper is organized as follows. In Sec. 2 we describe data collection and preparation. Sec. 3 explains our bpe optimization strategy to adapt out-of-domain data in the biomedical task. Sec. 4 shows our experimental setups and evaluation results, and finally, we conclude and discuss future works in the Sec. 5.

2 Data production

One of the critical topics in machine translation (MT) is selecting and fitting well-organized domain-relevant data (Wang et al., 2018). This section describes our data preparation approach to tune, clean, and optimize data for our translator model. The details of the dataset are described in the section 4.

2.1 In-domain dataset tuning

The gathered in-domain data is not well-tuned for the biomedical domain, so that we extracted a list of biomedical terms(word level) using the BabelNet API (Navigli and Ponzetto, 2012) by referring to the ”biomedical” tags in the BabelNet: bio-science, technology, medical practice, medical specialty, neurology, and orthopedics. To address it, we gathered a total of 5,800 biomedical terms for both English and Spanish languages. Secondly, we selected the sentences which specifically contain biomedical words. The outcome holds in-domain parallel data which each sentence at least carries a related biomedical term. Algorithm 1 shows our approach to select in-domain sentences.

Algorithm 1: Optimizing the parallel corpus using BabelNet; selecting sentences that contain at least one token in-domain word

2.2 In-domain forward translation

Considering a translation task of L1 → L2, where L1 has more significant monolingual data than L2, a forward translation translates the L1 to L2 and uses the translated L2 to recreate a synthetic parallel corpus. It has been widely reported that forward and back translation brings significant results. (Bogoychev and Sennrich, 2019). We benefited from this fact and produced bilingual data from the English source, which did not have any target or good target parallel translation. However, to ensure the availability of in-domain data, we first passed the previous step on the available monolingual side. Then we translated the source side using our MT model and added bilingual data for retraining. Finally, we merged the in-domain and out-of-domain parallel corpus to achieve a bigger train set.

3 Subword BPE optimization

Byte Pair Encoding, or BPE, is a subword segmentation algorithm that encodes rare and unknown words as sequences of subword units by merging the most frequent consecutive byte pair into a new subword (Sennrich et al., 2015). Since we enriched the train set with out-of-domain data, We propose "bpe-terms in-domain optimization" to handle open vocabulary problems and enhancing the morphology when out-of-domain data is available. Consequently, increasing the frequency of in-domain words in the subword bpe training raises the chance of having in-domain words in the vocabulary. As a result, out-of-domain data will not affect the quality of the model on translating the in-domain words, while they let the model learn on an enormous corpus. We performed this strategy by first learning the subwords on 10x duplicated in-domain parallel sentences with a size of eight million mixed with smaller out-of-domain corpora (no duplication) and then applying the trained subword model on the standard-sized corpus. After that, we expect to have the biomedical in-domain words directly translated to the target language without breaking them into subwords.

4 Experiments

Experiments illustrated in this section study the effects of the out-of-domain data on in-domain(biomedical) translation task as well as the possibility of adapting it by performing a tuned subword-bpe segmentation algorithm 3 to improve the translation quality. We split this section into four parts which start with data collection and prepossessing. Then, we describe the training system and, finally, the evaluation scores of the competition.

4.1 Data collection

We rely on the WMT21 official webpage to collect the (en/es) parallel in-domain data. Out of the provided resources, in particular, for the in-domain train set, we selected UFAL, Pubmed, Medline, IBECS (Villegas et al., 2018) and UNcorpus (Ziemski et al., 2016) along with the OPUS collection (Tiedemann, 2012). Next, we cleaned the data by removing empty lines, duplicates, and very short and long sentences. Also, to perform our experiments on out-of-domain data, we collected the parallel sentences provided from the same WMT21 official website.

4.2 Data preprocessing

To prepare our data for training, we followed the standard pipelines by performing normalization, tokenization, and removing words that contain non-alphabetic characters using Moses (Koehn et al., 2007). Then, we removed concise and long sentences by keeping the thresh-hold between 2 and 30 words for each sentence and implemented the strategy described in section 2 to select in-domain sentences. As a report, we collected 6,855,049 in-domain and added 1,965,824 out-of-domain parallel data (English/Spanish). We also translated 1,558,834 in-domain UFAL monolingual English data to Spanish and added it to our bilingual corpus for retraining the en/es model.

4.3 Training on optimized segmented data

Our method focuses on data preparation and investigates how the out-of-domain data affects the BLEU score. We imply that tuning the vocabulary of subwords would improve the accuracy of the in-domain translation(biomedical) even though some of the data is out of the domain.

The two crucial factors applied in our experiments are preprocessing the parallel corpus with BabelNet, and tuning the learning step of subwords to adapt out-of-domain data. following the strategy, four experiments have been done with two different trainsets, in-domain and mixture of in-domain and out-of-domain data:

1. In the first experiment, we used word-level data in both the source and target sides to evaluate the impact of out-of-domain usage in an in-domain task.

2. In the second experiment, we applied subword-bpe level on both source and target side with shared embeddings; however, the data were preprocessed by using Babelnet (described in section 2) to adjust the in-domain sentences in the train set for all the experiments.

3. We used the same strategy as the second experiment but with applying BPE-dropout (Provilkov et al., 2019) on both the source and target side of the data.

4. The last experiment was carried out by using tuned in-domain subword level data on both source and target sides as explained in the section 3.

In all experiments, we trained baselines on word-level and subword-bpe level to measure the proposed methods.

We selected a vocabulary size of 50k tokens and trained the data by the Transformer model with its default parameters using Open-nmt (Klein et al., 2017) neural machine translation framework.

4.4 Evaluation and results

The evaluation has been done on WMT18 and WMT19 test sets based on the BLEU score. We compared the trained models with word-level, standard subword bpe level, bpe drop out and tuned subword bpe level of the parallel corpus in the trainset to follow our experiments. We also studied the results with three types of trainsets:

- in-domain
- fair mixture of in-domain and out-of-domain sentences
- an unfair mixture of in-domain and out-of-domain with more in-domain sentences

We started and continued each training until it accomplished the best BLEU score on the validation set. We realized that using bpe dropout in the trainset gives worse results than the standard bpe level in terms of the BLEU score. Also, as expected, the worst results belong to word level and hybrid wordlevel+subword level trainset. On the other hand, using out-of-domain data in an in-domain task caused a dramatic drop in the BELU score. In this regard, there was a slight improvement in BLEU score by increasing the frequency of biomedical words in the mixture of in-domain and out-of-domain trainset in both fair and unfair distribution of each domain sentence. For WMT21 competition, we selected the models which achieved the highest scores in the wmt18 and wmt19 en2es and es2en test sets.

Table 1 describes our (en2es) results on a mixture of 2.7 million in-domain + 1.7 million out-of-domain parallel sentences (described the data in the section 2). As well, Table 2 shows the results on 2.7 million in-domain parallel sentences and also a mixture of 8 million in-domain + 1.7 million out-of-domain parallel data (all of that data). Similarly, we show the (es2en) results in the tables 3 and 4

5 Conclusion and future works

This work presented a method to adapt out-of-domain data in an in-domain(biomedical) task to improve the BLEU score. We tuned the parallel data by BabelNet, then found and increased the frequency of biomedical words in subword-learning to raise the weight of in-domain words in the vocabulary. Our results obtained in a different mixture of datasets show that our method improves the BLEU score compared with the standard subword-bpe approach. In the future, we plan to extend our approach to more low-resource languages and domains. Moreover, we plan to increase out-of-domain data and configure the frequency of in-domain words based on the domain type.

Abstract

This paper describes Huawei Artificial Intelligence Application Research Center's neural machine translation systems and submissions to the WMT21 biomedical translation shared task. Four of the submissions achieve state-of-the-art BLEU scores based on the official-released automatic evaluation results (EN→FR, EN↔IT and ZH→EN). We perform experiments to unveil the practical insights of the involved domain adaptation techniques, including finetuning order, terminology dictionaries, and ensemble decoding. Issues associated with overfitting and under-translation are also discussed.

1 Introduction

General-purpose machine translation systems have limited capability in addressing domain-specific tasks (Koehn and Knowles, 2017), for example, the WMT biomedical translation shared task, due to the low availability for high-quality in-domain data. In our WMT20 submission, various domain adaption technologies (Bawden et al., 2019, 2020) have been applied including practical approaches finetuning on general-purpose models, back-translation (Sennrich et al., 2016) and leveraging in-domain dictionaries (Peng et al., 2020b). Despite achieving state-of-the-art (SOTA) BLEU scores for most of the submissions, few efforts were put in place to disclose the practical insights associated with these techniques.

This year, the Artificial Intelligence Application Research Center (AARC) participate in the WMT21 biomedical translation task for eight language directions between English and other four languages (French, German, Italian, and Chinese). The baseline model is an in-house general-purpose NMT model built upon the transformer-big architecture (Vaswani et al., 2017). Apart from presenting an overview of the proposed biomedical Neural Machine Translation (NMT) system, we investigate the practical insights of the involved domain adaptation techniques, including finetuning order, terminology dictionaries, and ensemble decoding. Issues associated with overfitting to in-domain data and under-translation are also discussed.

2 The Data

In this section we detail the bilingual and monolingual data used in this shared task (Table 1).

2.1 Bilingual Data

In-domain bilingual data In all directions, we use the in-domain data (IND) provided by the shared task organizers to finetune the base model. [1] The IND data consists of WMT-released bitexts from Pubmed, UFAL [2] and Medline. [3]

We notice that the official release of IND data suffers from issues of misalignment between source and target sentences, and missing target sentences. The translation of a source sentence may be misplaced in a different line or even appeared in multiple lines on the target side. Moreover, a source sentence may have not been translated into in a target sentence. A data processing pipeline is developed to address the issues mentioned above (depicted in 3.4). The test data is the official release of the WMT19 shared task.

Augmented Bilingual Data We collect in-domain data from TAUS [4] for the English-French, English-Italian and English-Chinese language pairs (depicted in Table 1 as IND-Aug.) to address the in-domain data scarcity issue. For English-Chinese data, after collecting a portion of abstracts of China

FR→EN	3M	2.8M	62.5K	889K	53M	1.6K	952	40K
EN→DE	6M	2.4M	62.5K	-	5.5M	1.1K	963	42K
DE→EN	6M	2.4M	62.5K	-	53M	1.1K	794	42K
EN→IT	6M	139K	60.6k	235K	695k	0.8K	708	40K
IT→EN	6M	139K	60.6k	235K	55M	0.8K	760	40K
EN→ZH	3M	-	60.1K	847K	-	5K	774	50K
ZH→EN	3M	-	60.1K	847K	-	5K	418	50K

Table 1: Data used for training and evaluating the system. Note that "OOD" is short for the general domain data. "IND" is the in-domain data provided by the WMT organizers. "IND-Dict." refers to the in-domain dictionary. "IND-Aug." is the augmented IND data collected manually (not from MEDLINE, as depicted in 2.1). "IND-BT." is the IND monolingual data used for the back-translation. M is the acronym for "million," and K stands for "thousand".

Master's and Doctoral Dissertations, we align the data on the sentence level by using a model proposed by Açarçiçek et al. (2020). This is done by finetuning a RoBERTa (Liu et al., 2019) filter model on the TAUS dataset and selecting the source-target sentence pairs above a normalized log-probability threshold of 90%.

General-domain bilingual data We observe that finetuning the base model with IND data alone may incur sub-optimal BLEU scores. A conjecture is that the test data has a different distribution to that of the IND data. We present a case to show that finetuning the base model on a mixture of general domain data (OOD) and IND data can produce minor improvements (shown in 4.2).

2.2 Monolingual Data

A batch of monolingual Medline data in English (IND-BT.) dated before July 2018 has been collected and back-translated for data augmentation. The official released IND data from WMT is also back-translated. The models used for back-translation are from our last year's competition (Peng et al., 2020b).

3 The Approaches

The proposed systems are finetuned using the following methods. All models are trained on one Tesla V100 GPU, taking approximately 8-20 hours depending on the volumes of data involved.

3.1 Leveraging In-domain Dictionary

Leveraging domain-specific dictionaries is a viable solution for domain adaptation in NMT (Peng et al., 2020a,b) to enhance IND data coverage. We collect lexicons from SNOMED-CT [5], DOPPS[6], WFOT [7] and generate a terminology dictionary which is subsequently attached to the end of training data. Terminology is further entended to cover COVID-19 related terms obtained from Neulab.[8]

3.2 Ensemble

Ensembling methods is a machine learning technique that aggregates several base models to generate one optimal predictive model (Garmash and Monz, 2016). We choose the top two models to ensemble in an attempt to produce a more general NMT model.

3.3 Architecture

To train the in-domain NMT model, we choose the in-house NMT system trained on general domain data as a baseline built upon the transformer-big architecture. LazyAdam optimizer is used during the training phase with a learning rate of $1e^{-5}$ and a warm-up period of 16,000 steps. The dropout ratio is set to 0.1, and the batch size for training and validation is 6,144 and 32 tokens, respectively. The width of the beam search is 4. Early stopping is applied to the training.

Table 2: BLEU scores on all related submissions. The baseline models are finetuned in various configurations, including mixed finetuning on general-domain data (aka "OOD"), IND bitexts ("IND"), "IND-Dict." and the augmented IND data ("IND-Aug.").

3.4 Data Processing

Several pre-processing techniques are introduced to ensure the quality of the data.

- First, we perform punctuation normalization to standardize their formats using Moses library (Koehn et al., 2007).
- Then we carry out a primary data cleaning process to remove nonstandard sentences, including those with special characters, weblinks, extra spaces, and other bad cases.
- According to the length of the sentence after segmentation and the proportion of rare words, we remove bitexts with more rare words in the sentences. We further clean the data by skipping those sentence pairs with more than 100 subwords or less than one subword. The bitexts with a source and target sentence length ratio of more than 2.5 are excluded. A language detection tool [9] is used to filter out bitexts with abnormal language patterns, i.e., sentences with undesirable *langid*.
- An alignment model trained by fast-align (Dyer et al., 2013) [10] is used to score the corpus to remove misaligned parallel sentences.

After decoding, post-processing is performed to detokenize subwords and remove undesirable spaces between special characters and numbers, i.e., converting "rs = 0.9148" into "rs=0.9148".

4 Experimental Results and Analysis

The base systems are trained with OOD data and finetuned using IND data enhanced with monolingual data to produce the submitted results. We extract the OK-aligned data from the last two years (WMT19 and WMT20) and produce the test data to evaluate the NMT models. The BLEU scores are calculated using the MTEVAL script from Moses (Koehn et al., 2007). Results are shown in Table 2. The final two rows demonstrate the results of our submissions this year and the best official records released by the organizers.

4.1 Finetuning Order Does Matter

We identify the order of training is crucial in the experiment. We perform the experiment under the following three training strategies:

1. Strategy 1 (S1): the baseline is finetuned on the back-translation (BT) pseudo parallel corpus, followed by another finetuning using IND data.
2. Strategy 2 (S2): the baseline is finetuned using the IND data, followed by another finetuning using the BT data.
3. Strategy 3 (S3): the baseline is finetuned using a mixture of BT and IND data.

Table 5 presents the results of this comparative study for French→English translation direction. It can be observed that finetuning order generates significantly different BLEU scores, with Strategy 1 achieving a BLEU score +8.89 higher than that from Strategy 2. We follow the training strategy 1 in WMT21 shared task to this end.

4.2 OOD Data Mixed Finetuning

We observe that finetuning the base model with IND data alone (particularly with a limited amount of IND data) may result in sub-optimal BLEU scores. This may indicate overfitting to the training data, which has a different distribution to the test data. We perform a series of experiments to

OOD-6M + IND + IND-Dict.	38.32	-

Table 6: Mixed finetuning OOD data creates improvements to address overfitting to IND when training English⇔Italian translation models on WMT20.

disclose this issue. As shown in Tables 6 and 7, finetuning with a mixture of OOD and IND data generates minor improvements. Interestingly, the experiment results are sensitive to the amount of OOD data involved. Future work is planned to look into this issue in detail.

4.3 The Effect of Terminology Dictionaries

In this section, we perform an ablation study to show the effectiveness of terminology dictionaries. The IND dictionaries are appended to bitexts as a part of the corpus to train NMT models. Table 3 presents consistent improvements for all six models in the experiment.

Data	EN→FR	
	WMT19	WMT20
baseline	39.06	42.94
IND	43.56	45.03
OOD-3M + IND + IND-Dict.	**43.65**	**45.65**
OOD-9M + IND + IND-Dict.	39.70	43.50

Table 7: The effects of mixed finetuning OOD data in improving the potential overfitting issue with IND data when training English→French translation models.

4.4 Ensemble Decoding

Ensemble decoding is applied to improve the generality of the NMT model by averaging the logarithmic probabilities of a decoded token. It can be observed from Table 4 that ensemble decoding is marginally effective compared to well-learned NMT models. This finding is consistent with that obtained from Wang et al. (2020).

4.5 Under-translation with Overfitting

Under-translation occurs when the NMT model fails to decode a portion of the input sentence. One of Chinese→English models under-translates a particular sentence of the WMT21 test data. For example, as shown in Table 8, "无危险器官受累患者的预后显著优于有危险器官受累的患者" of the input has been left untranslated. After increasing the width of the beam search, under-translation can be avoided. In our opinion, under-translation may be caused by noisy IND data, in which the learned self-attentions are not differentiable during decoding. By ensembling the affected model with the baseline, we successfully rectify the problem.

sentence	example
input	The disease duration ranged from 2 weeks to 60 months (median, 4 months), and the affected segment was C All the patients were followed up 3 to 42 months (median, 12 months).
prediction	病程2周
input	The median age of the 30 patients was 56.5 (28-80) years old, among them, 25 patients were primary plasma cell leukemia, and 5 patients were secondary plasma cell leukemia.
prediction	30例患者的中位年龄为56.5（28
input	无危险器官受累患者的预后显著优于有危险器官受累的患者，患者10年OS率分别为100%和60.6%（P=0.0007）。
prediction	The 10-year os rate was 100% and 60.6% respectively (p=0.0007).

Table 8: Under-translated examples of English⇔Chinese. The portion of the sentence marked in red is under-translated.

5 Conclusion

This paper depicts Huawei's neural machine translation systems and submissions to the WMT21 biomedical shared task. We have achieved state-of-the-art BLEU scores for four of eight language pairs (EN→FR, EN↔IT and ZH→EN) based on the official-released results. We also explore practical issues for the involved domain adaptation techniques, including the effects of finetuning order, terminology dictionaries, and ensemble decoding on enhancing the performances of cross-domain NMT. We have discussed issues associated with overfitting and under-translation.

Acknowledgements

We express our gratitude to colleagues from HUAWEI AARC and Noah's Ark Lab for their continuous support. We also appreciate the WMT 21 organizers for hosting this shared task and the anonymous reviewers' insightful comments.

Tencent AI Lab Machine Translation Systems for the WMT21 Biomedical Translation Task

Xing Wang **Zhaopeng Tu** **Shuming Shi**
Tencent AI Lab, Shenzhen, China
{brightxwang,zptu,shumingshi}@tencent.com

Abstract

This paper describes the Tencent AI Lab submission of the WMT2021 shared task on biomedical translation in eight language directions: English-German, English-French, English-Spanish and English-Russian. We utilized different Transformer architectures, pre-training and back-translation strategies to improve the translation quality. Concretely, we explore mBART (Liu et al., 2020) to demonstrate the effectiveness of the pre-training strategy. Our submissions (**T**encent AI Lab **M**achine **T**ranslation, TMT) in German/French/Spanish⇒English are ranked 1st respectively according to the official evaluation results in terms of BLEU scores.

1 Introduction

This paper describes the Tencent AI Lab submission of the WMT2021 shared task on biomedical translation. Last year, we participated in three translation tasks: News (Wu et al., 2020), Chat (Wang et al., 2020a), and Biomedical (Wang et al., 2020b). In biomedical translation, we adopt DEEP TRANSFORMER (Dou et al., 2018, 2019), HYBRID TRANSFORMER (Hao et al., 2019) and DATA REJUVENATION[1] (Jiao et al., 2020). This year, we participated in eight language directions: English-German (En-De), English-French (En-Fr), English-Spanish (En-Es) and English-Russian (En-Ru) in the biomedical translation.

In this paper, we also apply the pre-train and fine-tune paradigm for the biomedical translation task. The pre-train model is first trained on the the large-scale monolingual data in a self-supervised manner, then is fine-tuned on downstream bilingual data. Specifically, we adopt the encoder-decoder pre-trained model mBART (Liu et al., 2020) to implement the pre-training strategy.

[1] https://github.com/wxjiao/Data-Rejuvenation

The rest of this paper is organized as below. Section 2 presents our system: Transformer and pre-trained model mBART. Section 3 describes the training and validation data used in our system. Section 4 reports experimental results in the participated eight language directions. Finally, we conclude our work in Section 5.

2 System

Our systems are implemented with Transformer (Vaswani et al., 2017) and the pre-trained model mBART. The training details of theses models are described in Section 4.

2.1 Transformer

We adopt the BIG and LARGE Transformer models used in the previous year (Wang et al., 2020b) as the basic Transformer models. BIG and LARGE Transformer models contain 6-layer and 20-layer encoders with TRANSFORMER-BIG setting (Vaswani et al., 2017), respectively.

2.2 Pre-train Model

For the sequence-to-sequence pre-training, we adopt mBART25 (Liu et al., 2020) as the pre-train model for our experiments, which consists of 12 encoder and decoder layers with the default size of hidden state is 1024. The model is pre-trained with the denoising objective on the large-scale monolingual data and is fine-tuned on the downstream tasks. mBART has achieved significant improvements on many low resource language paris.

3 Data

In this section, we present the training and validation data used in our system.

Besides the in-domain data provided by organisers, we collect the out-of-domain bilingual data from WMT news translation shared task.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 874–878

	En-De	En-Fr	En-Es	En-Ru
Out-of-domain	37.8M	28.0M	30.3M	92.0M
In-domain	2.5M	3.5M	1.6M	43.0K
Validation set	9.8K	1.5K	1.5K	4.0K

Table 1: The detailed statistics of training and validation data used in our system.

- En-De: Europarl-v10[2], Common Crawl corpus[3], ParaCrawl[4], News Commentary-v15[5] and Wiki Titles-v2[6].
- En-Fr: Europarl-v7[7], Common Crawl corpus, News Commentary[8], English-French Giga Corpus[9].
- En-Es: Europarl-v7[10], Common Crawl corpus, News Commentary[11], ParaCrawl[12].
- En-Ru: Common Crawl corpus, News Commentary[13], ParaCrawl[14], Yandex Corpus[15], Wiki Titles-v2, Back-translated news[16].

For the validation data, we use the Khresmoi development data[17] (En-De, En-Fr, En-Es) as the validation sets. We also use the HimL test sets 2015 and 2017[18] to enlarge the En-De validation set. For En-Ru, we randomly sample 4000 examples from the training data as the validation set.

The statistics of the in-domain and out-of-domain training data and the validation data are listed in Table 1.

To enlarge the in-domain bilingual corpus, we follow Wang et al. (2020b) to adopt back-translation method to generate synthetic bilingual sentence pairs. For English-X pair, we train a English-X LARGE model on the combination of in-domain and out-of-domain data, and use the model to generate synthetic bilingual data. We also collect the En-Ru bilingual biomedical data (about 1.0 M sentence pairs) from Internet as the in-domain data.

In this work, all corpora are tokenized by sentence-piece (Kudo and Richardson, 2018) model[19] without any pre-processing procedures.

4 Experiments

For the corpus filtering, we follow Wang et al. (2020b) to filter duplicate sentence pairs (Khayrallah and Koehn, 2018), sentence pairs with wrong language (Khayrallah and Koehn, 2018) or length problem (Ott et al., 2018).

For the synthetic bilingual data generation, we adopt iterative knowledge distillation (Li et al., 2019) to improve the translation quality. Our iterative knowledge distillation is performed with 3 BIG Transformer teachers and 3 iterations. We also try to use the Right-to-Left (R2L) training (Wu et al., 2020) but fail in achieving significant improvements on the test sets.

We follow Wang et al. (2020b) to train the BIG and LARGE Transformer models. Specifically, we first use the combination of the out-of-domain data and the in-domain data to train the teacher model. Then we use the teacher model to generate the synthetic bilingual data. Finally, we train the student model on the combination of the synthetic and real bilingual data (Jiao et al., 2021). The learning rate is set to 0.0007. All models are trained for 600K steps on 8 Tesla V100 GPUs where each is allocated with a batch size of 8192 tokens.

System	2019
Baseline	37.72
+ In-domain Data	38.14
+ Data Rejuvenation	38.47
+ Back-translation	38.66
+ Ensemble	39.14

Table 4: BLEU scores of the Transformer-Big model on the German⇒English WMT2019 biomedical test set. Only the correctly aligned sentences are used in the test set.

For the pre-train model, we adopt the publicly available mBART25[20] model and fine-tune the mBART25 on the in-domain data. In the fine-tuning phase, we minimize the label smoothed cross entropy with the smoothing factor of 0.2. We use the Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$, and $\epsilon = 1e{-}6$. The learning rate is scheduled to increase from 0 to the maximum value in the warm-up phase and decreases linearly to 0 in the remaining steps. The dropout rate is 0.3 for each residual connection and 0.1 for attention matrices.

We carry out ablation study on De→En translation task. The results are shown in Table 4. The in-domain data improves the baseline Transformer-Big model with 0.42 BLEU point. We then apply the Data Rejuvenation, Back-translation and model ensemble strategies and achieve the further improvement.

We adopt the In-domain Data, Data Rejuvenation, Back-translation as the default setting and apply the setting to Transformer-Big and Transformer-Large models on the eight language directions. We train 5 BIG and 5 LARGE Transformer models with different random seeds initialization. With the trained models, we employ the model ensemble strategy with the greedy based ensemble (Li et al., 2019; Wu et al., 2020) to get the final translation outputs. For model inference, the length penalty is set to 0.6 and the beam size is set to 4.

Translation results are reported in term of BLEU score in Table 2 and Table 3. From the tables, we find that 1) utilizing different Transformer architectures, pretraining and back-translation strategies achieve strong performance on the De→En, En↔Fr and Es→En translation tasks. 2) the lack of the large-scale in-domain data makes our En-Ru NMT system significantly lower than the state-of-the-art systems, demonstrating that the in-domain data plays a critical role in the development of NMT system.

Table 5: Official BLEU scores of our submissions for WMT21 biomedical task.

Post-process We find that several long sentences exist in the 2021 test sets, which pose a great challenge for our NMT system. Take the following two sentences for example:

Sentence 6 in doc73 in medline_fr2en_fr.txt: "Nous avons constaté que: (i) malgré le fardeau de plus en plus lourd des maladies non transmissibles, nombre de pays à faible et moyen revenu ne possédaient pas les fonds suffisants pour assurer des services de prévention; (ii) les professionnels de santé au sein des communautés manquaient fréquemment de ressources, de soutien et de formation; (iii) les frais non remboursables dépassaient 40% des dépenses de santé dans la moitié des pays étudiés, ce qui entraîne des inégalités; et enfin, (iv) les régimes d'assurance maladie étaient entravés par la fragmentation des systèmes publics et privés, le sous-financement, la corruption et la piètre mobilisation des travailleurs informels."

Sentence 3 in doc27 in medline_es2en_es.txt: "Este artículo tiene como objeto el análisis de los ensayos clínicos que permitieron dicha autorización, así como la revisión de nuevas terapias para el tratamiento del carcinoma urotelial localmente avanzado o metastásico. MÉTODO: Búsqueda bibliográfica realizada en Pub-Med y ClinicalTrials.gov mediante la combinación de las palabras clave, en español e inglés: "carcinoma urotelial", "cáncer de vejiga", "localmente avanzado","metastásico", "inmunoterapia", "CTLA-4", "PD1", "PDL-1", "atezolizumab", "nivolumab", "ipilimubab", "pembrolizumab","avelumab", "durvalumab", "tremelimumab", "terapia antiangiogénica", "terapia molecular dirigida" e "inhibidores VEGF"."

To address the problem, we manually split the long sentences into multiple sentences, and use the splitted ones as the system input to perform the translation.

We also find our system may generate wrong translations for the very short input sentences, e.g., "RéSUMé: " (Sentence 1 in doc92 in medline_fr2en_fr.txt), "(" (Sentence 4 in doc11 in medline_es2en_es.txt). To overcome the problem, we extract the target translation from the SMT phrase table and use it as the final translation output, as the NMT and SMT models are identical in modeling the bilingual knowledge (He et al., 2020).

5 Official Results

The official automatic evaluation results of our submissions for WMT 2021 biomedical translation task are shown in Table 5. Our final systems in German/French/Spanish⇒English are ranked 1st respectively, in terms of BLEU score.

6 Conclusion

In this paper, we present Tencent AI Lab machine translation systems for the WMT21 biomedical translation shared task. we participated in eight language directions: English-German (En-De), English-French (En-Fr), English-Spanish (En-Es) and English-Russian (En-Ru). Our systems German/French/Spanish⇒English are ranked 1st according to the official evaluation results in terms of BLEU scores.

It is worth mentioning that most advanced technologies reported in this paper are also adapted to our systems for news translation task (Wang et al., 2021), which achieve the 1st rank in Chinese⇒English task.

In the future, we plan to explore Non-Autoregressive machine Translation (NAT) models to improve the system performance (Zhou et al., 2020; Ding et al., 2020; Hao et al., 2021) and will integrate these advanced techniques in our Tencent TranSmart System (Huang et al., 2021)[21].

Abstract

This paper describes the submission of Huawei Translation Service Center (HW-TSC) to WMT21 biomedical translation task in two language pairs: Chinese↔English and German↔English (Our registered team name is HuaweiTSC). Technical details are introduced in this paper, including model framework, data pre-processing method and model enhancement strategies. In addition, using the wmt20 OK-aligned biomedical test set, we compare and analyze system performances under different strategies. On WMT21 biomedical translation task, Our systems in English→Chinese and English→German directions get the highest BLEU scores among all submissions according to the official evaluation results.

1 Introduction

We have witnessed great progress made by neural machine translations (Bahdanau et al., 2015; Vaswani et al., 2017) in recent years. However, domain adaptation remains to be a tough issue. As noted by Koehn and Knowles (Koehn and Knowles, 2017), translations by NMT systems in out-of-domain scenarios are relatively poor, and high-quality data in specific domains are difficult to obtain, which pose great challenges to certain translation tasks (e.g. biomedical translation). To address the domain adaptation issue, on one hand, we leverage data diversification (Nguyen et al., 2020), forward translation (Wu et al., 2019) and back translation (Sennrich et al., 2016a; Edunov et al., 2018) to generate synthetic in-domain corpora. On the other hand, fine-tuning (Sun et al., 2019) and ensemble (Freitag et al., 2017; Li et al., 2019) are used to further enhance system performances in the biomedical domain.

We introduce our data strategy in section 2, and model architectures as well as model enhancement techniques in section 3. Section 4 presents experimental results of both language pairs on the wmt20 OK-aligned biomedical test set. Section 5 is a conclusion of our work.

2 Dataset

2.1 Data Source

Our baseline model is trained with out-of-domain WMT21 news data. The sizes of bilingual and monolingual data for Chinese↔English and German↔English language pairs are shown in Table 1.

With regard to in-domain data, we use both the bilingual data and monolingual data provided by the WMT21 Biomedical Translation Shared task. For German↔English task, we select Biomedical Translation and UFAL Medical Corpus as in-domain training data. Besides, 21.43M in-house English monolingual data are used. For Chinese↔English task, the used in-house data includes: 1.35M parallel data, 21.43M English monolingual data, and 36.11M Chinese monolingual data. Table 2 shows the details of data in the biomedical domain for German↔English and Chinese↔English tasks.

2.2 Data Pre-processing

Our data pre-processing methods include:

- Filter out repeated sentences (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Normalize punctuations using Moses (Koehn et al., 2007).
- Filter out sentences with repeated fragments.
- Filter out sentences with mismatched parentheses and quotation marks.
- Filter out sentences of which punctuation percentage exceeds 0.3.
- Filter out sentences with the character-to-word ratio greater than 12 or less than 1.5.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 879–884
November 10–11, 2021.

Language	corpus WMT21 News Shared Task's Corpus	Mono English	Mono German	Mono Chinese
German↔English	96.6M	150M	150M	-
Chinese↔English	16.5M	150M	-	150M

Table 1: Out-domain data size of WMT21 Biomedical Translation Task

Language	corpus Biomedical Translation && UFAL	In-house Corpus	Mono English	Mono German	Mono Chinese
German↔English	3.06M	-	21.43M	-	-
Chinese↔English	-	1.35M	21.43M	-	36.11M

Table 2: In-domain data size of WMT21 Biomedical Translation Task

- Filter out sentences with more than 120 words.
- Apply langid (Joulin et al., 2017, 2016) to filter sentences in other languages.
- Use fast-align (Dyer et al., 2013) to filter sentence pairs with poor alignment.

It should be noted that for the German↔English translation task, we employ joint SentencePiece model(SPM) (Kudo and Richardson, 2018; Kudo, 2018) for word segmentation, with the size of the vocabulary set to 32k. As for the Chinese↔English translation task, Jieba tokenizer is used for Chinese word segmentation while Moses tokenizer for English word segmentation. Byte Pair Encoding (BPE) (Sennrich et al., 2016b) is adopted for Chinese and English sub-word segmentation. We train BPE models with 32,000 merge operations for both the source and target sides.

3 System overview

3.1 Model

Our system uses Transformer (Vaswani et al., 2017) model architecture, which adopts full self-attention mechanism to realize algorithm parallelism, accelerate model training speed, and improve translation quality. Two Transformer deep-large model architectures are used in our experiments:

- Deep 25-6 (Wang et al., 2018; Li et al., 2019): Based on the Transformer-base model architecture, the deep 25-6 model features 25-layer encoder, 6-layer decoder, 1024 dimensions of word vector, 4096-hidden-state, 16-head self-attention and layer normalization.
- Deep 35-6 (Wu et al., 2020; Sun et al., 2019): Based on the Transformer-base model architecture, the deep 35-6 model features 35-layer encoder, 6-layer decoder, 788 dimensions of word vector, 3072-hidden-staten, 16-head self-attention and layer normalization.

We use the open-source Fairseq (Ott et al., 2019) for training. The main parameters are as follows: Each model is trained using 8 GPUs. The size of each batch is set as 2048, parameter update frequency as 32, learning rate as 5e-4 (Vaswani et al., 2017) and label smoothing as 0.1 (Szegedy et al., 2016). The number of warmup steps is 4000, and the dropout is 0.1. We also use the Adam optimizer (Kingma and Ba, 2015) with $\beta 1 = 0.9$, $\beta 2 = 0.98$. In the inference phase, The beam-size is 8, The length penalties for Chinese→English and German→English are set to 0.5, and the length penalties for the other two directions are set to 1.5.

3.2 Data augmentation

Given the small size of in-domain bilingual data, how to generate more training data becomes a crucial issue for model performance enhancement in the biomedical field. We adopt three data augmentation methods:

- Data diversification (Nguyen et al., 2020): Data diversification is a simple but effective strategy to enhance the performance of NMT. It uses predictions from multiple forward and backward models and then combines the results with raw data to train the final NMT model. The method does not require additional monolingual data and is suitable for all types of NMT models. It is more efficient than knowledge distillation and dual learning, and exhibits strong correlation with model integration. In our Chinese↔English and German↔English systems, we use only the forward model and the backward model to

create synthetic data and add the data to the original parallel corpora.

- Forward translation (Wu et al., 2019): Forward translation usually refers to using source language monolinguals to generate synthetic data through beam search decoding, and then add synthetic data to the training data so as to increase the training data size. Although merely using forward translation may not work well, forward translation can be used in conjunction with a back translation strategy, which also works better than using back translation alone. We do not use forward translation for the German→English system task due to the lack of high-quality in-domain German monolinguals. We then give up forward translation for the English→German direction because forward translation and back translation cannot be used jointly for better effects. Ultimately, we only adopt forward translation for our Chinese↔English systems.

- Back translation (Edunov et al., 2018): Back translation translates target side monolingual data back to the source language so as to increase the training data size, which has been proved to be an effective method to improve neural machine translation performances. There are many methods for generating synthetic corpus through back translation. In a non-extremely low-resource scenario, sampling or noisy beam search decoding method is more effective than beam search or greedy search, and the synthetic data generated by sampling or noisy beam search decoding method may introduce more diversity to training data. In our experiment, sampling decoding is adopted. We use back translation for all directions expect English→German, due to the lack of high-quality in-domain German monolinguals.

3.3 Training strategy

We first use in-domain training data to conduct incremental training with baseline models trained by WMT21 news data for domain transfer. Then, we use three monolingual enhancement strategies, data diversity, forward translation and back translation, to create synthetic data and add them to the in-domain training data to further expand the scale of the training data, and then perform incremental training again. In addition, we fine-tune our models with test sets from previous years of the same task in hope of further improving in-domain performances. Specifically, we ensemble multiple models to forward translate the source side of test sets to increase the size of the training data, and then add noise (Meng et al., 2020) to the target side of the training data to achieve a better fine-tuning effect. Finally, multiple models are ensembled to achieve better performance.

Algorithm 1: Strategies for selecting ensemble models

Input : The list of all NMT models to be selected $M := [M^1, ..., M^n]$, n is the Number of M, and the test Set T;
Output : The optimal model combination $B := [M^i, ..., M^j]$;

```
Initialize the test set T's maximum BLEU score maxbleu := 0;
Initialize the optimal model combination B := [];
for num ∈ range(1, n) do
    Generate a list of model combination numlist, which is all possible combination of num models in M;
    for current model combination subnumlist ∈ numlist do
        Calculate the current BLEU score curbleu of the current combined model on the test set T.;
        if curbleu > maxbleu: then
            B := subnumlist
            maxbleu := curbleu
        end
    end
end
return B
```

3.4 Ensemble

For each translation task, we randomize two sets of training data and train four models using the two model architectures mentioned above. In the course of our experiments, we find that directly ensemble all models does not necessarily perform better on test set than a single model. To achieve a better ensemble effect, we design an algorithm, as shown in the algorithm 1. The core idea is to traverse all combinations of models and find the best one in the

System	English→Chinese	Chinese→English
baseline	40.0	28.3
+ biomedical corpus	44.5 (+4.5)	31.4 (+3.1)
+ data diversification	44.9 (+0.4)	32.3 (+0.9)
+ forward translation & back translation	45.8 (+0.9)	34.6 (+2.3)
+ fine-tuning	47.6 (+1.8)	35.9 (+1.3)
+ ensemble	**47.7** (+0.1)	**36.4** (+0.5)
WMT20 best official	46.9	35.3

Table 3: Chinese↔English BLEU scores on the WMT20 OK-aligned biomedical test set.

test set. The experiment results show that ensemble with the best combination found by the traverse strategy is much better than simply ensemble all models. In our experiment, the model combination that performs best on the wmt20 OK-aligned biomedical test set is used as the final submission.

4 Experimental result

We train baseline models using WMT21 news data, then incrementally train them using medical bilingual corpora and synthetic data generated by data augmentation techniques, fine-tune models with previous years' test sets, and finally ensemble multiple models to produce submitted results. We benchmark our submissions using the WMT20 OK-align test set. BLEU scores are calculated using the MTEVAL script from Moses (Koehn et al., 2007). The results are shown in Table 3 and Table 4. Our models outperform last year's official best results in three language directions. The tables mainly show the results of deep 35-6 models. Only in the last ensemble phase, multiple model architectures are used. we compare our results with the best official results from last year. We notice that our baseline models trained by WMT news data may also perform quite well in the biomedical field. For example, in German→English, Our baseline model is only 2.2 BLEU below last year's best result.

4.1 Chinese↔English

For Chinese↔English task, we first train the baseline model on WMT21 news data. Then, incremental training is conducted with in-domain bilingual and synthetic data. Finally, models are fine-tuned with the previous test sets, and multiple models are ensembled to produce the final result. The experimental results of Chinese↔English are shown in Table 3. Compared with the baseline model, the final systems achieve improvements of 8.1 BLEU and 7.7 BLEU on Chinese→English and English→Chinese directions, respectively. Incremental training alone leads to increases of 3.1 BLEU and 4.5 BLEU on Chinese→English and English→Chinese respectively. Besides, the combination of data diversity, forward translation, and back translation also lead to significant improvements (3.2 BLEU increase for Chinese→English and 1.3 BLEU for the opposite direction). Fine-tuning on previous test sets further improves the model quality by 1.3 BLEU for Chinese→English and 1.8 BLEU for English→Chinese. Notably, no further improvements is achieved by ensemble all models, while ensemble the model combinations found through the ergodic approach further improves translation quality by 0.5 BLEU and 0.1 BLEU on Chinese→English and English→Chinese, respectively. Ultimately, on Chinese↔English task, our results outperform last year's official best results.

4.2 German↔English

For German↔English task, the model training strategy used is similar to that for Chinese↔English task, except data augmentation techniques. As mentioned above, due to the lack of in-domain German monolingual data, we use data diversity and back translation strategies for German→English direction and only data diversity for English→German direction. The German↔English experiment results are shown in Table 4. Data augmentation results in significant performance improvements, with 1.1 BLEU and 1.7 BLEU on German→English and English→German respectively. Fine-tuning with previous years' test sets has also improved the quality of in-domain translations. On German→English, we fine-tune the model with wmt18 and wmt19 test sets and see an improvement of 1.1 BLEU. On English→German, fine-tuning leads to an increase of 0.4 BLEU.

System	English→German	German→English
baseline	33.8	39.5
+ biomedical corpus	34.9 (+1.1)	39.8 (+0.3)
+ data diversification	35.5 (+0.6)	40.4 (+0.6)
+ back translation	-	40.6 (+0.2)
+ fine-tuning	35.9 (+0.4)	41.7 (+1.1)
+ ensemble	36.5 (+0.6)	**42.4** (+0.7)
WMT20 best official	**36.9**	41.7

Table 4: German↔English BLEU scores on the WMT20 OK-aligned biomedical test set.

Ensemble the model combinations found through the ergodic approach contribute to 0.7 BLEU increase for German→English and 0.6 BLEU for English→German. Ultimately, due to the lack of effective in-domain German monolingual data, we only surpass last year's official best results on German→English direction.

5 Conclusion

This paper presents the submissions of HW-TSC to the WMT21 Biomedical Translation Task. We perform experiments with a series of pre-processing and training strategies. The effectiveness of each strategy is demonstrated by our experiment results. Combining with data augmentation strategies, incremental training with in-domain data on the basis of a baseline model from new domain can effectively improve in-domain translation quality. Our systems in English→Chinese and English→German directions get the highest BLEU scores among all submissions according to the official evaluation results.

RTM Super Learner Results at Quality Estimation Task

Ergun Biçici
orcid.org/0000-0002-2293-2031
bicici.github.io

Abstract

We obtain new results using referential translation machines (RTMs) with predictions mixed to obtain a better mixture of experts prediction. Our super learner results improve the results and provide a robust combination model.

1 Introduction

Quality estimation task in WMT21 (Specia et al., 2021) (QET21) address machine translation (MT) performance prediction (MTPP), where translation quality is predicted without using reference translations, at the sentence-level (Tasks 1, 2, and 3) and with classification of sentences into containing a critical error or not (Task 3). Task 1 predicts the sentence-level direct assessment (DA) in 11 language pairs categorized according to the MT resources available:

- high-resource, English–German (en-de), English–Chinese (en-zh), and Russian-English (en-ru),
- medium-resource, Romanian–English (ro-en) and Estonian–English (et-en),
- low-resource, Sinhalese–English (si-en) and Nepalese–English (ne-en), and
- no-resource, English–Czech (en-cs), English–Japanese (en-ja), Pashto–English (ps-en), and Khmer–English (km-en) for zero-shot prediction.

en-ru contains sentences from both Wikipedia and Reddit articles while others use only Wikipedia sentences with 7000 sentences for training, 1000 for development, 1000 for test QET in 2020, and 1000 for testing at QET21. The target to predict in Task 1 is z-standardised DA scores, which changes the range from $[0, 100]$ for DA scores to $[3.178, -7.542]$ in z-standardized DA scores.

	Task	Train	Test	RTM interpretants setting	Training	LM

Table 1: Number of instances in the tasks and the size of the interpretants used.

The target to predict in Task 2 is sentence HTER (human-targeted translation edit rate) scores (Snover et al., 2006). We participated in sentence-level subtasks. Table 1 lists the number of sentences in the training and test sets for each task and the number of instances used as interpretants in the referential translation machine (RTM) (Biçici and Way, 2015; Biçici, 2020) models (M for million). In zero-shot prediction, we use all of the training instances made available to the task in all 7 translation directions. We tokenize and truecase all of the corpora using Moses' (Koehn et al., 2007) processing tools.[1] Language models (LMs) are built using `kenlm` (Heafield et al., 2013).

2 RTM for MTPP

We use RTM models for building our prediction models. RTMs predict data translation between the instances in the training set and the test set using interpretants, text data selected close to the task instances in bilingual training settings or

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 885–889
November 10–11, 2021.

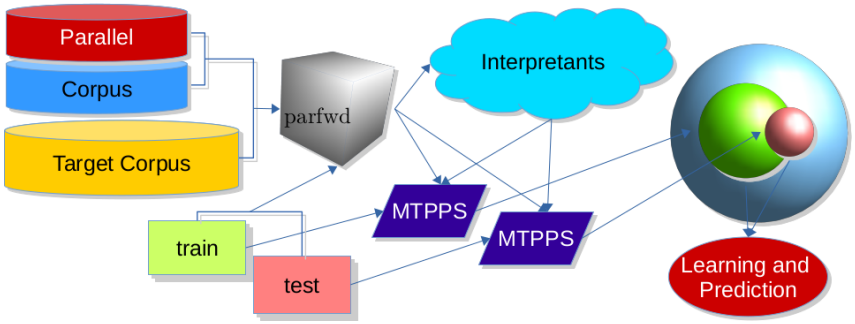

Figure 1: RTM: parfwd selects interpretants close to the training and test data using parallel corpus in bilingual settings and monolingual corpus in the target language or just the monolingual target corpus in monolingual settings; an MTPPS use interpretants and training data to generate training features and another use interpretants and test data to generate test features in the same feature space (largest sphere); learning and prediction use these features as input.

monolingual LM settings. Interpretants are text data that provide context for the prediction task and are used during the derivation of the features measuring the closeness of the test sentences to the training data, the difficulty of translating them, and to identify translation acts between any two data sets for building prediction models. With the enlarging parallel and monolingual corpora made available by WMT[2], the capability of the interpretant datasets selected to provide context for the training and test sets improve with parallel feature weight decay (`parfwd`) instance selection (Biçici, 2019). RTMs use `parfwd` for instance selection and for machine translation performance prediction system (MTPPS) (Biçici et al., 2013; Biçici and Way, 2015) to obtain the features, where additional features from word alignment are added. Figure 1 depicts RTMs and explains the model building process.

We treated all of Tasks 1, 2, and 3 as bilingual tasks where parallel corpora are obtained from WMT translation task.[3] The related monolingual or bilingual datasets are used during feature extraction. The machine learning models we use include ridge regression (RR), support vector regression (SVR) (Boser et al., 1992), gradient tree boosting, extremely randomized trees (Geurts et al., 2006), and multi-layer perceptron (Bishop, 2006) in combination with feature selection (FS) (Guyon et al., 2002) and partial least squares (PLS) (Wold et al., 1984) where most of these models can be found in `scikit-learn`.[4] We use RR to estimate the noise level for SVR, which obtains accuracy with 5% error compared with estimates obtained with known noise level (Cherkassky and Ma, 2004) and set $\epsilon = \sigma/2$. We use Pearson's correlation (r), mean absolute error (MAE), root mean squared error (RMSE), relative absolute error (RAE), relative MAE (MAER), and mean RAE relative (MRAER) as evaluation metrics (Biçici and Way, 2015). Our best non-mixed results are in Table 2. Official evaluation metric is r_P.

3 Mixture of Experts Models

We use prediction averaging (Biçici, 2018) to obtain a combined prediction from various prediction outputs better than the components, where the performance on the training set is used to obtain weighted average of the top k predictions, $\hat{y}$ with evaluation metrics indexed by $j \in J$ and weights with w:

$$\begin{aligned} w_{j,i} &= \frac{w_{j,i}}{1-w_{j,i}} \\ \hat{\boldsymbol{y}}_{\mu_k} &= \frac{1}{k}\sum_{i=1}^{k}\hat{\boldsymbol{y}}_i && \text{MEAN} \\ \hat{\boldsymbol{y}}_{j,w_k^j} &= \frac{1}{\sum_{i=1}^{k} w_{j,i}}\sum_{i=1}^{k} w_{j,i}\,\hat{\boldsymbol{y}}_i \\ \hat{\boldsymbol{y}}_k &= \frac{1}{|J|}\sum_{j\in J}\hat{\boldsymbol{y}}_{j,w_k^j} && \text{MIX} \end{aligned} \quad (1)$$

MEAN is the averaged results and MIX is the weighted average. We assume independent predictions and use $p_i/(1-p_i)$ for weights where p_i represents the accuracy of the independent classifier i in a weighted majority ensemble (Kuncheva and Rodríguez, 2014). We use the MIX prediction only when we obtain better results on the training set. We select the best model using r and mix the

Table 2: RTM test results in sentence-level MTPP in tasks 1 and 2 using the best non-mix result. r_P is Pearson's correlation.

results using r, RAE, MRAER, and MAER. We filter out those results with higher than 0.95 relative evaluation metric scores.

We also use generalized ensemble method (GEM) as an alternative to MIX to combine using weights and correlation of the errors, $C_{i,j}$, where GEM achieves smaller error than the best combined model (Perrone and Cooper, 1992):

$$\begin{aligned} \hat{\mathbf{y}}_{\text{GEM}} &= \sum_{i=1}^{L} w_i \psi_i(\mathbf{x}) = \mathbf{y} + \sum_{i=1}^{L} w_i \epsilon_i \\ C_{i,j} &= E[\epsilon_i, \epsilon_j] = (\psi_i(\mathbf{x}) - \mathbf{y})^T (\psi_i(\mathbf{x}) - \mathbf{y}) \\ w_i &= \frac{\sum_{j=1}^{L} C_{i,j}}{\sum_{k=1}^{L} \sum_{j=1}^{L} C_{k,j}} \end{aligned}$$

Super learner (Polley and van der Laan, 2010) is a stacking model on a library of L learning models that are V-fold cross-validated on the training set and constructs an $V \times L$ level 1 dataset. Theoretical results show that as the number of different predictors in the ensemble increase, the ensemble result gets closer to the oracle result (Dudoit and van der Laan, 2005). The function that minimize the empirical risk on the validation set will achieve lower error than the function that minimize the overall risk: $\frac{1}{m}\sum_{i=1}^{m} \mathcal{L}(\psi^*, y_i) - \frac{1}{m}\sum_{i=1}^{m} \mathcal{L}(\hat{\psi}, y_i) \geq 0$ (Vapnik, 1998).

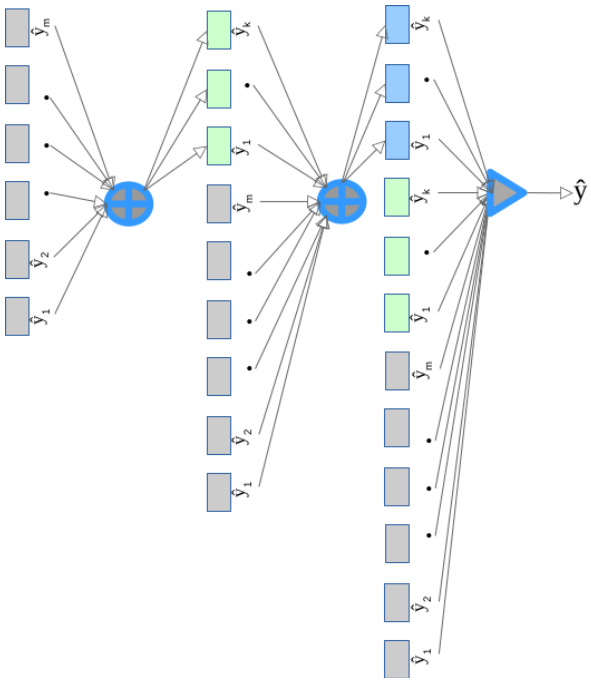

Figure 2: Model combination.

Model combination (Figure 2) selects top k combined predictions and adds them to the set of predictions where the next layer can use another model combination step or just pick the best model according to the results on the training set. We use a two layer combination where the second layer is a combination of all of the predictions obtained. The last layer is an $\arg\max$.

Our test set results using super learner are in Table 3. Before model combination, we further filter prediction results from different machine learning models based on the results on the training set to decrease the number of models combined and improve the results. A criteria that we use is MREAR ≥ 0.95 since MRAER computes the mean relative RAE score, which we want to be less than 1. In general, the combined model is better than the best model in the set. Super learner improve the results (Table 3).

The baseline deepQuest (Ive et al., 2018) use bidirectional gated recurrent unit type recurrent neural networks to model QET. RTM + deepQuest combination results in Task 2 use linear interpolation of RTM and deepQuest results with weights $0 \leq \lambda \leq 1$ and $1 - \lambda$ respectively as well as polynomial function fits to find the best combination model optimized on the development set. The most common function fit found is $f(x) =$

4 Conclusion

Referential translation machines pioneer a language independent approach and remove the need to access any task or domain specific information or resource and can achieve good results in automatic, accurate, and language independent prediction of translation scores. We present RTM ensemble results with super learner.

Abstract

This paper presents our work in WMT 2021 Quality Estimation (QE) Shared Task. We participated in all of the three sub-tasks, including Sentence-Level Direct Assessment (DA) task, Word and Sentence-Level Post-editing Effort task and Critical Error Detection task, in all language pairs. Our systems employ the framework of Predictor-Estimator, concretely with a pre-trained XLM-Roberta as Predictor and task-specific classifier or regressor as Estimator. For all tasks, we improve our systems by incorporating post-edit sentence or additional high-quality translation sentence in the way of multitask learning or encoding it with predictors directly. Moreover, in zero-shot setting, our data augmentation strategy based on Monte-Carlo Dropout brings up significant improvement on DA sub-task. Notably, our submissions achieve remarkable results over all tasks.

1 Introduction

Quality Estimation (QE) focuses on estimating the quality of machine translation (MT) system output when no ground truth reference is available (Specia et al., 2018). QE covers wide range of tasks including word-level, sentence-level and document-level. It has wide range of applications in MT quality check and post-editing effort estimation.

In WMT2021 Quality Estimation shared task[1], there are three sub tasks — Sentence-Level Direct Assessment task, Word and Sentence-Level Post-editing Effort task and Critical Error Detection task. Each sub task involves several language pairs. Our team participated in all the above three tasks over all language pairs. We summarized our main contributions as follow:

- We employ Predictor-Estimator architecture (Kim et al., 2017b; Kim and Lee, 2016) which is a two-stage model consisting of a word prediction model trained from large-scale parallel corpora, and a estimation model trained from quality-annotated QE data. Different from the original Predictor-Estimator model in (Kim et al., 2017a), we use pre-trained XLM-Roberta large as predictor instead of RNN-based model to achieve better QE features, and use task-specific classifier or regressor as quality estimator.

- We extend PE assisted QE (PEAQE) (Kepler et al., 2019; Wang et al., 2020) by integrating real PE or addtional high-quality translation in the way of multitask learning or directly encoding it with predictor.

- We explore data augmentation method based on Monte Carlo (MC) dropout (Gal and Ghahramani, 2016) to enhance the performance of zero-shot language pairs in Direct Assessment(DA) task.

Our methods achieve impressive performance on both word and sentence level tasks. Specifically, we peak the top-1 on sentence-level DA over English-German and English-Japanese pairs. For word and sentence-level post-editing effort task, our submissions of the majority language pairs obtain the best Pearson's correlation or Matthews correlation coefficient. We also win the first place in critical error detection task in English-Chinese and English-Japanese.

We will describe the tasks, datasets, and our methods for DA task, post-editing task, and critical error detection task in section 2, section 3, and section 4 respectively. Section 5 presents details of our experimental setup and results, with a brief discussion and conclusion in the end.

* Indicates equal contribution.

2 Sentence-Level Direct Assessment Task

2.1 Task Description

The sentence-level Direct Assessment task focuses on estimating sentence-level translation quality scores which are annotated with Direct Assessment (DA) scores by professional translators. The original DA scores are in scale of 0-100. The scores are then standardised using the z-score by rater. The goal is to estimate a z-standardised DA score for each translation sentence.

Sentence-level DA task is evaluated by Pearson's correlation between the predicted score and the gold human annotated z-standardised DA score. The system is assessed from two aspects: single language pair and multilingual track which takes all languages into account, including zero-shot pairs, calculating the averaged Pearson correlation overall.

2.2 Dataset

For each language, 7000, 1000 and 1000 sentence pairs are provided officially as training, development and test20 set before releasing another 1000 for the real blind test21, including high-resource English-German (En-De) and English-Chinese (En-Zh), medium-resource Romanian-English (Ro-En) and Estonian-english (Et-En), low-resource Sinhalese-English (Si-En) and Nepalese-English (Ne-En), as well as Russian-English (Ru-En). Besides, 4 language pairs — English-Czech (En-Cz), English-Japanese (En-Ja), Pashto-English (Ps-En) and Khmer-English (Km-En), are only offered blind test (1000), without training data.

2.3 Implemented Systems

The systems for DA employ Predictor-Estimator architecture. Following previous sota works (Fomicheva et al., 2020; Moura et al., 2020; Rei et al., 2020), we use a pre-trained XLM-Roberta (XLM-R)(Conneau et al., 2019) model as a predictor due to its impressive performance on cross-lingual downstream tasks.

Practically, we concatenate source(SRC) and target(MT) sentences in the format `[CLS] SRC [EOS] [SEP] MT [EOS]` following XLM-R usage, and take the embedding of pooled output of [CLS] token as features of a sentence pair. For Estimator, we simply stack two-layer FFN, taking the [CLS] feature generated above as the input to predict sentence-level DA scores.

2.3.1 PE Assisted Sentence-Level DA Prediction

Inspired by the Pseudo-PE techniques (Kepler et al., 2019; Wang et al., 2020), we take full use of post-editing sentences provided in Post-editing Effort task through multitask learning. The model jointly learns to score (SRC, MT) pair in a regression task, and distinguish between translations and post-edited sentences — which is the better translation in a classification task. In inference stage, the model only conducts regression task to predict DA score, as post-editing sentences are not available for blind test set.

The regression task applies loss function as:

$$\mathcal{L}_{reg} = (\phi(E_{s,t}) - Y_{human})^2 \quad (1)$$

where $E_{s,t}$ is the embedding of sentence pair (source, mt), ϕ is the regressor taking them as input, through a two-layer FFN to compute DA score, and Y_{human} is the Z-normalized DA score annotated by human.

The classification task forces the model to capture more expressive cross-lingual sentence representation which is paramount for DA score. In implementation, we get the model to learn which is the pair with better translation between embedding of concatenated source and target $E_{s,t}$ and embedding of concatenated source and PE $E_{s,p}$. We splice two vectors in random order and apply two stacked FFN layers to compute classification result, in which 0 means the former pair is the better (i.e. the former contains PE), 1 means the former is the worse and 2 means translation and post-edit are exactly the same. Equation (2) gives the loss function for the classification task, where M is the number of classes ($M = 3$), Y is the binary indicator (0, 1, 2) if class label c is the correct classification for observations, P is the model predicted probabilities that the observation is of classes.

$$\mathcal{L}_{cls} = -\sum_{c=0}^{M-1} Y_c \log(P_c) \quad (2)$$

2.3.2 Data Augmentation for Zero-shot Languages

Instead of directly applying the multilingual DA model trained on other 7 language pairs to zero-shot languages, we exploit a data augmentation strategy based on MC dropout to improve the performance. Specifically, we compute the expectation and variance for the set of estimated DA scores

of zero-shot languages obtained by performing N (N=30) stochastic forward passes through the well-trained but dropout-perturbed QE model. In order to control the uncertainty introduced by the disturbance, we only retain dropout in estimator and last two layers in XLM-R. We take variance as an indicator to detect observations with less uncertainty and use expectation as DA score label. Then, we mix the generated zero-shot DA data with randomly selected non-zero-shot training set to fine-tune the model. Experiments show that our data augmentation is effective to improve the performance, achieving better Pearson correlation.

3 Word and Sentence-Level Post-editing Effort Task

3.1 Task description

Word-Level QE estimates the translation quality by producing a sequence of tags for source and target. For target sentences(MT), each token is tagged as either OK or BAD, each gap between two words is tagged as BAD if one or more missing words should have been there, and OK otherwise. So the number of total tags for each target sentence is $2N + 1$, where N is the number of tokens in the target sentence. For source sentences(SRC), tokens are tagged as OK if they were correctly translated, and BAD otherwise. The number of total tags for each source sentence is M, where M is the number of tokens in the source sentence. The evaluation metrics of the word-level task is the Matthews Correlation Coefficient (MCC).

Sentence-Level QE predicts the Human Translation Error Rate (HTER). HTER is the ratio between the number of edits (insertions / deletions / replacements) needed and the reference translation length. The evaluation metrics of the sentence-level task is Pearson's correlation metric.

3.2 Dataset

The dataset in these task provides the same source and translation as DA task, with an extra post-edit sentence for each observation and task-specific token-level and sentence-level labels. Besides, we generate addition-translation sentence (AMT) for each source sentence by using well-trained machine translation systems. The motivation here is to add an additional criterion which is in the same language as the provided translation sentence. We suppose that to detect the difference between two sentence in the same language is a simpler task for model. There are some important label properties to highlight:

- The number of BAD tags and OK tags is imbalanced, especially for GAP tags.
- AMT's BLEU score is significantly lower than MT taking post-edits as reference. Its average HTER is higher than MT. It indicates that the generated AMT is less closer to post-edits than MT.

3.3 Method

The systems for QE shared task2 also employ Predictor-Estimator architecture(Kim et al., 2017b).

Predictor. Similar to Task1, we use pre-trained XLM-Roberta (XLM-R) model as predictor after fine-tuning it with mask language modeling task(Devlin et al., 2018) using the provided source and PE sentences. In order to improve the performance, refers to approach in (Wang et al., 2020), we concatenate SRC, MT, AMT sentences together in the format of `[BOS] SRC [EOS] [SEP] MT [EOS] [SEP] AMT [EOS]`.

We notate the predictor as f; SRC, MT and AMT text as X and Y and Z, corresponding features as H_x, H_y, H_z respectively:

$$H_x, H_y, H_z = f(X, Y, Z), \tag{3}$$

Estimator. We utilise 4 independent 2-layers FFN including binary three classification tasks to predict SRC word tags, MT/AMT word tags, MT/AMT gap tags respectively, and a regression task to predict HTER score of MT/AMT. All predictions are obtained by performing specific transformations ϕ. We define the predicted logits of SRC word, MT word, MT gap, AMT word, AMT gap as $\hat{V_{xw}}$, $\hat{V_{yw}}$, $\hat{V_{yg}}$, $\hat{V_{zw}}$, $\hat{V_{zg}}$; and HTER predicted score of MT and AMT as $\hat{V_{yh}}$, $\hat{V_{zh}}$. The estimator can be described as:

$$\begin{aligned}
\hat{V_{xw}} &= \phi_{xw}(H_x), \\
\hat{V_{yw}} &= \phi_{w}(H_y), \\
\hat{V_{zw}} &= \phi_{w}(H_z), \\
\hat{V_{yg}} &= \phi_{g}(f_{cat}(H_y, \hat{V_{yw}})), \\
\hat{V_{zg}} &= \phi_{g}(f_{cat}(H_z, \hat{V_{zw}})), \\
\hat{V_{yh}} &= \phi_{h}(f_{gap}(f_{cat}(H_y, \hat{V_{yw}}, \hat{V_{yg}}))), \\
\hat{V_{zh}} &= \phi_{h}(f_{gap}(f_{cat}(H_z, \hat{V_{zw}}, \hat{V_{zg}}))),
\end{aligned} \tag{4}$$

where f_{cat} is the concatenate method in the last dimension, f_{gap} is the global average pooling in

the second dimension ignoring padding tokens in a batch just like (Lin et al., 2013) 3.2.

Loss. We prepend and append two special <*pad*> labels to the original word label sequence, append a special <*pad*> label to the original gap label sequence during training, but loss of the padded labels is not computed. For all classification tasks, to deal with the problem of imbalance between OK and BAD number, we use weighted cross entropy as the loss function, and the weight is calculated as $w_i = \frac{N}{\sum C_i}$, where w_i is the inverse of the proportion of the instance with class C_i. For sentence-level HTER score loss, we use mean squared error (MSE) as the loss function. We define the tags of SRC word, MT word, MT gap, AMT word, AMT gap as V_{xw}, V_{yw}, V_{yg}, V_{zw}, V_{zg}; and HTER score of MT and AMT as V_{yh}, V_{zh}.

The model is trained under the multi-task learning framework by summing up the loss of all subtasks with specific weights:

$$loss = \sum_{\tau \in \{xw,yw,yg,zw,zg\}} \lambda_\tau log P(V_\tau | X, Y, Z) + \sum_{\tau \in \{hy,hz\}} \lambda_\tau \sqrt{\sum (V_\tau - \hat{V}_\tau)^2}, \quad (5)$$

where xw, yw, yg, zw, zg represents for classification tasks, hy, hz represents for regression tasks, λ is the weight of loss for a specific task. The multi-task framework can improve the overall performance.

4 Critical Error Detection

4.1 Task Description

This is a new QE task focusing on predicting sentence-level binary scores indicating whether or not a translation contains (at least one) critical error. The key point is to identify whether the translation will lead to misleading or more serious consequences, e.g. the translation involves critical mistranslation, hallucination or critical content deletion. Only binary prediction (whether or not any critical error contained) is required. The evaluation metrics of this task is also the MCC.

4.2 Dataset

The dataset contains 4 languages which are English-German, English-Chinese, English-Czech, English-Japenese. 7000 training, 1000 validation, and 1000 blind test sentence pairs are available for each language. Ground truth label has two classes, NOT means no catastrophic error, and ERR means at least one catastrophic error in the translation. It is noticed that the number of NOT and ERR tag is imbalanced.

4.3 Methods

Similar as the above two tasks, our baseline system takes pre-trained XLM-R as predictor, stacked FFN layers as binary classifier. We also experimented with replacing XLM-R by mBART (Liu et al., 2020) and replacing FFN layers with TextCNN, Bi-LSTM and other types of network.

Based on the intuition that the semantic difference between two monolingual sentences are easier to distinguish than that of two cross-lingual sentences, we propose to incorporate a "good" MT of the source sentence into *(src. mt)* pair during training, so that the auxiliary information provided by the "good" MT can help the model to directly compare *mt* with MT+*src*, instead of only depending on cross-lingual *src*. With consideration of expensive overhead of manual translation, we assume that au-

tomatic machine translation (AMT) of top commercial machine translation tools can also be competent at this work. Practically, we apply Baidu Fanyi [2] and Google Translate [3] API, obtaining two corresponding AMTs given a source sentence. Then we concatenate it with source and original machine translation in the format of `[CLS] SRC [EOS] [SEP] MT [EOS] [SEP] AMT [EOS]`, followed by encoding the concatenated triplet to the predictor.

Voting-Based Ensemble. Finally, we ensemble several models and take their majority voting as prediction results.

5 Experimental Results

5.1 Task1: Sentence-level Direct Assessment

Experimental Settings Our system is implemented with hugging face transformers package. The pre-trained xlm-roberta-large model which has approximately 550M parameters is taken as predictor. We train the predictor and the estimator together on the multilingual QE DA dataset using Adam(Kingma and Ba, 2015) as optimizer with constant learning rate of $1e^{-6}$ and training batch size of 16. The model is trained on a Nvidia Tesla V100 GPU.

Results Table 1 shows the results on test20 set. Our baseline is the system described in section 2.3. +multitask method is introduced in section 2.3.1. To achieve more competitive scores while also maintain a relatively small number of parameters, we ensemble our result with MC dropout approach, that is to run N (N=50) pass forwards with dropout and take the expectation of the N predictions as final answers. Table 2 presents the experimental results on blind test21 set. The baseline here is the same as Table 1 baseline. +AugData is the approach mentioned in section 2.3.2. +All is our final submitted result that integrates multi-task, data augmentation and ensemble.

Table 4: MCC of all language pairs over development(dev) set and test set.

5.2 Task2: Word and Sentence-Level Post-editing Effort Task

Settings: The batch size in training stage is 8. We use Adam as optimizer with learning rate of $2e^{-5}$. Each estimator FFN layer has a 0.1 dropout. Loss weight are: ($\lambda_{yh} = 2$, $\lambda_{zh} = 2$, $\lambda_{xw} = 4$, $\lambda_{yw} = 1$, $\lambda_{yg} = 1$, $\lambda_{zw} = 1$, $\lambda_{zg} = 1$) / 12. Our model params is 560,944,640, disk footprint(in bytes, without compression) is 2,243,954,093.

Results Table 3 shows the results on dev and test21 set. Our baseline is the QE system without AMT data. +AMT method is the QE system with AMT data. In the experiments, we generate 3 different kinds of AMT data with the machine translation system trained for the WMT2021 Machine Translation of News Shared Task, Baidu Fanyi [4] and Google Translate[5]. For each kind of AMT, we run N (N=10) pass forward with dropout=0.1 using the a unified model trained with all AMT together. The expectations of 3N predictions of score and token labels is taken as the final answers.

5.3 Task3: Critical Error Detection

Table 4 shows the results of our system on development and blind test set. Experiments show that the best results obtained when applying XLMR-Large and FFN layer on development set. The involvement of AMT also brings significant improvement over all language pairs. For ensemble settings, we ensemble multiple models with different pre-trained models and classification layers using voting-based method as introduced in section 4.3.

In order to solve the problem of label imbalance, we also investigate different label weights when computing cross-entropy loss. Due to the large gap between the number of NOT and ERR labels in the dataset, the weights(NOT:ERR) are clipped as 1:6, 1:4, 1:5, 1:15 for enzh, ende, encs, enja. Meanwhile, to better fit the data in the test set and avoid over-fitting, we utilise dropout with rate of 0.1 and weight decay of $1e^{-5}$.

6 Conclusion

We present our work on WMT 2021 QE shared task in this paper. For all the three tasks to estimate sentence-level DA, token and sentence-level post-edit effort and sentence-level critical error, we employ predictor-estimator framework as our baseline. To further boost performance, we investigate the usage of additional high-quality translations. For task1, we mainly focus on introducing post-edits with multi-task learning. Also, the effect of data augmentation method based on MC dropout is studied here to improve the result of zero-shot pairs. For task 2 and 3, we generate high-quality translations for each observation using multiple well-trained machine translation systems. By directly concatenating AMT with the original source and target sentence then encoding it with pre-trained predictor, we achieved remarkable results over all language pairs and tasks. In future, we will continue to invest time and effort on studying the effect of involving additional translations into QE tasks, for example, how the additional translation quality will affect QE performance, what the better ways are to incorporate additional translations in.

Abstract

Quality Estimation (QE) is an important component of the machine translation workflow as it assesses the quality of the translated output without consulting reference translations. In this paper, we discuss our submission to the WMT 2021 QE Shared Task. We participate in Task 2 sentence-level sub-task that challenge participants to predict the HTER score for sentence-level post-editing effort. Our proposed system is an ensemble of multilingual BERT (mBERT)-based regression models, which are generated by fine-tuning on different input settings. It demonstrates comparable performance with respect to the Pearson's correlation and beats the baseline system in MAE/ RMSE for several language pairs. In addition, we adapt our system for the zero-shot setting by exploiting target language-relevant language pairs and pseudo-reference translations.

1 Introduction

Progress in machine translation (MT) has accelerated due to the introduction of deep learning based approaches, dubbed as neural machine translation (NMT) (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014). Several metrics (e.g., BLEU (Papineni et al., 2002), METEOR (Agarwal and Lavie, 2008)) are used to automatically evaluate the quality of the translations outputted by the NMT systems. However, these evaluation metrics require comparing the NMT outputs against human-prepared reference translations, which cannot be readily obtained. To tackle this predicament, recently quality estimation (QE) (Blatz et al., 2004; Specia et al., 2018) has emerged as an alternative evaluation approach for NMT systems. QE obviates the need for human judgements and hence can be efficiently integrated into the dynamic translation pipeline in the industry setting.

QE is performed at different granularity (e.g., word, sentence, document) (Kepler et al., 2019a); in this work we focus on the sentence-level post-editing effort task, which predicts the quality of the translated sentence as a whole in terms of the number of edit operations that need to be made to yield a post-edited translation, termed as HTER (Snover et al., 2006).

Sentence-level QE using neural approaches is generally treated as a supervised regression problem involving mainly two steps. In the first step, an encoder is used to learn vector representation/s of the source and translation sentences. While in the second step, the learned representations are passed through a sigmoid output layer to estimate the HTER score. These two steps can be performed either with a single model in an end-to-end fashion (e.g., Bi-RNN (Ive et al., 2018)), or using two separate models (e.g., POSTECH (Kim et al., 2017)). The different QE systems vary in their choice of the encoder, which range from RNN-based to Transformer-based models.

In this work, we leverage the fine-tuning capability of a Transformer-based encoder, namely the mBERT (Devlin et al., 2018) pre-trained model. Alongside the standard practice of feeding both the source and target (i.e., translation) sentences as the input sequence (Kepler et al., 2019a; Kim et al., 2019), we also explore other input settings based on only the target-side sentences (i.e., monolingual context). To this end, our final QE system is an ensemble of several mBERT models [1], each generated by fine-tuning on a different input combination comprising the source and/or target sentences. We experiment with the following three input settings: (1) both source and target, (2) just target and (3) both target and a randomly-sampled target sentence in the data forming the input se-

*work done during internship at IQVIA

[1] we also experimented with XLM-RoBERTa (Conneau et al., 2019) as the component model in our preliminary run; however, the results were worse compared to mBERT

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 897–903
November 10–11, 2021.

quence. Empirical analysis on 6 language pairs shows that the ensemble model is able to perform better than the individual fine-tuned models. Moreover, we provide experimental results for zero-shot QE, where training data for the test language pair is not available. This we tackle by improvising on the available training/dev data that match the target language of the test language pair and also by generating the pseudo-reference translations in that language.

2 Data

We use the WMT21 QE Shared Task 2 sentence-level data (Specia et al., 2021; Fomicheva et al., 2020a,b) for the following 7 language pairs: English-German (En-De), Romanian-English (Ro-En), Estonian-English (Et-En), Nepalese-English (Ne-En), Sinhala-English (Si-En), Russian-English (Ru-En) and Khmer-English (Km-En). Source-side data for each language pair includes sentences from Wikipedia articles, with part of the data gathered from Reddit articles for Ru-En. To obtain the translations, state-of-the-art MT models (Vaswani et al., 2017) built using fairseq toolkit (Ott et al., 2019) were used. The label for this task is the HTER score for the source-translation pair. Annotation was performed first at the word-level with the help of TER [2] tool. The word-level tags were then aggregated deterministically to obtain the sentence-level HTER score. The training, development, test and blind test data sizes for each language pair (except Km-En) are 7K, 1K, 1K and 1K instances respectively. As Km-En language pair was introduced for zero-shot prediction, only the test data containing 990 source and translation sentences was provided.

3 Our Approach

A key innovation in recent neural models lies in learning the contextualized representations by pre-training on a language modeling task. One such model, the multilingual BERT (mBERT) [3], is a transformer-based masked language model that is pre-trained on monolingual Wikipedia corpora of 104 languages with a shared word-piece vocabulary. Training the pre-trained mBERT model for a supervised downstream task, aka *finetuning*, has dominated performance across a wide spectrum of NLP tasks (Devlin et al., 2018). Our proposed approach leverages this fine-tuning capability of mBERT so as to form the component models in the ensemble QE system (Section 3.3). That is, each component model is a re-purposed mBERT that is fine-tuned for the sentence-level HTER score prediction task on one of the three input settings discussed in Section 3.2.

3.1 Fine-tuning mBERT for Regression

mBERT's model architecture is similar to BERT [4] and contains the following parameter settings: 12 layers, 12 attention heads and 768 hidden dimension per token. However, the only difference is that mBERT is trained on corpora of multiple languages instead of just on English. This enables mBERT to share representations across the different languages and hence can be conveniently used for all language pairs in the WMT21 data.

We first load the pre-trained mBERT model [5] and use its weights as the starting point of fine-tuning. The pre-trained mBERT is then trained on QE-specific input sequences (Section 3.2) for a few epochs such that the constructed sequence X is consumed by mBERT to output the contextualized representation $\mathbf{h} = (h_{CLS}, h_{x_1}, h_{x_2}, ..h_{x_T}, h_{SEP})$. Here, $[CLS]$ is a special symbol that denotes downstream classification and $[SEP]$ is for separating non-consecutive token sequences. Considering the final hidden vector of the $[CLS]$ token as the aggregate representation, it is then passed into the output layer with sigmoid activation to predict the HTER score:

$$y = sigmoid(\mathbf{W} \cdot \mathbf{h}_{CLS} + \mathbf{b}) \qquad (1)$$

$\mathbf{W}$ is a weight matrix for sentence-level QE fine-tuning that is trained along with all the parameters of mBERT end-to-end.

3.2 Input Settings

We construct the input sequence for each language pair in the following three ways:

SRC-MT: Given a source sentence $\mathbf{s} = (s_1, s_2, ...s_N)$ from a source language (e.g., English) and its translation $\mathbf{t} = (t_1, t_2, ...t_M)$ from a target language (e.g., German), we concatenate them together as $X = ([CLS], t_1, t_2, ...t_M, [SEP], s_1, s_2, ...s_N, [SEP])$ to form the input sequence.

[2] http://www.cs.umd.edu/ snover/tercom/

[3] https://github.com/google-research/bert/blob/master/multilingual.md

[4] https://huggingface.co/bert-base-uncased

[5] https://huggingface.co/bert-base-multilingual-uncased

MT: The target sentence is only used to form the input sequence, $X = ([CLS], t_1, t_2, ...t_M, [SEP])$.

MT-MT':

Given the translation **t** for a source sentence **s**, we randomly sample another translation **t'** $= (t'_1, t'_2, ...t'_K)$ from the training data having HTER label close to **t** [6]. Although the source sentences for **t** and **t'** are different, we assume the additional monolingual context would help mBERT learn the correlating QE-specific features between **t** and **t'** for the target-side language. The resultant input sequence is $X = ([CLS], t_1, t_2, ...t_M, [SEP], t'_1, t'_2, ...t'_K, [SEP])$.

We fine-tune each of these mBERT models using AdamW optimizer (Kingma and Ba, 2014; Loshchilov and Hutter, 2017) for two epochs with a batch size of 32 and a learning rate of $2e^{-5}$.

3.3 Ensemble Model

To take advantage of the individual strengths of the three mBERT component models fine-tuned on the aforementioned input settings, we combine their HTER score predictions by training an ensemble model. In particular, we experiment with three different ensemble models - Gradient Boosting (Friedman, 2001), AdaBoost (Freund and Schapire, 1997) and Average. For Gradient Boosting and AdaBoost we use the implementation in scikit-learn [7] with 10-fold cross validation. The settings for Gradient Boosting are: number of estimators 600, learning rate 0.01, minimum number of samples 3 and other default settings. We use the default settings for AdaBoost. In Average ensembling, we average the HTER score predictions by the three mBERT models. Our system submission to WMT21 is based on Gradient Boosting as it gave the best performance on the test data, as shown in Table 1.

3.4 Zero-Shot QE

Performing sentence-level QE in the zero-shot setting presents a unique challenge as the QE system is expected to predict HTER scores for sentences in a test language pair (e.g., Km-En) without having been trained on any instances from that test language pair. We address this by training on language pairs in the WMT21 QE data that match the target-side language (i.e., En) in the test language pair. The reason we focus on the target-side language is because the component mBERT models in the proposed ensemble QE system are fine-tuned on monolingual input sequences in the target-side language, which could potentially help the QE system generalize on the unseen test language pair. We consider the training and development data for the following language pairs in WMT21 QE data: Ro-En, Si-En, Et-En. Additionally, we augment this data by generating pseudo-references in the target language. A *pseudo-reference* (Scarton and Specia, 2014) is a translation for a source sentence that is outputted by a different NMT system than the one that produced the actual translations (e.g., transformer-based translation system proposed in (Vaswani et al., 2017)) and has shown to improve sentence-level QE performance (Soricut and Narsale, 2012). We use Google Translate [8] to get the pseudo-references in En for the Ro, Si and Et source sentences. The HTER scores for the translation and pseudo-reference pairs are then obtained using the TER tool. We train the ensemble QE system on the combined WMT21 QE data and the pseudo-reference parallel data, and test on the unseen test language pair.

Table 1: Performance of ENSBRT with different ensemble methods on the En-De test set.

	Avg	**AdaBoost**	**GradBoost**
Pearson's	0.266	0.458	**0.473**
Spearman's	0.249	0.436	**0.443**

4 Baseline

The baseline QE system (BASELINE) set by the WMT21 organizers this year is the Transformer-based Predictor-Estimator model (Kepler et al., 2019b; Moura et al., 2020). XLM-RoBERTa is used as the Predictor for feature generation. The baseline system is fine-tuned on the HTER scores and word-level tags jointly.

5 Results

	MAE ↓	0.183	0.142	0.255	0.204	0.195	0.205	0.241
	RMSE ↓	0.129	0.115	0.188	0.159	0.149	0.160	0.196
ENSBRT	Pearson's ↑	0.519	0.795	0.376	0.522	0.666	0.572	0.529
	MAE ↓	**0.171**	0.171	**0.251**	0.206	**0.171**	**0.176**	0.262
	RMSE ↓	0.129	0.141	0.189	0.162	**0.132**	**0.139**	0.197

input settings, as well as the performance of the ensemble of the three mBERT models, which we call *ENSBRT*. First, comparing among the three input settings, it seems that mBERT exhibits competitive results even when it does not have knowledge of the source-side text in the MT and MT-MT' settings, in particular for the following language pairs - En-DE, Si-En, Ne-En. While the ensemble mBERT model, ENSBRT, outperforms the independent counterparts for all the language pairs. This shows that the ensemble method can help to balance out the weakness of any component model, thereby benefiting the sentence-level QE task overall. We also visualize ENSBRT's predictions against the ground truth HTER scores in Figure 1.

Table 3 compares the QE performance between the BASELINE and ENSBRT in terms of Pearson's correlation, RMSE and MAE on the WMT21 blind test set, for which the ground truth HTER scores were not available at the time. We submitted results for 6 language pairs (En-De, Ro-En, Ru-En, Si-En, Et-En, Ne-En) in the normal QE setting and one language pair (Km-En) for zero-shot prediction. ENSBRT demonstrates comparable performance to the BASELINE for Pearson's and outperforms it in either MAE or RMSE for the following language pairs: En-De, Ru-En, Et-En and Ne-En.

6 Conclusion

In this work, we describe the *ENSBRT* system submission to the WMT21 QE Shared Task. ENSBRT is based on fine-tuning the multilingual BERT pretrained model for sentence-level translation quality score prediction. We explore three different input settings for fine-tuning which include either bilingual or monolingual context, and combine the predictions of the three models using ensemble methods as our final system. Furthermore, zero-shot QE is facilitated by using labeled data for existing language pairs and pseudo-references that align with the target language of the unseen test data.

Abstract

This paper presents the JHU-Microsoft joint submission for WMT 2021 quality estimation shared task. We only participate in Task 2 (post-editing effort estimation) of the shared task, focusing on the target-side word-level quality estimation. The techniques we experimented with include Levenshtein Transformer training and data augmentation with a combination of forward, backward, round-trip translation, and pseudo post-editing of the MT output. We demonstrate the competitiveness of our system compared to the widely adopted OpenKiwi-XLM baseline. Our system is also the top-ranking system on the MT MCC metric for the English-German language pair.

1 Introduction

In the machine translation (MT) literature, quality estimation (QE) refers to the task of evaluating the translation quality of a system without using a human-generated reference. There are several different granularities as to the way those quality labels or scores are generated. Our participation in the WMT21 quality estimation shared task focuses specifically on the *word-level* quality labels (word-level subtask of Task 2), which are helpful for both human (Lee et al., 2021) and automatic (Lee, 2020a) post-editing of translation outputs. The task asks the participant to predict one binary quality label (`OK`/`BAD`) for each target word and each gap between target words, respectively.[1]

Our approach closely follows our contemporary work (Ding et al., 2021), which focuses on en-de and en-zh language pairs tested in the 2020 version of the shared task. The intuition behind our idea is that translation knowledge is very useful for predicting word-level quality labels of translations. However, usage of machine translation models is limited in the previous work mainly due to (1) the difficulties in using both the left and right context of an MT word to be evaluated; (2) the difficulties in making the word-level reference labels compatible with subword-level models; and (3) the difficulties in enabling translation models to predict gap labels. To resolve these difficulties, we resort to Levenshtein Transformer (LevT, Gu et al., 2019), a model architecture designed for non-autoregressive neural machine translation (NA-NMT). Because of its iterative inference procedure, LevT is capable of performing post-editing on existing translation output even just trained for translation. To further improve the model performance, we also propose to initialize the encoder and decoder of the LevT model with those from a massively pre-trained multilingual NMT model (M2M-100, Fan et al., 2020).

Starting from a LevT translation model, we then perform a two-stage finetuning process to adapt the model from translation prediction to quality label prediction, using automatically-generated pseudo-post-editing triplets and human post-editing triplets respectively. All of our final system submissions are also linear ensembles from several individual models with weights optimized on the development set using the Nelder-Mead method (Nelder and Mead, 1965).

2 Method

Our system building pipeline is consisted of three different stages:

- **Stage 1**: Training LevT for translation
- **Stage 2 (Optional)**: Finetuning LevT on synthetic post-editing triplets
- **Stage 3**: Finetuning LevT on human post-editing triplets

Stage 1: Training LevT for Translation We largely follow the same procedure as Gu et al.

* Shuoyang Ding had a part-time affiliation with Microsoft at the time of this work.

[1] While there is another sub-task for predicting source-side quality labels, we do not participate in that task.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 904–910
November 10–11, 2021.

(LevT, 2019) to train the LevT translation model, except that we initialize the embedding, the encoder, and decoder of LevT with those from the small M2M-100-small model (418M parameters, Fan et al., 2020) to take advantage of large-scale pretraining. Because of that, we also use the same sentencepiece model and vocabulary as the M2M-100 model.

For to-English language pairs, we explored training multi-source LevT model. According to the results on devtest data, this is shown to be beneficial for the QE task for ro-en, ru-en and ne-en, but not for other language pairs.

Stage 2: Synthetic Finetuning During both finetuning stages, we update the model parameters to minimize the NLL loss of word quality labels and gap quality labels, for the deletion and insertion head, respectively. To obtain training targets for finetuning, we need *translation triplet data*, i.e., the aligned triplet of source, target, and post-edited segments. Human post-edited data naturally provides all three fields of the triplet, but only comes in a limited quantity. To further help the model to generalize, we conduct an extra step of finetuning on synthetic translation triplets, similar to some previous work (Lee, 2020b, *inter alia*). We explored five different methods for data synthesis, namely:

1. `src-mt-tgt`: Take the source side of a parallel corpus (`src`), translate it with a MT model to obtain the MT output (`mt`), and use the target side of the parallel corpus as the pseudo post-edited output (`tgt`).

2. `src-mt1-mt2`: Take a corpus in the source language (`src`) and translate it with two different MT systems that have clear system-level translation quality orderings. Then, take the worse MT output as the MT output in the triplet (`mt1`) and the better as the pseudo post-edited output in the triplet (`mt2`).

3. `bt-rt-tgt`: Take a corpus in the target language (`tgt`) and back-translate it into the source langauge (`bt`), and then translate again to the target language (`rt`). We then use `rt` as the MT output in the triplet and `tgt` as the pseudo post-edited output in the triplet.

4. `src-rt-ft`: Take a parallel corpus and translate its source side and use it as the pseudo post-edited output (`ft`), and round-trip translate its target side (`rt`) as the MT output in the translation triplet.

5. `Multi-view Pseudo Post-Editing (MVPPE)`: Same as Ding et al. (2021), we take a parallel corpus and translate the source side (`src`) with a multilingual translation system (`mt`) as the MT output in the triplet. We then generate the pseudo-post-edited output by ensembling two different *views* of the same model: (1) using the multilingual translation model as a translation model, with `src` as the input; (2) using the multilingual translation model as a paraphrasing model, with `tgt` as the input. The ensemble process is the same as ensembling standard MT models, and we perform beam search on top of the ensemble. Unless otherwise specified, we use the same ensembling weights of $\lambda_t = 2.0$ and $\lambda_p = 1.0$ as Ding et al. (2021).

Stage 3: Human Post-editing Finetuning We follow the same procedure as stage 2, except that we finetune on the human post-edited dataset provided by the shared task organizers for this stage.

Compatibility With Subwords As pointed out before, since LevT predicts edits on a subword-level starting from translation training, we must construct reference tags that are compatible with the subword segmentation done for both the MT and the post-edited output. Specifically, we need to: (1) for inference, convert subword-level tags predicted by the model to word-level tags for evaluation, and (2) for both finetuning stages, build subword-level reference tags. We follow the same heuristic subword-level tag reference construction procedure as Ding et al. (2021), which was shown to be helpful for task performance.

Label Imbalance Like several previous work (Lee, 2020a; Wang et al., 2020; Moura et al., 2020), we also observed that the translation errors are often quite scarce, thus creating a skewed label distribution over the `OK` and `BAD` labels. Since it is critical for the model to reliably predict both classes of labels, we introduce an extra hyperparameter μ in the loss function that allows us to upweight the words that are classified with `BAD` tags in the reference.

$$\mathcal{L} = \mathcal{L}_{OK} + \mu\mathcal{L}_{BAD}$$

Ensemble For each binary label prediction made by the model, the model will give a score $p(\texttt{OK})$,

Language Pair	Data Source	Sentence Pairs
English-German	WMT20 en-de parallel data	44.2M
English-Chinese	shared task en-zh parallel	20.3M
Romanian-English	shared task ro-en parallel	3.09M
Russian-English	shared task ru-en parallel	2.32M
Estonian-English	shared task et-en parallel	880K
Estonian-English	shared task et-en parallel + NewsCrawl 14-17	3.42M
Nepalese-English	shared task ne-en parallel	498K
Pashto-English	WMT20 Parallel Corpus Filtering Task	347K

Table 1: Source and statistics of parallel datasets used in our experiments.

which are translated into binary labels in post-processing. To ensemble predictions from k models $p_1(\texttt{OK}), p_2(\texttt{OK}), \ldots, p_k(\texttt{OK})$, we perform a linear combination of the scores for each label:

$$p_E(\texttt{OK}) = \lambda_1 p_1(\texttt{OK}) + \lambda_2 p_2(\texttt{OK}) + \cdots + \lambda_k p_k(\texttt{OK})$$

To determine the optimal interpolation weights, we optimize towards target-side MCC on the development set. Because the target-side MCC computation is not implemented in a way such that gradient information can be easily obtained, we experimented with two gradient-free optimization method: Powell method (Powell, 1964) and Nelder-Mead method (Nelder and Mead, 1965), both as implemented in `SciPy` (Virtanen et al., 2020). We found that the Nelder-Mead method finds better optimum on the development set while also leading to better performance on the devtest dataset (not involved in optimization). Hence, we use the Nelder-Mead optimizer for all of our final submissions with ensembles. We set the initial points of Nelder-Mead optimization to be the vertices of the standard simplex in the k-dimensional space, with k being the number of the models.

We find that it is critical to build ensembles from models that yield diverse yet high-quality outputs. Specifically, we notice that ensembles from multiple checkpoints of a single experimental run are not helpful. Hence, for each language pair, we select 2-8 models with different training configurations that also have the highest performance to build our final ensemble model for submission.

3 Experiments

3.1 Data Setup

LevT Training We used the same parallel data that was used to train the MT system in the shared task, except for the en-de, et-en, and ps-en language pairs. For en-de language pair, we use the larger parallel data from the WMT20 news translation shared task. For et-en language pair, we experiment with augmenting with the News Crawl Estonian monolingual data from 2014 to 2017, which was inspired by Zhou and Keung (2020). For ps-en language pair, because there is no MT system provided, we take the data from the WMT20 parallel corpus filtering shared task and applied the baseline LASER filtering method. For the multi-source LevT model, we simply concatenate the data from ro-en, ru-en, es-en (w/o monolingual augmentation) and ne-en. The resulting data scale is summarized in Table 1.

Following the setup in Gu et al. (2019), we conduct sequence-level knowledge distillation during training for all language pairs except for ne-en and ps-en[2]. For en-de, the knowledge distillation data is generated by the WMT19 winning submission for that language pair from Facebook (Ng et al., 2019). For en-zh, we train our own en-zh autoregressive model on the parallel data from the WMT17 news translation shared task. For the other language pairs, we use the decoding output from M2M-100-mid (1.2B parameters) model to perform knowledge distillation.

Synthetic Finetuning We always conduct data synthesis based on the same parallel data that was used to train the LevT translation model. For the only language pair (en-de) where we applied the `src-mt1-mt2` synthetic finetuning for shared task submission, we again use the WMT19 Facebook's winning system (Ng et al., 2019) to generate the higher-quality translation `mt2`, and the system provided by the shared task to generate the MT output in the pseudo translation triplet `mt1`. For all other combinations of translation directions, language pairs and MVPPE decoding, we use the M2M-100-

[2]The exception was motivated by the poor quality of the translation we obtained from the M2M-100 model.

Configuration	Stage 2	Stage 3	Target MCC
en-de OpenKiwi	N	default	0.337

mid (1.2B parameters) model.

Human Annotation Finetuning We follow the data split for human post-edited data as determined by the task organizers and use `test20` as the devtest for our system development purposes.

Reference Tag Generation We implemented another TER computation tool[3] to generate the word-level and subword-level tags that we use as the reference for finetuning, but stick to the original reference tags in the test set for evaluation to avoid potential result mismatch.

[3] `https://github.com/marian-nmt/moses-scorers`

3.2 Model Setup

Our LevT-QE model is implemented based on Fairseq (Ott et al., 2019). All of our experiments uses Adam optimizer (Kingma and Ba, 2015) with linear warmup and `inverse-sqrt` scheduler. For stage 1, we use the same hyperparameters as Gu et al. (2019) for LevT translation training, but use a smaller learning rate of 2e-5 to avoid overfitting for all to-English language pairs. For stage 2 and beyond, we stick to the learning rate of 2e-5 and perform early-stopping based on the loss function on the development set. For stage 3, e also experiment with label balancing factor $\mu = 1.0$ and $\mu = 3.0$ for each language pair and pick the one that works the best on devtest data, while for stage 2 we keep $\mu = 1.0$ because early experiments indicate that using $\mu = 3.0$ at this stage is not helpful.

For pre-submission developments, we built OpenKiwi-XLM baselines (Kepler et al., 2019) following their `xlmroberta.yaml` recipe. Keep in mind due to the fact that this baseline model is initialized with a much smaller XLM-Roberta-base model (281M parameters) compared to our M2M-100-small initialization (484M parameters), the performance comparison is not a strict one.

3.3 Devtest Results

Our system development results on `test20` devtest data are shown in Table 2[4]. In all language pairs, our systems can outperform the OpenKiwi baseline based upon the pre-trained XLM-RoBERTa-base encoder. Among these language pairs, the benefit of LevT is most significant on the language pairs with a large amount of available parallel data. Such behavior is expected, because the less parallel data we have, the less knowledge we can extract from the LevT training process. Furthermore, the lack of good quality knowledge distillation data in the low-resource language pairs also expands this performance gap. To our best knowledge, this is also the first attempt to train non-autoregressive translation systems under low-resource settings, and we hope future explorations in this area can enable us to build a better QE system from LevT.

In terms of comparison between multilingual and bilingual models for to-English language pairs, the results are mixed, with the multilingual model per-

[4] Note that the results on en-zh also reflect a crucial bug fix on our TER computation tool that we added after the system submission deadline. Hence the results shown here are from a different system as in the official shared task results. The bug fix should not affect the results of the other language pairs.

Configuration	Stage 2	Stage 3	Target MCC	F1-OK	F1-BAD
ro-en multilingual	N	$\mu = 1.0$	**0.612**	0.949	**0.659**
ro-en multilingual	mvppe	$\mu = 1.0$	0.611	**0.951**	**0.659**
ro-en multilingual	src-mt1-mt2 (Bing mt2)	$\mu = 1.0$	0.585	0.936	0.630
ro-en bilingual (Bing KD)	N	$\mu = 1.0$	0.581	0.949	0.632

et-en bilingual	src-mt1-mt2 (Bing mt2)	$\mu = 3.0$	**0.563**	0.919	**0.634**
et-en bilingual (Bing KD)	N	$\mu = 3.0$	0.557	0.918	0.629
et-en bilingual (Bing KD)	src-mt1-mt2 (Bing mt2)	$\mu = 3.0$	0.559	0.916	0.631

Table 4: Analysis of `src-mt1-mt2` and `mvppe` method on ro-en and et-en language pair.

forming significantly better for ru-en language pair, but significantly worse for et-en language pair. Finally, our Nelder-Mead ensemble further improves the result by a small but steady margin.

3.4 Analysis

Ding et al. (2021) already conducted comprehensive ablation studies for techniques such as the effect of LevT training step, heuristic subword-level reference tag, as well as the effect of various data synthesis methods. In this section, we extend the existing analyses by studying if the synthetic finetuning is still useful with M2M initialization, and if it is universally helpful across different languages. We also examine the effect of label balancing factor μ and take a detailed look at the prediction errors.

Synthetic Finetuning We redo the analysis on en-de synthetic finetuning with the smaller 2M parallel sentence samples from Europarl, as in Ding et al. (2021), but with the updated `test20` test set and models with M2M-100-small initialization. The results largely corroborate the trend in the other paper, showing that `src-mt1-mt2` and `mvppe` being the most helpful two data synthesis methods. We then extend those two most helpful methods to ro-en and et-en, using the up-to-date Bing Translator production model as the stronger MT system (a.k.a. `mt2`) in the `src-mt1-mt2` synthetic data. The result is mixed, with `mvppe` failing to improve performance for both language pairs, and `src-mt1-mt2` only being helpful for et-en language pair. We also trained two extra ro-en and et-en LevT models using the respective Bing Translator models to generate the KD data, which are neither helpful for improving performance on their own nor working better with `src-mt1-mt2` synthetic data.

We notice that the `mvppe` synthetic data seems to significantly improve the F1 score of the `OK` label in general, for which we don't have a good explanation yet.

Configuration	Target MCC	F1-OK	F1-BAD
ro-en $\mu = 1.0$	**0.612**	**0.949**	**0.659**
ro-en $\mu = 3.0$	0.577	0.930	0.619
ru-en $\mu = 1.0$	0.267	**0.960**	0.284
ru-en $\mu = 3.0$	**0.339**	0.943	**0.390**
et-en $\mu = 1.0$	0.478	**0.933**	0.511
et-en $\mu = 3.0$	**0.512**	0.925	**0.587**
ne-en $\mu = 1.0$	0.660	**0.885**	0.774
ne-en $\mu = 3.0$	**0.681**	0.855	**0.788**

Table 5: Analysis of different label balancing factors initialized on to-English language pairs. All results are based on the multilingual model and not performing synthetic finetuning step.

Label Balancing Factor We find the QE task performance to be quite sensitive to the label balancing factor μ, but there is also no universally optimal value for all language pairs. Table 5 shows this behavior for all to-English language pairs. Notice that while for most of the cases μ simply controls a trade-off between the performance of `OK` and `BAD` outputs, there are also cases such as ro-en where a certain choice of μ hurts the performance of both classes. This might be due to a certain label class being particularly hard to fit, thus creating more difficulties with learning when the loss function is designed to skew to this label class.

It should be noted that this label balancing factor does not correlate directly with the ratio of the `OK` vs. `BAD` labels in the training set. For example, to obtain the best performance, ne-en requires $\mu = 3.0$ while en-de requires $\mu = 1.0$, while the `OK` to `BAD` ratio for ne-en (2.14:1) is much less skewed

Table 6: Detailed evaluation metric breakdown of all submitted ensemble system on `test20` test set.

compare to en-de (10.2:1).

Detailed Error Breakdown We found it hard to develop an intuition for the model performance from the MCC metric. To further understand which label categories our models struggle with the most, we breakdown the target-side metric into a cross product of {`MT`, `GAP`} tags and {`OK`, `BAD`} classes and compute precision, recall and F1-score for each category. The breakdown is shown in Table 6. It can be seen that our model is making the most mistakes with the `GAP BAD` category, while the category with the least mistakes is the `GAP OK` category. Also, note that for MT word tags, the models often seem to suffer more from low precision rather than low recall, while for gaps it is the opposite.

Overall, we see that the highest F1 scores we can achieve for detecting bad MT words or gaps are rarely higher than 0.8, which indicates that there should be ample room for improvement. It would also be interesting to measure the inter-annotator agreement of these word-level quality labels, in order to get a sense of the human performance we should be aiming for.

4 Conclusion

In this paper, we present our WMT21 word-level QE shared task submission based on Levenshtein Transformer training and a two-step finetuning process. We also explore various ways to create synthetic data to build more generalizable systems with limited human annotations. We show that our system outperforms the OpenKiwi+XLM baseline for all language pairs we experimented with. Our official results on the blind test set also demonstrate the competitiveness of our system. We hope that our work can inspire other applications of Levenshtein Transformer beyond the widely studied case of non-autoregressive translation.

Abstract

This paper presents our submissions to the WMT2021 Shared Task on Quality Estimation, Task 1 *Sentence-Level Direct Assessment*. While top-performing approaches utilize massively multilingual Transformer-based language models which have been pre-trained on all target languages of the task, the resulting insights are limited, as it is unclear how well the approach performs on languages unseen during pre-training; more problematically, these approaches do not provide any solutions for *extending* the model to new languages or unseen scripts—arguably one of the objectives of this shared task. In this work, we thus focus on utilizing massively multilingual language models which only *partly* cover the target languages during their pre-training phase. We extend the model to new languages and unseen scripts using recent adapter-based methods and achieve on par performance or even surpass models pre-trained on the respective languages.

1 Introduction

In Machine Translation (MT), the Quality Estimation (QE) task attempts to characterize the quality of a translation, without the availability of a (gold-label) reference translation. The introduction of a QE system would consequently allow for the automatic analysis of machine-translated sentences without costly human reference translation, with numerous applications, such as: the selection of candidate translations, the estimation of human editing effort, or the detection of low-quality or misleading translations (Kepler et al., 2019). However, in order to acquire training data, professional human translators are required to score the translation quality of many examples, making labeled data difficult to obtain, especially for low-resource languages. This highlights the importance of cross-lingual zero-shot transfer of QE systems, one of the objectives of the WMT21 shared task (Specia et al., 2021), which introduces zero-shot evaluation sets of four new language pairs.

Previous approaches have predominantly focused on languages for which training data is available, such as the QE task at WMT20. The best results were obtained by fine-tuning massively multilingual Transformer-based language models (Vaswani et al., 2017) such as multilingual BERT (mBERT) (Devlin et al., 2019) or XLM-R (Conneau et al., 2020) (Specia et al., 2020; Ranasinghe et al., 2020b; Sun et al., 2020a; Nakamachi et al., 2020, *inter alia*), on the target QE tasks. These supervised methods considerably outperform unsupervised methods (Zhao et al., 2020; Fomicheva et al., 2020c; Sun et al., 2020a; Zhao et al., 2021; Song et al., 2021) even in zero-shot settings (Sun et al., 2020a). However, analyzing the applicability of fine-tuning multilingual models on the target language pairs that are covered during pre-training considerably limits the generated insights. They are only applicable to the $\sim$100 languages covered during pre-training, excluding the remaining majority of languages as the "curse-of-multilinguality" (Conneau et al., 2020) prohibits the over 7000 languages in the world (Joshi et al., 2020) to be represented within a single model

In this work, we thus aim to address these limitations by utilizing multilingual language models that only cover a subset of the target languages. Here we focus on mBERT which—in contrast to XLM-R—has not seen the languages Sinhala, Pashto, and Khmer, all part of the WMT21 shared task. As the script of Sinhala and Khmer are not included in the mBERT vocabulary, it is impossible for the corresponding tokenizer to correctly tokenize text in those languages. Following Pfeiffer et al. (2020b, 2021b) we thus propose an adapter-based approach to extend mBERT to new languages and new scripts.

Our contributions are as follows: **1)** we analyze adapter-based supervised approaches for QE

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 911–919

and demonstrate their competitive performance compared to full model fine-tuning, both in supervised as well as zero-shot settings; **2)** we use recent adapter based methods to extend mBERT to unseen languages and scripts, achieving considerable performance gains over standard mBERT for unseen languages; **3)** we demonstrate competitive performance of our adapted mBERT approach compared to XLM-R, which has seen the respective languages during pre-training. We release our code and adapters at https://github.com/Aaronsom/wmt21-qe-tudarmstadt/.

2 Method

We describe our adapter-based approaches for supervised QE and the extension to unseen languages.

2.1 Task Formulation

We model QE as a regression task. The Transformer receives as input both the source sentence and the translation hypothesis and is trained to predict the quality score for the sentence pair. For this, we take the final contextualized representation of the special [CLS]-token produced by the Transformer and feed it into a multi-layer regression head to compute the predicted quality $f(s,t)$:

$$f(s,t) = \mathbf{W}_2 \cdot (\tanh(\mathbf{W}_1 \cdot \mathbf{r}_{[CLS]}(s,t))) \quad (1)$$

with $\mathbf{W}_1 \in \mathbb{R}^{h \times h}$, $\mathbf{W}_2 \in \mathbb{R}^{1 \times h}$, tanh is the hyperbolic tangent, h is the hidden dimension of the Transformer, and $\mathbf{r}_{[CLS]}(s,t)$ is the output representation of the [CLS]-token for the source-translation input pair s,t. We train the model using mean squared error.

2.2 Adapters

Adapters are randomly initialized weights, newly introduced at every layer of the pre-trained Transformer model. During fine-tuning, *only* the adapter weights (and the regression head) are updated while the remaining model weights are kept frozen.

Houlsby et al. (2019) propose a feed-forward bottleneck adapter architecture consisting of a down-projection, a non-linearity, and finally an up-projection, both after the multi-attention as well as after the feed-forward component at every Transformer layer. We use the adapter architecture proposed by Pfeiffer et al. (2021a) which achieves on par results while reducing the number of trainable parameters of Houlsby et al. (2019) by only placing adapters after the feed-forward component (see Figure 1a). Adapters at layer l are defined as follows:

$$a_l(\mathbf{h}_l, \mathbf{r}_l) = \mathbf{U}_l \cdot (\mathrm{ReLU}(\mathbf{D}_l \cdot \mathbf{h}_l)) + \mathbf{r}_l \quad (2)$$

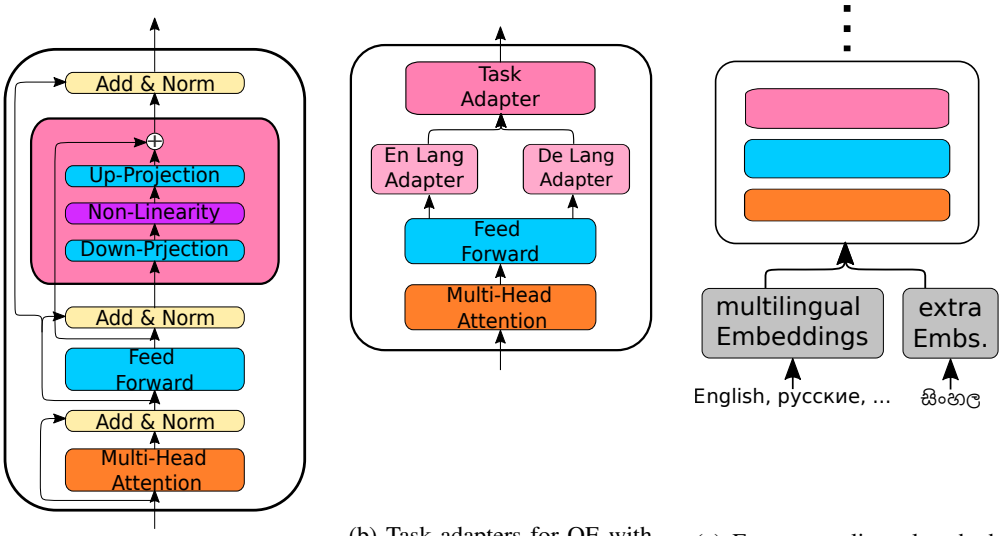
where $\mathbf{D}_l \in \mathbb{R}^{\lfloor \frac{h}{r} \rfloor \times h}$, $\mathbf{U}_l \in \mathbb{R}^{h \times \lfloor \frac{h}{r} \rfloor}$, ReLU is the rectified linear unit, $\mathbf{h}_l$ is the hidden input representation, $\mathbf{r}_l$ is the residual after the fully-connected layer, and r is the reduction factor—a hyperparameter that decides how much the adapter compresses the hidden representation.

2.3 Extending to Unseen Languages

While both XLM-R and mBERT have been pre-trained on a large number of languages, XLM-R has seen all languages appearing in the WMT21 dataset, while mBERT has not been pre-trained on Sinhala, Khmer, and Pashto. Further, the scripts of Sinhala and Khmer are not covered by mBERT's vocabulary. We thus follow Pfeiffer et al. (2020b, 2021b) to extend both the latent Transformer as well as input embedding representations to the respective languages, using adapter-based approaches.

Language Adapters. Language adapters (LAs) (Pfeiffer et al., 2020b) are trained to encode idiosyncratic, language-specific information, and transform the underlying multilingual model's latent representations to better align with the respective languages. Correspondingly, they are trained monolingually using the masked language modeling (MLM) objective on unlabeled textual data in the target language.

Extending to unseen scripts. Word piece tokenizers can (arguably inadequately (Rust et al., 2021)) tokenize unseen languages that are written in seen scripts, with a fall-back character-level tokenization. Unfortunately, these tokenizers fail for unseen scripts, as even character-level tokens are not part of the vocabulary, leaving the tokenizer only with instantiating *unknown* placeholder tokens (UNKs) as alternatives. Consequently, even by extending the overall capacity of the language model using language adapters, the model will not be able to adequately represent the respective languages. To extend the model to unseen scripts, we learn a new language-specific tokenizer and train a new embedding matrix, initialized with lexically overlapping tokens of the original embedding matrix, and random initialization for the remaining



(a) Pfeiffer adapter architecture used by us. Each adapter comprises of an down- and up-projection and is inserted after the feed-forward layer within each Transformer layer.

(b) Task adapters for QE with multiple language adapters for the multilingual input. The input parts are passed through the respective language adapter before the entire representation is passed to the task adapter.

(c) Extra monolingual embeddings for scripts and languages not included in the multilingual embeddings alongside the multilingual embeddings. The input embedding is chosen depending on the input language.

Figure 1: The architecture additions to the Transformer architecture: (a) Adapters; (b) Language and task adapters with multilingual input; (c) Extra monolingual embeddings alongside multilingual embeddings.

unseen tokens (Pfeiffer et al., 2021b). Here, language adapters are trained together with the new embedding matrix, while the pre-trained Transformer weights are frozen. Similar to standard LAs, these components are trained monolingually using the MLM objective on unlabeled textual data in the target language.

Task Adapters. For target task fine-tuning we stack task-specific adapters on top of the pre-trained LAs. For most tasks, sentences of only one language are passed through the model, while for QE the original sentence in the source language and the translation of the target language are simultaneously passed through the model. The tokens of the respective languages are thus passed through their respective LA. The subsequent task adapter is shared between the two languages (see Figure 1b). For cross-lingual transfer, the LAs of the training languages are replaced with the LAs of the evaluation languages. For this reason, not only the transformer weights but also the LAs are frozen during training and only the task adapters are fine-tuned on the target task. For languages with scripts not covered during pre-training, the new embedding matrix is used. The embedding representations are subsequently concatenated (see Figure 1c).

3 Data

The sentence-level direct assessment task of WMT21 builds upon the data of WMT20 task 1 (Fomicheva et al., 2020a). The WMT20 dataset consists of seven language pairs ranging from the high-resource English–German (En-De) and English–Chinese (En-Zh), to the medium-resource Romanian–English (Ro-En), Estonian–English (Et-En) and Russian-English (Ru-En), and the low-resource Sinhalese–English (Si-En) and Nepalese–English (Ne-En). For each pair, sentences in the source language are sampled from Wikipedia (or in the case of Russian, from Wikipedia and Reddit), translated with fairseq (Ott et al., 2019) to the target language, and then annotated by at least three professional translators with Direct Assessment (DA) (Guzmán et al., 2019). The DA scores are z-normalized for each annotator and averaged to form the final score. For each of the seven language pairs, the dataset contains 7000 training pairs and 1000 test and dev pairs.

The WMT21 dataset extends the WMT20 dataset by providing new test sets—with unpublished labels—consisting of 1000 sentences for each language pair of the WMT20 dataset. In addition, they provide testsets for four new language pairs for zero-shot evaluation, each compris-

ing of 1000 sentence pairs with unpublished labels: English–Czech (En-Cs), English–Japanese (En-Ja), Pashto–English (Ps-En), Khmer–English (Km-En).

4 Experiments

We describe our experimental setup along with the training and implementation details.

Training & Model Hyperparameters. We initialize our models with mBERT and XLM-R (both large and base-sized). We use a reduction factor r of 8 for our task adapters. Language adapters use $r = 2$ and have been trained on Wikipedia articles of the respective language. The additional embeddings for Khmer and Sinhala contain 10k tokens each and have been fine-tuned together with the respective LAs on the Wikipedia data.

We fine-tune our models using AdamW (Loshchilov and Hutter, 2019) with a linear learning rate schedule without warm-up. We simulate early stopping by storing the checkpoint with the best dev set performance—evaluating every 500 steps. For all models, we use a learning rate of 1e-4 and a batch size of 8. We train each model for 8k steps. Hyperparameters have been chosen based on the WMT20 dev set performance. We have chosen the above hyperparameters from the following values ranges: learning rate {5e-5, 1e-4, 2e-4, 5e-4}, batch size {4, 8, 16, 32, 96}, reduction factor r for the task adapters {4, 8, 16}, and training steps {2k, 3k, 5k, 8k, 10k}.

Implementation Details. To train adapters, we use the AdapterHub framework (Pfeiffer et al., 2020a) which builds upon the Hugging Face Transformers library (Wolf et al., 2020). In each batch we samples examples from only one language pair.

Experimental Setup. We evaluate the performance of our QE models using Pearson correlation between the predicted quality and the actual label (Specia et al., 2020).

We evaluate our adapter approaches in an ALL and a leave-one-out zero-shot setup (ZERO). In the ALL setup, we train a model on all seven language pairs with training data available and then evaluate the model on all eleven language pairs—the seven pairs with training data and the four pairs without. In the ZERO setting, for each of the seven language pairs which have a training set, we train a model with six of the pairs and then evaluate on the left-out seventh pair.

We evaluate both the large-sized XLM-R with adapters (denoted A-XLMR$_{\text{LARGE}}$) and base-sized mBERT and XLM-R with adapters (denoted A-MBERT and A-XLMR$_{\text{BASE}}$ respectively). For mBERT, we use both language adapters (+LA) and additional embeddings for Sinhala and Khmer (+EMB). We denote the setup with both as A+LA+EMB-MBERT. We also consider adapter ensembles for XLM-R. Here, we train five adapters in the ALL setup using different random seeds. During the evaluation, we average the predictions of the five adapters for the final prediction.

5 Results & Discussion

We present the Pearson correlation results for our models on the WMT21 test set. The reported values are obtained from the CodaLab competition.[1]

5.1 Language Extension Results

We present our results on the WMT21 test set for our two setups. The results for the ALL setup where we train with all seven pairs that have training data and then evaluate the model on all eleven pairs, i.e. the seven with training data and the four which are zero-shot, are found in Table 1. The leave-one-out ZERO results where we train on six of the seven pairs with training data and then evaluate in a zero-shot setup on the left-out pair are in Table 2.

We consider how our language extension methods improve the results for the unseen languages Sinhala, Khmer, and Pashto. We first evaluate how much we gain by representing input in the unseen script with extra embeddings instead of simply replacing all by the [UNK]-token. For this, we compare A-MBERT with A+EMB-MBERT. When we train with the Si-En data in ALL, the additional embeddings only give a relatively small performance boost of 0.04 points on top of already quite good results. This is unexpected since half the input is not correctly represented. We investigate this in more detail in §5.2. In zero-shot (Table 2 for Si-En and Table 1 for Km-En), the extra embeddings result in greatly improved results for Si-En by 0.25 points and by 0.05 points for Km-En.

Next, we compare models with and without language adapters in both setups. For the languages seen by mBERT during pre-training, there is little difference between A(+EMB)-MBERT and A+LA(+EMB)-MBERT in both setups. This

Table 2: Pearson correlation results of the leave-one-out ZERO setup for zero-shot results of the seven language pairs with training set. We report the results for our adapters with mBERT and XLM-R (base & large). For mBERT, we extend the model with language adapters (+LA) and additional embeddings for Sinhala and Khmer (+EMB)

aligns with the findings by Pfeiffer et al. (2020b) and suggests that language adapters are less helpful for seen languages. For the three pairs with unseen languages, the language adapters can greatly improve the performance. In zero-shot situations (Table 2 for Si-En and Table 1 for the other two), we gain 0.18 points for Si-En, 0.07 for Km-En, and 0.28 points for Ps-En. Similar to extra embeddings, when we train with the Si-En data in ALL, we only gain 0.03 points more with language adapters.

Finally, we compare mBERT with language adapters and additional embeddings (A+LA+EMB-MBERT) to a base-sized XLM-R A-XLMR$_{\text{BASE}}$. This comparison is not ideal due to the differences in pre-training between the Transformers—training set, selected languages, etc.—but we can assume that for the unseen languages, XLM-R serves as an estimated upper bound for the performance. For seen language pairs (i.e., not Si-En, Km-En, and Ps-En), both methods perform comparably. For unseen languages, our adapter-based extensions to mBERT close the gap to XLM-R for most languages, except for Km-En where there is still a noticeable performance difference.

A-MB$_{\text{S}}$	0.19	0.53	0.56	0.63	0.60	0.33	0.30	0.45

Table 3: Pearson correlation for mBERT with adapters (A-MB)—without language extensions—on the WMT20 test set trained with all pairs where we use both source and translation (S+T), only the translation (T), or only the source (S) during training. Evaluation is performed with both source and translation.

5.2 Analysis of Results on Trained Pairs

For the three unseen languages, we achieve large performance gains in zero-shot scenarios. However, while we witness large performance gains in zero-shot scenarios of the adapter-based methods, the difference considerably smaller when training data in the target language is available. Intuitively, we would expect a larger boost, considering half the input is in an unknown language and mostly not encoded. However, these results align with previous findings. Sun et al. (2020b) show for WMT19 and WMT18 that training with *only* the translation still results in strong results—77-100% of the per-

Table 4: Pearson correlation on the WMT20 test set for the ALL and ZERO setup. We group the results in the setups in base-sized and large models. TransQuest and BERGAMOT-LATTE use fully fine-tuned models. TransQuest results are taken from (Ranasinghe et al., 2020b), BERGAMOT-LATTE from (Sun et al., 2020a)—their best models are the winners of the WMT20 shared task and additionally use ensembles.

formance of training with the complete pair. We are able to reproduce these findings for WMT20 in Table 3, and achieve similar results for Si-En when passing *only* the English translation as input to the model, compared to when training on both inputs. However, when training with only the (Sinhala) source, we witness the expected drop in performance. It is likely that in the zero-shot setup, the model cannot learn to exploit the statistical cues that allow it to function without the source sentence. Hence, we obtain more appropriate representations with adapter-based methods where the language-specific word-embedding representations result in considerable performance gains.

5.3 Ensembles

Ensembles have been used in previous work with great success (Ranasinghe et al., 2020a; Fomicheva et al., 2020b; Nakamachi et al., 2020). With an adapter ensemble, the underlying Transformer weights are re-used resulting in a very parameter-efficient setup—our ensemble with five adapters adds only 6.5% more parameters on top of the large XLM-R Transformer. However, our adapter ensemble A-XLMRLARGE$_{ENSEMBLE}$ only brings a slight performance boost, smaller than the reported boost by the ensembles of previous works. More work is needed here to investigate why this is the case.

5.4 Comparison to Fully Fine-Tuned Models

We evaluate the general performance of adapters for the QE task in comparison to fully fine-tuned models. For this, we compare our models on the WMT20 test set against the top submissions of the WMT20 shared task in Table 4. We find that they achieve competitive results with fully fine-tuned models that do not employ additional techniques like ensembles in both the ALL and ZERO setups. Our highest-scoring submission, A-XLMRLARGE$_{ENSEMBLE}$, places in the midfield for the WMT21 competition.

5.5 Parameter Count

Adapters are considerably more parameter efficient with respect to the number of *fine-tuned* parameters, compared to fully fine-tuned models. The number of adapter parameters is equivalent to only 1.3% of the Transformer parameters for our models. This makes adapters very lightweight for model sharing or for loading multiple adapters on the same GPU, e.g., for language adapters or for multiple task adapters in a pipeline (Nguyen et al., 2021; Rücklé et al., 2021). The extension for the unseen languages for mBERT also adds only a small number of parameters: 2.4% for each language adapter and 1.4% for each monolingual embedding.

6 Conclusion

In this work, we proposed the use of adapters to fine-tune massively multilingual Transformers for the sentence-level QE task. We demonstrated that adapters are able to achieve competitive results with fully fine-tuned models. However, as fully fine-tuned approaches are limited to the languages seen during pre-training, we have employed recent language extension methods to integrate languages

unseen by mBERT. We extended mBERT with language adapters and monolingual embeddings for Sinhala, Khmer, and Pashto. These methods greatly improved the zero-shot performance of the model and largely closed the gap to XLM-R which has been pre-trained on all languages appearing in WMT21. This demonstrates that our approach is applicable, not only to languages seen during pre-training, but also to unseen languages, even with unseen scripts. This suggests that our method is able to extend multilingual models to a wider range of language not covered during pre-training.

We suggest that future shared tasks should consider disentangling languages which massively multilingual language models have been pre-trained on, from those that are unseen during pre-training, to more closely reflect realistic scenarios, as the majority of languages cannot be represented within a single model (Conneau et al., 2020).

Abstract

This paper describes POSTECH's quality estimation systems submitted to Task 2 of the WMT 2021 quality estimation shared task: Word and Sentence-Level Post-editing Effort. We aim to improve the stability of recently proposed quality estimation models, which usually have a single encoder based on the self-attention mechanism to simultaneously process both of the two input data: a source sequence and its machine translation; considering that such models are not propped up by pre-trained language models' monolingual word representations, which are generally accepted as reliable representations for various natural language processing tasks. Therefore, our model first uses two pre-trained monolingual encoders and then exchanges their output information through two additional cross attention networks. According to the official leaderboard, our systems outperform the baseline systems in terms of the Matthews correlation coefficient for machine translations' word-level quality estimation and in terms of the Pearson's correlation coefficient for sentence-level quality estimation by 0.4126 and 0.5497 respectively.

1 Introduction

Quality estimation (QE) is the task of estimating the quality of given machine translations without regard to their reference translations (Blatz et al., 2004; Specia et al., 2009). As reference translations are generally unavailable in real life, QE should help to treat output texts of machine translation (MT) systems. QE can be categorized into several subtasks, and this round of the WMT QE task has three subtasks, yet we focus on Task 2: Word and Sentence-Level Post-editing Effort. In Task 2, while sentence-level QE aims to predict the Human-Targeted Translation Edit Rate (HTER, Snover et al. 2006), which measures the edit distance between an MT output (*mt*) and its human post-edited text (*pe*), word-level QE aims to predict OK–BAD tags for three sequences of tokens: the sequence of words in a source text (*src*) depending on whether they are correctly translated referring to *mt*; the sequence of words in *mt* depending on their correctness; and <GAP> tokens, which each represent the gap between two adjacent words, depending on the existence of any missing words (Specia et al., 2020).

As other recent QE models do, our method also applies transfer learning, considering that pre-trained language models (LM) have been successfully applied to various natural language processing (NLP) tasks including QE; many previous studies (Fomicheva et al., 2020; Hu et al., 2020; Wu et al., 2020; Lee, 2020; Moura et al., 2020; Nakamachi et al., 2020; Rubino, 2020) that apply pre-trained LMs to QE have adopted multilingual or cross-lingual LMs such as multilingual-BERT (Pires et al., 2019), XLM (Conneau and Lample, 2019), and XLM-R (Conneau et al., 2020) to process the two input data *src* and *mt*. Such cross-lingual LMs have a single Transformer (Vaswani et al., 2017) encoder using only the self-attention mechanism to create vector representations of the input data and predict the labels. However, it appears possible to further improve the stability of those models, considering that they are not propped up by pre-trained LMs' monolingual word representations, which are generally accepted as reliable representations for various NLP tasks.

With this background, we propose a QE model that has two separate pre-trained encoders that each produce monolingual representations of *src* and *mt*, respectively. On top of each encoder, we add a cross attention network for the learning of the cross-lingual context between *src* and *mt*; these networks will produce two sets of cross-lingual representations for QE. We conduct simple experiments to compare the performance of our systems and ensembles of them with that of the baseline systems and that of other submitted systems for

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 920–927
November 10–11, 2021.

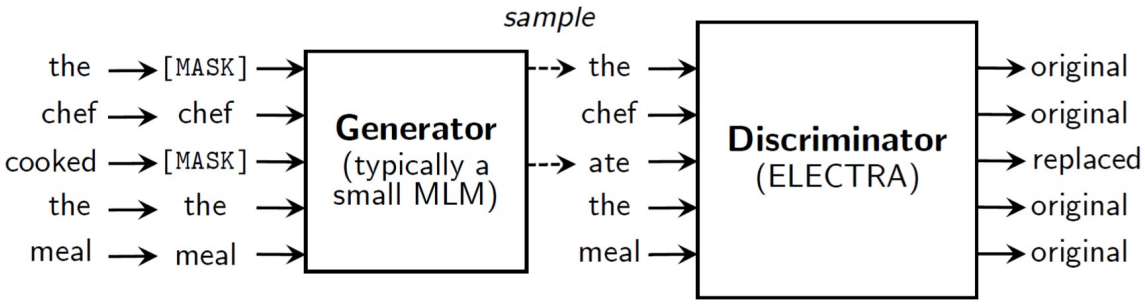

Figure 1: A diagram depicting the training task of ELECTRA (Clark et al., 2020)

Task 2. Experimental results imply that although our systems do not always outperform the baseline systems, they do in terms of the Matthews correlation coefficient (MCC) for *mt*'s word-level QE and in terms of the Pearson's correlation coefficient (PCC) for sentence-level QE by 0.4126 and 0.5497 respectively.

2 Related Work

Because our model does not confine its monolingual encoders to specific pre-trained LMs, all pre-trained LMs can be considered relevant. Among them, most of the recently proposed pre-trained LMs are denoising autoencoders, of which the pre-training task is usually to select about 15% of tokens in unlabeled input sequences and apply the attention mechanism to those tokens (Yang et al., 2019) or is to mask certain tokens (Devlin et al., 2019) and then restore them. However, in our experiments, our systems use ELECTRA (Clark et al., 2020). ELECTRA introduces "replaced token detection" as an additional pre-training task and let the language model learn to distinguish between real input tokens and specious but artificially generated tokens. In detail, when the generator network predicts the tokens in the masked positions, some of the predicted tokens are corrupted, and then this output sequence is fed into a Transformer-based discriminator network, which predicts whether each token in the fed sequence is the same as the original one or is a replaced one (Figure 1). We suppose that this process and QE are similar to each other in that both of them predict the soundness of the given tokens, so ELECTRA would be one of the most appropriate pre-trained LMs for our QE model's monolingual encoders, especially for Task 2.

3 Model Description

Our model uses two ELECTRAs: one ELECTRA[1] that is pre-trained with English corpora and the other ELECTRA[2] pre-trained with German corpora. Figure 2 depicts the overall structure of our model.

3.1 Dual Monolingual Encoders

Our model has dual encoders: a pre-trained English ELECTRA processing *src* and a pre-trained German ELECTRA processing *mt*. These encoders will produce reliable monolingual representations of *src* and *mt* respectively to provide these refined representations to the upper cross attention networks.

Because unlike other pre-trained QE models that have a single Transformer encoder being fed with the concatenation of *src* and *mt*, our model lets the two different encoders process the two input data respectively, we exclude the segment embeddings, which are used to distinguish one language from another, and assign different positional embeddings to each input data. In addition, for sentence-level QE, *mt*'s special token `<CLS>` is used to predict the HTER.

3.2 Cross Attention Networks

We attach a cross attention network to each pre-trained encoder; it learns the cross-lingual context information by using the encoders' refined monolingual representations of the two input data. Although the structure of a cross attention network is identical to that of the encoders, the cross attention networks are not pre-trained, so we train them after the random initialization of their parameters. We

[1] https://huggingface.co/google/electra-base-discriminator

[2] https://huggingface.co/german-nlp-group/electra-base-german-uncased

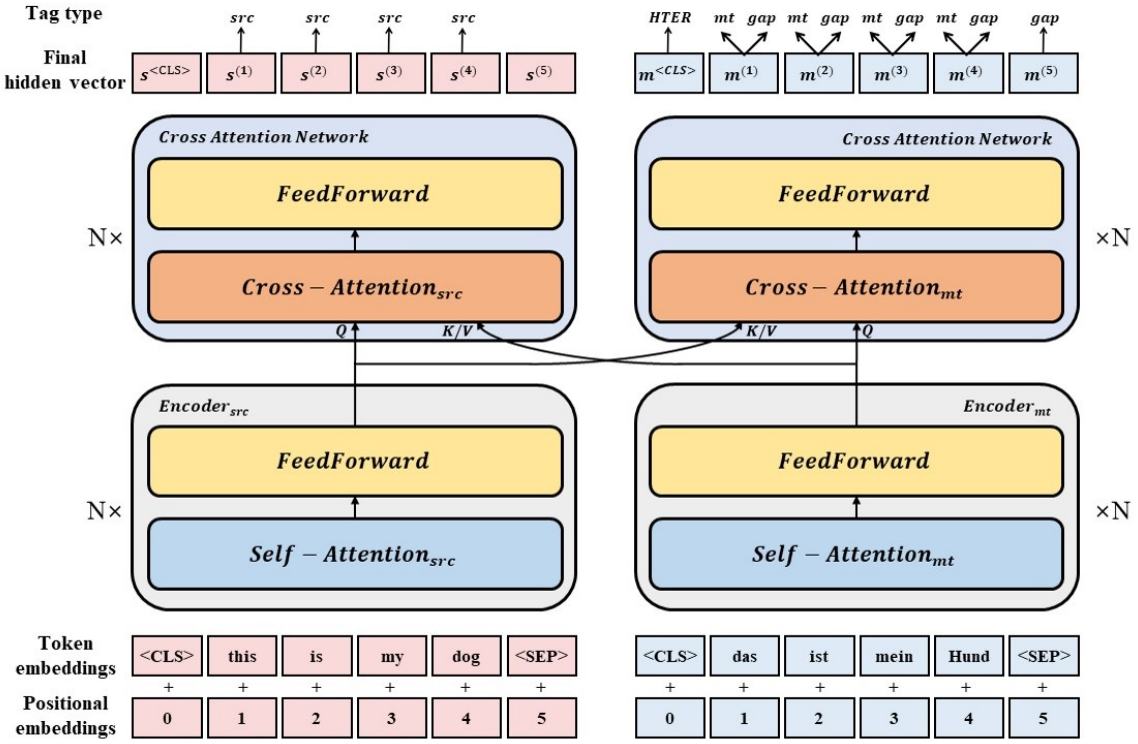

Figure 2: The overall structure of our model

find that applying transfer learning to the cross attention networks is not available due to the absence of pre-trained language models that are pre-trained to perform cross attention on cross-lingual input data by using one side as a query vector and the other side as both a key vector and a value vector just as the Transformer decoder performs multi-head attention on the output of the Transformer encoder.

3.2.1 Sentence-Level QE

To predict the HTER for sentence-level QE we employ the final hidden vector $m^{\texttt{<CLS>}}$ of the *mt*-side cross attention network, which is the final representation of the `<CLS>` token, as the representation of the *mt* sequence as a whole. After this representation passes through double linear layers with the GELU (Hendrycks and Gimpel, 2016) activation function, the HTER of the given *mt* sentence is estimated as follows.

$$\mathbf{l} = \mathbf{W}_h m^{\texttt{<CLS>}} + \mathbf{b}_0$$
$$\hat{y}_{\text{HTER}} = \mathbf{w}_h^T \text{GELU}(\mathbf{l}) + b_1 \quad (1)$$

We have trainable parameters $\mathbf{W}_h \in \mathbb{R}^{H \times H}$, $\mathbf{w}_h \in \mathbb{R}^H$, $\mathbf{b}_0 \in \mathbb{R}^H$, and $b_1 \in \mathbb{R}$; H denotes hidden vectors' dimension.

We use the mean squared error of this estimator, that is, the difference between the estimated HTER $\hat{y}_{\text{HTER}}$ and the ground truth HTER value y_{HTER}, as the training loss

$$\mathcal{L}_{\text{HTER}} = \text{MSE}(\hat{y}_{\text{HTER}}, y_{\text{HTER}}). \quad (2)$$

3.2.2 Word-Level QE

***src*-Side Prediction** We use the final hidden vector $s^{(i)}$ ($i \in \{1, ..., |S|\}$, where $|S|$ is the number of tokens in the tokenized *src* sequence) of the *src*-side cross attention network corresponding to each token in *src* to predict OK or BAD in the token's position. After each of these representations passes through a linear layer, the word-level probability of the corresponding token being OK or BAD is predicted with a sigmoid activation function:

$$P_s^{(i)} = \text{sigmoid}(\mathbf{w}_s^T s^{(i)}), \quad (3)$$

where $\mathbf{w}_s \in \mathbb{R}^H$ is a trainable parameter.

We use the binary cross-entropy loss function; we also introduce an extra hyperparameter k_s to prevent our model from being overfitted because the statistics of the ratio between the number of OK tags and that of BAD tags in our training data (Table 1) can misguide the model to have the tendency

		# of words	OK	BAD
Artificial data	*src*	54.6M	34.3M (62.81%)	20.3M (37.19%)
	mt.word	50.5M	29.7M (58.82%)	20.8M (41.18%)
	mt.gap	53.5M	50.6M (94.53%)	2.9M (5.47%)
WMT 21 train	*src*	115K	84K (73.05%)	31K (26.95%)
	mt.word	112K	81K (71.85%)	32K (28.15%)
	mt.gap	119K	114K (95.41%)	5K (4.59%)
WMT 21 dev	*src*	16K	12K (74.21%)	4K (25.79%)
	mt.word	16K	12K (72.49%)	4K (17.51%)
	mt.gap	17K	16K (95.83%)	0.7K (4.17%)

Table 1: Statistics of QE datasets used in our experiments.

of outputting OK even when it should output BAD. The *src*-side loss is as follows:

$$\mathcal{L}_{src} = \frac{1}{|S|}\sum_{i=1}^{|S|}\Big\{k_s y_s^{(i)} log P_s^{(i)} + (1-y_s^{(i)}) log(1-P_s^{(i)})\Big\}, \quad (4)$$

where $y_s^{(i)}$ is a ground-truth OK–BAD tag.

***mt*-Side Prediction** We use the final hidden vector $m^{(i)}$ ($i \in \{1, ..., |M|\}$, where $|M|$ is the number of tokens in the tokenized *mt* sequence) of the *mt*-side cross attention network corresponding to each token in *mt* to predict OK or BAD in the token's position. We estimate the probabilities of the word tokens

$$P_m^{(i)} = \text{sigmoid}(\mathbf{w}_m^T m^{(i)}), \quad (5)$$

where $\mathbf{w}_m \in \mathbb{R}^H$ is a trainable parameter.

We also use the final hidden vector $m^{(j)}$ ($j \in \{1, ..., |M|+1\}$ including the vector in the position of the last <SEP> token to predict OK or BAD for the last <GAP> token. We estimate the probabilities of the <GAP> tokens

$$P_g^{(j)} = \text{sigmoid}(\mathbf{w}_g^T m^{(j)}), \quad (6)$$

where $\mathbf{w}_g \in \mathbb{R}^H$ is a trainable parameter.

The *mt*-side prediction loss equals the sum of the losses for word tokens and <GAP> tokens:

$$\mathcal{L}_{mt} = \mathcal{L}_m + \mathcal{L}_g, \quad (7)$$

where

$$\mathcal{L}_m = \frac{1}{|M|}\sum_{i=1}^{|M|}\Big\{k_m y_m^{(i)} log P_m^{(i)} + (1-y_m^{(i)}) log(1-P_m^{(i)})\Big\}, \quad (8)$$

and

$$\mathcal{L}_g = \frac{1}{(|M|+1)}\sum_{j=1}^{|M|+1}\Big\{k_g y_g^{(j)} log P_g^{(j)} + (1-y_g^{(j)}) log(1-P_g^{(j)})\Big\}, \quad (9)$$

$y_m^{(i)}$ and $y_g^{(j)}$ being ground-truth OK–BAD tags for a word token and a <GAP> token respectively and hyperparameters k_m and k_g being introduced for the same reason why we introduce k_s.

Finally, we define the word-level loss and the overall QE loss of our model as follows.

$$\mathcal{L}_{\text{word}} = \mathcal{L}_{src} + \mathcal{L}_{mt} \quad (10)$$

$$\mathcal{L}_{\text{QE}} = \mathcal{L}_{\text{word}} + \mathcal{L}_{\text{HTER}} \quad (11)$$

4 Experiments

4.1 Datasets

In our experiments, we used the eSCAPE (Negri et al., 2018) dataset, which is a collection of data triplets each of which is composed of *src*, *mt*, and *pe*; we used this dataset to make artificial QE training data. In this process, to make our artificial data have a similar statistics as those of WMT 2021's official training data, we filtered eSCAPE triplets according to various criteria, such as the sequence lengths of *src* and *mt*, the sequence length ratio

between *src* and *mt*, and TER. Then, we created a tuple of labels (T_{src}, T^{word}_{mt}, T^{gap}_{mt}, the TER (Snover et al., 2006)) for each triplet [3]. Finally, we tokenized and truncated both of the artifical data and the WMT 2021 official data by using a pre-trained tokenizer based on WordPiece (Wu et al., 2016).

4.2 QE Pre-training

After obtaining about three million of artificial triplets, we made the final QE pre-training data by joining the artificial training data and the official human-labeled data together; especially, we augmented the quantity of the latter by replication to allow our systems to learn from both kinds of training data relatively more evenly during the QE pre-training. Our systems learn to predict all kinds of labels jointly (L_{QE}, Eqn. 11) considering the close correlation among the subtasks in Task 2. We used 1,000 triplets in the WMT 2021's official development dataset as validation data.

4.3 Fine-Tuning

We used only the WMT 2021 human-labeled data for fine-tuning. In contrast with the QE pre-training, we fine-tuned our systems to each subtask: the prediction of the sentence-level task (L_{HTER}, Eqn. 2) and the word-level task (L_{word}, Eqn. 10) Considering the overproportion of OK tags in our training data (Table 1), we set a large k_s, k_m, and k_g (§ 3.2.2) in our experiments.

4.4 Ensemble Learning

Besides single fine-tuned systems, we also made ensembles of our best fine-tuned systems, each of which has a different random seed from that of the others. In detail, after fine-tuning several single systems with different random seeds, for each seed, we picked out the top two systems, each of which is different from the other in certain variable training conditions such as how its cross attention networks have been randomly initialized in that instance, in terms of their performance on our validation dataset. Finally, we averaged the weights of the systems element-wisely for better generalization and made the ensembles.

4.5 Hyperparameters

We used ELECTRA-base (Clark et al., 2020)s as pre-trained monolingual LMs for our dual monolingual encoders[4]. In the QE pre-training, we used `get_schedule_with_warmup`[5] as our learning rate scheduler with 3,000 warm-up steps. We used the AdamW (Loshchilov and Hutter, 2018) optimizer that has a weight decay with λ=0.5, β_1=0.9, β_2=0.999, and ϵ=1e-8, together with gradient clipping. Setting a batch size of 64 for both the QE pre-training and fine-tuning, we set a learning rate of $1e{-}5$ and a tuple of ($k_s = 1$, $k_m = 1$, $k_g = 3$) for the QE pre-training and a learning rate of $5e{-}5$ and a tuple of ($k_s = 2$, $k_m = 2$, $k_g = 4$) for the

fine-tuning, respectively. We validated the performance of our systems on our validation set every 5,000 steps during the QE pre-training and every 200 steps during the fine-tuning, respectively; we applied early stopping with a patience of 30.

4.6 Results

In comparison with our single system, our ensembles report an improved PCC, *mt*-side words MCC, and *mt*-side <GAP>s MCC of about 0.5497, 0.4296, and 0.1225 respectively (Table 2). Compared to other systems submitted to the WMT 2021 English–German QE Task 2, our systems outperform the baseline systems in terms of the sentence-level PCC (Table 3) and the *mt*-side words MCC (Table 4). Our systems are inferior to the baseline systems in terms of the *src*-side MCC and the *mt*-side <GAP>s MCC by a narrow margin (Table 4). However, because our systems have a smaller number of parameters than other submitted systems, we expect that it is possible to improve the performance of our systems by adopting larger pre-trained LMs such as ELECTRA-large (Clark et al., 2020).

5 Conclusion

We model our systems submitted to Task 2 of the WMT 2021 QE shared task on our proposed model, which uses dual pre-trained monolingual encoders and two additional cross attention networks to process the two input data *src* and *mt* more effectively considering that the latest Transformer-based QE models are not propped up by pre-trained monolingual word representations. We expect that the cross attention networks enable the two pre-trained monolingual encoders to exchange cross-lingual information without losing their stability and to learn the subtasks of Task 2 jointly and also separately. Experimental results partially supports this expectation: according to the official leaderboard, our systems outperform the baseline systems in terms of the *mt*-side words MCC and the sentence-level PCC by 0.4126 and 0.5497 respectively, although they do not in terms of the *src*-side MCC and the *mt*-side <GAP>s MCC. Neverhteless, it appears possible to improve the performance of our systems by adopting larger pre-trained LMs, and thus, our future work will explore such aspects and other related new methods.

{genze.jiang20, zhenhao.li18, l.specia}@imperial.ac.uk

Abstract

This paper presents Imperial College London's submissions to the WMT21 Quality Estimation (QE) Shared Task 3: Critical Error Detection. Our approach builds on cross-lingual pre-trained representations in a sequence classification model. We improve the base classifier by (i) adding a weighted sampler to deal with imbalanced data and (ii) introducing feature engineering, where features related to toxicity, named-entities and sentiment, which are potentially indicative of critical errors, are extracted using existing tools and integrated to the model in different ways. We train models with one type of feature at a time and ensemble those models that improve over the base classifier on the development set. Our official submissions achieve very competitive results, ranking second for three out of four language pairs.

1 Introduction

Critical Error Detection (CED) is a new task which has been introduced in the WMT21 Quality Estimation (QE) Shared Task.[1] The purpose of CED is to address a challenging problem in Machine Translation (MT): translations produced by state-of-the-art MT systems can be grammatical and fluent but do not always retain the meaning of the source text. More importantly, incorrect translations can be misleading and even have catastrophic consequences such as health, safety, legal, or financial implications. However, these can be hard errors to capture by general QE architectures, which have been shown to be prone towards relying mainly on the translated sentence (Sun et al., 2020).

According to the Shared Task definition, a critical translation error is a type of error that occurs when the meaning of the translation deviates from source sentence in a critical way. The task data (Section 2.1) includes five categories of such errors: deviation in toxicity (TOX), in named entities (NAM), in sentiment polarity or negation (SEN), or in numbers (NUM), or introduction of health or safety risks (SAF).

The baseline model for this task utilises the XLM-RoBERTa (Conneau et al., 2020) for sequence classification model, following the Mono-TransQuest architecture proposed by Ranasinghe et al. (2020). Inspired by the fact that these five critical error types refer to specific linguistic phenomena, we aim to bring additional information to the models on the presence of such phenomena. The intuition is that sentences containing certain types of linguistic features, such as named entities or dates, are more likely to lead to errors. Therefore, we first process the dataset to extract features reflecting the sentences' toxicity, sentiment and named entities, using off-the-shelf toolkits or APIs (Section 2.2). We then enhance the baseline architecture with this additional information.[2]

We experiment with two approaches to take the additional features into account, at token and hidden state levels. We build multiple models taking one type of feature at a time and finally ensemble "promising" models. Promising models are those that lead to improvements over the baseline on the dev set (Section 2.3).

Our results comparing different features show that some of the features are indeed useful, but there is no general pattern that applies to all language pairs (Section 3.1). The official submission, which uses an ensemble of the models that lead to improvements over the baseline on the dev set for each language shows that ensembling only models with promising features are better than ensembling models with all kinds of features (Section 3.2). Upon manual inspection, we observed that additional features indeed help the model to make predictions but this is subject to the accuracy of features (Section 3.3).

2 Experiment Settings

2.1 Dataset

According to the description of WMT21 CED Shared Task, the dataset for this task was collected from Wikipedia comments (Wulczyn et al., 2017) in English with translations generated by the ML50 multilingual translation model (Tang et al., 2020), consisting of four language pairs: English-Czech (En-Cs), English-German (En-De), English-Japanese (En-Ja) and English-Chinese (En-Zh). The number of data samples in the training set differs for the four language pairs but is around 6500-8000. Each language pair has 1000 data samples in the dev set and 1000 data samples in the test set. For each sentence pair in the dataset, there are three labels given by three human annotators. The three labels are aggregated to the final label of the dataset using majority strategy. The final label is either `ERR` or `NOT`, where `ERR` means the translation has at least one critical error and `NOT` means the translation does not have a critical error.

Pair	Dataset	Count	Label	Count
En-Cs	Train set	7476	NOT	6188
			ERR	1288
	Dev set	1000	NOT	840
			ERR	160
	Test set	1000	–	–
En-De	Train set	7878	NOT	5674
			ERR	2204
	Dev set	1000	NOT	719
			ERR	281
	Test set	1000	–	–
En-Ja	Train set	7658	NOT	6939
			ERR	719
	Dev set	1000	NOT	904
			ERR	96
	Test set	1000	–	–
En-Zh	Train set	6859	NOT	5749
			ERR	1110
	Dev set	1000	NOT	859
			ERR	141
	Test set	1000	–	–

Table 1: Statistics of datasets for four language pairs. The distribution of labels for the test set is unknown as this is a blind evaluation task.

The dataset information for each language pair can be found in Table 1. As can be seen, the data is very imbalanced, with the En-Ja dataset suffering the most: the `ERR` label only accounts for 9.4% in the training set. The En-De dataset is the least imbalanced compared to other three language pairs, where the proportion of `ERR` label in En-De training set reaches 27.9%.

2.2 Features

We extract features reflecting sentences' toxicity score, sentiment and named entities. The expectation is that these features could be helpful in detecting critical errors since these errors stem from issues with the translation/introduction of these and other linguistic phenomena. Ideally we would have wanted to extract this information for both source and translated sentences to be able to perform some sort of comparison between the two, for example, presence of toxicity in the translation but not in the source sentence. However, we are limited by the availability of tools in the four language pairs, as we explain below.

For all features, our goal is to have a discrete representation which will allow us to easily incorporate them to the architecture, as will be explained in Section 2.3.2. Therefore, we need to threshold some of these features.

The toxicity score is produced by Perspective API,[3] which supports only English and German amongst our five languages. Based on some manual inspection of the predictions by Perspective, we consider that if the toxicity score of a sentence is greater than 0.5, the sentence will be regarded as toxic. We leave for future work experiments varying this threshold. Since this API does not support Czech, Japanese and Chinese, we were only able to extract a toxicity feature in the source sentences for En-Cs, En-Ja and En-Zh.

The sentiment score is produced by Google Cloud Natural Language API,[4] which supports English, German, Japanese and Chinese. Therefore, we can get the sentiment feature of both source sentence and translation for En-De, En-Ja and En-Zh. The score returned by this API is a float number ranged from -1 to 1. Empirically, we consider a sentence to be negative if the score is smaller than -0.2, and positive if the score is greater than 0.2, otherwise the sentence's sentiment is neutral. In our experiments, the sentiment feature is not applied to En-Cs because Czech is not supported by this API.

The information of named entities (NE) is extracted using spaCy,[5] which can recognise over 15 NE types. We count the number of named entities for each NE type and finally choose seven NE types with the highest counts as features. The description

[3] https://www.perspectiveapi.com/
[4] https://cloud.google.com/natural-language
[5] https://spacy.io/

of the seven NE types can be found in Table 2. We extract named entities in both source sentence and translation for En-De, En-Ja and En-Zh. However, Czech is not supported by spaCy, therefore we do not use NE features for En-Cs.

Type	Description	Abbr.
ORG	Organisation name	ORG
PERSON	Person name	PER
DATE	Year, month or day	DAT
CARDINAL	Numerals	CRD
ORDINAL	Ordinal numerals	ORD
NORP	Religious group, etc	NRP
GPE	Geographical name	GPE

Table 2: Descriptions of seven types of NE features and their abbreviations.

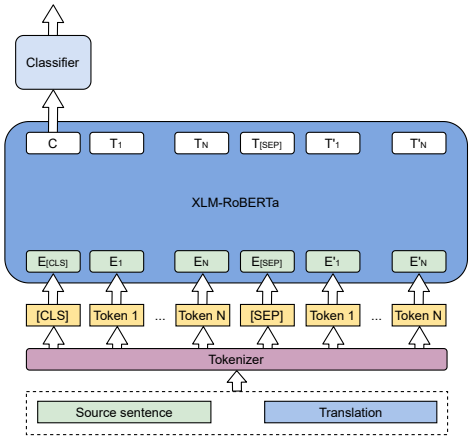

Figure 1: Architecture of baseline model. This is a MonoTransQuest model where we pass the output of the `[CLS]` token to a classifier.

2.3 Models

2.3.1 Baseline Model

The baseline model employs the MonoTransQuest framework (Ranasinghe et al., 2020), which is proposed for general quality estimation (QE) tasks and is shown in Figure 1. Essentially this is used to produce the baseline score of CED Shared Task. The model is based on a pre-trained XLM-RoBERTa transformer model (Conneau et al., 2020) and is used to perform sentence-level classification tasks. The model takes a sequence of tokens as input which starts with `<s>`, denoting `[CLS]` token, followed by tokens for source sentence and translation and ended with `</s>` token. The source sentence and its translation, separated by `[SEP]` token, are fed into one single transformer encoder at the same time. Then the output of the transformer encoder is fed into a classification head where cross-entropy is adopted as the loss function. We use pre-trained XLM-RoBERTa models released by HuggingFace's model repository (Wolf et al., 2020) for the implementation.

To alleviate the influence of imbalanced training data, a weighted sampler can be applied to the data loader during training. The weighted sampler is to make the label distribution in the training batch as balanced as possible. The weight of the sampler is computed as reciprocals of label proportions.

2.3.2 Model with Features

To utilise the features mentioned in Section 2.2, we proposed two different approaches.

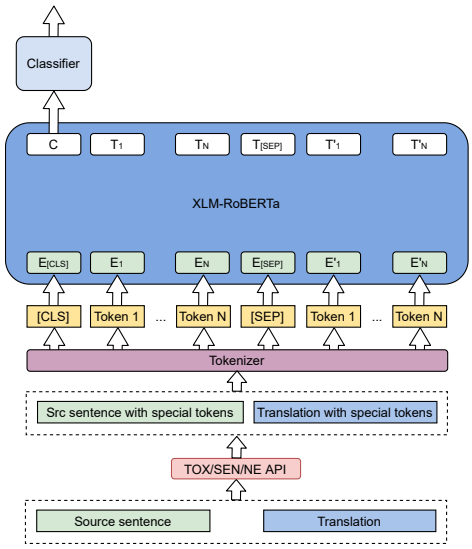

Figure 2: Architecture of the first approach (adding special tokens). We insert TOX/SEN/NE information to the source sentence and its translation as special tokens, and then feed sentences with special tokens to the baseline architecture.

The first approach (shown in Figure 2) is to **add special tokens**. Here the features (toxicity, sentiment, named entities) are directly inserted as special tokens to the input source sentence and, where available, its translation before getting tokenised. To correctly tokenise sentences with features, these special tokens are also added to the XLM-RoBERTa tokeniser. The remaining architecture is the same as the baseline model except for the dimension of model's word embeddings as the model's token embeddings should be resized when adding new tokens.

For the toxicity feature, a special token `[TOX]` is added to the beginning of the input token sequence if and only if the sentence is toxic. If the sentence is not toxic, the `[TOX]` token will not be

added. For En-De, the [TOX] token is applied to both source sentence and translation. But for other three language pairs it is only applied to the source sentence (English), because the Perspective API does not support Czech, Japanese and Chinese.

For the sentiment feature, there are three special tokens, [SEN_POS], [SEN_NEG], [SEN_NEU], representing positive, negative and neutral sentiment respectively. Each time only one token denoting sentence's sentiment is added to the beginning of that sentence. All the sentences should have one sentiment token at the beginning. The sentiment token is applied to both source sentence and translation for En-De, En-Ja and En-Zh. We do not perform experiments on sentiment feature for En-Cs due to lack of support on Czech from sentiment analysis API.

For named-entities feature, there are seven special token pairs corresponding to seven types of named entities generated by SpaCy API, e.g. [ORG] and [/ORG], [DAT] and [/DAT], etc. We use special token pairs to encase the named entities with relevant type in sentences at word level. Similarly to sentiment feature, the tokens of named-entities feature are also applied to both source and translation for En-De, En-Ja and En-Zh. Czech is not supported by spaCy, hence we do not apply this feature to En-Cs.

By adding extra features to the texts, we expect to guide the model with the toxicity/named-entities/sentiment information on the source sentence or the discrepancy of such information between the source sentence and the translation, which might indicate the existence of critical translation errors.

The second approach (shown in Figure 3) is to **modify hidden states**, where the extracted features are presented as numerals and appended to the hidden states of [CLS] token. Due to limited time, we only experimented with NE features using this approach. Since some named entity types are similar, they can be grouped as one type. In this approach, except for DAT, which is an independent category, we group ORG and PER as a category, CRD and ORD as a category, NRP and GPE as a category so that finally we have four categories. The feature that is used here is the count of the four NE types in source and target sentences. It is presented as a vector of length 8, where the first 4 numbers represent the counts of these NE categories for the source sentence, and the last 4 numbers are for the translation. First we feed the source sentence and its translation into the XLM-RoBERTa encoder, then we append the vector of counts to the output of the [CLS] token. The modified hidden states is then fed to the classification head.

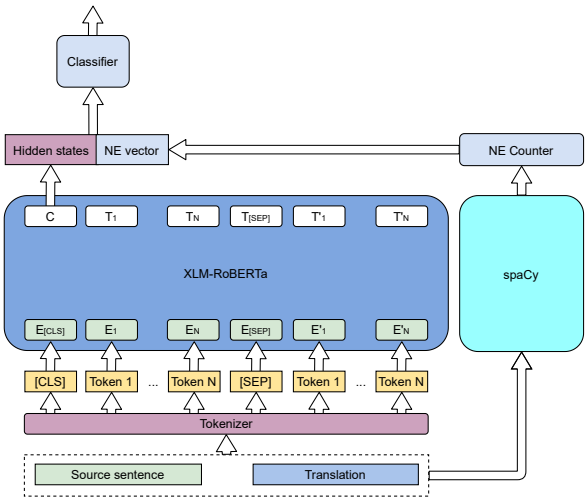

Figure 3: Architecture of the second approach (modifying hidden states). The sentence pair is fed into the XLM-RoBERTa encoder and into spaCy to generate NEs, resulting in the NE vector with the count of name entities of different types. We concatenate the output of [CLS] with the NE vector and send the modified hidden states to the classifier.

Our expectation is that the additional information (vector of counts) could guide the classifier to give more accurate predictions, because a deviation in named entity counts may be indicative of critical errors. For example, if the source sentence contains 3 named entities and the translation contains only 1 named entity, the translation may be missing some named entities.

2.3.3 Ensemble

To boost the performance, we ensemble several models to produce the final predictions. We experiment with two ensemble strategies. One strategy is label-level (late) ensemble. We first obtain the label predictions generated by different models using different features, then combine these predicted labels by performing majority vote to get a final label. The other strategy is logit-level ensemble, where we average the logits produced by different models and then produce the final label using the averaged logits.

3 Results

This section presents the evaluation results of the proposed methods. Except for the baseline score on

Method		En-Cs	En-De	En-Ja	En-Zh
Baseline		0.393	0.413	0.217	0.255
Baseline	best	0.397	0.422	0.231	0.276
(with sampler)	average	**0.396**	0.418	0.224	0.262
Adding TOX token	best	0.391	0.448	0.254	0.284
	average	0.385	**0.435**	0.220	0.261

Table 3: Matthews's Correlation Coefficient (MCC) between predictions and gold labels using different methods on development set, trained on XLM-RoBERTa-base model. "Best" and "average" stand for the highest score and average score of three runs respectively. The bold numbers are the best result for the average of three runs in that language pair. For En-Cs, we only experiment on two cases due to lack of feature availability for Czech.

test set in Section 3.2 which is produced by MonoTransQuest using pretrained XLM-RoBERTa-base model with batch size of 128, learning rate of 2e-5, and a linear learning rate warm-up ratio of 10%, all the other scores (including baseline score on dev set in Section 3.1) are produced using following hyperparameters: 64 for batch size, 2e-5 for learning rate, 30% for the warm-up ratio.

3.1 Results on Dev Set

As described in Section 2.2, we explore nine feature types: source and target toxicity, source and target sentiment and 7 types of source and target named entities. We trained our model using the first approach (adding special token) for each of the nine feature types and the second approach (modifying hidden states) for named entities only. For each method or feature, we run the model for three times with different seeds and report average performance, as well as the performance of the best of the three models. The results on the development set are shown in Table 3.

The results follow our expectation that En-De could achieve the highest MCC score among the four language pairs as the training set of En-De is more balanced, compared to other three language pairs. Meanwhile, En-Ja has the lowest MCC score, as the dataset is the most imbalanced. The results also show that adding a weighted sampler to deal with imbalanced data improves the models' performance in most cases. As for the additional features, some of them are useful, but it depends on the language pair. For example, the toxicity feature can improve the score in En-De but cannot improve performance in En-Ja and En-Zh, while the sentiment token is helpful in En-Ja and En-Zh but not boost the score in En-De.

We note that the results may be affected by fluctuations because of different random seeds. Sometimes multiple runs of the same case will produce fairly different results. This is a general problem of neural models for QE as well as other tasks and requires further investigation. For example, the results of three runs of adding NE (NRP) feature in En-Ja vary a lot. The best score from the three runs is 0.247 which is over the baseline score, but the average score is 0.193 which is largely below the baseline.

3.2 Results on Test Set

We use ensembling to produce final results. The different models to ensemble are trained using different features, and hence focus on difference types of errors, thus potentially leading to different predictions. Not all these models lead to improvements over the base (no features) model; in fact, adding

some features decreases the performance for some languages. Therefore, we tested ensembles of models with all feature and ensembles of only models with features which achieve higher score on the development set in our ablation experiments (Table 3). We found that ensembling all models leads to a lower score than ensembling the best few models.

In our experiments, ensembling models with better performance than the base model improves the results of all languages except En-De. For that language pair, the best result is achieved by only adding NE (DAT) token to the XLM-RoBERTa-large base architecture. The final results of submission for CED shared task and ranks are shown in Table 4.

Method	**En-Cs**	**En-De**	**En-Ja**	**En-Zh**
Baseline	0.388	0.397	0.214	0.187
Ours (*gjiang*)	0.473 (2nd) reached by ensembling following: • 4 × baseline models (base) • 1 × baseline model (large)	0.498 (2nd) reached by single model: • 1 × NE (DAT) model (large)	0.314 (2nd) reached by ensembling following: • 1 × baseline models (base) • 1 × NE (CRD) model (base) • 1 × TOX model (large)	0.305 (4th) reached by ensembling following: • 1 × baseline models (base) • 2 × SEN models (base) • 1 × TOX model (base) • 1 × baseline model (large) • 1 × NE (DAT) model (large) • 1 × TOX model (large)

Table 4: Final results and ranks of CED shared task in WMT 2021. These results can also be found on CodaLab result page where the name of our team is *gjiang*. The metric in the table is Matthews's Correlation Coefficient (MCC) between predictions and gold labels. Below our score for each language pair is the model(s) that we used to achieve this score. "(base)" and "(large)" denotes this model is trained using XLM-RoBERTa-base and XLM-RoBERTa-large respectively.

Source	YOU SUCK IT!!! AS YOU'RE USED TO SUCK PHALLUS, NAZI HINDUIST LIKE HITLER!!!
Translation	你吸了它, 就像你以前吸过帕卢斯一样, 纳西迷人就像希特勒一样!
Baseline label	NOT
Our label	ERR
True label	ERR
Analysis	The source sentence is toxic and has negative sentiment. But the sentiment of translation is positive. Therefore, there is a deviation in sentiment between source and translation and this is a critical error.
Source	Upon further research I have found irrefutable proof that he got the nickname for the masterful way he cleaves beavers with his massive member.
Translation	经过进一步的研究, 我发现了不可否认的证据, 那就是他用他巨大的成员把贝弗切开的巧妙方法获得了绰号。
Baseline label	NOT
Our label	ERR
True label	ERR
Analysis	The source sentence is not toxic and the sentiments of both sentences are neutral. However, the machine translator mistakenly regards "beavers" as a name and produce a name in Chinese, which is detected by spaCy. The translation introduces one named entity which does not exist in source sentence. Therefore, this is a critical error.
Source	REDIRECT Talk:Historical Archive of the City of Cologne
Translation	主题演讲: 科隆市历史档案
Baseline label	NOT
Our label	ERR
True label	NOT
Analysis	In this case, spaCy does not report "Cologne" as a named entity in source sentence, but in translation it reports the city name in Chinese as a named entity (GPE). Therefore, our model regards the translation introduces a new named entity. There is a deviation in named entities between source and translation and this is mistakenly classified as a critical error.
Source	Goanikontes is an oasis is hidden within the Goanikontes Region.
Translation	戈亚尼科恩特是戈亚尼科恩特地区内的一个绿洲。
Baseline label	NOT
Our label	ERR
True label	NOT
Analysis	Similarly to previous case, spaCy correctly detects "Goanikontes" as a location name, but in translation spaCy mistakenly reports the corresponding location name in Chinese as person's name. Hence, our model thinks there is a deviation in named entities and predicts this case to a critical error. The mistakes from APIs are likely to lead the model to give wrong predictions.

Table 5: Case study: comparison of baseline predictions and our ensembled predictions in En-Zh

3.3 Qualitative Analysis

We conducted manual inspection on En-Zh in an attempt to understand whether the additional features actually contribute to better performance. The choice of the language pair that we analysed was determined by the availability of understanding languages in both sides. We compared our final submitted predictions on test set with the baseline predictions. We found that, compared to the baseline result, our final model predicts more `ERR` labels. 82 out of 1000 samples' label in test set are flipped from `NOT` to `ERR`, among which 35 samples are correct change (from false negative to true positive), 47 are incorrect (from true negative to false positive). We give some examples in Table 5 to compare our predictions with the baseline results. These examples show that feature engineering actually pushes the model to predict more `ERR`s. Overall this improves the performance to some extent, but is subjected to the correctness of the feature extractor. Inaccurate results from APIs will give the model wrong information and limit the improvement of performance of our models.

4 Conclusions

This paper describes our submission to sentence-level CED task in WMT21. Our work extends the baseline MonoTransQuest architecture by exploring feature engineering and model ensembling, as well as weighted sampling to deal with imbalanced datasets. Potentially due to the skewed distribution of labels in the dataset, the model performance varies substantially over different runs. However, our results averaged over multiple random seeds show that our feature engineering and ensembling lead to large improvements over the baseline. Our official submission achieves the 2nd position in En-Cs, En-De, En-Ja, and the 4th postion in En-Zh.

Abstract

This paper describes Papago's submission to the WMT 2021 Quality Estimation `Task 1: Sentence-level Direct Assessment`. Our multilingual Quality Estimation system explores the combination of Pretrained Language Models and Multi-task Learning architectures. We propose an iterative training pipeline based on pretraining with large amounts of in-domain synthetic data and finetuning with gold (labeled) data. We then compress our system via knowledge distillation in order to reduce parameters yet maintain strong performance. Our submitted multilingual systems perform competitively in multilingual and all 11 individual language pair settings including zero-shot.

1 Introduction

Quality Estimation (QE) evaluates the quality of machine translated output without human reference translation (Blatz et al., 2004). QE has a variety of applications in the Machine Translation (MT) pipeline and is particularly useful in industry settings by informing translation quality to end-users. High performance in sentence-level QE (Specia et al., 2020) is achieved by building a model on top of Pretrained Language Model (PLM); XLM-RoBERTa-large (Conneau et al., 2020) performs particularly well as shown in previous WMT sentence-level QE Shared Task. However, such PLMs contain extremely large number of parameters. This year's task is different from the previous years' task as submitted systems are ranked based on both model size[1] and model performance[2]. For concurrent work Gajbhiye et al. (2021) applies knowledge distillation (Hinton et al., 2015) from a PLM-based QE architecture to a much lighter BiRNN-based architecture, reducing memory requirements. Data scarcity is another issue relevant to QE tasks where there are often limited amount of gold training data. Previous WMT systems incorporate data augmentation techniques and show improvements in model performance when training with additional sources of data (Baek et al., 2020; Ranasinghe et al., 2020a).

Our system builds a model on top of PLM and trains with Multi-task Learning (MTL) (Caruana, 1997). Similar to Hoang et al. (2018); Zhang et al. (2018) where back-translation is iteratively applied to the same monolingual corpus to successively generate higher quality synthetic training data in the context of Neural Machine Translation (NMT), our proposed approach consists of an iterative knowledge transfer procedure which aims to repeatedly produce better quality pseudo labels for large amounts of synthetic training data. During the final stage of our training pipeline, knowledge distillation is applied from teacher to student model in order to reduce model size while maintaining competitive performance. We participate in WMT 2021 Quality Estimation (Specia et al., 2021) `Task 1` for multilingual and all individual language pair settings. Our system is a single multilingual sentence-level QE model that performs very strongly in both multilingual and individual language pair settings.

2 Data

In this year's task, participants are provided with 7K train set (`Train`), 1K development set (`Dev`), and 1K test set (`Test20`) for 7 language pairs: high-resource English-German (En-De) and English-Chinese (En-Zh), medium-resource Romanian-English (Ro-En) and Estonian-English (Et-En), and low-resource Sinhalese-English (Si-En) and Nepalese-English (Ne-En), as well as Russian-English (Ru-En). The source side sentences of language pairs excluding Ru-En are col-

[1] Disk space without compression and number of parameters.

[2] Pearson's correlation coefficient, root mean square error (RMSE), mean absolute error (MAE).

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 935–940

lected from Wikipedia data; the source side sentences of Ru-En is collected from a combination of Wikipedia articles and Reddit articles. Target side sentences are collected by translating source side sentences using NMT models and each sentence pair is annotated by at least three professional translators with a score between 0-100 according to the perceived translation quality. Systems are required to inference z-standardized direct assessment (DA) scores for 1K blind test set for each language pair. This year's task also include zero-shot scenario for 4 new language pairs: English-Czech (En-Cs), English-Japanese (En-Ja), Pashto-English (Ps-En), and Khmer-English (Km-En). As additional resource, participants are also provided with parallel data used to train NMT models (except for Ru-En and zero-shot language pairs) and NMT models used to generate target side sentences of the dataset.

3 Approach

Figure 1 summarizes our approach. Below we describe relevant components to our sentence-level QE model.

3.1 Base Model Architecture

Our QE model stacks feed-forward layers on top of feature vector extracted from Pretrained Language Models (PLM). Our choices of PLM are XLM-RoBERTa-base ($L = 12$) and XLM-RoBERTa-large ($L = 24$). Given source sentence src^X in language X and target sentence tgt^Y in language Y, the concatenation of src^X and tgt^Y are fed as input to the PLM and feature vector CLS_{cat} is produced by taking the concatenation of [CLS] representations from all layers of the PLM; our feature vector is based on using [CLS] token representation due to its superior performance over other pooling strategies (Ranasinghe et al., 2020b; Fomicheva et al., 2020). QE model f predicts direct assessment scores as follows:

$$\begin{aligned} f(src^X, tgt^Y) = W_{score} \cdot LeakyReLU(\\ W_2 \cdot LeakyReLU(\\ W_1 \cdot CLS_{cat} + b1) + b2) \end{aligned} \quad (1)$$

where $W_{score} \in \mathbb{R}^{1\times512}$, $W_2 \in \mathbb{R}^{512\times2048}$, $b_2 \in \mathbb{R}$, $W_1 \in \mathbb{R}^{2048\times N}$, $b_1 \in \mathbb{R}$, and N is XLM-RoBERTa's hidden dimension size (1024) times number of layers (L).

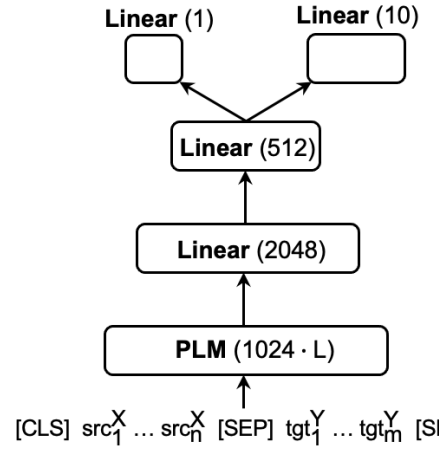

Figure 2: The network architecture for Multi-task Learning (§3.2) with XLM-RoBERTa as PLM. Concatenation of source and target sentences (with special tokens) are tokenized and fed as input to the PLM. Numbers in parenthesis denote the output dimension size of each network block.

3.2 Multi-task Learning (MTL)

We train our QE model in multi-task fashion by adding a classification objective to the base model architecture (§3.1). As shown in Figure 2, a classification layer W_{class}, where $W_{class} \in \mathbb{R}^{10\times512}$, is stacked next to W_{score} in equation (1). Given the n_{th} train set sample's z-standardized DA score $score_n$, we scale $score_n$ by applying min-max normalization and assign bin (class) labels to each sample. For our experiments, the number of bins is set to 10. Note that min-max scaling is applied to each language pair data set in order to account for different scales of $score_n$ per data set. The model is trained with a combined loss of mean squared error and cross entropy loss as shown in equation (2), with λ set to 0.6. Our intuition is that QE is inherently a complex task even for humans such that human-labeled DA scores may contain noise. We expect that training with an auxiliary classification loss, where bin labels are less susceptible to noise, can make training more robust and produce a model that is more generalizable.

$$\mathcal{L} = \lambda \cdot \mathcal{L}_{mse} + (1 - \lambda) \cdot \mathcal{L}_{ce} \quad (2)$$

3.3 Data Augmentation

We create large amounts of synthetic direct assessment samples for 7 language pairs (non zero-shot) using parallel data and NMT models which both are provided as additional resource. For data augmentation, we utilize source side sentences from parallel data. We sub-sample from parallel data

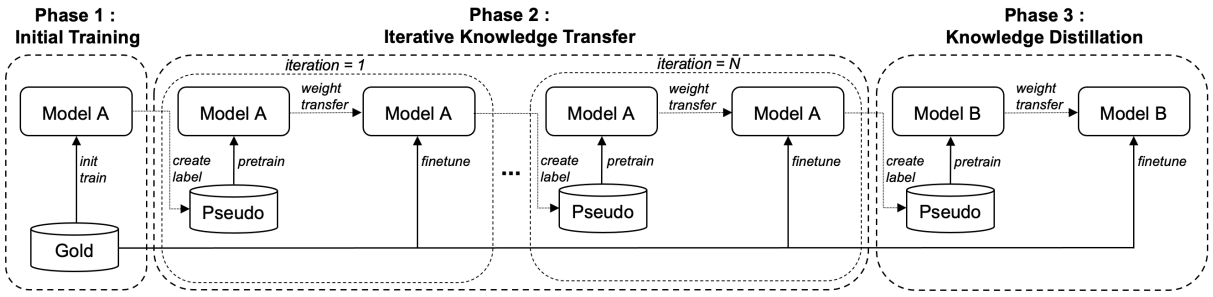

Figure 1: Pipeline of our proposed approach. `Gold` refers to `Train` set provided by task organizers (§2). `Pseudo` refers to synthetic sentence pairs generated as described in §3.3, while labels for `Pseudo` are created as described in §3.4. `Phase 2` and `Phase 3` each refer to §3.4 and §3.5 respectively. `Model A` and `Model B` each refer to large and small models in terms of model size. In our experiments, the architecture for `Model A` is a base model architecture (§3.1) with MTL (§3.2) using XLM-RoBERTa-large as PLM, which we denote as **Base$_{\text{large}}$ + MTL**; `Model B` instead uses XLM-RoBERTa-base as its PLM and we denote it as **Base$_{\text{small}}$ + MTL**.

Language	# parallel data	# sampled
En-De	19,298,476	400,000
En-Zh	15,178,232	400,000
Ro-En	3,901,626	400,000
Et-En	879,922	400,000
Ne-En	498,272	73,207
Si-En	646,781	400,000
Ru-En	12,061,155	400,000

Table 1: Number of parallel data provided in WMT2021 Task 1 and number of synthetic sentence pairs sampled as augmented data. For Ru-En, we collect parallel data from the Commoncrawl dataset.

for each language pair such that the distribution of sampled source sentences follows the distribution of source side sentences of gold data (§2) in terms of sentence length; this is to reduce the discrepancy between actual data and synthetic data. We then forward-translate source side sentences to target using provided NMT models to collect approximately 2.4M pseudo sentence pair data which are used as additional training resource. Table 1 shows the total amount of parallel data provided and the amount of synthetic sentence pairs generated. We describe how pseudo labels for synthetic data are created in the next section (§3.4).

3.4 Iterative Knowledge Transfer (IKT)

Given a QE model that is initially trained only on gold data (refer to `Phase 1` in Figure 1), iterative knowledge transfer aims to produce higher quality training signals or pseudo labels for synthetic data by iteratively performing pretraining and finetuning as shown in `Phase 2` in Figure 1. For pretraining, the model is always initialized with random weights (PLM weights are loaded from HuggingFace[3]) and is trained using synthetic direct assessment sentence pair data collected from §3.3. Pseudo labels for synthetic data in the current iteration are created with score predictions from model trained in the prior phase or iterative step. The aim of pretraining is to expose our model to large amounts of in-domain synthetic training data with sub-optimal labels. Similar to Sellam et al. (2020), the key aspect of the pretraining technique is to "warm up" the model before finetuning on gold data. At the start of finetuning, the model is initialized with parameter weights from the pretrain stage and is trained only with gold data. Because psuedo labels for synthetic data are newly generated for each iterative step in `Phase 2`, we expect the quality of "warm up" during pretraining to increase in each successive iteration. We stop the iterative process when the model's Pearson's correlation performance does not improve on `Test20`; we empirically find that performance does not improve after the second iteration.

3.5 Knowledge Distillation (KD)

`Phase 3` in Figure 1 demonstrates knowledge distillation from a large to smaller model. Akin to `Phase 2` (§3.4), a 2 stage pretrain-to-finetune training procedure is conducted and pseudo labels for synthetic data is generated using a teacher model which is the model produced from the last iteration of `Phase 2`. As our results will show, the compressed model performs on par with our baseline large model with approximately less than half the number of model parameters.

Table 2: Pearson's correlation with human judgments on the `Dev` and `Test20` set. Model names starting with + sign indicates approaches that are cumulative.

4 Settings

For all training phases and experiments, we train our model in data parallelism on multiple NVIDIA Tesla V100 GPUs for 3 epochs with batch size of 8 and is optimized with Adam (Kingma and Ba, 2015) with a learning rate of $7e^{-6}$. Dropout (Srivastava et al., 2014) with 0.15 is applied to activation function outputs in equation 1. Each model variant is trained 3 times with different random seeds, and for each model variant the best performing system in terms of Pearson's correlation coefficient is reported.

All models trained within the scope of this paper are multilingual QE models. We concatenate the `Train` set of each individual language pair to create a single multilingual train set for training. We apply the same for `Dev` and `Test20` set such that validation, model selection and evaluation can be performed at a multilingual level.

5 Results

In this section, we present results of our architectures described in §3. Pearson's correlation coefficient between predictions and gold standard scores is the main evaluation metric to measure performance; this year's task also considers model size to rank systems. Table 2 shows the Pearson's correlation with human judgments on the development and test set (`Dev` and `Test20`). Each row in Table 2 corresponds to model variants derived from certain phases of the training pipeline as described in Figure 1. We first observe that incorporating **MTL** (§3.2) improves over both our small baseline model $\textbf{Base}_{\textbf{small}}$ and large baseline model $\textbf{Base}_{\textbf{large}}$ with respect to all language pair settings. We observe further improvements in performance using Iterative Knowledge Transfer (§3.4) where the average performance of second iterative model $\textbf{Base}_{\textbf{large}}\textbf{+MTL+IKT}_{\textbf{iter=2}}$ is better than the first iterative model. Comparing $\textbf{Base}_{\textbf{large}}\textbf{+MTL+IKT}_{\textbf{iter=2}}$ to our large baseline model $\textbf{Base}_{\textbf{large}}$, the average performance gain is 3.4 percentage point but gain with respect to individual language pairs varies, with 10.2 percentage point increase for En-De being the greatest.

Our final compressed model $\textbf{Base}_{\textbf{large}}\textbf{+MTL+IKT}_{\textbf{iter=2}}\textbf{+KD}$ not only outperforms $\textbf{Base}_{\textbf{small}}\textbf{+MTL}$ in all language pairs but also outperforms our large baseline model $\textbf{Base}_{\textbf{large}}$ in 4 out of 7 language pair settings with less than half the number of model parameters.

Table 3 compares performance between the organizer's baseline model and two of our submitted systems. We submit two systems: $\textbf{Base}_{\textbf{large}}\textbf{+MTL+IKT}$ and $\textbf{Base}_{\textbf{large}}\textbf{+MTL+IKT+KD}$. Systems can be evaluated on two ranking schemes: `R1` indicates overall ranking[4] which considers both model performance and size, while `R2`[5] ranks systems based only on model performance. As shown

[4]Overall ranking is computed by taking the average of individual ranks of the following metrics: Pearson's correlation coefficient, root mean square error, mean absolute error, disk space without compression and number of parameters.

[5]Ranking scheme based on Pearson's correlation coefficient

	+ IKT (§3.4)		+ KD (§3.5)		Organizer's

Table 4: Changes in performance on the `Test21` blind set when transitioning from `+IKT` (before compression) to `+KD` (after compression). `Supervised` indicates 7 language pairs that are provided in `Train`, `Dev` and `Test20`; `Zero-shot` indicates 4 zero-shot language pairs that are only evaluated with `Test21` blind set. Δ `metric` (row 1 to 3) measures the change in performance; % Δ `metric` (row 4 to 6) measures the percentage change.

in Table 3, when ranking systems based purely on performance (`R2`), **Base$_{\text{large}}$+MTL+IKT** performs strongly. However, when systems are ranked based on both performance and size (`R1`), our compressed model **Base$_{\text{large}}$+MTL+IKT+KD** ranks very competitively. Moreover, our compressed model outperforms the organizer's baseline in all language pair settings with a great margin using approximately 5.7% more parameters.

We observe in Table 3 that our compressed model is relatively less competitive under zero-shot than in supervised settings when ranked based on `R1`. As demonstrated in Table 4, model compression causes performance degradation in all language pairs with respect to all three performance metrics. In particular, the amount of degradation in terms of Pearson's correlation coefficient is greater under zero-shot than in supervised settings. Interestingly, this trend does not apply to other performance metrics (RMSE, MAE) where the amount of degradation under zero-shot and supervised settings is not significantly different. This indicates that model compression degrades the strength of correlation particularly more under zero-shot than in supervised settings, while degradation in performance measured by magnitude of error is not significantly different between two settings.

6 Conclusions

In this paper, we describe our submission to the WMT 2021 Quality Estimation `Task 1: Sentence-level Direct Assessment`. We introduce a QE model architecture trained with multi-task objective and show improvements in performance. We show that iterative knowledge transfer techniques applied in QE tasks can further

improve model's performance and demonstrate that knowledge distillation is effective for building a competitive lighter-weight QE model, making it more suitable for practical use. Although our submitted systems show strong performance in general, we observe that our compressed model becomes relatively less competitive under zero-shot settings. Further analysis of this phenomenon and improvements on zero-shot are challenges that we need to overcome in future work.

Abstract

This paper presents the NICT Kyoto submission for the WMT'21 Quality Estimation (QE) Critical Error Detection shared task (Task 3). Our approach relies mainly on QE model pretraining for which we used 11 language pairs, three sentence-level and three word-level translation quality metrics. Starting from an XLM-R checkpoint, we perform continued training by modifying the learning objective, switching from masked language modeling to QE oriented signals, before finetuning and ensembling the models. Results obtained on the test set in terms of correlation coefficient and F-score show that automatic metrics and synthetic data perform well for pretraining, with our submissions ranked first for two out of four language pairs. A deeper look at the impact of each metric on the downstream task indicates higher performance for token oriented metrics, while an ablation study emphasizes the usefulness of conducting both self-supervised and QE pretraining.

1 Introduction

This paper describes the NICT Kyoto submission to the WMT'21 Quality Estimation (QE) shared task. We participated in Task 3 "Critical Error Detection" involving four language pairs, namely English–Chinese, English–Czech, English–Japanese and English–German. A critical error is defined as a translation error falling into one of the following five categories: toxicity, health or safety risk, named entity, sentiment polarity and number or unit deviation.[1]

The objective of the task is to classify a sequence pair, composed of a sentence in the source language and its automatic translation in the target language, in a binary fashion whether it contains or not at least one of the five types of critical errors. This task differs from the other QE tasks as not all translation errors should be detected but only critical ones. Labels were produced by majority vote over three annotators for each pair leading to two possible classes: *ERR* (or class 1) when at least one critical error is spotted and *NO* (or class 0) when no critical errors are present.

Our approach relies mainly on QE model pretraining leveraging a large amount of synthetic data produced using parallel corpora and MT systems. Because annotating translations for critical error is costly, we propose to pretrain a model on translation quality scores computed with automatic metrics. To capture multiple translation error granularities during pretraining, we employ multiple metrics and evaluate their performance individually on the downstream task. Additionally, we pretrain the QE model jointly on all WMT QE shared tasks language pairs as a data augmentation method. Transfer learning is then conducted for each language pair by finetuning the pretrained model on the downstream task with the officially released training data annotated with critical errors.

The remainder of this paper is organized as follows. In Section 2, we introduce our approach involving multimetric and multilingual pretraining. In Section 3, the data, tools and training procedure are presented, followed by the experimental results and their analysis in Section 4, before the conclusion in Section 5.

2 Multimetric & Multilingual Pretraining

Multilingual pretrained masked language models (LMs) were shown to perform well in several downstream natural language processing tasks (Devlin et al., 2019; Conneau et al., 2020; Liu et al., 2020). Starting from an XLM-R checkpoint (Conneau et al., 2020), we performed continued (or intermediate) training (Phang et al., 2018; Rubino and Sumita, 2020) with large amount of automatically

[1] More details about these categories and the task itself can be found here: http://statmt.org/wmt21/quality-estimation-task.html

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 941–947
November 10–11, 2021.

translated source language texts (thereafter called *synthetic data*), replacing the masked LM objective with QE oriented ones. Because XLM-R is multilingual and all languages in this model share a common vocabulary of sub-words, we decided to conduct QE pretraining on the 11 language pairs from all subtasks of WMT'21 QE. These language pairs all share English, whether on the source or target side, and this method can be seen as a data augmentation approach to increase vocabulary coverage.

The objective of QE Task 3 is to classify sentence pairs in a binary fashion. Formally, given a source sequence s and its translation t, we want to learn a function f: $f_\theta(s,t) \rightarrow y$ where $y \in \{0,1\}$ is the class associated with the sequence pair (s,t) and θ represents the model parameters. While fine-tuning a pretrained model on the official QE task 3 data allows us to directly learn model parameters approximating y given (s,t), we do not have such classes for synthetic data. We decided to use MT automatic metric scores as objective instead, assuming that critical error classes could correlate with translation quality scores at least in extreme cases (e.g. no translation errors also means no critical errors).

Several automatic metrics are used by the research community to evaluate the performance of MT systems by measuring translation accuracy against a human-produced reference at different granularity levels. We opted for metrics capturing quality information at the character (chrF (Popović, 2017)), token (TER (Snover et al., 2006)) and token n-gram (BLEU (Papineni et al., 2002)) levels. For the latter, the smoothed sentence-level BLEU was chosen (Chen and Cherry, 2014). In addition to sentence-level metrics, token-level binary tags were also extracted following the usual procedure to determine post-editing effort (Specia et al., 2020).[2]

To allow for sentence-level QE predictions, we added a feed-forward layer on top of XLM-R for each of the three metrics employed without parameter sharing, following:

$$\hat{y}_s = \tanh\left(\phi(h)W_{s1} + b_{s1}\right)W_{s2} + b_{s2} \quad (1)$$

where $\hat{y}_s \in \mathbb{R}^1$ is the sentence-level score, $W_{s1} \in \mathbb{R}^{d\times d}$, $b_{s1} \in \mathbb{R}^d$, $W_{s2} \in \mathbb{R}^{d\times 1}$ and $b_{s2} \in \mathbb{R}^1$ are parameters of the model with dimensionality $d = 1,024$, ϕ is a pooling function and $h \in \mathbb{R}^{n\times d}$ is the set of contextual embeddings corresponding to the n tokens in (s,t). The pooling function is the *class* token added at the beginning of each input sequence. For token-level predictions, we used a linear transformation from contextual embeddings to two-dimensional output (for binary token-level classes): $\hat{y}_t = \text{softmax}\left(hW_t + b_t\right)$, with $\hat{y}_t \in \mathbb{R}^{n\times 2}$ are token-level scores, $W_t \in \mathbb{R}^{d\times 2}$ and $b_t \in \mathbb{R}^2$ are the parameter matrix and bias. Parameters of the model are learned with mini-batch stochastic gradient descent based on losses computed for sentence-level and token-level predictions. For the former loss, we used mean squared error, while cross-entropy was used for the latter. All losses are linearly summed with equal weights before back-propagation. The parameters of the classification and regression heads are optimized along with XLM-R.

3 Data and Tools

This section presents the data used in our experiments, including the synthetic data produced for pretraining and the official QE task 3 corpora, along with the tools required to train our models and the procedure employed for both pretraining and fine-tuning.

3.1 Datasets

In order to gather as much data as possible for many language pairs, we collected all parallel data from the QE shared tasks (from all subtasks). Additionally, we retrieved parallel data from the WMT news translation task (Barrault et al., 2020) and from OPUS (Tiedemann, 2016).[3] The source side of these parallel corpora was translated using publicly available neural MT models based on the Transformer architecture (Vaswani et al., 2017). For Estonian–English (et–en), Nepalese-English (ne–en), Romanian–English (ro–en), Russian–English (ru–en), Sinhala–English (si–en), English–German (en–de) and English–Chinese (en–zh), we used the MT systems made available by the shared task organizers,[4] while for English–Czech (en–cs), English–Japanese (en–ja), Khmer–English (km–en) and Pashto–English (ps–en), we used the mBART50

[2]Scripts and procedure available at https://github.com/deep-spin/qe-corpus-builder

[3]The corpora from OPUS used in our experiments are: Common Crawl, ParaCrawl, OpenSubtitles, DGT, IWSLT, KFTT and XLEnt.

model (Liu et al., 2020; Tang et al., 2020).[5]

Statistics about the synthetic corpora after translation are presented in Table 1, along with the official QE data for Task 3 released by the shared task organizers. After deduplicating and cleaning the synthetic corpora produced to conduct QE pretraining, the total amount of data reached 72.3M triplets (source, translation and reference sentences).

3.2 Tools

Data preprocessing was conducted using the tokenizer and truecaser from the Moses distribution (Koehn et al., 2007), except for Chinese, Japanese, Nepalese and Sinhala, for which the tokenization was conducted using *jieba*,[6] *KyTea*[7] and FLORES (Goyal et al., 2021) respectively.

To compute the sentence-level and token-level scores, we used automatic metrics implementations available in the tools *SacreBLEU* (Post, 2018) for BLEU and chrF and *tercom* (Snover et al., 2006) for TER and token-level classes.

The XLM-R checkpoint used was the *xlm-roberta-large* from HuggingFace Transformers library (Wolf et al., 2020). We used in-house Pytorch (Paszke et al., 2019) code and V100 GPUs hardware for QE pretraining and finetuning, 8 GPUs for the former step and 1 GPU for the latter.

3.3 Training Procedure

Model pretraining on synthetic data was conducted for one epoch (approx. 500k updates) with batches of 128 source and target sequences for a total training time of 3 days. The AdamW optimizer (Loshchilov and Hutter, 2019) was used with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and $\epsilon = 1 \times 10^{-6}$, while the weight decay was set to 0. A linear learning rate warmup was used during the first 50k updates to reach a maximum value of 5×10^{-6}, which remained without decay until the end of the first epoch. The dropout rates were set to 0.1 for both the embeddings and the transformer blocks (feed-forward and attention layers). A total of four models were pretrained with different random seeds before being finetuned on the official QE Task 3 data.

To conduct finetuning, we added a classification layer on top of XLM-R following:

$$\hat{y}_e = \text{softmax}(\tanh(\phi(h)W_{e1} + b_{e1})W_{e2} + b_{e2}) \quad (2)$$

where $\hat{y}_e \in \mathbb{R}^2$ is the sentence-level probability distribution over the two classes, $W_{e1} \in \mathbb{R}^{d \times d}$, $b_{e1} \in \mathbb{R}^d$, $W_{e2} \in \mathbb{R}^{d \times 2}$ and $b_{e2} \in \mathbb{R}^2$ are parameters of the model with $d = 1,024$. The pooling function ϕ is the same as the one employed during pretraining presented in Section 2. Due to the class imbalance of the critical error dataset, we used the weighted cross-entropy loss function to finetune our models. The weight given to the error class (the least populated) was tuned on the validation set in a grid-search manner, with integer values ranging from 1 to 8.

During finetuning, which lasted 40 minutes per model, we used the validation set to select the best performing models according to the Matthews correlation coefficient (MCC), which is the main metric chosen by the shared task organizers for the final evaluation. One model per seed was selected and a total of four models were ensembled to produce our final submission to the shared task.

4 Results and Analysis

We present in this section the main results obtained on the official shared task test set as reported by the organizers, followed by an analysis with ablation study and various pretraining objectives.

4.1 Shared Task Results

The official results reported by the shared task organizers are presented in Table 2. We compare our final ensemble results, obtained with four models trained on different seeds, to our baseline, obtained with a single model. We also include the official baseline provided by the shared task organizers. All our submissions outperform the official baseline and our ensembles reach the highest performance according to the correlation score and F-measure. One exception, however, is for the English–Japanese language pair. Despite several attempts to improve our ensembling method for this pair, we could not improve over our baseline.

A comparison with other shared task participants in terms of MCC and F1 scores shows that our submissions were ranked first for English–Czech and English–German, third for English–Chinese and sixth for English–Japanese. We assume that the smaller amount of synthetic data, as well as a possible preprocessing mismatch between the official data and our synthetically generated corpora, could be the reason behind the low performance of the two latter language pairs. More precisely, the data preprocessing pipeline for English, German and Czech are commonly based on the Moses tokenizer and truecaser, and it is possible to infer the parameters used with these tools by looking at the official training data released for the task. For Chinese and Japanese, however, due to the lack of details given by the shared task organizers, it was not possible to use the same preprocessing tools and parameters with certainty.

4.2 Impact of Pretraining Steps

While our approach relied on a two-step process, QE pretraining on synthetic data followed by finetuning on the task specific training set, we still made use of a pretrained XLM-R model by initiating QE pretraining from a checkpoint. Overall, three steps are thus required to obtain the results presented in Table 2. XLM-R and QE pretraining, as well as producing synthetic data, are the most computationally expensive steps, whereas finetuning is relatively cheap to perform due to the small amount of task specific data. Therefore, we performed an ablation study aiming at evaluating the impact of each pretraining step and ran two sets of experiments following the same experimental setup employed for our main submission to the shared task.

For the first set of experiments, no pretraining of XLM-R was conducted, meaning that we did not start QE pretraining from an existing checkpoint, but instead randomly initialized XLM-R parameters and ran QE pretraining *from scratch* (this setup is noted *No Checkpoint*). For the second set of

Table 4: Results obtained on the WMT'21 QE Task 3 "Critical Error Detection" validation set with single models (no ensemble) based on various learning objectives used during pretraining. Results in bold indicate the best MCC scores among the pretraining configurations for a given language pair.

experiments, we finetuned the XLM-R checkpoint directly on the task specific data, without conducting QE pretraining. This alleviates the need to produce large amount of synthetic QE data (this setup is noted *No QE Pretraining*). We conducted an additional set of experiments based on XLM-R and QE pretraining without finetuning on the official training set but the obtained results were subpar compared to the baseline, due to the randomly initialized parameters of the classification layer (see eq. (2)) which was not tuned for the task following this configuration. We present the results of the two ablation experiments in Table 3.

While combining both the use of a pretrained XLM-R with masked LM and QE pretraining on synthetic data leads to the best results on the four language pairs, *No QE Pretraining* performs better than the *No Checkpoint* configuration. These results emphasize the usefulness of large self-supervised LM pretraining. The amount of data used for QE pretraining is smaller compared to the large quantity of monolingual and parallel data used to train *xlm-roberta-large*, which could be an explanation for the difference in downstream performances according to the MCC and F1 metrics.

4.3 Impact of Pretraining Objectives

As an additional analysis, we propose to evaluate the impact of different metrics used as pretraining objectives on the downstream critical error detection task. Several independent QE pretraining were conducted for this purpose: one for each sentence-level translation quality metrics, one for the combination of sentence-level metrics and finally one for word-level metrics which includes source, target and gap error predictions as described in Section 2. The finetuning step for each pretrained model is identical, only the learning objective during pretraining differs. The results obtained on the validation set for the critical error detection task are presented in Table 4.

Based on MCC scores, using sentence-level metrics during pretraining is not leading to the best downstream performance compared to using word-level metrics or combining both sentence and word-level quality indicators. From the three sentence-level metrics used as learning objectives during pretraining, TER and BLEU outperform chrF. For English–German and English–Chinese, using word-level metrics outperforms the combination of all metrics, while it is the opposite for English–Czech and English–Japanese. These results show that the optimal quality indicator for QE pretraining depends on the language pair and the translation direction, and should therefore be considered as a hyper-parameter to be optimized. However, due to the costly nature of large model pretraining, combining multiple translation quality indicators in a multi-task learning fashion appears to be an efficient solution, in addition to using masked LM pretrained model as shown in the results presented in Section 4.2.

5 Conclusion

This paper presented the NICT Kyoto submission for the WMT'21 QE Task 3 "Critical Error Detection". Our submissions were ranked first for two out of four language pairs. Our approach relies mainly on model pretraining with large amount of

synthetic data, followed by finetuning on the official data released for the shared task. We proposed a novel QE pretraining approach which allows for a multimetric learning objective based on relatively cheap to compute MT automatic metrics. An analysis of each automatic metric used during QE pretraining shows the complementarity of metrics both at level of sentences and words. The ablation study emphasized the usefulness of both self-supervised and QE pretraining. Future work focuses on exploring additional metrics and their performance on various downstream QE tasks.

Abstract

Quality Estimation, as a crucial step of quality control for machine translation, has been explored for years. The goal is to investigate automatic methods for estimating the quality of machine translation results without reference translations. In this year's WMT QE shared task, we utilize the large-scale XLM-Roberta pre-trained model and additionally propose several useful features to evaluate the uncertainty of the translations to build our QE system, named *QEMind*. The system has been applied to the sentence-level scoring task of Direct Assessment and the binary score prediction task of Critical Error Detection. In this paper, we present our submissions to the WMT 2021 QE shared task and an extensive set of experimental results have shown us that our multilingual systems outperform the best system in the Direct Assessment QE task of WMT 2020.

1 Introduction

Quality estimation (QE) aims to predict the quality of a machine translation (MT) system's output without any access to ground-truth translation references or human intervention (Blatz et al., 2004; Specia et al., 2009, 2018). Automatic methods for QE are highly appreciated in MT applications when we expect to efficiently obtain the quality indications for a larget amount of machine translation outputs in a short time, or even at run-time. This paper describes Alibaba's submissions to the WMT 2021 Quality Estimation Shared Task. We developed a novel QE system, called QEMind, that have been applied to two tasks this year, the sentence-level direct assessment (DA) and binary score prediction of Critical Error Detection (CED).

Common approaches in the previous years heavily focus on human-crafted rule-based feature engineering mode such as QuEst++ (Specia et al., 2015).

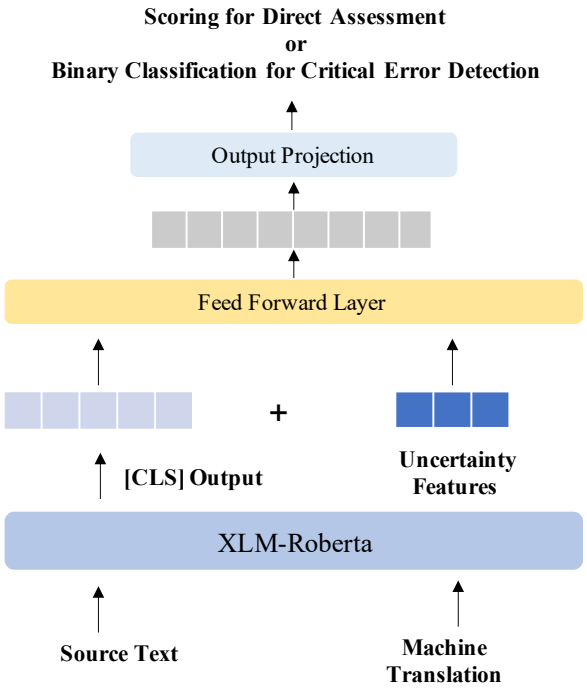

Figure 1: Structure of the uncertainty quantification feature-enhanced model.

The features extracted are usually fed into traditional machine learning algorithms such as a support vector regression for the sentence-level scoring or a sequence-labeling model with conditional random fields for the word-level labeling respectively. With the development of neural networks applied in machine translation and other NLP tasks, a neural predictor-estimator framework for QE was proposed and achieved better results in WMT 2017 and WMT 2018 QE shared tasks (Fan et al., 2019; Kim et al., 2017). This framework extensively requires a pre-training procedure with a large amount of parallel corpora in the predictor mode and stacks a downstream estimator mode with additional layers for a supervised regression or classification task. Since 2019, state-of-the-art (SOTA) QE systems (Kepler et al., 2019; Ranasinghe et al., 2020) have

* indicates equal contribution.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 948–954
November 10–11, 2021.

hit record high with transfer learning by leveraging SOTA pre-trained NLP neural network models, for example, mBERT (Pires et al., 2019) and XLM-Roberta (Conneau et al., 2019). Till then, only "black-box" QE methods had been mainly used in WMT QE shared tasks.

Furthermore, with the accessibility to the NMT systems, some "glass-box" QE features have been explored and verified to bring improvements upon "black-box" approaches (Moura et al., 2020). In addition, Fomicheva et al. (2020) have showed that useful information that are extracted from the MT systems performs good correlation with human judgements of quality. Inspired by these works, we propose more useful features in this paper, among which, some are derived from the NMT systems and others are created via utilizing the masked language model of XLM. We develop our QE systems by incorporating all the features that can potentially evaluate the uncertainty of the machine translations into a supervised QE model based on the transfer learning from XLM-Roberta. We evaluate our method on the Direct Assessment QE tasks of WMT 2020 and WMT 2021 and our experiment results demonstrate the efficiency and versatility of the features we have proposed on the quality estimation in different language pairs.

2 Task & Data Set

We participate the sentence-level Direct Assessment task and Critical Error Detection tasks of this year's QE shared task. (1) For the DA task, we merge 7000 and 1000 labeled data in the training and development data sets as our training set and treat the test20 data set as our development set for each of the seven language pairs. However, for the four zero-shot language pairs, we only have the blind test sets. (2) For the CED task, we observed that the distributions of two classes, NOT and ERR, are extremely unbalanced for all four language pairs. Therefore, we simply up-sample the samples with ERR labels to get a relatively balanced training set. This strategy of data augmentation has also been empirically verified to be valid.

3 Methodology

In this section, we provide a complete view of our uncertainty feature enhanced approach, including:

(1) The overall framework of QEMind is carried out in Section 3.1: how uncertainty features are combined with a pre-trained multilingual language model to enhance transfer learning;

(2) Uncertainty features used in QEMind are described in Section 3.2: how uncertainty features are defined and extracted for translation quality estimation;

(3) Strategies we applied in the WMT QE shared task to further improve the system's performance, such as data augmentation and model ensemble, are explained in Section 3.3.

3.1 QEMind Framework

QEMind follows the general transfer learning procedure while allowing extra meta features to enhance the model. We concatenate the source text and machine translation and feed them into the pre-trained XLM-Roberta model to get the output representation of the special [CLS] token. Afterwards, the output representation is combined with the normalized uncertainty features described in Section 3.2. They are fed into a simple linear regression/classification layer to predict the continuous or binary quality score. The architecture of our feature enhanced model is shown in Figure 1. This model is equivalent to TransQuest's (Ranasinghe et al., 2020) when no extra feature is used. Considering the size of the training set is small, we have not added extra parameters, such as bottleneck adapter layers used in Moura et al. (2020), to fuse uncertainty features and the output from XLM-Roberta.

3.2 Uncertainty Features

Fomicheva et al. (2020) proposed several "glass-box" features extracted from the NMT model. Estimating translation quality with these features achieves state-of-the-art results as an unsupervised approach. However, the performances of this approach are still far below those of the supervised model from transfer learning (Ranasinghe et al., 2020). Moura et al. (2020) combined limited "glass-box" features with the hidden state of a bottle-neck adapter layer attached on the output from the XLM-Robert, and the results indicate that these features can bring slight but significant improvements to the transfer learning model. Wang et al. (2021) proposed more unsupervised "glass-box" and "black-box" QE features and investigated further on the contributions of each one to the QE model's performance via a feature-enhanced supervised model.

Inspired by their work, we explored deeply in the aspect of uncertainty quantification to obtain uncertainty features in this section to enhance the transfer learning model. First, we extend "glass-box" features in Fomicheva et al. (2020) to the *Decoding Probability Features* and the *Monte Carlo Dropout Features*. And then, the *Noised Data Features* are proposed similar to the *Monte Carlo Dropout Features*.

Decoding Probability Features. For autoregressive sequence generating models like Transformers (Vaswani et al., 2017), the decoding probability at each step can be extracted from the softmax layer directly in a "glass-box" setting:

$$P_{step}^{(\mathbf{x},t,\theta)} = \log P(y_t|\mathbf{y}_{<t}, \mathbf{x}, \theta) \tag{1}$$

where $\mathbf{x}$ represents the input source text and $\mathbf{y}$ is the output machine translation. P_{step} is a probability sequence with the same length of the generated sequence $\mathbf{y}$. Three statistical indicators of P_{step} can be used to estimate the uncertainty of the output: expectation, standard deviation, and the combined ratio of them:

$$\mathbb{E}(P_{step}|\mathbf{x}, \theta) = \frac{1}{T}\sum_{t=1}^{T} P_{step}^{(\mathbf{x},t,\theta)} \tag{2}$$

$$\begin{aligned}&\sigma(P_{step}|\mathbf{x}, \theta)\\ =&\sqrt{\mathbb{E}(P_{step}^2|\mathbf{x}, \theta) - \mathbb{E}^2(P_{step}|\mathbf{x}, \theta)}\end{aligned} \tag{3}$$

$$Combo(P_{step}|\mathbf{x}, \theta) = \frac{\mathbb{E}(P_{step}|\mathbf{x}, \theta)}{\sigma(P_{step}|\mathbf{x}, \theta)} \tag{4}$$

Intuitively, larger expectation, smaller deviation and larger combined ratio of P_{step} indicate lower uncertainty and higher quality. P_{step} is an extended version of the TP feature in Fomicheva et al. (2020) and the expectation of P_{step} is the same as TP.

Monte Carlo Dropout Features. Monte Carlo (MC) Dropout sampling, that has been exploited in Gal and Ghahramani (2016), is an efficient "glass-box" approach to estimate uncertainty. It enables random dropout on neural networks during inference and the predictive probabilities through different sampling paths are used to obtain measures of uncertainty (Fomicheva et al., 2020). The output sequences $\hat{\mathbf{y}}$ sampled across stochastic forward-passes by MC dropout with different sampled model parameters $\hat{\theta}$ can be different as well. If $\mathbf{y}$ is a high-quality output with low uncertainty, the Monte Carlo sampled outputs $\hat{\mathbf{y}}$ should be close to $\mathbf{y}$ and the variance of $\hat{\mathbf{y}}$ should be low. Hence, two measurements of sampling based on text similarity are carried out here:

$$MC\text{-}Sim = Sim(\mathbf{y}, \hat{\mathbf{y}}_i) \tag{5}$$

$$MC\text{-}Sim\text{-}Inner = \frac{1}{N}\sum_{j=1}^{N} Sim(\hat{\mathbf{y}}_i, \hat{\mathbf{y}}_j) \tag{6}$$

where $\hat{\mathbf{y}}_i$ is the i-th sample of $\hat{\mathbf{y}}$, and $1 \leq i \leq N$. For the similarity score function, as in Fomicheva et al. (2020), Meteor metric (Denkowski and Lavie, 2014) is applied. Besides, as a sentence-level probability score, $\mathbb{E}(P_{step})$ can also be calculated with different model parameters $\hat{\theta}$ by MC dropout sampling:

$$MC\text{-}P_{step} = \mathbb{E}(P_{step}|\mathbf{x}, \hat{\theta}) \tag{7}$$

The expectation, standard deviation, and combined ratio of $MC\text{-}Sim$, $MC\text{-}Sim\text{-}Inner$ and $MC\text{-}P_{step}$ are calculated over all MC dropout samples and will be used as "glass-box" uncertainty features. Among them, $\mathbb{E}(MC\text{-}P_{step})$, $\sigma(MC\text{-}P_{step})$, $Combo(MC\text{-}P_{step})$, and $\mathbb{E}(MC\text{-}Sim\text{-}Inner)$ are equivalent to $D\text{-}TP$, $D\text{-}Var$, $D\text{-}Combo$, and $D\text{-}Lex\text{-}Sim$ in Fomicheva et al. (2020)

Noised Data Features. Monte Carlo Dropout approaches mentioned above can be regarded as a robustness test of the NMT model. Due to its validity in Fomicheva et al. (2020), it is rational to believe that a similar way with appropriate noise in the input of MT may perform comparably. Therefore, we define the following uncertainty features similar to $MC\text{-}Sim$, $MC\text{-}Sim\text{-}Inner$ and $MC\text{-}P_{step}$. The differences are: (1) the NMT model weights are fixed θ without MC dropout sampling; (2) the model decodes translations $\tilde{\mathbf{y}}$ with a noised input $\tilde{\mathbf{x}}$.

$$Noise\text{-}Sim = Sim(\mathbf{y}, \tilde{\mathbf{y}}_i) \tag{8}$$

$$Noise\text{-}Sim\text{-}Inner = \frac{1}{N}\sum_{j=1}^{N} Sim(\tilde{\mathbf{y}}_i, \tilde{\mathbf{y}}_j) \tag{9}$$

$$Noise\text{-}P_{step} = \mathbb{E}(P_{step}|\tilde{\mathbf{x}}, \theta) \tag{10}$$

One crucial point in designing this type of features is how to generate noised input $\tilde{\mathbf{x}}$. One solution is

Algorithm 1 Generate Noise Input with "Post-Editing"

Require: input $\mathbf{x} = \{x_t | t = 1, 2, ..., T\}$, hyper-parameters R, p_i, p_d.

1: Initialize $\mathbf{x}_{mask} = \mathbf{x}$
2: **for** $r = 1, ..., R$ **do**
3: $\mathbf{x}_{mask}$ = randomly delete tokens from $\mathbf{x}_{mask}$ with probability p_d
4: $\mathbf{x}_{mask}$ = randomly insert special <*mask*> tokens into $\mathbf{x}_{mask}$ with probability p_i
5: **end for**
6: $\tilde{\mathbf{x}} = MLM(\mathbf{x}_{mask})$, where MLM is a pre-trained masked language model.
7: **return** $\tilde{\mathbf{x}}$

a "black-box" way that takes the advantage of the masking strategy of the pre-trained XLM-Roberta. Basically, we can mask some words in the source text and get a noised source text by the predictions from the pre-trained model in the masked positions. This simple approach only conducts substitutions on $\mathbf{x}$ with the [mask] token, but it limits the diversity of the noised sample inputs. To enrich the variety of $\mathbf{x}$, we adjust the imitation learning algorithm in Wang et al. (2020) to a simplified version to obtain noised input $\tilde{\mathbf{x}}$. We "post-edit" the input $\mathbf{x}$ by randomly deleting tokens and inserting masks for several rounds to get $\mathbf{x}_{mask}$. Then, the pre-trained XLM-R is used as a masked language model to predict the tokens in the masked positions of $\mathbf{x}_{mask}$ to get the post-edited $\tilde{\mathbf{x}}$. Pseudo codes of this "post-editing" algorithm is provided in Algorithm 1.

3.3 Strategies

Multilingual Training. Considering zero-shot language pairs in the DA task, we mix up all seven language pairs' training data to fine-tune the XLM-Roberta model and predict on the whole test set including zero-shot language pairs. We have tried two different ways of mixing up training data from different language pairs to fine-tune XLM-Roberta: (1) source sentence + translation sentence; (2) English sentence + non-English sentence. Our experimental results demonstrate that multilingual models usually perform better than bilingual models trained on a single language pair, but there is no prominent difference in performance of the two different multilingual strategies. We keep both multilingual models and bilingual models for model ensemble.

Data Augmentation. Two data augmentation strategies are applied for the CED task. First, considering the imbalance between positive and negative samples in the CED dataset, we up-sample the data with*ERR* labels in each language pair to obtain a balanced dataset. Secondly, inspired by examples provided by the organizer, we have also tried to replace the original machine translation with a back-translated sentence and hope that the gap between the source sentence and the back-translated sentence can provide insights of the detection of potential critical errors. The back translations come from the released ML50 multilingual translation model (Tang et al., 2020).

Model Ensemble. For the DA task, models trained with different multilingual strategies and different uncertainty features are ensembled by averaging predicted scores. While for the CED task, we average classification probability outputs from models trained with different data augmentation strategies and uncertainty features to obtain ensemble results. We apply a greedy ensemble strategy. First, all models are sorted by their performance on the development sets. Then, upon the best single model, we take one more model into the ensemble at each step until there is no more performance gain on the development sets or the maximum step is reached. We set the maximum step to avoid overfitting on the development sets.

4 Experiments

4.1 Model Settings

We follow the model settings of Transquest (Ranasinghe et al., 2020) to fine-tune our QE model based on the XLM-Roberta large model with a classification/regression head on a single P100 GPU. The training batch size is set to 8 and the training process takes about 2 hours to convergence. For the DA task, the total number of parameters of QE-Mind with uncertainty features is 560981507; if no uncertainty features are used, it is 560941571. And for the CED task, the numbers of parameters with and without uncertainty features are 560982532 and 560942596 respectively.

4.2 Experiments of DA task

We conduct all experiments and evaluate our model on last year's test sets to optimize model configurations for each language pair. In particular, the model performed best on all seven language pairs in average is selected to generate submissions for

Model	High-Resource		Mid-Resource			Low-Resource

Table 5: Matthews correlation results of WMT 2021 CED task on test sets

zero-shot language pairs.

The Pearson's correlations between our model's predictions and the human DA judges (z-standardized mean DA score) are shown in Table 1. *TransQuest Single* and *TransQuest Ensemble* are the best single and ensemble models of Ranasinghe et al. (2020), which is the winner system of last year's DA task. *QEMind-Bi* and *QEMind-Multi* are models without uncertainty features, between which, the difference is that the model is trained on bilingual data or mixed multilingual data. *QEMind-Multi + UNC* is the complete QEMind model enhanced by various uncertainty features described in Section 3.2. Finally, predictions from bilingual models, multilingual models, and uncertainty features enhanced models are ensembled following Section 3.3, marked as *QEMind Ensemble* in the table.

Results on the DA test sets of WMT 2020 show that: (1) multilingual strategies work well on this task, especially for high-resource language pairs; (2) the uncertainty features enhanced multilingual model achieves the highest performance among all single models, which verifies that these uncertainty features are useful to all language pairs and can be fused in multilingual models. (3) ensemble of multiple models of different settings can further improve the performance of QEMind systems.

We pick the best single and ensemble models

for each language pair and produce predictions on the newly released blind test sets of WMT 2021, including the 4 zero-shot language pairs. Results of Pearson's correlations are shown in Table 2 and Table 3.

4.3 Experiments of CED task

We test different strategies and uncertainty features on the CED development sets. Brief results of Matthews correlations (MCC) on development sets are shown in Table 4. All models are trained on up-sampled training data of each language pair. From the results observations, compared to *QEMind*, which only applies up-sampling on the training data, the strategies of back-translation (*QEMind + BK*) and uncertainty features (*QEMind + UNC*) can achieve comparable or better performances. The ensemble of all these models makes a significant improvement. Similar to the DA task, the best single and ensemble models are picked to generate our final submissions. Results on test sets of this year are listed in Table 5.

5 Conclusion

This paper introduces our machine translation quality estimation model, QEMind, for the sentence-level Direct Assessment and Critical Error Detection tasks of WMT 2021. We propose novel features to estimate the uncertainty of machine translations and incorporate them into the transfer learning from the large-scale pre-trained model, XLM-Roberta. Besides, three important strategies are particularly utilized for improving the QE system's performance such as multilingual training, data augmentation and model ensemble. Our system has achieved the first ranking in average Pearson correlation across all languages, including the zero-shot ones in the multilingual DA task of WMT 2021.

Direct Exploitation of Attention Weights for Translation Quality Estimation

Abstract

The paper presents our submission to the WMT2021 Shared Task on Quality Estimation (QE)[1]. We participate in sentence-level predictions of human judgments (Task 1) and post-editing effort (Task 2). We propose a glass-box approach based on attention weights extracted from machine translation systems. In contrast to the previous works, we directly explore attention weight matrices without replacing them with general metrics (like entropy). We show that some of our models can be trained with a small amount of a high-cost labelled data. In the absence of training data our approach still demonstrates a moderate linear correlation, when trained with synthetic data.

1 Introduction

Quality Estimation (QE, Blatz et al., 2004; Specia et al., 2009) is an essential part of the machine translation (MT) pipeline, which estimates the quality of the translation output without relying on any reference.

Unlike the previous year, three QE sentence-level tasks were presented in the WMT2021 Shared Task (Specia et al., 2021). The goal of Task 1 is to predict direct assessments (DA), i.e. human judgments of translation quality (Graham et al., 2015), whereas in Task 2, the task is to estimate the post-editing effort required to obtain a correct translation which is measured by the HTER metric (Snover et al., 2006). The goal of Task 3 is to determine if the translation output contains at least one critical error.

We propose a lightweight glass-box approach that can be applied to Task 1 and Task 2. The approach is based on using the encoder-decoder attention weight matrices as input features for supervised translation quality estimation. Next we describe our approach (Section 2) and evaluate it experimentally (Sections 3–5).

2 Approach

There are several QE models based on attention weights of neural MT systems described earlier (Yankovskaya et al., 2018; Fomicheva et al., 2020a,b). Their main idea is to compute the entropy of encoder-decoder attention weights for each target token and then average these entropies to get a sentence-level metric:

$$Entropy = -\frac{1}{I}\sum_{i=1}^{I}\sum_{j=1}^{J}\alpha_{ji}\log\alpha_{ji},$$

where α represents attention weights, I is the number of target tokens and J is the number of source tokens.

Yankovskaya et al. (2018) work with attention weights extracted from LSTM (Hochreiter and Schmidhuber, 1997) MT systems. As LSTM has only one attention matrix, the approach of computing entropies is straightforward. However, neural MT models based on Transformer (Vaswani et al., 2017) have several layers and heads, so the number of computed entropies equals [Layers $\times$ Heads] for each sentence, which introduces some difficulties in this approach. To overcome it, Fomicheva et al. (2020a) summarise entropies by taking the average or minimum value to get an unsupervised attention-based QE metric. Fomicheva et al. (2020b) use the obtained entropies as features of regression models.

In this article, we propose another approach of using attention weights obtained from Transformer MT models: instead of summarising them into one metric, we feed all encoder-decoder attentions weights into a convolutional neural network (CNN) to get a QE score. We test the approach in a supervised setting, and also show that it can be applied in a zero-shot scenario when training data for the required language pair is not available.

3 Data

This year, three sentence-level tasks are available: predicting human judgments, post-editing effort and critical errors. In this work, we have focused on the first two tasks.

`Task 1` and `2` include eleven language pairs, seven of which have training (7 000 sentences), development (1 000 sentences) and two test sets (WMT2020 and WMT2021, 1 000 sentences each). For the other four languages only test sets (1 000 sentences) are available, which is called the zero-shot subtask. WMT2020 test set includes gold-labels whereas WMT2021 is the usual blind test without labels before submission.

To test our approach, we have focused on two language pairs with training data: English-German (En-De) and Estonian-English (Et-En), as well as one language pair without training data: English-Czech (En-Cz).

Besides data provided by the shared task organizers, we used additional parallel corpora to train CNN networks: the OpenSubtitles (Lison and Tiedemann, 2016), JRC Acquis (Steinberger et al., 2006), EuroParl (Koehn, 2005), DGT and EMEA (Tiedemann, 2012) corpora.

4 Settings

To compare the performance of our approach with CNN models to a previous baseline, we also ran experiments with models based on machine learning algorithms with entropies as input features (ML-Ent).

Below we present the experimental settings which we used for training ML-Ent and CNN models.

4.1 Machine Learning models with entropies as input features (ML-Ent)

There are two machine learning methods that we used. Random Forest (Ho, 1995) was chosen as a relatively easy and fast approach. We used the `sklearn`[2] library, set a randomized search on the hyperparameters and performed 5-fold cross-validation.

The second method is ensemble building based on (Caruana et al., 2004). The main idea behind the method is doing a greedy search over all trained models to find such models that would improve the ensemble's performance when added. We used the `mljar`[3] library, Random Forest and CatBoost (Prokhorenkova et al., 2018) algorithms, set Pearson as the evaluation metric and ran 5-fold cross-validation.

For both models and both tasks, we combined the proposed training and development sets (8 000 sentences in total) and used `[Heads × Layers]` (in our case 48) entropies for each translation as input.

4.2 CNN-based models

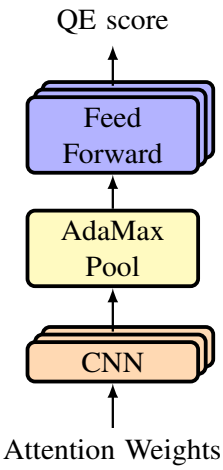

Figure 1: The proposed architecture of the QE model.

The base architecture of proposed CNN models is presented on Figure 1. The model's input is attention weights with shape (`[Heads × Layers]`, number of the source tokens, number of the target tokens). The number of `[Heads × Layers]`[4] is constant for all weights obtained from the same system, whereas the number of source and target tokens of each sentence can vary noticeably. To reduce the amount of padding added to each batch, we sort all sentences by the number of source/target tokens (max(src, tgt)) and only after that form a batch. Each CNN-based model consists of two or three CNN blocks, each of them comprises 2D-CNN, Batch Normalization, MaxPooling and Dropout Layers. We use `Relu` as the activation function. To handle the variable size of input batches, we use the Adaptive Max pooling layer. The last block of the model consists of three feed-forward layers. As a result, the model is trained to produce the desirable score: DA or HTER. We optimised our neural models with Adam (Kingma

and Ba, 2015).

`Task 1`**:** To predict DA scores, we considered three models with different training sets:

CNN-DA: we use human-labelled data provided by the shared task organizers: 7 000 for training set and 1 000 for development set;

CNN-BLEURT: we experiment with pre-training on synthetic data and for that we compute the BLEURT (Sellam et al., 2020) score for randomly chosen 300 000 sentences and use them as labels for training and development tests. We have chosen BLEURT to get artificial labels due to its good agreement with human judgments (Mathur et al., 2020);

CNN-BLEURT+: we fine-tune the model **CNN-BLEURT** on data provided by the organizers.

`Task 2` evaluates the proposed QE models for post-editing purposes.

CNN-HTER: we train a model with data provided by the shared task organizers;

CNN-HTERart: we use synthetically computed HTER between translation and reference. Though the preliminary experiments showed a poor performance compared to **CNN-HTER**, but this setting might be used in the absence of the human annotated training data.

5 Results

Below we present the obtained results and discuss the most interesting observations. To assess the performance of sentence-level QE models, Pearson correlation coefficient is used.

Table 1 shows results for the `Task 1`. For Et-En language pair, both CNN-BLEURT models show better results compared to ML-Ent models and CNN model trained only on DA score. For En-De, results are mixed. The CNN-DA model shows abysmal performance compared to both CNN-BLEURT and ML-Ent models. In contrast to Et-En, we can see that the performance of CNN-BLEURT and ML-Ent models is comparable.

Results for `zero-shot` En-Cs are not impressive (Table 1). One of the possible reasons for that is not using enough synthetic training data: while there are 300 000 examples for experiments with En-De and Et-En, we only use 50 000 for En-Cs.

The essential advantage of using CNN-BLEURT models is that they might be used for `zero-shot` settings when a training dataset is not available. However, the building and tuning of the neural network is not an easy task compared to ML-Ent models. The benefits of last ones are relatively fast training and fewer parameters that need to be tuned.

Table 2 presents results for the `Task 2`. We can see that for both languages, the results of ML-Ent and CNN-HTER models are pretty similar and

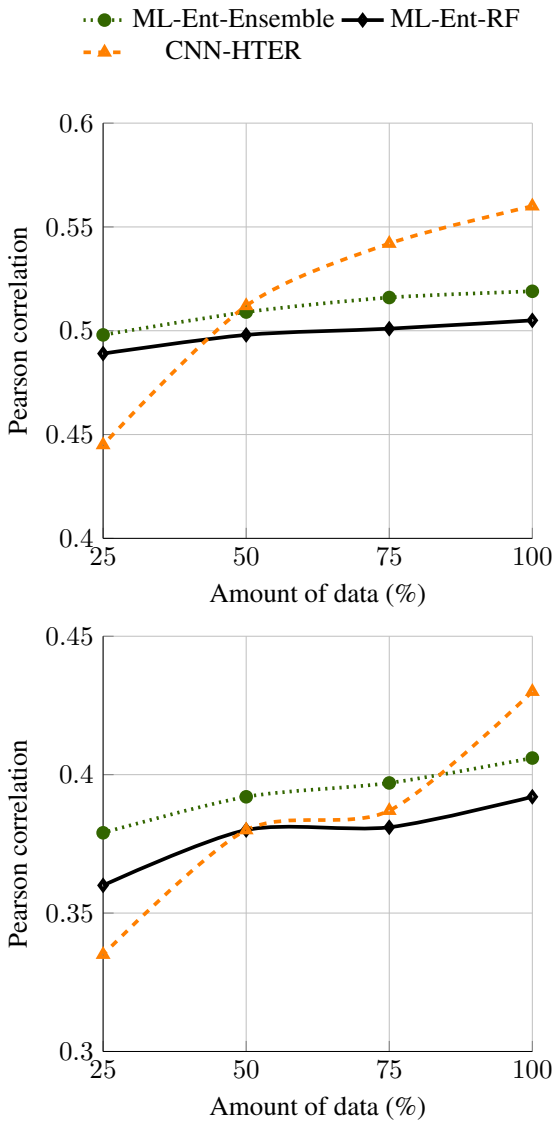

Figure 2: Pearson correlation coefficient between predicted values of WMT2020 test set and HTER scores for Et-En (top) and En-De (bottom) language pairs.

show a moderate correlation. As we mentioned in the previous chapter, the performance of CNN-HTERart is not as good as CNN-HTER, that is why we focus in this chapter only on CNN-HTER model.

Features of ML-Ent models are identical across DA- and HTER-models as well as CNN-DA and CNN-HTER share the same input features. Computed correlation coefficients of HTER- and DA-models are comparable for Et-En language pair. Nevertheless, we see a completely different picture for En-De: coefficients of DA-models are noticeably lower compared to HTER-models. As discussed in (Fomicheva et al., 2020a), the low results of DA models for En-De language pair might be caused by highly-skewed distribution of DA scores, as most translations have high quality scores.

Getting DA scores as well as HTER scores is a time-consuming and expensive task, so the less data you need, the better. To examine how labelled data we need to train models, we ran 10 tests for each examined amount of data (25%, 50%, 75%) and averaged the obtained correlation coefficients. According to our experiments, both discussed approaches, ML-Ent and CNN-HTER/DA, show comparable high performance even with a small amount of training/validation data. As Figure 2 shows, the performance of ML-Ent models for Et-En (top) and En-De (bottom) language pairs slightly worsens with decreased amounts of training data. The performance of CNN-HTER models decreases more noticeably, but still remains quite high. Especially in case of the En-Et language pair, all models demonstrate a moderate linear correlation with post-editing effort even with using 2000 training/validation examples (1750 for training and 250 for validation).

Raganato et al. (2018); Voita et al. (2019) showed that different layers play different roles in the attention mechanism. To examine it from the QE point of view, we compared CNN-HTER models with attention weights extracted from the first three layers, the last three layers and all six layers. According to Table 3, the performance of

	Et-En	En-De
all layers	0.580	0.43
first 3 layers	0.490	0.136
last 3 layers	0.536	0.43

Table 3: Pearson correlation coefficients between predicted values of WMT2020 test set and HTER scores. Results of three settings of CNN-HTER model are presented: with attention weights obtained (1) from all layers, (2) from the first three layers and (3) from the last three layers.

the models with last layers is comparable to the "all layers" models, whereas the difference between models with first layers and "all layers" models is more noticeable. While the performance gap between different models is not so noticeable for Et-En, then for En-De the difference is significant and even more, the lower layers do not provide any "useful" information to the model.

6 Conclusions

We presented sentence-level quality estimation models based on attention weights. The proposed models demonstrated a moderate linear correlation with human judgments as well as with required post-editing effort. The described models can be used as a cost-effective and light-weight QE approach in the machine translation pipeline. Results of empirical evaluation show a good performance even with a small amount of training data, as well as moderate performance in the absence of training data ("zero-shot" settings).

Abstract

We present the joint contribution of IST and Unbabel to the WMT 2021 Shared Task on Quality Estimation. Our team participated on two tasks: Direct Assessment and Post-Editing Effort, encompassing a total of 35 submissions. For all submissions, our efforts focused on training multilingual models on top of `OpenKiwi` predictor-estimator architecture, using pre-trained multilingual encoders combined with adapters. We further experiment with and uncertainty-related objectives and features as well as training on out-of-domain direct assessment data.

1 Introduction

Quality estimation (QE) is the task of evaluating a translation system's quality without access to reference translations (Blatz et al., 2004; Specia et al., 2018). This paper describes the joint contribution of Instituto Superior Técnico (IST) and Unbabel to the WMT21 Quality Estimation shared task (Specia et al., 2021), where systems were submitted to two tasks: 1) sentence-level direct assessment; 2) word- and sentence-level post-editing effort.

This year's submission combines several ideas built on top of the `OpenKiwi` framework. Motivated by the mixture of *blind* and *seen* language pairs in the test sets, we experimented with extensions that would allow us to train multilingual models that maintain good generalization ability and are robust to the presence of epistemic and aleatoric uncertainty.

For both tasks we trained and submitted an ensemble of multilingual models. All submitted models follow the predictor-estimator architecture (Kim and Lee, 2016; Kim et al., 2017) and use pre-trained models for feature extraction. Also, we fine-tune all models on the provided QE data using stacked adapter layers (Pfeiffer et al., 2020). We show that we can thus achieve comparable performance across language pairs while minimising the number of trainable parameters (see Table 1). Furthermore, we experimented with different types of uncertainty-related information to leverage it's benefits, improving performance and robustness of the submitted systems (see §3.1.1). All related code extensions will be publicly available.

Our main contributions are:

- We build on our `OpenKiwi` architecture by exploring adapter layers (Houlsby et al., 2019; Pfeiffer et al., 2020) for quality estimation as these demonstrated to be less amenable to overfitting while presenting the same or superior quality performance than fine-tuning the whole base pre-trained model for different NLP tasks (He et al., 2021).
- We incorporate different types of uncertainty into our architectures. We make use of the glass-box features (Fomicheva et al., 2020) extracted from the NMT models, the *aleatoric* (data) uncertainty derived from the human annotations and the *epistemic* (model) uncertainty (Hora, 1996; Kiureghian and Ditlevsen, 2009; Huellermeier and Waegeman, 2021) that originates from the QE model.
- We show that training the QE models on additional out-of-domain direct assessment (DA) data gives considerable gains in performance for the new language pairs from the *blind* test sets.

2 Quality Estimation Tasks

In this year's shared task edition we submitted models for the first two tasks:

1. Task 1: sentence-level direct assessment
2. Task 2: word- and sentence level post-editing effort, comprising of two subtasks: a) predicting the HTER score of the translated sentence

∗ The first three authors have equal contribution.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 961–972
November 10–11, 2021.

(hypothesis); and b) predicting `OK/BAD` tags for the words and gaps (both in source and translation)

We note that this year, both tasks 1 and 2 provided additional *blind* test sets with language pairs that were not included in the data made available for training/development, providing an interesting challenge and motivating multilingual and generalisable approaches.

3 Implemented Systems

3.1 Task 1

For Task 1 our final submission consisted of an ensemble of two different multilingual models, that differ in the way they process the input source (original sentence) and hypothesis (machine translation). Both models are based on the predictor-estimator architecture, using different pre-trained models to extract features and different training approaches to optimise for the QE task.

The key idea explored with our first model (denoted by M1 variations in the experiments), revolved around pursuing highly generalisable multilingual models, robust to overfitting. To this end, we train a cross-lingual transformer (XLM-RoBERTa (Conneau et al., 2020)) on large, multilingual data with direct assessments and then use adapters (Houlsby et al., 2019; Pfeiffer et al., 2020) to adapt to the domain specific data of the QE task with minimal training effort. In line with our efforts for good generalisation, we use only task-specific adapters and refrain from using specific adapters for each language pair. For these experiments we build on the `OpenKiwi` architecture (Kepler et al., 2019), using a pre-trained `xlm-roberta-large` encoder as a feature predictor. The source and hypothesis sentences are jointly encoded with hypothesis first. Then, source and hypothesis features are generated using average pooling over the hypothesis embeddings and forwarded to the estimator module which corresponds to a feed-forward layer. Figure 1 provides the general architecture[1]

The model was first trained on the direct assessment data provided in the Metrics shared tasks (Mathur et al., 2020), as described in §3.1.2. Upon training, the XML-R encoder is frozen and the the model is fine-tuned on sentence regression with

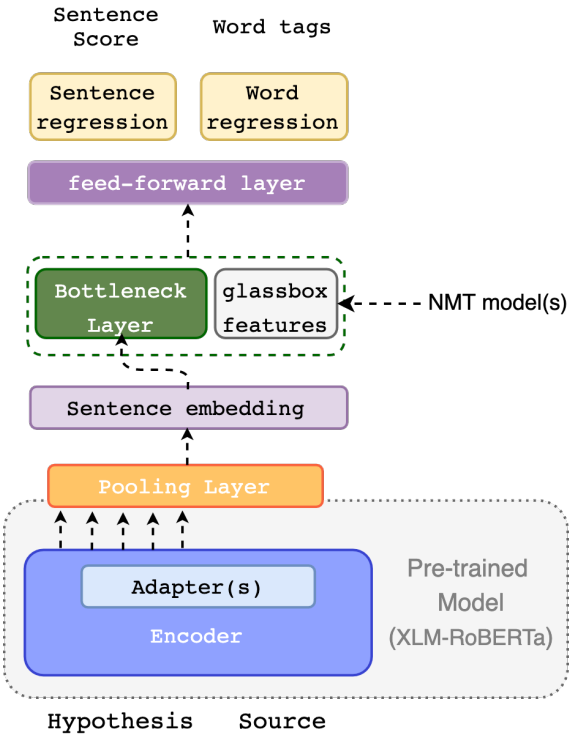

Figure 1: General architecture of M1 model variations. Word tag prediction is used only for Task 2.

the task-specific data, using stacked adapters. We hence manage to maintain a low number of trainable parameters during fine-tuning and minimize training time while learning to predict task-specific sentence scores.

For the second model (denoted by M2-KL-G-MCD) we aimed to explore the potential of a large pre-trained multilingual model (trained with MT objectives). We use the mBART (Liu et al., 2020) encoder-decoder architecture to encode the source and force-decode the hypothesis. We specifically use the mBART50 model (Tang et al., 2020) which is trained with multilingual finetuning on 50 languages, including all languages of interest for the QE 2021 task. We obtain the features by averaging the decoder embeddings and concatenating with the `<eos>` token of the sequence. The estimator part of the model consists of a *bottleneck* feed-forward layer that reduces the dimensionality of the decoder output, and is concatenated with a vector with additional glass-box features from the NMT models (see §3.1.1). The combined vector is then forwarded to a feed-forward estimator and the full model is fine-tuned on the task specific QE data. Apart from the glass-box features we experimented further with methods that allow the model to be

[1]Note that glass-box features are integrated but not used in this submission as they did not significantly improve performance.

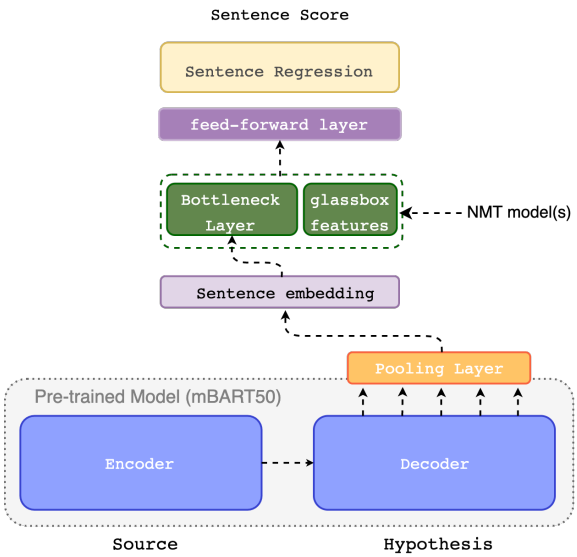

Figure 2: General architecture of M2 model variations.

more robust towards the underlying uncertainty of its predictions. We elaborate that in the next section. Figure 2 provides a general architecture of the M2 model variations.

3.1.1 Learning from uncertainty

Multiple neural models are involved in the process of obtaining and scoring machine translations, which naturally leads to several sources of uncertainty. These sources can be very informative and useful for MT evaluation. In this work we try to consider three types of uncertainty: (1) uncertainty of the NMT models used to obtain the *hypotheses*, (2) data (aleatoric) uncertainty for which we use the inter-annotator disagreement as a proxy, and (3) uncertainty of the MT evaluation model itself.

NMT model uncertainty The idea of extracting uncertainty-related features from the MT systems in order to estimate the quality of their predictions, was originally introduced by Fomicheva et al. (2020). This glass-box approach to QE is mostly focusing on capturing epistemic uncertainty, and the proposed features are extracted either using Monte Carlo (MC) dropout on the NMT or using the output probability distributions obtained from a standard deterministic MT system. In our last year's submission (Moura et al., 2020) the integration of such features proved to be effective, thus we decided to incorporate it into our new model as well. We list the extracted features below:

- `TP` sentence average of word translation probability
- `Softmax-Ent` sentence average of softmax output distribution entropy
- `Sent-Std` sentence standard deviation of word probabilities
- `D-TP` average TP across N(N = 30) stochastic forward-passes
- `D-Var` variance of TP across N stochastic forward-passes
- `D-Combo` combination of D-TP and D-Var defined by $1 - D - TP/D - Var$
- `D-Lex-Sim` lexical similarity - measured by METEOR score (Lavie and Denkowski, 2009) - of MT output generated in different stochastic passes.

Aleatoric uncertainty The noise and complexity of the training data is a source of predictive uncertainty in itself, referred to as data or aleatoric uncertainty (Kiureghian and Ditlevsen, 2009). This uncertainty is often reflected in the disagreement between human annotations for the same *source-hypothesis* segment (Cohn and Specia, 2013; Fornaciari et al., 2021). We hypothesize that the direct assessments can be better modelled as normally distributed scores rather than a single score, and that a model trained to predict this distribution (mean and standard deviation) could provide better quality estimates [2]. We formalise this as a KL divergence objective, using the closed form solution to estimate the KL divergence between the target distribution $p(x) = N(\mu_1, \sigma_1)$ and the predicted distribution $q(x) = N(\mu_2, \sigma_2)$, as shown in Eq. 1.

$$KL(p||q) = \log \frac{\sigma_2}{\sigma_1} + \frac{\sigma_1^2 + (\mu_1 - \mu_2)^2}{2\sigma_2^2} - \frac{1}{2} \quad (1)$$

where we take the mean and standard deviation (std) of the direct assessment z_scores as the target (ground truth proxy) values p. This way, we account for the annotator disagreement (reflected in the std value) during learning.

QE epistemic uncertainty We use MC dropout (Gal and Ghahramani, 2016) to account for the uncertainty of the QE model. Specifically, we enable dropout during inference and run multiple forward runs over each test instance. Thus we obtain a distribution of quality predictions for each instance

[2]Note that for this task's data we only had access to 3 scores per segment so the mean and std values are calculated over these numbers.

instead of a single point estimate. We use the estimated mean of the distribution as our predicted quality estimate. MC dropout has been shown to improve predictive accuracy and perform on par or even better compared to deep ensembles for MT evaluation tasks (Glushkova et al., 2021). It thus allows us to simulate ensembling in a cheap and effective way, without the need to train multiple checkpoints.

3.1.2 Out-of-domain direct assessment data

The QE data is relatively limited, making it harder to train multilingual models with a large number of parameters without over-fitting. Thus, as explained in §3.1 we aimed to investigate whether we could obtain models that generalise better and are more robust to noise and out-of-distribution data by training the XLM-RoBERTa model first on a larger –yet noisier and out-of-domain dataset. To that end we leverage the data provided for the past Metrics shared tasks, which covers the language pairs used in this year's QE task, including the blind tests for which we had no in-domain data available. Altogether, it encompasses 30 language pairs from the news domain (versus 7 in the QE dataset). We provide more detailed statistics for each language pair of the Metrics data in Appendix C. We refer to experiments using the model initially trained on the Metrics data as M1M-. We also show that using the trained XLM-RoBERTa encoder from the M1M model can prove beneficial for the predictions on post-edited data of Task 2 (see Table 3).

3.2 Task 2

For Task 2 we submitted an ensemble of two variations of the first model (M1-ADAPT and M1M-ADAPT) presented for Task 1 (see §3.1). In both cases, we use multi-task training and a feed-forward for each output types: hypothesis word tags, hypothesis gap tags, source word tags, and sentence regression (on HTER scores). Both variations use a pre-trained XLM-RoBERTa (`large`) encoder to extract features as described for Task 1, but differ in the training of the encoder. In the first case we use the pre-trained model [3] and fine-tune on the QE data using stacked adapters. In the second variation we swap the original pre-trained model with the XLM-RoBERTa model that has been trained on the Metrics data as described in §3.1.2. We note that the two variations favor different language pairs, hence we combine multiple checkpoints from each variation (ranging training steps). We use the `test-20` split of the data to optimise the hyper-parameters and following this approach we use the estimated top-3 checkpoints from each variation using the combined dataset [4] and the top checkpoint for the non-augmented model trained exclusively on the train set, resulting in total 7 checkpoints in our final ensemble.

4 Experimental Results

We present the performance of the implemented models on the `test-20` dataset.

4.1 Task 1

The results can be seen in Tables 1 and 2. In line with the shared task guidelines we treat Pearson r as the primary performance metric and select the submitted models accordingly. We can observe, that while on average the M1 model and its variations outperform the M2 model, their performance is comparable, and M2-KL-G-MCD can even outperform M1M-ADAPT for specific language pairs, hence it made sense to combine them in the final ensemble. We can also see that fine-tuning the M1 model on the Metrics data, results in performance gains for the majority of the language pairs. Specifically, even applying the M1M directly, without further fine-tuning on QE data, achieves competitive performance for most pairs, which further improves upon fine-tuning. It helps in increasing the performance on the *blind* sets (denoted as *zero-shot* in the Appendix B). The performance gains concern mostly the correlation performance indicators (Pearson and Spearman correlations), since especially for M1 the error-based indicators (MAE and RMSE) seem to favor the versions of the model that have not seen the Metrics data. One possible explanation for this discrepancy could lie in the differences between the range and distribution of DA scores for the two datasets. Indicatively, the range of scores on the `train-dev-test-20` concatenation of the QE data is $[-7.542, 3.178]$ and for the Metrics data $[-8.624, 4.332]$. The target DA scores in both datasets are calculated via standardizing (taking the z score) the direct assessments for each annotator and then averaging all standardized

assessments for each segment. Thus, the difference in target score range and distribution could affect the magnitude of predicted scores and the distance to the ground truth values, which is reflected in the MAE and RMSE metrics. These findings, further supported by the results on Task 2, is a first step in exploring the underlying connection and bridging the gap between the Metrics and Quality Estimation shared tasks.

4.2 Task 2

The results can be seen in Table 3. Similarly to Task 1, the primary evaluation metric for the sentence level sub-task of Task 2 is the Pearson r coefficient, while the word level sub-task is evaluated using the Matthews correlation coefficient (MCC, (Matthews, 1975)) as the primary performance indicator.

We can see that while HTER scores do not always correlate highly with DAs (see Table 4), the use of the M1M model encoder that was trained on large data with direct assessments can still prove useful. Indeed, when fine-tuning on the Task2 data, the model using the M1M encoder (M1M-ADAPT in the table 3) provides a performance boost for the Pearson correlation in most language pairs, and competitive performance for the rest. Based on these results, we deem it worthwhile to include checkpoints trained with this configuration in the ensemble estimating that they will contribute in higher performance, especially on the blind test sets. This can be further confirmed when

5 Conclusions

We presented a joint contribution of IST and Unbabel to the WMT 2021 QE shared task. Our submissions are ensembles of multilingual checkpoints extending the `OpenKiwi` framework. We found adapter-tuning to be suitable for fine-tuning OpenKiwi on the QE tasks data and less prone to overfitting. We showed that pre-training on large, out-of-domain annotated data can prove beneficial both for the direct assessment and the post-editing QE tasks. We also demonstrated that handling uncertainty-related sources of information improves the performance when integrated into the QE system. For Task 2 we do multi-task training based on the models from the previous task and use multiple checkpoints to create the submitted ensemble.

Abstract

In this paper, we present the systems submitted by our team from the Institute of ICT (HEIG-VD / HES-SO) to the Unsupervised MT and Very Low Resource Supervised MT task. We first study the improvements brought to a baseline system by techniques such as back-translation and initialization from a parent model. We find that both techniques are beneficial and suffice to reach performance that compares with more sophisticated systems from the 2020 task. We then present the application of this system to the 2021 task for low-resource supervised Upper Sorbian (HSB) to German translation, in both directions. Finally, we present a contrastive system for HSB-DE in both directions, and for unsupervised German to Lower Sorbian (DSB) translation, which uses multi-task training with various training schedules to improve over the baseline.

1 Introduction

In this paper, we present the systems submitted to the WMT 2021 task on Unsupervised MT and Very Low Resource Supervised MT. We first build a series of baseline systems, driven mostly by considerations of simplicity, trained on data from the 2020 edition of the task, for translation between Upper Sorbian (HSB) and German (DE). These systems, described in Section 3, enable us to quantify the merits of using additional back-translated data (Sennrich et al., 2016) and of initializing the system for a low-resource pair with parameters learned on a high-resource pair (same target language and related source language).

The systems described above serve as the basis for our 2021 baseline submitted to the shared task, for DE→HSB and HSB→DE, presented in Section 4, which improves upon our 2020 baseline with the addition of more parallel data, and achieves competitive performance with the use of back-translation and parent-initialization only. However, this approach does not lead to an effective baseline for unsupervised German to Lower Sorbian (DSB) translation (Section 5). In Section 6, we present experiments with a contrastive system that implements multi-task learning, with several schedules, in which denoising tasks together with translation are presented to the systems in increasing order of complexity, leading to more robust HSB↔DE systems, together with a strategy of diverse ensembling. We also use our DE→HSB system to initialize a multi-task DE→DSB system for the unsupervised task, although in this case the performance is not competitive.

2 Datasets

We use various Upper Sorbian datasets from the 2020 edition of the task, and additional WMT data, as presented in Table 1. The monolingual HSB data from 2020 comes from three sources: `sorbian_institute_monolingual` consists of a mix of high- and medium-quality HSB data provided by the Sorbian Institute; `witaj_monolingual` consists of high-quality HSB data from the Witaj Sprachzentrum; finally, `web_monolingual` consists of web-scraped noisier HSB data gathered by the Center for Information and Language Processing from LMU Munich (Fraser, 2020). We kept from all datasets only sentences that have strictly more than 2 and strictly fewer than 301 words.

3 Baseline HSB→DE System on 2020 Data

3.1 Subword Vocabulary

For the HSB→DE system, we use CS→DE initialization in several experiments, because Czech (CS) is a high-resource language and close neighbor to Upper Sorbian. Therefore, we create a tri-lingual shared subword vocabulary (CS, DE, HSB) using the Unigram LM model (Kudo,

Table 1: Monolingual and parallel corpora with their languages and numbers of lines (sentences) and words, before and after filtering by length (keeping sentences with more than 2 and fewer than 301 words).

2018) as implemented in SentencePiece.[1] We apply 32,000 merges and the other parameters of SentencePiece are kept to default values. We obtain 600k sentences of HSB data from `sorbian_institute_monolingual`, `witaj_monolingual` and `train.hsb-de`, the latter being the HSB side of the 2020 training data. We do not use `web_monolingual` as it appears to be noisy, due to the collection process. For CS and DE, 600k sentences are selected randomly from the monolingual corpora listed in Table 1. The vocabulary generated by SentencePiece is converted from log probabilities to frequencies using the `spm_to_vocab.py` tool from the OpenNMT-py toolkit. Using a common SentencePiece model for the three languages is not obligatory, but appeared to improve the performance by 2-3 BLEU points in most cases.

3.2 System Parameters and Results

We use OpenNMT-py (Klein et al., 2017) for our experiments.[2] We start with Transformer-Base (Vaswani et al., 2017) (78M parameters) but also experiment with Transformer-Big (245M parameters), with their main parameters described in Table 2. We apply the same regularization and optimization procedures to the two models. We accumulate gradients over 2 batches and train on 2 GPUs, with a `batch_size` of 1k for Base and and 2k for Big. We use the "noam" learning rate schedule (Vaswani et al., 2017) with its values at each step multiplied by two, and 8k warmup steps. We evaluate and save checkpoints every 5k steps. Final translations are generated with a beam width of 5, ensembling the last two checkpoints in these experiments. We report BLEU scores (Papineni et al., 2002) obtained with SacreBLEU (Post, 2018) on detokenized text.

	N	h	d_{model}	d_{ff}	P_{drop}	steps
Base	6	8	512	2048	0.1	60k
Big	6	16	1024	4096	0.3	100k

Table 2: Parameters of the two Transformer models used in our experiments. Other parameters are set to the default values of the OpenNMT-py toolkit.

3.3 Use of Back-translated Data

The first HSB→DE system we trained, for comparison purposes, used only the HSB/DE parallel data provided for the WMT 2020 Low-Resource task. Its BLEU scores are 47.98 on the 'dev' set (`devel.hsb-de`) and 41.22 on the 'devtest' set (`devel_test.hsb-de`) after 60k steps of training (first line of Table 3). The already high BLEU scores that are reached, compared to scores generally observed on high-resource language pairs,

[1] https://github.com/google/sentencepiece (v. 0.1.95)
[2] https://github.com/OpenNMT/OpenNMT-py (v. 2.0.1)

indicate that the 'dev' and 'devtest' sets are probably quite similar to the training data.

We obtain additional training data through back-translation (Sennrich et al., 2016) of widely available monolingual German data. To this end, we train a DE→HSB model on the same parallel corpus as above, which reaches BLEU scores of 45.23 / 40.62 respectively on 'dev' and 'devtest'. Using this model, we translate News Commentary V15 from German into Upper Sorbian. The resulting pseudo-parallel data (noisy on the HSB side) is used in addition to the initial data for training a new HSB→DE model, which reaches a score of 52.91 / 44.39 (second line of Table 3). The improvement of this single enrichment with imperfect data of the initial low-resource system thus exceeds 4 BLEU points.

3.4 Initialization with Parameters from a High-Resource Pair

The second technique we use for improvement is transfer from a high-resource pair (Zoph et al., 2016; Kocmi and Bojar, 2018), i.e. initialization with parameters from an MT system trained on such a pair. As Upper Sorbian has many similarities with Czech, which is a high-resource language, we initialize the HSB-DE model with the parameters of a model trained for CS→DE, then train it with the same data as in the previous subsection. Firstly, the CS→DE model is trained using Europarl and News Commentary, and reaches a BLEU score of 27.13 on a sample test set extracted from these two corpora.

The resulting HSB→DE system reaches BLEU scores of 55.99 / 47.53, a further increase of about 3 BLEU points (third line of Table 3). The use of an even larger dataset further improves performance: the addition of the JW300 corpus (Agić and Vulić, 2019) to the CS→DE training data increases BLEU by half a point (56.5 on 'dev'). The rather small increase could be attributed to the large difference in domains between JW300 and the HSB/DE data.

Since back-translation can provide very large amounts of data, we also trained a Transformer Big (with the parameters shown in Table 2) with the addition of the monolingual German corpora of Europarl and JW300 backtranslated into Upper Sorbian. This model reaches 58.08 / 49.99 BLEU points respectively on 'dev' and 'devtest', improving performance by more than 1.5 BLEU points. This is currently our best baseline model for HSB→DE, obtained with two simple augmentation techniques only.

We can compare this score with three of the highest-scoring systems on the 2020 HSB→DE 'devtest' set, noting some of the differences between them and our baseline. Scherrer et al. (2020) achieved a BLEU score of 56.9 using back-translation and bilingual pre-training with CS→DE, but also scheduled multitask with several monolingual and multilingual tasks. Knowles et al. (2020) achieved a BLEU score of 58.9 using iterative back-translation, multiplication of the HSB data for BPE training, and character- and word-level lexical modifications of Czech to make it more similar to Upper Sorbian. Libovický et al. (2020) achieved a score of 56.0 with much larger corpora for back-translation and CS→DE pre-training (14M lines) and the use of an unsupervised CS→HSB system to translate the CS side of the DE/CS parallel data into HSB.

3.5 Initialization with Parameters from Other High-Resource Pairs

We studied the role of the closeness between Upper Sorbian and the high-resource source language used for initialization, by reproducing the above initialization experiments (CS→DE) with Polish and French instead of Czech. Polish is a West Slavic language just as Czech and Upper Sorbian, although geographically more remote, whereas French is a Romance language: we thus expected the former to outperform the latter. To keep training time more manageable, we used a Transformer-Base, and trained the parent model on Europarl and JW300, because News Commentary is not available for Polish. For each experiment we build a different tri-lingual SentencePiece model trained with 600k sentences per language.

The use of the PL→DE model (with a 22.33 BLEU score on its respective test set) for initialization leads to a HSB→DE performance of 56.07 / 47.94, which is very similar to the system initialized with CS→DE parameters (55.99 / 47.53). The use of the FR→DE model (with a 19.25 BLEU score) for initialization leads to a HSB→DE system reaching 54.92 / 46.30. This is about 1.3 BLEU points lower than with Polish or Czech, although the difference is smaller than expected given the linguistic distance between French and Upper Sorbian. These results are in line with the findings of Aji et al. (2020) who argue that no parent is clearly better than other for transfer learning in MT.

System	HSB→DE		DE→HSB	
	dev	devtest	dev	devtest
1. Transformer-Base, 2020 parallel data	47.98	41.22	45.23	40.62
2. Add back-translated data to #1	52.91 *(+4.93)*	44.39 *(+3.17)*	51.00 *(+5.77)*	43.23 *(+2.61)*
3. Initialize #2 with high-resource pair	55.99 *(+3.08)*	47.53 *(+3.14)*	–	–
4. Transformer-Big with #3	58.08 *(+2.09)*	49.99 *(+2.46)*	–	–
5. Add 2021 parallel data to #4	59.29 *(+1.21)*	51.86 *(+1.87)*	57.22 *(+6.22)*	49.95 *(+6.72)*

Table 3: Scores of our 2020 (1–4) and 2021 (5) baseline systems, with absolute improvements brought by each additional technique or data set.

3.6 Two Rounds of Back-Translation

Multiple rounds of back-translation can be done on each side, but this computational effort is not always compensated by a significant increase of the BLEU score. Using the best HSB→DE system above, we translate monolingual HSB data and use it to train an improved DE→HSB model, which reaches 51.00 on the 'dev' data (+5.77 with respect to the initial DE→HSB system) and 43.23 on the 'devtest' data (+2.61). We then use this improved model to translate the monolingual German data again and use the resulting pseudo-parallel data to train a new HSB→DE model. The model without CS initialization reaches BLEU scores of 53.62 on 'dev' (+0.62) and 44.95 on 'devtest' (+0.43). If CS initialization is used, the models reaches respectively 58.44 (+0.36) and 50.03 (+0.04) on 'dev' and 'devtest'. The improvement brought by the additional rounds of back-translation is quite marginal, therefore we do not pursue this approach, and focus on a system which is initialized from a parent high-resource pair and trained with original and back-translated data, where the latter comes from a reverse system trained only with the original parallel HSB-DE data provided by the shared task.

4 Baseline HSB↔DE Low Resource Systems for 2021

Given the results of the previous section, we choose the Transformer-Big for our 2021 baseline. We change the dropout level from 0.3 to 0.1 since our experiments revealed an increase in performance with the latter value. Furthermore, we add the 87,502 sentences of additional parallel HSB-DE training data provided in 2021 to the datasets used in our 2020 baseline. We use the same SentencePiece model with DE, HSB, and CS data that we used for our 2020 baseline system, with approximately 700k lines for each language. At translation time, after observing a number of out-of-vocabulary tokens, we replace the unknown tokens with the source token that has the highest attention weight. We do not make any further changes regarding our 2020 Transformer-Big model.

The scores of our baseline systems on 2020 and 2021 data are synthesized in Table 3 for the various techniques we experimented with. Our baseline HSB→DE model with combined 2021 and 2020 data is system #5 in Table 3: it reaches BLEU scores of 59.29 on the 'dev' set and 51.86 on the 'devtest' set after training for 150,000 steps and by ensembling the best 4 saved checkpoints. For our DE→HSB model, we obtain 57.22 on the 'dev' set and 49.95 on the 'devtest' set after training for 85,000 steps and by ensembling the best 4 saved checkpoints.

After the submission to the 2021 shared task, we continued training the above HSB→DE model up to 300,000 steps- Ensembling the *last* 4 saved checkpoints, BLEU scores were close to the ones shown in the last line of Table 3, reaching 59.42 on the 'dev' set and 51.37 on the 'devtest' set. However, several checkpoints gained almost 2 BLEU points on 'dev', pointing to the potential benefits of training for a longer time.

5 Baseline for Unsupervised DE→DSB Translation

Moreover, we studied the same techniques for translating Lower Sorbian (DSB), for which no parallel resources are provided. We translated the monolingual DSB data provided by the organizers with our HSB→DE model, hypothesizing that the differences between DSB and HSB are small enough to obtain an acceptable DSB-DE pseudo-parallel corpus, with high-quality text on the DSB side, following insights from our experience with Swiss-German dialects (Honnet et al., 2018).

We use the parameters from our best DE→HSB model to initialize a DE→DSB model that we train

for 120k steps with the DSB-DE pseudo-parallel data. When ensembling the best 4 checkpoints, we reach BLEU scores of 8.25 / 8.22 without observing any significant increase of the scores during training. In fact, the initial score, which is the performance of a DE→HSB model on the DE-DSB 'devtest' data, is even slightly higher. An even lower BLEU score was reached when using our CS→DE model to translate monolingual DSB data into DE to obtain a pseudo-parallel corpus, thus confirming the finding that this approach does not lead to pseudo-parallel corpora of sufficient quality. Therefore, we did not submit these translations to the 2021 shared task.

6 Contrastive HSB↔DE and DE→DSB Systems using Multi-Task Learning

In contrast to the baseline systems presented above, we study an innovative approach, in which we train multitask systems with denoising auxiliary tasks that are presented in order of increasing complexity. This insight is drawn from curriculum learning (Bengio et al., 2009). We thus test whether increasing the complexity of the tasks makes it easier for an NMT model to learn the simple tasks first, and the harder ones later in training.

As Raffel et al. (2020) showed, source–to–source pre-training and multitasking improves translation, but not enough to compete with state-of-the-art setups. Therefore, instead, we perform target–to–target and source+target–to–target denoising. Considering their findings, we decide not to introduce special tokens into our vocabulary, such as mask tokens (instead just deleting the tokens with wish to mask), or sentence and language separators. Finally, due to computational constraints, we use the Transformer-Base as our architecture.

6.1 Data and Auxiliary Tasks

For our contrastive system we consider two new monolingual corpora in Czech and in German: the document-separated news crawls from WMT20 (Barrault et al., 2020), consisting of text extracted from online newspapers. They contain 17M lines and 43M lines respectively in each language. To keep training time within acceptable limits, we sample 1.4M lines from these corpora (including empty lines that serve as document-separators), we apply the same length-based filtering criterion ($2 < L < 301$) as for our baseline data, and we also delete all sentences that are made of more than 15% non-alphabetic characters. The resulting Czech corpus is 1.3M lines and 131,644 documents long, and the German corpus is 1.2M lines and 130,891 documents long.

For our document-level denoising tasks, we first divide into "chunks" a tokenized document-separated corpus so that each chunk is no more than 500 subwords in length, made up of consecutive lines in the same document; we only select documents made of at least 3 sentences. In Table 4 we list all corpora that we use to create our auxiliary data, including monolingual corpora back-translated with our baseline systems. The DE→DSB back-translated data was obtained with a baseline DE→HSB model.

We make use of the four following auxiliary denoising tasks (the main task being of course standard sentence-level translation, with all parallel and back-translated data), with the first two inspired by Devlin et al. (2019); Raffel et al. (2020) and Conneau and Lample (2019):

1. **Masking** (`MASK`): randomly delete 15% of words of a line on the source side, but keep the full original sequence on the target side.
2. **Translation Language Modeling** (`TLM`): concatenate the source and target sentences from a parallel corpus, and apply separately the `MASK` algorithm to each one. The target is the original target sentence.
3. **Mask Document First Words** (`MF`): for each chunk, leave the first sentence untouched, and for the remaining ones delete the first word of each sentence, with the target being the full original sequence in the same language.
4. **Next Sentence Generation** (`NSG`): for each chunk, leave all the sentences untouched except the last one, of which delete all but the two longest words; the model has to output the full original sequence. Keeping the two longest words (in characters) is based on the assumption that they are the most informative ones in the sentence.

The denoising tasks are listed above by increasing complexity. Indeed, `MASK`, as a monolingual sentence-level task, is the simplest denoising task we present, with `TLM` following, as it includes a context in a different language which needs to be identified. The two document-level tasks are more

complex, as they require a larger context. In particular, NSG is harder than MF, since it consists of reconstructing a whole sentence with just two words from the original sequence, forcing the model to look for a more abundant context to estimate the correct answer. Furthermore, predicting the first word requires to take into account exclusively inter-sentential context, whereas masking a single random word allows also for the use of intra-sentential context, with the latter providing more direct context than the former.

Corpus	Lines	Words	Aux. tasks
CS-DE	1.5M	25M / 28M	TLM
HSB-DE	144k	2M / 2M	TLM
CS	1.3M	41M	MF, NSG
DE	1.2M	44M	MF, NSG
HSB	640k	9M	MASK
DSB	128k	2M	MASK
HSB→DE	4.5M	94M / 104M	
DE→HSB	637k	10M / 9M	
DE→DSB	124k	2M / 2M	

Table 4: Parallel (2), monolingual (4), and back-translated corpora (3) used for our contrastive system trained with multi-tasking. Each corpus is assembled from the raw datasets presented in Table 1 with the filtering setup described in Subsection 6.1. For bilingual corpora, we indicate the number of words in each language.

6.2 Training Schedules

All our models translate to one target language only, therefore the target side of our datasets is always the same language, be it for the monolingual denoising tasks or for TLM. Since all datasets correspond to sequence-to-sequence tasks, we are in essence simply removing and introducing datasets during training. The specific splits of the tasks in each training schedule have been manually set, guided by the reasons given below, without any attempt for fine-tuning.

All the hyperparameters of the models are those presented in Section 3, with the only exception of the parameters of CS↔DE models for initialization, which were trained on 4 GPUs to reduce training time. When we introduce new tasks during the training of a model, we continue training from the last checkpoint of the previous task.

Training CS↔DE models. Both directions are trained according to the same schedule, shown in Table 5, with simply the source and target languages switched. First, we train for 30k steps with a TLM task, then we train for another 30k steps with a mixture of the MF auxiliary task (50% of the samples) and the main translation task (50%). Then we continue for another 30k steps, changing MF to NSG. Finally, we finish with 30k steps on translation only. In total, the model is being trained for 30k steps (25%) with TLM, 15k steps (12.5%) with MF, 15k steps (12.5%) with NSG, and 60k steps (50%) with the main task, i.e. sentence-level translation.

	Steps ×1000			
Task	0-30	30-60	60-90	90-120
TLM	100%			
MF		50%		
NSG			50%	
Translation		50%	50%	100%

Table 5: Training schedule of the parent models in CS↔DE. For each direction, the model is only trained to output target language, so corpora differ depending on the direction (see 6.1). Both models are trained for 120k steps with three auxiliary denoising tasks and the main sentence-level translation task.

HSB→DE. The schedules of the child models are shown in Table 6 for the (DE, HSB) pair. For HSB→DE, we continue training from the best scoring checkpoint of the last 60k steps of the parent CS→DE model, and start with a TLM task for 60k steps. Then, we introduce back-translated data only for 60k steps. We continue with 60k steps with true parallel data only.

Additionally, we train two more models by continuing to train another 60k steps from the best scoring checkpoint (which is also the last one saved), with one of the models having its learning rate schedule reset. Although at first performance worsens due to a more aggressive learning rate during the warmup steps, the model ends up converging to a score similar to the one we obtain if we continue to train without resetting the learning rate schedule. The goal is to emulate a multiple-run seeding strategy for ensembling, by achieving a different weight distribution among the two models. We additionally train a randomly-initialized model with parallel data only, for 60k steps, also for ensembling. We generate our translations of the test data with an ensembling of 16 models: the best 4 checkpoints from the parallel-only randomly-initialized

model, the best 4 of our main setup during the first 60k steps of parallel-only training, and the 4 checkpoints each for the two runs that continued to train with, and respectively without, resetting the learning rate schedule.

DE→HSB. We continue training from the best-scoring checkpoint of the last 60k steps of DE→CS, and provide it with a MASK task for 60k steps, since the model has not seen the target language at all during pre-training, for this direction. Then, we provide the model with a TLM task for 60k steps. Since in this direction we have much less back-translated data than in the opposite, we decide to train for 60k more steps with 50% of the samples being from the back-translated data, and the other 50% from the true parallel corpora. Finally, we continue training two more models in the same manner as explained for the HSB→DE direction. We additionally train a randomly-initialized parallel data only model for 60k steps for ensembling. We translate with the same ensembling setup as described for the HSB→DE direction.

	Steps ×1000		
Task	0-60	60-120	120-180
	HSB→DE		
TLM	100%		
Trans-BT		100%	
Trans-Parallel			100%
	DE→HSB		
MASK	100%		
TLM		100%	
Trans-BT			50%
Trans-Parallel			50%

Table 6: Training schedule of the child models for the HSB→DE and DE→HSB models presented in 6.2.

DE→DSB. We start training with a MASK task for 60k steps from the highest-scoring checkpoint DE→HSB. We continue training for 60k steps with just the back-translated data, although we notice that the quality of the translation affects negatively the scores. To address this issue, for another 60k steps we give it the back-translated corpus for 50% of the samples and the MASK task for the other 50%, starting training from the previous highest-scoring checkpoint. Finally, for another 60k steps we give it a parallel-only DE-HSB task for 50% of the samples, MASK for 30%, and back-translated data for 20%. After testing, using just the highest-scoring checkpoint for the back-translation only, back-translation + MASK, and DE-HSB + back-translation + MASK appeared to work better on the development data than using the highest four ones.

	Steps ×1000			
Task	0--60	60--120	120--180	180--240
MASK	100%		50%	30%
Trans-BT		100%	50%	20%
DE-HSB				50%

Table 7: Training schedule of the child DE→DSB models presented in 6.2

6.3 Results

The scores of the parent DE→CS and CS→DE models obtained with multi-task training are shown in Table 8. Compared to the CS→DE models from Sections 3 and 4, the present models have markedly lower scores. This difference can be due to the use of Transformer-Base vs. Big, or to differences in training data, apart from the multi-task training procedure itself. Still, we decided to use these models as parents for initializing the DE→HSB and HSB→DE models respectively, so that both parents and children are trained with multi-tasking. Although changes in the parameters of a parent model that result in better translations may not necessarily also result in better child initialization, it would be interesting to also test here the parent models from Section 4.

System	**DE→CS**	**CS→DE**
1. MF + translation	14.05	15.46
2. NSG + translation	15.30	16.17
3. Translation	18.19	19.80

Table 8: BLEU scores of parent models after each stage of the training schedule described in 6.2, on the 'devtest' set from 4.

Our child DE↔HSB models show that the scheduled training improves results over the baseline. The HSB→DE model with a training schedule (system 2 in Table 9), trained with a lighter architecture (Base vs. Big) and lower quality parent model (19.8 vs. 24.5), achieves a higher BLEU score than the system in Section 4, as shown in Table 3: 52.2 vs. 51.86. Additionally, the diversity of the ensembling of the models appears to improve the overall quality of the translation.

System	DE→HSB	HSB→DE
1. Parallel data	50.37	48.50
2. Multi-task	52.10	52.21
3. #2 cont. train	53.42	52.37
4. #2 cont. train with l. r. reset	53.05	52.12
Ensemble	54.58	53.21

Table 9: BLEU scores of child DE↔HSB models for various training schedules on the 2021 'devtest' set.

The scores of our DE→DSB model (Table 10) show that the quality of the back-translated data with our HSB→DE model improved slightly with the addition of the `MASK` monolingual task, but not with the addition of a DE→HSB translation task. However, when including in the ensemble the models trained on a DE→HSB task, scores improved from 8.7 to 9.6 on the 'devtest' set. This was the version submitted to the shared task on unsupervised MT (DE→DSB).

System	DE→DSB
1. Back-translation only	8.23
2. BT + `MASK`	8.57
3. BT + `MASK` + DE→HSB	7.14
Ensemble	9.62

Table 10: BLEU scores of child DE↔DSB models for various training schedules on the 2021 'devtest' set.

Finally, as we can see in Table 11, even with our possibly suboptimally trained parent models and lighter architecture, the strategy of diverse ensembles and scheduled multi-task training improved over our best performing baselines given in Section 4 for all directions of the low-resource MT task.

HSB→DE		DE→HSB		DE→DSB	
dev	devtest	dev	devtest	dev	devtest
62.74	53.21	62.49	54.58	9.22	9.62
(+3.45)	*(+1.35)*	*(+5.27)*	*(+4.63)*	*(+0.97)*	*(+1.40)*

Table 11: BLEU scores of our primary system's final configurations, on the development data, with the improvements over our highest baselines from Section 4.

7 Conclusion

In this work, we showed that non-iterative back-translation and parent-model transfer learning provide improvements for translation in a low-resource setting. Furthermore, multi-task scheduled training with monolingual or cross-lingual tasks also resulted in better models. In particular, child models starting with Translation Language Modeling tasks and Masking tasks improved over the baseline in all translation directions. Finally, our strategy of ensembling diverse models also produced higher scores than a mere checkpoint ensemble strategy.

Abstract

This paper describes the methods behind the systems submitted by the University of Groningen for the WMT 2021 Unsupervised Machine Translation task for German–Lower Sorbian (DE–DSB): a high-resource language to a low-resource one. Our system uses a transformer encoder-decoder architecture in which we make three changes to the standard training procedure. First, our training focuses on two languages at a time, contrasting with a wealth of research on multilingual systems. Second, we introduce a novel method for initializing the vocabulary of an unseen language, achieving improvements of 3.2 BLEU for DE→DSB and 4.0 BLEU for DSB→DE. Lastly, we experiment with the order in which offline and online back-translation are used to train an unsupervised system, finding that using online back-translation first works better for DE→DSB by 2.76 BLEU. Our submissions ranked first (tied with another team) for DSB→DE and third for DE→DSB.

1 Introduction

Unsupervised Neural Machine Translation (UNMT) has become increasingly useful in the field of MT, given that monolingual data is easier to gather compared to bilingual (or parallel) data. Such is especially the case for low-resource languages, which constitute the majority of languages in the world.

The WMT 2021 Unsupervised MT Task focuses on one such low-resource language: Lower Sorbian (DSB). The task is to translate between German (DE), a high-resource language, and Lower Sorbian, which is a very low resource language with roughly 150 thousand sentences of monolingual data available for the task at hand. The unsupervised task from prior years of WMT focused on German–Czech and German–Upper Sorbian translation. Unique to this year however is the relatively small amount of monolingual data available for DSB, compared to last year in which roughly 750 thousand sentences of Upper Sorbian were available. This makes it increasingly difficult to rely on the ubiquitous state-of-the-art UNMT methods (Lample and Conneau, 2019; Song et al., 2019; Liu et al., 2020), as they typically rely on a large amount of monolingual data available for both languages.

To alleviate the difficulty that comes with the lack of monolingual data for DSB, this year's WMT task allows for the use of monolingual and parallel data outside of DE–DSB. Specifically, all Upper Sorbian (HSB) data from WMT20 and all parallel data for German (DE) from WMT and OPUS (Tiedemann and Nygaard, 2004) are made available to use. Additionally, as auxiliary languages related to DSB, monolingual data for Czech (CS) and Polish (PL) is also provided.

Given the success of language transfer via multilingual models such as mBART (Liu et al., 2020), this fundamentally changes this year's unsupervised task from a bilingual NMT task to a multilingual task. However, pretrained multilingual models like mBART cannot be used as they do not fit the limitations on the training data that one is allowed to use for this shared task.

As the problem is unique to date due to the limited available data as well as the limitation on pre-existing pretrained models, we aim to establish a standard for training systems under these restrictions. Specifically, we ask three research questions (RQs):

1. Is it better to pretrain and fine-tune a multilingual model or to focus the training on a few languages at a time when data and time are limited?

2. How can we obtain a good initialization for the vocabulary of an unseen language for

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 982–988
November 10–11, 2021.

which there is very limited training data?

3. Given there are two methods for doing back-translation, online and offline, what is the best way to combine them?

Concerning RQ1, there is a wealth of research into multilingual models, however these typically require a large amount of monolingual data for each language in addition to a wealth of computational resources and time. Therefore, we develop the hypothesis that under limited constraints (time and computational resources) training only on two languages at a time will result in better performance due to there being fewer training objectives. Specific to this task, we propose training on DE coupled with CS, then HSB, then DSB itself, following the order of least to most linguistically similar to the low resource language that we target: DSB.

As for RQ2, due to the scarcity of monolingual data and complete absence of parallel data for DSB, our ability to train the model on this language is limited, thus the model's initialization for the language plays an increasingly important role in its resulting performance. Relying on the similarity of the two Sorbian languages, we aim to improve this initialization by transferring the model's knowledge of the HSB vocabulary to the DSB vocabulary.

Finally, with respect to RQ3, Garcia et al. (2020) established a method for incorporating offline and online back-translation (BT) into their MT system by first using offline BT then online BT, both following a multilingual pretraining. However, the reverse order (i.e. online BT followed by offline BT) has not been tested to the best of our knowledge, and theoretically doing online BT should improve the quality of the synthetic data that would be used for offline BT. Therefore, we test Garcia et al.'s method as well as the reverse order to establish the best practice for this task specifically.

The remaining of the paper is organized as follows. We first outline the data we chose to use and our preprocessing steps in Section 2. We then specify our architecture and training methods in Section 3. Our results are in Section 4, followed by our conclusions in Section 5.

2 Data

Apart from our main language pair of DE and DSB, we opted to use data from two languages that are related to the latter, namely CS and HSB.[1]

For HSB and DSB, we use all of the data provided for training by WMT. For DE and CS, we use data from WMT NewsCrawl, years 2010-11 and 2018-20. We chose these years as they are the most frequent years occurring in the HSB data, following Edman et al. (2020). For DE, we take the first 1 million sentences each from 2018-20 and 0.5 million from 2010-11, totalling 4 million. For CS, we take 0.5 million and 0.25 million from the respective years, totalling 2 million.

In terms of parallel CS–DE data, we use MultiParaCrawl, Europarl v8, WMT News v2019, and News Commentary v16, all available from the OPUS project (Tiedemann and Nygaard, 2004). The datasets are shown in Table 1.

Language(s)	Dataset Name	Sentences
CS	NewsCrawl 2010-11, 18-20	2,000,000
DE	NewsCrawl 2010-11, 18-20	4,000,000
DSB	WMT 2021	145,198
HSB	WMT 2020	696,271
CS–DE	Europarl v8	568,589
	MultiParaCrawl v7.1	5,680,308
	NewsCommentary v16	204,311
	WMT News v2019	20,567
HSB–DE	WMT 2020-21	147,521

Table 1: Training data used in our models.

While MultiParaCrawl (MPC) is the largest portion of Czech–German data, it is constructed using English as a pivot language, so we anticipate the data to be lower quality in general. As such, we run 2 models, 1 including MPC and 1 without MPC.

For development and testing, we use the DE–HSB and DE–DSB `devel` and `devel_test` datasets provided by WMT. For CS–DE, we make use of the WMT News Translation Task dev set, using `newstest2012` for development and `newstest2013` for testing.

All data is tokenized using the Moses toolkit (Koehn et al., 2007). We then apply BPE (Sennrich et al., 2016), for all languages jointly, using FastBPE.[2] The segmentation is applied on the same number of randomly-selected sentences for each language, roughly 145 thousand, matching the number of sentences in the DSB training data. We experiment with the number of joins used (trying {20, 40, 50, 60, 80} thousand), finding 50 thousand

[1] We initially also used Polish data but did not see any improvements so we ultimately left it out.

[2] https://github.com/glample/fastBPE

to perform the best, according to BLEU scores after step 4.

3 Method

3.1 Architecture

We used the MASS (Song et al., 2019) model, which is a 12-layer encoder-decoder (6 layers each) Transformer model identical to the XLM (Lample and Conneau, 2019) architecture. The difference comes in the training, using the MASS sequence masking (MA) objective allows both the encoder and decoder to be trained in the language model pretraining phase. This can be contrasted with XLM, which only pretrains the encoder.

3.2 Training

The training objectives we use are:

- MASS sequence masking (MA): Reconstructing a sentence fragment (a token sequence) given the remaining part of the sentence.
- Machine translation (MT): The standard translation objective with a cross-entropy loss.
- Denoising auto-encoding (AE): Reconstructing the original text from a noisy version corrupted by a set of functions.
- Back-translation (BT): Both online (on-the-fly) and offline back-translation, where synthetic data created from the forward direction is used to train the backward direction, and vice versa.
- Cross-lingual back-translation (XBT) (Li et al., 2020): Using an intermediate reference language for forward and backward translation during online BT.

We tested various training schemes, ultimately deciding upon a 6-step process, shown in Figure 1.

In Figure 1, UNMT (steps 4 and 6) refers to the combination of AE, online BT, and XBT. For the AE, we use word shuffling, masking, and removal as noise functions, following XLM (Lample and Conneau, 2019). Online BT is done on DE–DSB as well as on HSB–DSB.[3] XBT is done using our DE–HSB parallel data for the directions HSB→DSB→DE and DE→DSB→HSB.[4]

[3]We found in initial testing that including HSB–DSB gave a slight improvement to BLEU scores.

[4]We also tried using our DE–CS data for XBT, but this performed worse.

3.3 Vocabulary Transfer

To facilitate a better alignment of DSB to DE, we make use of the linguistic similarity of DSB to HSB, coupled with the fact that HSB is expected to be reasonably well-aligned to DE after training with the HSB–DE parallel data (step 2). As the model is language agnostic, apart from the language embeddings as well as word embeddings that occur exclusively in one language, we initially align these parts on the DSB side to the HSB side (step 3), prior to the first UNMT training (step 4).

We align the language embeddings by copying the HSB language embeddings to the DSB language embeddings. To align the vocabulary, we first train two word embeddings on the DSB and HSB data using fastText (Bojanowski et al., 2017). Next, we align these two embeddings using VecMap (Artetxe et al., 2018), treating identical words in HSB and DSB as the same.

From the aligned embeddings, we construct a bilingual dictionary. This is done by first getting the top 10 nearest HSB neighbors, according to the cosine similarities of the aligned embeddings, for each DSB word. From these 10 candidates, we choose the closest HSB word, determined by the lowest Levenshtein distance between the DSB word and the respective HSB candidate.[5] We also filter out DSB words that occur frequently in the DE training data, removing all those which occur more than 0.001% of the time.

We use this filtered bilingual dictionary to copy the embeddings within the encoder and decoder of the MASS model. Specifically, all of the embeddings for the words on the DSB side of the bilingual dictionary are copied from the embedding of their corresponding HSB word pair.

As DSB has not yet been seen in the training, a large number of the embeddings for DSB words are essentially not learned at this stage. However, since the Sorbian languages are closely related and often the differences between words are merely in spelling, we expect this approach to help with initializing the model's DSB vocabulary.

3.4 Experimental Setup

Training is done on an Nvidia V100 32GB GPU. Each training step of the model is limited to 24 hours, with the exception of our model using MPC data, in which the first step is trained for 2 days

[5]We strip accents before calculating the Levenshtein distance.

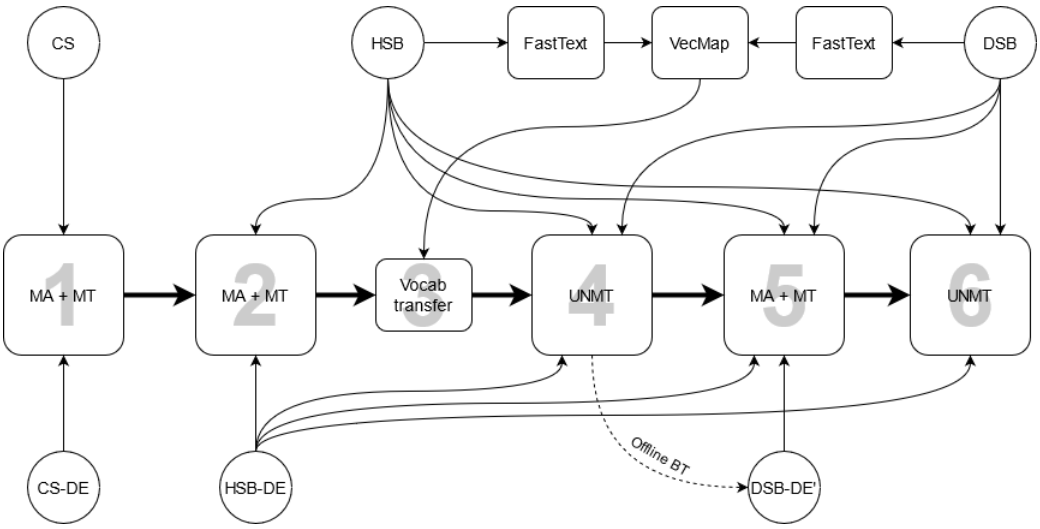

Figure 1: Diagram of the training steps. The circular nodes are datasets, the larger boxes are training steps of the MASS model, and the smaller boxes represent the steps for vocabulary transfer. German monolingual data is not shown as it is used in every step.

Data	Training Step	DE→DSB	DSB→DE
Without MPC	4	22.46	30.04
	5	**24.92**	28.48
	6	23.22	31.34
With MPC	4	23.03	30.70
	5	23.62	24.92
	6	22.95	**32.06**

Table 2: BLEU scores for our submitted models at various training steps. Best scores are in bold, and underlined scores are the models submitted to OCELoT, the submission system used for the shared task.[6] We compare performances of models trained with or without MultiParaCrawl (MPC) data.

due to the large amount of data. The training of fastText and VecMap and application of vocabulary transfer take less than an hour, and the offline BT for DSB→DE takes around 1 hour.

We use an additional stopping criterion of no improvement on the validation set in 1 million iterations. The metric we use for measuring improvement is the into-DE BLEU score, with the exception of step 6, in which we use the into-DSB BLEU score.

The hyperparameters used follow those used in Song et al. (2019), except for the epoch size being set at 100 thousand steps, rather than 200 thousand steps [7]. We shorten this as it saves systems more often and early stopping is applied more quickly. Our code is made freely available.[8]

Model	DE->DSB	DSB->DE
Multilingual	19.70	25.29
Multilingual + VT	20.30	28.14
Ours	19.25	26.00
Ours + VT	**22.46**	**30.04**

Table 3: BLEU scores comparing the two-language versus multilingual training schemes, with and without vocabulary transfer (VT).

4 Results

Table 2 shows our BLEU scores for our submitted models DE–DSB, starting from step 4. As we can see, the 5th step of MT using the synthetic data obtained from offline BT scores the best for DE→DSB, as such we used our models at this step for our submissions for this direction. For DSB→DE, we see the BLEU score actually drops for step 5, but the second phase of UNMT training improves the BLEU by roughly 1 point over step 4.

4.1 Pretraining Two Languages at a Time

In our first research question, we asked if it is best to train on two languages at a time. To answer this, we compare our model (without the MPC data) to another model trained on all 4 of our languages from the start. Specifically, we do MA for all languages, and MT for those with parallel data. We train this for 2 days, so that it is trained for the same length as steps 1 and 2. We then train using

Model	DE→CS	CS→DE	DE→HSB	HSB→DE
Multilingual	11.56	14.36	49.22	49.14
Ours (step 1)	**15.05**	**16.16**		
Ours (step 2)			**52.14**	**51.57**

Table 4: BLEU scores of the auxiliary directions during pretraining.

Transfer Method	DE→DSB	DSB→DE
None	19.25	26.00
Simple	**22.64**	29.98
Levenshtein	22.46	**30.04**

Table 5: BLEU scores comparing no vocabulary transfer to our 2 methods.

Transfer Method	DSB→DE
None	3.15
Simple	19.00
Levenshtein	**21.27**

Table 6: Comparison of our model from step 2 with and without vocabulary transfer.

the UNMT objectives. The results are shown in Table 3.

Despite the model being exposed to DSB for longer, the performance is equal compared to our model without vocabulary transfer, and worse compared to the model with vocabulary transfer.

Without vocabulary transfer, the results being equal shows that exposing the model to DSB early within the training is not important to the final performance. We expect this might be due to the limited training data of DSB, as Wu and Dredze (2020) similarly found that the multilingual model mBERT performed more poorly on languages lacking in monolingual data.

With vocabulary transfer, we see that the model that has not seen DSB at all benefits more from the initialization than the model which has. We believe this shows the underlying advantage of training a model on few languages at a time, as it develops a better internal representation for the auxiliary languages, which enables better transfer. Table 4 shows that the performance of our model on the auxiliary languages is better when it can focus on learning one language pair at a time.

Moreover, while the multilingual model could learn to mimic its internal representation of HSB when encoding DSB, its representation according to Table 4 is poorer, and our model with vocabulary transfer explicitly copies the only language-dependent information the model receives, forcing an internal representation of DSB based on that of HSB.

4.2 Vocabulary Transfer Analysis

We also conduct an ablation of our novel method of vocabulary transfer. Table 5 shows the results of step 4, with and without vocabulary transfer. We also show results for a simpler transfer method: rather than taking the top 10 most similar candidates and choosing based on Levenshtein distance, we simply select the most similar candidate.

The addition of vocabulary transfer adds over 3 BLEU to the performance. We also see both transfer methods are competitive with each other in terms of improvement to performance. We expect the simple method to work better for language pairs with less similar spelling than the Sorbian languages. However our following analysis leads us to believe the Levenshtein version may perform better for similar languages.

We also perform a form of "zero-shot" transfer, where we use the model from Step 2 and test its ability to translate DSB→DE, despite the neural model never being trained on DSB at this stage. We contrast that with applying our 2 transfer methods. The results are in Table 6.

Without vocabulary transfer, the model expectedly has trouble with translation as it has not yet seen any DSB, so its vocabulary is not properly initialized. However with vocabulary transfer, we see an improvement of 16-18 BLEU, with the Levenshtein version performing best. This shows the degree to which a good initialization of the word embeddings can play a role in the overall performance of the model on an unseen language. Although UNMT (step 3) helps narrow the gap in performance, the difference of 3 BLEU also shows that unsupervised training can also stand to benefit from a better vocabulary initialization.

4.3 Back-translation

Our final research question concerns the order of back-translation. Garcia et al. (2020) found that, using a multilingual model trained on a hub language (e.g. German), one can achieve noticeable improvement by first zero-shot translating into the hub language (e.g. DSB→DE as done in step 5), then using this synthetic data for MT training. This can be followed by UNMT training (which includes online BT) for further improvement. We compare this method with the reverse, where we do UNMT training before offline BT, with the assumption that

Back-translation	DE→DSB	DSB→DE
Offline	21.74	22.74
Offline ⇒ Online	21.88	**30.14**
Online	22.46	30.04
Online ⇒ Offline	**24.64**	27.89

Table 7: BLEU scores for the different back-translation methods.

the better-quality translation after first training with online BT will result in better MT training. We show the results in Table 7.

As we can see, the performance of the model using only offline BT produces lower quality translations compared to using only online BT. While following offline BT with online BT makes up the difference in performance into DE, it still performs much worse into DSB. This supports our assumption that the better quality synthetic data leads to better MT training, as the main goal of creating synthetic DE data is to improve training with DSB on the target side.

5 Conclusion

The translation of Lower Sorbian to and from German presents a unique challenge in the field of unsupervised MT, due to the absence of parallel data and the scarcity of monolingual data for training. Therefore, the task necessitates an initial pretraining with similar, higher-resource languages. With this assumption, we experimented with various methods of pretraining, positing that training on 2 languages at a time is competitive with training with all languages at once, while allowing for a better initialization of DSB.

We also showcase a new method for transferring knowledge to the word embeddings of a transformer, provided a similar language is used in pretraining. We intend to experiment with this method further to gauge its applicability for more distantly-related languages. Finally, the use of both online and offline back-translation can improve the performance of a model, and if not done in an iterative fashion, the order in which they are performed can greatly affect the results.

Acknowledgments

We would like to thank the Center for Information Technology of the University of Groningen for their support and for providing access to the Peregrine high performance computing cluster.

The LMU Munich Systems for the WMT21 Unsupervised and Very Low-Resource Translation Task

Jindřich Libovický and **Alexander Fraser**
Center for Information and Language Processing
LMU Munich
{libovicky,fraser}@cis.lmu.de

Abstract

We present our submissions to the WMT21 shared task in Unsupervised and Very Low-Resource machine translation between German and Upper Sorbian, German and Lower Sorbian, and Russian and Chuvash. Our low-resource systems (German↔Upper Sorbian, Russian↔Chuvash) are pre-trained on high-resource pairs of related languages. We fine-tune those systems using the available authentic parallel data and improve by iterated back-translation. The unsupervised German↔Lower Sorbian system is initialized by the best Upper Sorbian system and improved by iterated back-translation using monolingual data only.

1 Introduction

In this paper, we describe systems for translation between German (*de*) and Upper Sorbian (*hsb*), German (*de*) and Lower Sorbian (*dsb*), and Russian (*ru*) and Chuvash (*cv*) developed at LMU Munich for the WMT21 shared task on unsupervised and very low resource machine translation (MT).

Upper Sorbian is a minority language spoken by around 30,000 people in today's German federal state of Saxony, Lower Sorbian has around 7,000 speakers and is spoken in the German federal state of Brandenburg. With such a small number of speakers, machine translation and automatic processing of Sorbian language is an inherently low-resource problem without any chance that the resources available for Sorbian would ever approach the size of resources for languages spoken by millions of people. On the other hand, being Western Slavic languages related to Czech and Polish, it is possible to take advantage of relatively rich resources collected for these two languages.

Unlike our last year's submission for Upper Sorbian (Libovický et al., 2020), we decided not to use synthetic data from unsupervised translation between Czech and Upper Sorbian and only did iterative back-translation. Despite having more authentic parallel data than last year, our system reaches approximately the same translation quality. Our Upper Sorbian systems ranked third out of six systems in the official ranking.

We leverage the relatedness between the Sorbian languages and use the Upper Sorbian system as a starting point for iterative back-translation using monolingual data only. Our Lower Sorbian Systems ranked second (de→dsb) and third (dbs→de) out of four teams in the official ranking.

Chuvash is a minority language spoken in the Volga region in the southwest of Russia. Although it uses the Cyrillic script, it is not related to eastern Slavic languages, but it is a Turkic language, relatively isolated in the Turkic language family. As a language with the highest number of speakers in this shared task, it also has the highest amount of available parallel data. We adopt a similar approach as for German-Upper Sorbian translation and pre-train our models on the related Kazakh language. In addition, we experiment with character-level models in the hope that they will be particularly effective for agglutinative morphology.

2 Experimental Setup

Most of our experimental setup is shared across all the language pairs. All our models use the Transformer architecture (Vaswani et al., 2017) as implemented in FairSeq (Ott et al., 2019).

All data is segmented using BPE (Sennrich et al., 2016b) with 16k merge operations as implemented in YouTokenToMe[1] without previous explicit tokenization. The merges are computed using a concatenation of all training data: German, Czech, Upper and Lower Sorbian in the first set of experiments, Russian, Kazakh, and Chuvash in the second set of experiments.

For the supervised task, we first pre-train mod-

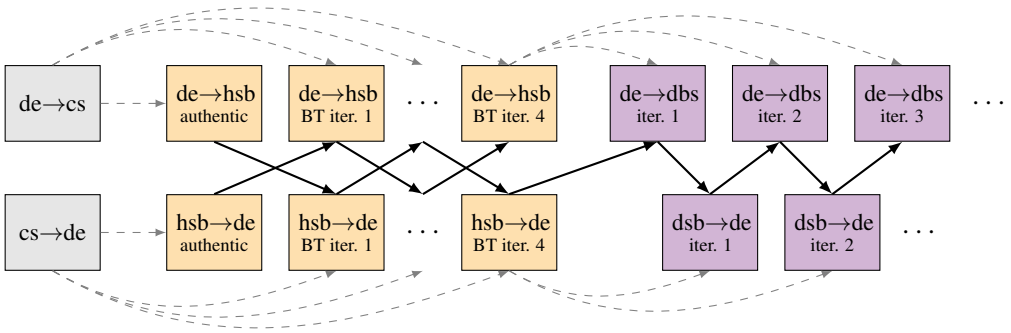

Figure 1: A diagram of the training procedure of the German↔Upper/Lower Sorbian systems. Gray dashed arrows (- - ▸) denote model initialization, solid black arrows (——▸) denote syntetic data generation by back-translation.

els on high-resource related languages: Russian-Kazakh for Chuvash and German-Czech for Upper Sorbian. We first train Transformer Base models on authentic data. These systems are used to generate back-translation (Sennrich et al., 2016a) of monolingual data. Using tagged back-translation (Caswell et al., 2019), we trained Transformer Big models for German↔Czech and Russian↔Kazakh translation. All back-translation steps use sampling and simple length-based filtering as proposed by Edunov et al. (2018)[2]. We upsample the authentic parallel data to match the size of the synthetic data.

We keep most default hyperparameters from the predefined architectures in FairSeq (`transformer` for the Base model, `transformer_wmt_en_de_big_t2t` for the Big model. The batch size is 6k tokens for the Base models, 2k tokens for Big models on a single GPU, Because we always start with high-resource training, we keep the dropout on the standard value of 0.1.

We use these models to initialize the weights (Nguyen and Chiang, 2017; Kocmi and Bojar, 2018) of the supervised low-resource models without restarting the optimizer. Because the learning rate is already low at that stage of training, we do not need to change the dropout to prevent overfitting. First, we train the supervised models using the authentic parallel data only, then we continue with iterated back-translation. The best Upper Sorbian-to-German model is used to translate Lower Sorbian monolingual data into German. In the next steps, we continue with a standard iterative back-translation procedure for unsupervised neural machine translation (Artetxe et al., 2018; Lample et al., 2018).

[2]We re-used the published code `https://github.com/pytorch/fairseq/tree/master/examples/backtranslation`.

Our final submission is an ensemble (with the vote strategy) of the best-scoring systems in the process of iterated back-translation. Language-pair-specific descriptions and results are discussed in the following sections.

We evaluate our systems using the BLEU Score (Papineni et al., 2002), chrF score (Popović, 2015) as implemented in SacreBLEU (Post, 2018).[3] Further, we evaluate the models using BERTScore (Zhang et al., 2020)[4] with XLM-RoBERTa Large (Conneau et al., 2020) as an underlying model for German and Russian and mBERT (Devlin et al., 2019) for Chuvash. Similar to the official task evaluation, we also report for each system the number of significantly worse systems in each metric at the significance level 0.95 with bootstrap resampling (Koehn, 2004) with 1k samples. For each metric, each system receives one point for each system it significantly outperforms in the metric at the significance level of 0.95.

3 German ↔ Upper Sorbian

Pre-training. For training the German↔Czech systems, we followed the same setup as in our last year's submission (Libovický et al., 2020). We used all parallel datasets from the Opus project (Tiedemann, 2012), which was 15.4M sentences after filtering by length and language identity. We trained a Transformer Base model on this data and used this model to generate back-translation. We used 20M Czech and 20M German sentences from the WMT News Crawl. We mix the back-translated and authentic parallel data one-to-one and train Transformer Big models on it.

Table 1: Quantitative results of the German↔Upper Sorbian translation systems on the development test data.

Sorbian data. We used all Upper Sorbian data provided for the shared task, i.e., 148k parallel sentence pairs (this is 88k sentence pairs more than last year), we did not apply any filtering on the parallel dataset. The development validation and the development test set of 2k sentences were the same as the last year.

Back-translation. We used 15M German sentences from the WMT News Crawl and all available monolingual Upper Sorbian data, 696k sentences, for back-translation. We applied the same rule-based statistical fixing of hyphenation-related OCR errors as the last year (Libovický et al., 2020, § 3.1). To better leverage the limited amount of monolingual data, we sample the Upper Sorbian translations 5×. We iterated the back-translation 4 times, always initializing the model with the Czech-German models (see Figure 1).

Results. The results are presented in Table 1. In the translation direction into German, the translation quality gradually increased between the back-translation steps. In the opposite direction, the translation quality oscillated. We attribute this to a larger amount of authentic German sentences. Ensembling only has a negligible effect. Note also that for translation into Sorbian, no differences between the models are statistically significant. In the opposite direction, the BLEU and the chrF score only separate the systems into two clusters, whereas the differences among BERTScores are always significant in the bootstrap testing, even though the absolute score differences are smaller. The best system for translation into German is a single from the last iteration of back-translation despite scoring slightly worse in the BLEU score.

4 German ↔ Lower Sorbian

Data. Because this is a purely unsupervised task, we did not use any Lower Sorbian parallel data.

		BLEU	chrF	BERTScore
dsb→de	Single	33.7	.606	.873
	Ensemble	33.8	.602	.874
de→dsb	Single	30.1	.587	—
	Ensemble	30.1	.588	—

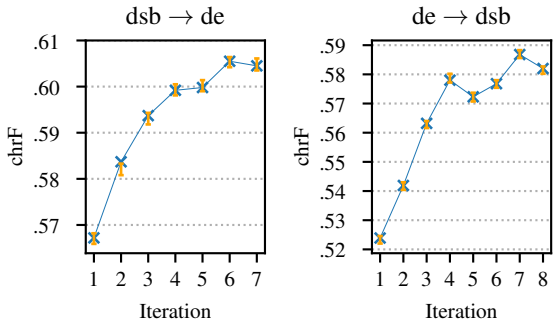

Figure 2: chrF scores during iterative back-translation for unsupervised German↔Lower Sorbian translation. The orange vertical lines denote 95%-confidence intervals using bootstrap resampling.

We used the same German monolingual data as we used for back-translation for Upper Sorbian. We use all the Lower Sorbian monolingual data, 145k sentences, provided by the organizers.

Iterative back-translation. Similarly to Upper Sorbian, we sample the back-translation of Lower Sorbian 10× for higher diversity in the training data.

Results. The final results are tabulated in Table 2. Figure 2 shows the translation quality in terms of chrF score during back-translation iterations. Similar to Upper Sorbian, the direction into German that uses larger monolingual data tends to improve more smoothly than the opposite direction. Also, the ensembling of the three best-scoring systems only has a negligible effect. The single system and

the ensemble do not significantly differ in any of the metrics.

5 Russian ↔ Chuvash

Pre-training. Similar to Upper Sorbian systems, we pre-train the systems on high-resource related language pair, Kazakh-Russian. We used the crawled Kazakh-Russian corpus of 5M sentence pairs published for WMT19 (Barrault et al., 2019) to train a Transformer Base model. We used these models to back-translation 3M Kazakh and 3M Russian sentences from the WMT News Crawl from the most recent years.

Chuvash data. We used all parallel data provided by the organizers, 717k sentence pairs, without any filtering. For back-translation, we used all 2.8M monolingual Chuvash sentences provided for the competition. For Russian, we used 18M monolingual sentences from the WMT News Crawl.

Back-translation. We ran two iterations of back-translation. We sample from the model during back-translation. We sampled 4 different translations for each Chuvash sentence to increase the training data diversity. We mix the authentic and synthetic parallel training data in the one-to-one ratio. All models are initialized by the Russian↔Kazakh models.

Character models. We further experiment with finetuning the system to the character level. Libovický and Fraser (2020) managed to train a character-level system for another Turkic language, English-to-Turkish translation. Here, we test if this is a property of Turkic languages or an artifact of the dataset English-Turkish dataset. We follow Libovický and Fraser (2020) and finetune the subword model to the character level.

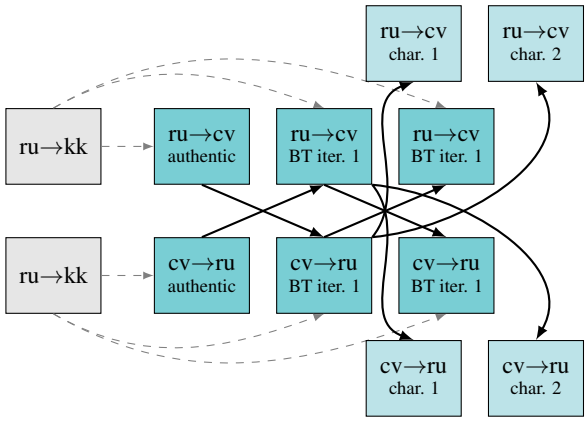

Figure 3: A diagram of the training procedure of the Russian↔Chuvash. Gray dashed arrows (- - ▸) denote model initialization, solid black arrows (⟶) denote syntetic data generation by back-translation.

Results. The results are presented in Table 3. Compared to other language pairs, back-translation had a surprisingly small effect on the translation quality. We suspect this result might be due to errors in data processing or signalize a need for a better data filtering technique. Model ensembling has no effect here. The character-level systems are on average 2 BLEU points worse than their subword counterparts, which is consistent with the results of character-level models on high-resource languages (Libovický and Fraser, 2020). Surprisingly, the character-level models seem to have much larger gains from model ensembling than the subword-based models. In fact, the ensemble of the character-level models is statistically indistinguishable from the best subword-based models.

6 Conclusions

We presented our systems for low-resourced translation between German and Upper Sorbian, unsu-

pervised translation between German and Lower Sorbian, and translation between Chuvash and Russian.

Our systems used standard state-of-the-art techniques for low-resource and unsupervised machine translation but did not exhaust all available methods. Better results could be achieved using more monolingual data and by more careful filtering of the synthetic parallel data.

A Training hyper-parameters

We use the following command line options for `fairseq-train` command in all experiments. For the Transformer Base models, we use the pre-defined `transformer` architecture, for Transformer Big, we use `transformer_wmt_en_de_big_t2t`. The batch size is 6000 tokens for the Base models and 2000 tokens for the Big models.

Abstract

This paper describes our submission for the shared task on Unsupervised MT and Very Low Resource Supervised MT at WMT 2021. We submitted systems for two language pairs: German ↔ Upper Sorbian (de ↔ hsb) and German ↔ Lower Sorbian (de ↔ dsb). For de ↔ hsb, we pretrain our system using MASS (Masked Sequence to Sequence) objective and then finetune using iterative back-translation. We perform final finetuning using the provided parallel data for translation objective. For de ↔ dsb, no parallel data is provided in the task, we use final de ↔ hsb model as initialization of the de ↔ dsb model and train it further using iterative back-translation, using the same vocabulary as used in the de ↔ hsb model.

1 Introduction

Transformer based architecture (Vaswani et al., 2017) has become the de-facto approach for training NMT models. These models have achieved good performance for resource rich languages. NMT models are usually data hungry and require lot of parallel data to get trained. However, many low-resource languages have very little or no parallel data to train a NMT model. For low resource language pairs, unsupervised MT (Artetxe et al., 2018; Lample et al., 2018; Lample and Conneau, 2019; Song et al., 2019), and transfer learning (Zoph et al., 2016a) have proven to be helpful in improving the translation performance. Unsupervised MT has gained a lot of attention in the past 3 years as it utilizes only monolingual data to train a NMT system.

In this paper, we present our system for shared task on Unsupervised MT and Very Low Resource Supervised MT at WMT2021. The task covers three languages pairs German (de) ↔ Lower Sorbian (dsb), German (de) ↔ Upper Sorbian (hsb), and Russian (ru) ↔ Chuvash (ch). We submitted systems for de ↔ hsb and de ↔ dsb. For de ↔ dsb there is no parallel data provided but for de ↔ hsb, there is small parallel data.

Summary of our submitted systems:

- We use language model pretraining using MASS (Song et al., 2019) objective to pretrain a model for de ↔ hsb using shared encoder, shared decoder, and shared vocabulary, which is followed by finetuning using iterative back-translation. The final model is finetuned using parallel data with translation objective.
- For de ↔ dsb, our model is trained using provided monolingual dsb and de data using iterative back-translation. The model is initialized using the final model of de ↔ hsb.

2 Related Work

Supervised NMT using transformer based architectures (Vaswani et al., 2017) has achieved high translation accuracy for high resource languages like English-French and English-German. Supervised NMT requires lots of parallel data to get trained. For low resource languages (which does not have large amount of parallel data) the performance of NMT systems is usually poor. We briefly describe some literature on Unsupervised MT and transfer learning.

2.1 Unsupervised NMT

Unsupervised MT gained quite a lot of attention of researchers because of its ability to train MT system without using any parallel data. The research in Unsupervised MT started with techniques which are based on statistical decipherment (Ravi and Knight, 2011; Dou and Knight, 2012, 2013; Dou et al., 2014, 2015). The approaches proposed in Artetxe et al. (2018); Lample et al. (2017) are majorly based on unsupervised cross-lingual embeddings, denoising auto-encoders, and iterative

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 995–998

back-translation. Later, some approaches of Unsupervised SMT have been proposed where a phrase table is constructed using bilingual embeddings and training is performed using language model and distortion model (Artetxe et al., 2019; Lample et al., 2018).

State of the art approaches of Unsupervised NMT are based on cross-lingual language model pretraining followed by iterative back-translation (Lample and Conneau, 2019; Song et al., 2019; Lewis et al., 2019). All these models differ with respect to pretraining objective. Lample and Conneau (2019) pretrain encoder and decoder separately using masked language modeling objective, while Song et al. (2019) pretrains encoder and decoder together using MASS (masked sequence to sequence) objective. Lewis et al. (2019) pretrains encoder and decoder using an objective similar to MASS but here the decoder is supposed to predict the whole sentence rather than only predicting the masked span of tokens.

2.2 Transfer Learning

Transfer learning have proven to be helpful for low resource languages (Zoph et al., 2016b; Dabre et al., 2017; Nguyen and Chiang, 2017). In Zoph et al. (2016b), authors use a model trained on one language pair as the initialization of the model for another language pair, they do not consider or do anything with the vocabulary. Gheini and May (2019) proposed to create a universal vocabulary before starting the training of the parent model. The transfer learning works best if the language pairs are related (Dabre et al., 2017). Aji et al. (2020) shows that the internal layers are most important in transfer learning.

3 System Overview

In this section, we describe the details of the submitted systems to shared task on Unsupervised MT and Very Low Resource Supervised MT at WMT 2021. We report results for our 2 types of models:

- **Language model pretraining using MASS objective**: For de ↔ hsb, we pretrain our model using MASS objective and then finetune it using iterative back-translation. Final finetuning is performed using parallel data of de ↔ hsb provided in the task.
- **Transfer learning**: For de ↔ dsb, we use the final model of de ↔ hsb to initialize the model of de ↔ dsb and train it further using iterative back-translation using monolingual data of de and dsb.

To train our models, we use shared encoder-decoder transformer architecture. We also use shared vocabulary of both source and target languages. For de ↔ dsb, we use the same vocabulary as used in de ↔ hsb model without considering the vocabulary mismatch.

4 Experiments

In this section, we describe the experimental setup and the hyper-parameters used.

4.1 Data and Preprocessing

For de ↔ hsb, we use monolingual data of hsb provided in the task and we use a subset (equal to the size of the hsb monolingual data) of news-crawl-2020 dataset downloaded from WMT[1] provided in the WMT news translation task for de monolingual data, and also use the parallel data provided in the task. For de ↔ dsb, we use monolingual data of dsb provided in the task together with a subset (equal to the size of the dsb data) of news-crawl-2020 dataset provided in WMT news translation task for de monolingual data.

We tokenize using Moses tokenizer (Koehn et al., 2007). We use fastBPE[2] to learn BPE (Byte pair encoding) (Bojanowski et al., 2017) with 32k BPE codes over the combined tokenized data of both languages. For de ↔ dsb, we use the same vocabulary and codes learnt for de ↔ hsb.

4.2 Experimental Setup

We use 6 layers in the encoder and decoder with 8 attention heads and 1024 embedding dimension. We use Adam (Kingma and Ba, 2015) optimizer. We use, a warm-up phase of 4000 steps with initial learning rate starting from $1e^{-7}$ to $1e^{-4}$, in the warm-up phase learning rate is increased linearly and then starts to decrease with inverse square root learning rate schedule. We use mini-batches of size 2000 tokens and set the dropout to 0.1 (Gal and Ghahramani, 2016). Maximum sentence length is set to 100 after applying BPE. At the time of decoding, we set beam size to 1. For experiments, we are using MASS[3] codebase.

[1] http://statmt.org/wmt21/translation-task.html

[2] https://github.com/glample/fastBPE

[3] https://github.com/microsoft/MASS

The pretraining is performed for 100 epochs for both de ↔ hsb. de ↔ hsb model is further finetuned using iterative back-translation for 60 epochs and then trained using parallel data for 60 epochs. de ↔ dsb model is further finetuned for iterative back-translation using the final de ↔ hsb model for 60 epochs. Epoch size is set to .2M sentences.

4.3 Results and Discussion

Lang Pair	Train	Valid	Test
de-hsb	147521	2000	2000
de-dsb	0	601	602

Table 1: Parallel data (Number of sentences)

Language	Train
hsb	695721
dsb	145198

Table 2: Monolingual data (Number of sentences) (We use equal amount of german data from news-crawl2020 as dsb and hsb to train their respective models)

Lang Pair	Our system	Best system
de-hsb	60.2	66.3
hsb-de	60.1	67.7
de-dsb	6.4	29.9
dsb-de	5.9	33.5

Table 3: Results: BLEU scores for our system and highest scoring system in the task

All the results are shown in 3. We achieve BLEU score of 60.2 and 60.1 for de → hsb and hsb → de respectively. Using the final model of de ↔ hsb as initialization of the model for de ↔ dsb, we achieve BLEU score of 6.4 and 5.9 for de → dsb and dsb → de respectively even with using the same vocabulary of de ↔ hsb. The percentage of vocabulary overlap (the percentage of de ↔ dsb vocabulary that is present in de ↔ hsb vocabulary) is 68.21 after applying BPE which makes the transfer learning work. After MASS pretraining and iterative back-translation (without using any parallel data), the BLEU scores are 4.74 and 4.92 for de → hsb and hsb → de respectively. We are able to achieve above BLEU scores without using any parallel data because of the similarity between de and hsb. The percentage of vocabulary overlap between de and hsb (the percentage of vocabulary of de present in hsb) is 60.73, which makes them highly similar languages. Similarly, the percentage of vocabulary overlap between de and dsb (the percentage of vocabulary of de present in dsb) is 54.26. The vocabulary here refers to the number of unique tokens after applying BPE.

5 Conclusion

In this paper, we study the impact of language model pretraining together with iterative back-translation for very low resource language pair i.e. de ↔ hsb. We also study the impact of transfer learning from de ↔ hsb to de ↔ dsb. In future, we plan to filter bad back-translated data while training for de ↔ dsb using iterative back-translation and also different transfer learning techniques to improve the performance for de ↔ dsb.

NRC-CNRC Systems for Upper Sorbian–German and Lower Sorbian–German Machine Translation 2021

Rebecca Knowles* and **Samuel Larkin***
National Research Council Canada
{Rebecca.Knowles, Samuel.Larkin}@nrc-cnrc.gc.ca

Abstract

We describe our neural machine translation systems for the 2021 shared task on Unsupervised and Very Low Resource Supervised MT, translating between Upper Sorbian and German (low-resource) and between Lower Sorbian and German (unsupervised). The systems incorporated data filtering, backtranslation, BPE-dropout, ensembling, and transfer learning from high(er)-resource languages. As measured by automatic metrics, our systems showed strong performance, consistently placing first or tied for first across most metrics and translation directions.

1 Introduction

This work describes our machine translation (MT) systems for translating between Upper Sorbian–German and Lower Sorbian–German (all translation directions). We focused primarily on the supervised task of Upper Sorbian–German, and then applied those systems to the task of building simple Lower Sorbian–German systems.[1]

Upper Sorbian and Lower Sorbian are Slavic minority languages spoken in eastern Germany, alongside German. The shared task data was provided to the organizers through collaborations with the Sorbian Institute[2] and the Witaj Language Centre,[3] as described in Fraser (2020), to which we direct interested readers for additional information on the languages and data. Following the 2020 shared task, the Witaj Language Centre released a publicly-available Sorbian–German MT system `sotra` (Witaj Language Centre, 2021) based on Moses (Koehn et al., 2007) and OpenNMT (Klein et al., 2017).[4]

We provide an overview of the data, preprocessing, and model architectures in Sections 2, 3, and 4. We then discuss baselines, systems, experiments in monolingual filtering, and backtranslation (all focused on Upper Sorbian–German) in Sections 5, 6, 7, and 8. In Section 9, we discuss how we applied and finetuned our existing Upper Sorbian MT systems for the task of translating Lower Sorbian. Section 10 discusses additional experiments with negative results. Finally, Sections 11 and 12 summarize the final systems and our conclusions.

2 Data

We used all provided parallel German–Upper Sorbian data and all monolingual Upper Sorbian data (after filtering), along with German–Czech parallel data from Open Subtitles (Lison and Tiedemann, 2016),[5] DGT (Tiedemann, 2012; Steinberger et al., 2012), JW300 (Agić and Vulić, 2019), Europarl v10 (Koehn, 2005), News-Commentary v15, and WMT-News.[6] We also used the monolingual Upper Sorbian Web, Witaj and Sorbian Institute datasets as well as the Lower Sorbian monolingual data (the latter for Lower Sorbian tasks only).[7] We used the provided `devel` sets for development, and the `devel_test` systems for measuring progress and choosing which systems to submit.

3 Preprocessing and Postprocessing

As preprocessing, we first clean all of the available training data (but not development or test data) using `clean-utf8-text.pl` with the `-no-phrase-sep` flag from `PortageTextProcessing`.[8] For parallel training data, we use `clean-corpus-n.perl`

*Both authors contributed equally to this work.

[1] We abbreviate language names as follows: *cs* (Czech), *de* (German), *dsb* (Lower Sorbian), and *hsb* (Upper Sorbian).

Table 1: Data and how it was used, whether for BPE training and vocabulary extraction, parent model training, or child model training. All numbers of lines reflect data after initial cleaning and filtering by known characters. Special tags (for language or backtranslation) are shown where they are used, upsampling is shown with ×, and BPE-dropout is shown.

from Moses (Koehn et al., 2007) with ratio 15, and for monolingual data we remove empty lines. We normalize punctuation with Moses's `normalize-punctuation.perl` and remove the non-breaking space `\xa0`. We perform additional sentence splitting to improve tokenization,[9] then tokenize with Moses's `tokenizer.perl -a -l $LNG` (where $LNG is cs, de, or hsb), then re-merge the sentences that were split into single lines. For all German-Czech parallel data and all monolingual German or Czech data, we removed any lines that contained characters that had not been observed in DE-HSB training data, WMT-News, or Europarl. This helps clean data of unusual encoding issues, as well as removing text that is clearly in other languages (i.e., written in other scripts).

We build BPE vocabularies of size 10k, 15k, 20k, and 25k merges using `subword-nmt`[10] (Sennrich et al., 2016). We also add all Moses and Sockeye special tags (ampersand, <unk>, etc.) and a number of additional reserved tags (for backtranslation, languages, etc.) to a glossary file used for applying BPE, which prevents them from being segmented. For building the BPE models, we used all HSB-DE data, the Sorbian Institute and Witaj monolingual HSB data, CS-DE data, and news-commentary (DE) data; the HSB data was upscaled twice (see Table 1 for full details). The same datasets were used for extracting the joint vocabulary, which was then used for source and target.

In standard postprocessing, we de-BPE and detokenize (using the Moses `detokenizer.perl -a -l $LNG`).

4 Models

We built Transformer models (Vaswani et al., 2017) using Sockeye (Hieber et al., 2018) version 2.3.14 and cuda-10.1. We used the default value of 6 encoder/decoder layers, 8 attention heads, the Adam (Kingma and Ba, 2015) optimizer, label smoothing of 0.1, a cross-entropy-without-softmax-output loss, and a model size of 512 units with a FFN size of 2048. We performed early stopping after 32 checkpoints without improvement. We chose custom checkpoint intervals of 4000 updates when the train corpus was deemed big enough and 500 updates when the train corpus was small. We optimized for BLEU (Papineni et al., 2002)[11] and used the whole validation set during validation. The batch size was set to 8192 tokens, and the maximum sequence length for both source and target was set to 200 tokens. We used weight tying and vocabulary sharing, but we set gradient clipping to absolute and kept the initial learning rate of 0.0002. We used a beam size of 5 in all submit-

[9] Using `utokenize.pl -p -ss -notok -paraline -lang=en` from `PortageTextProcessing`.

[10] https://github.com/rsennrich/subword-nmt

[11] All BLEU scores were computed using `sacreBLEU` (Post, 2018) with the signature `BLEU+case.mixed+numrefs.1+smooth.exp+tok.13a+version.1.4.14`. The chrF scores (Popović, 2015) were generated in the submission interface.

ted systems.[12] When systems deviate from these (i.e., different learning rates or label smoothing), we make note of it in our descriptions.

5 Baselines

We build several types of baselines against which to measure our improvements. They are shown in Table 2 and discussed in the following sections.

System	DE-HSB	HSB-DE
Translation Memory	16.3	15.5
2020 Bitext Baseline	47.0 (10k)	45.7 (10k)
Bitext Baseline	53.2 (10k)	51.9 (15k)
2020 Final Submission	59.4 (20k)	58.9 (10k)

Table 2: BLEU scores for baseline systems measured on devel_test data (vocabulary size in parentheses).

5.1 Translation Memory

We build translation memory baselines, following Simard and Fujita (2012). For each source sentence in devel_test, we find the most similar (as measured by sentence-level BLEU) source sentence in the full training set and return its translation as our hypothesis. The relatively high scores obtained demonstrate the high levels of similarity between the devel_test and train domains (though we note that very few sentences are *exact* matches for ones in the training data).

5.2 Bitext Baselines

We build baselines using the available DE-HSB bitext, first with only the bitext available for the 2020 iteration of the task, and then with the 2020 and 2021 training data combined. As we see in the middle rows of Figure 2, the increase in data from 60,000 to 147,521 lines resulted BLEU score increases of +6.2 in both translation directions.

5.3 2020 Final Systems

As a last "baseline", we consider our final submissions to the 2020 shared task. In the DE-HSB direction, this was a four system ensemble, all of which were child systems incorporating backtranslation and built on top of parent systems trained on either DE-CS or DE-"pseudo-HSB", with a mix of types of BPE-dropout. The HSB-DE direction was an ensemble of 5 child systems using backtranslation on top of a similar set of parent systems. These are described in detail in Knowles et al. (2020).

[12] In paraphrasing experiments where we generated 10-best lists, we used a beam size of 10, but these did not contribute to our final systems.

6 Systems

Here we describe the general types of systems that we have built, including parent DE-CS systems, multilingual systems, and the child (and grandchild) systems we built on top of those.

6.1 Parent Systems

We first built DE-CS and CS-DE parent systems, using OpenSubtitles, DGT, JW300, Europarl, News-Commentary, and WMT-News as training data. The training data is used once in its original form, and concatenated with 10 different versions each generated by an iteration of BPE-dropout (both source and target)[13] with a dropout rate of 0.1. We use newstest2019-csde as the development set. This results in DE-CS and CS-DE systems with BLEU scores between 22 and 25 on the newstest2019-csde development set. We use these parent systems for transfer learning.

6.2 Multilingual Systems

When we build CS-DE and DE-CS parent systems and then use them for transfer learning by finetuning on HSB-DE or DE-HSB data, they undergo "catastrophic forgetting" (Thompson et al., 2019; Gu and Feng, 2020) and lose the ability to translate Czech while gaining the ability to translate Upper Sorbian, as measured on their respective development sets. While we don't necessarily *need* to maintain the ability to translate Czech, we explored whether multilingual systems might improve performance on our task of interest. To this end, we build multilingual systems, which incorporate CS-DE data, upsampled HSB-DE data, and backtranslated data (DE in the case of HSB-DE systems, HSB in the case of DE-HSB systems). In these systems we performed upsampling with the aim of having approximately 1 part CS-DE to 4 parts HSB-DE data (reflective of our priority to translate HSB-DE). We did not experiment with additional ratios; we leave this to future work.

For DE-HSB multilingual systems, we used monolingual HSB data (backtranslated and upsampled 6 times) tagged with <BT> tags, DE-CS data (Europarl, News-Commentary, WMT-News; upsampled 3 times) tagged with <CS>, and the parallel DE-HSB training data (upsampled 21 times and untagged). For HSB-DE multilingual systems,

[13] Note that we only apply BPE-dropout to training data, never to development or test data.

we used a sample[14] of the news 2019 DE data backtranslated and tagged with <BT>, the same three CS-DE corpora tagged with <CS> and upsampled, and the HSB-DE training data upsampled (the upsampling of these latter corpora depended on the size of the backtranslated data).

6.3 Child Systems

Child systems are initialized with the parameters of some given system and are then finetuned on a new set of data with continued training. This is how we perform transfer learning, taking a parent system trained on CS-DE (or DE-CS) data and converting it to an HSB-DE (or DE-HSB) system by starting from the parent system parameters and training on the appropriate language data, as in Kocmi and Bojar (2018). In some cases, we repeat this process multiple times with different sets of data, building "grandchild" systems on top of child systems.

7 Monolingual Data Filtering

Given the tight coupling between the domain of the development/development-test data and the training data, the large quantity of monolingual data available for backtranslation from German, and inspired by the filtering used in the high-performing 2020 submission by Scherrer et al. (2020) we examined whether we should subsample data for backtranslation.[15] We used the 2020 final systems described in Knowles et al. (2020) to backtranslate all available News 2019 DE. This enabled us to train child systems with a random sample of 1.5 million lines of text, the full available backtranslated data, and several approaches to sampling the data.

We first describe HSB-DE experiments with the fixed data size of 1.5 million lines of backtranslated DE monolingual data. We use a *random* sample as a baseline. We compare to it two approaches to using pretrained Sentence-Transformer embeddings[16] (Reimers and Gurevych, 2019) and cosine similarity for domain filtering: ranking sentences in the monolingual data based on their similarity to the *average* embedding of the full DE side of the DE-HSB training data and selecting the 1.5 million most similar,[17] and selecting the 1.5 million sentences most similar to any *individual* sentence in the DE side of the DE-HSB training data.[18] We also apply *Moore-Lewis* filtering (Moore and Lewis, 2010), again treating the DE side of the DE-HSB training data as the "in-domain" data. Moore-Lewis (M-L) uses language models[19] to compare out-of-domain data to in-domain data on the basis of cross-entropy, enabling the sampling of in-domain-like text from the out-of-domain set.

Filter	Both	Src.	None
Random	57.5	57.1	*57.3*
Average	57.5	*57.4*	57.1
Individual	**57.7**	56.9	57.1
Moore-Lewis	**57.7**	57.2	*57.3*
M-L thresh.: 0	**57.7**	**58.1**	**57.9**

Table 3: BLEU scores of HSB-DE child systems trained on authentic HSB-DE parallel text (upsampled) and 1.5 million lines of backtranslated (iteration 1) News 2019 data, sampled using different approaches. Results shown are for 15k vocabulary. Columns indicate type of BPE-dropout (both source and target, source only, and neither). The last line shows thresholded Moore-Lewis, with 5,071,268 lines selected.

We find that the Moore-Lewis approach outperforms or matches the random baseline across three variations of BPE-dropout. Table 3 shows results for 15k BPE, but we found the same across 10k, 15k, 20k, and 25k vocabularies. With both source and target BPE-dropout, the Moore-Lewis sample was always best or tied for best, with source side or no dropout it was always best or second best.

We also built systems with no BPE dropout, using full backtranslated News 2019 data; for larger BPE sizes, the Moore-Lewis samples outperformed the full data (despite being much smaller and thus more efficient), while for the smaller BPE sizes, Moore-Lewis came in second behind the full data.

With 1.5 million as a relatively arbitrary size, we proceeded with using a threshold for Moore-Lewis filtering. A threshold of 0 resulted in 5,071,268 lines sampled from News 2019. With upsampling

[14] As described in Section 7, Moore-Lewis filter.

[15] Data subsampling or filtering or of one sort or another was also used by several other submissions in 2020, including: Dutta et al. (2020), Edman et al. (2020), and Knowles et al. (2020).

[16] From https://github.com/UKPLab/sentence-transformers, with model *paraphrase-xlm-r-multilingual-v1*, a multilingual version of *paraphrase-distilroberta-base-v1*, trained on parallel data for 50+ languages (Reimers and Gurevych, 2020).

[17] Similar to the domain-cosine approach in Aharoni and Goldberg (2020).

[18] We note that this uses external pretrained models, and we have done this only for the purpose of experimenting with backtranslation; none of our final submissions are built using these approaches, so they remain constrained.

[19] 4-gram language models built with MITLM (https://github.com/mitlm/mitlm).

HSB-DE data to match it in size, we found that the Moore-Lewis threshold child models outperformed the 1.5 million size and also outperformed or matched the full data size systems.

We also tested Moore-Lewis filtering on the Upper Sorbian monolingual data, but found it to be less useful in that case, likely due to the much smaller size of available data, and potentially to closer matches (due to the shared origins of the training data and some of the monolingual data).

8 Backtranslation

8.1 BT1

For our first iteration of backtranslation, BT1, we use our final submitted systems from last year's task, as described in Section 5.3.

8.2 BT2

Our second iteration of backtranslation was performed using ensembles of (at the time) best-performing systems at the midpoint of the shared task. Keeping in mind that ensembles typically outperform single systems, and that we found that diverse ensembles seemed to outperform less diverse ensembles, we chose our best-performing systems and then two variants of each to ensemble for the second round of backtranslation. For DE-HSB, the child systems ensembled were the `both`, `src`, and `none` BPE-dropout variants trained on the true DE-HSB data (upsampled 3 times) and BT1 backtranslated HSB data, with a 25k vocabulary. For HSB-DE, the child systems ensembled were also `both`, `src`, and `none` BPE-dropout variants trained on the the true DE-HSB data (upsampled 35 times) and BT1 News 2019 DE data filtered using Moore-Lewis and a threshold of 0, with a 15k vocabulary.

8.3 Analysis of Backtranslation

We compared BT1 and BT2 outputs and found them to be quite similar, sometimes even identical. This brought us to a closer examination of the backtranslation systems and the training data itself. As part of our analysis and experiments, we performed backtranslation of the full DE-HSB training data.

Doing so, we observed that significant portions of the training data had been memorized by many of our systems, and where differences existed, they tended to be quite small. As evidence of this, for both BT1 and BT2, in both translation directions, the BLEU scores for backtranslated training data were 98.2 or higher. Nevertheless, the high automatic metric scores on held-out data suggest that these systems are still able to generalize (that is, they have not *only* memorized data), though it does raise questions about *how* general the models are: would they perform nearly as well on out-of-domain data?

9 Lower Sorbian

The data provided for Lower Sorbian consists of 145,196 lines of monolingual data and the small (approx. 600 line) parallel devel and devel_test sets. In order to build systems, we relied on the relatedness of Lower Sorbian and Upper Sorbian. Since we primarily focused on Upper Sorbian, our BPE vocabularies were *not* learned using Lower Sorbian; we leave an exploration of that to future work. Here we describe our process of building Lower Sorbian systems from Upper Sorbian systems.

9.1 Initial Round

Without any parallel data, we first tried simply translating with our existing HSB-DE and DE-HSB systems and ensembles. In the DE-DSB direction, the resulting devel_test DSB scores were between 7.7 and 8.1 BLEU, while in the DSB-DE direction, the scores were naturally a bit higher (since the system *has* trained on the output language of German), between 17 and 19 BLEU.

From there, we translated the full DSB monolingual data using one of our best HSB-DE single systems: 25k vocabulary, standard parent CS-DE (BPE-dropout both), finetuned child system using BT2 M-L threshold 0 news data and the original HSB-DE training data with BPE-dropout (both) and label smoothing of 0.15. The relatively high BLEU scores that we observed when translating DSB devel and devel_test data with HSB-DE systems allowed us to assume that the output might be more than just noise, and ideally at least good enough for use as the source side.

For backtranslation of DE into DSB, we used an ensemble of two 25k vocabulary DE-DSB systems. The first started from a default parent DE-CS system with BPE-dropout (both) and was then finetuned as a multilingual system using BT2 backtranslated HSB monolingual data and DE-CS data (as described in Section 6.2) with BPE-dropout (both). Then it was finetuned with the initial round backtranslated DSB monolingual data just described, again with BPE-dropout (both). The

second also started from the default DE-CS BPE-dropout (both) system and was finetuned with BT2 backtranslated HSB monolingual data with BPE-dropout (both) and learning rate of 0.0001. This was then also finetuned with initial round backtranslated DSB monolingual data, with BPE-dropout (both) and a learning rate of 0.0001.

9.2 Next Round

We also built another DSB-DE system for performing next round backtranslation. It began with a 20k vocabulary standard parent CS-DE (BPE-dropout both), as with previous systems, finetuned child system using BT2 M-L threshold 0 news data and the original HSB-DE training data with BPE-dropout (both) and label smoothing of 0.15. We then finetuned this with the DE side of the full HSB-DE training data, backtranslated to DSB using the initial round DE-DSB system.

10 Inconclusive and Negative Results

We now discuss negative results, i.e., experiments that we performed that were unsuccessful. All of these were performed on Upper Sorbian-German.

10.1 Fuzzy Matching

We performed brief and ultimately unsuccessful experiments with using similar translations from the training data to guide translation, as in Xu et al. (2020). In this approach, for each source sentence (train, development, or test), we first extract its best "fuzzy match" from a translation memory (we use the parallel HSB-DE data for this, and select the best *non-exact* fuzzy match) if any is available. The system input then consists of the source sentence, followed by a special token, followed by the target language sentence corresponding to the closest source fuzzy match from the translation memory (called **FM**$^{\#}$ in Xu et al. (2020)). We also tried an approach like their **FM*** approach, where target language tokens are masked with a special token if they do not align[20] to a source language word that is contained in the source sentence to be translated. In either case, if no fuzzy match is returned, a special null token replaces the target language text in the input. Both approaches performed almost identically to the baseline, so we did not proceed with additional experiments (including those approaches that used factors). We experimented with a range of thresholds for fuzzy matches (0.0, 0.35, 0.5), all using `FuzzyMatch-cli`[21] but all performed comparably. We believe this remains an open area for exploration: did the systems fail to outperform the baseline because the baseline had already attained high quality? Did the small size of the translation memory hurt performance?

10.2 Backtranslation as Paraphrasers

Inspired by work like Khayrallah et al. (2020), we also experimented with whether we could treat our high-quality backtranslation systems as paraphrasers to generate more diverse data by translating the HSB-DE parallel data (in each direction) with sampling rather than using one-best output of beam search. We tried building children with this data (both with only authentic target side data and with full combinations of sampled datasets), but did not find that it improved over comparable systems. One issue is that the HSB-DE training data is nearly memorized, as discussed in Section 8.3, so even in the sampled data, many of the differences between translations are quite small.

10.3 Backtranslation-Only Systems

Following Abdulmumin et al. (2021), we experimented with finetuning our parent systems using *only* backtranslated data, followed by then finetuning on the authentic parallel data. We had mixed results with this approach – one of them was high-performing enough to include in our HSB-DE final ensemble, but there was not enough evidence for this language pair to conclude that the approach is broadly useful (beyond providing additional diversity to ensembles).

11 Final Systems

According to preliminary automatic metric results from the shared task organizers, our systems performed quite well. The metrics considered were BLEU, chrF, and – in the case of translation into German – BERT Score. Each translation direction saw five systems submitted, with the exception of DSB-DE, which only had four. Our HSB-DE had the best BERT score (0.981), the second-best BLEU score (67.3, 0.4 BLEU behind NoahNMT), and the best chrF score; it was significantly better than all four other systems in terms of BERT score, while in terms of BLEU and chrF it was better than three other systems (tying with NoahNMT).

[20] We used `fast_align` (Dyer et al., 2013).

	Test		devel_test	
System	**BLEU**	**chrF**	**BLEU**	**BLEU (sing.)**
HSB-DE	67.3 (-0.4)	0.836 (+0.002)	60.0	58.5
DE-HSB	66.3 (+0.4)	0.837 (+0.004)	59.9	58.1
DSB-DE	33.5 (+0.2)	0.638 (+0.016)	34.9	34.5
DE-DSB	29.9 (+2.4)	0.599 (+0.020)	31.0	30.1

Table 4: Final submission scores on test sets. In parentheses, we show the difference between our system and the best performing system by another task participant (positive indicates our system scored highest, negative indicates that the other team's score was higher). The last two columns show scores on devel_test, first for the ensemble and then for the single best component systems in the ensemble (sing.).

Our DSB-DE system had the best BLEU and chrF scores and was tied for the best BERT score (0.953) with CL_RUG; in terms of BLEU and chrF it was significantly better than one other system (alongside CL_RUG and LMU) and in terms of BERT score it was significantly better than two other systems (alongside CL_RUG). Both of our systems translating out of German had the highest BLEU and chrF scores. Our DE-HSB system was, alongside NoahNMT, significantly better than three other systems in both automatic metrics. Our DE-DSB system was, alongside LMU, significantly better than three other systems in both automatic metrics.

11.1 HSB-DE

Our Upper Sorbian-German submission is an ensemble of eight systems with 25k vocabulary, which scored 67.3 BLEU (0.836 chrF) on the test set. The first six systems in the ensemble are children and grandchildren of a CS-DE system (with both source and target BPE-dropout). The final two were multilingual systems trained on a mix of CS-DE and HSB-DE data. Their details are as follows:

1. HSB-DE data, BT2 news (M-L threshold 0), BPE-dropout (both), and label smoothing set to 0.15 (best single system)
2. HSB-DE data, BT2 news (M-L threshold 0), BPE-dropout (both), and transformer dropout at 0.20
3. Child of system 1, finetuned on only HSB-DE (with BPE-dropout, both)
4. Multilingual (mix of CS-DE language-tagged, BT1 news M-L top 1.5M tagged as BT, and HSB-DE upscaled)
5. HSB-DE data, BT1 and BT2 (M-L threshold 0, each), BPE-dropout (both)
6. Child of a backtranslation-only, BT1 and BT2 (M-L threshold 0, each), BPE-dropout (both)
7. Multilingual (not a child) mix of CS-DE and HSB-DE data, BT2 (M-L threshold 0), BPE-dropout (both)
8. Multilingual (not a child) mix of CS-DE and HSB-DE data, BT1 (M-L top 1.5M), BPE-dropout (both)

11.2 DE-HSB

Our German-Upper Sorbian system is an ensemble of seven systems with 25k vocabulary, of which the first five are children or grandchildren of a DE-CS parent system (with both source and target dropout). The final two are multilingual systems. In all cases, any backtranslation listed (BT1 or BT2) is backtranslation of the monolingual HSB data. For this language direction, our primary submission does *not* use additional postprocessing. While the additional postprocessing improved all other language directions/pairs, it decreased BLEU by 0.1 in this pair (chrF remained unchanged). The system scored 66.3 BLEU (0.837 chrF) on test.

1. Multilingual system with BT2 and BPE-dropout (both)
2. Child of system 1, finetuned on DE-HSB with BPE-dropout (both)
3. DE-HSB data, BT2, BPE-dropout (both), label smoothing set to 0.15
4. Same as system 3, with transformer dropout set to 0.15
5. DE-HSB data, BT1, BPE-dropout, both
6. Multilingual (not child), BT2, BPE-dr. (both)
7. Multilingual (not child), BT1, BPE-dr. (both)

11.3 DSB-DE

Our Lower Sorbian-German system is an ensemble of two systems with 20k vocabulary, scoring 33.5 BLEU (0.6388 chrF) on test. Both systems are

children of the 20k vocabulary equivalent of the first component of the HSB-DE ensemble: taking a CS-DE parent, then training on HSB-DE data and BT2 news (M-L threshold 0), with BPE-dropout (both), and label smoothing set to 0.15.

They train on authentic DE data that is paired with DSB backtranslations, generated by the initial round DE-DSB ensemble (described in Section 9.1).

1. Child trained on backtranslation paired with DE side of the DE-HSB training data, BPE-dropout (both), learning rate 0.0001.
2. Same as the first system, with the addition of backtranslated news 2019 (M-L threshold 0).

11.4 DE-DSB

Our German-Lower Sorbian system is an ensemble of four 20k BPE systems, and scored 29.9 BLEU (0.599 chrF) on test. All four systems are based on a default DE-CS parent with BPE-dropout (both). The first three are then finetuned with BT2 backtranslated HSB data and BPE-dropout (both). The last was finetuned with a multilingual system (again with BT2 backtranslated HSB and BPE-dropout both). We now describe how those systems were finetuned to the DE-DSB task (all used BPE-dropout both):

1. Finetuned with DSB monolingual data (initial round backtranslated).
2. Finetuned with DSB monolingual data (next round backtranslated).
3. Same as system 2 with learning rate 0.0001.
4. Same as system 3 (different parent).

12 Conclusions

As with last year's task, we found that our best systems consisted of ensembles, with more diverse ensembles performing better than less diverse ones. The very high automatic metric scores along with our experiments in backtranslation led us to examine the state of memorization of the training data, which we found to be quite high. We also found that the close relationship between Upper Sorbian and Lower Sorbian enabled us to bootstrap seemingly strong Lower Sorbian systems through iterative backtranslation. We believe that the true test of these systems will be through human evaluation, as well as an analysis of how well they perform in a real-life setting (i.e., with more out-of-domain test data), as the current set seems potentially quite constrained in domain.

Abstract

This paper describes the NoahNMT system submitted to the WMT 2021 shared task of Very Low Resource Supervised Machine Translation. The system is a standard Transformer model equipped with our recent technique of dual transfer. It also employs widely used techniques that are known to be helpful for neural machine translation, including iterative back-translation, selected finetuning, and ensemble. The final submission achieves the top BLEU for three translation directions.

1 Introduction

In this paper, we describe the NoahNMT system submitted to one of the WMT 2021 shared tasks. The shared task features both unsupervised machine translation and very low resource supervised machine translation. As our core technique is mainly suitable for low resource supervised machine translation, we participated in four translation directions between Chuvash-Russian (chv-ru) and Upper Sorbian-German (hsb-de).

Our core technique is called dual transfer (Zhang et al., 2021), which belongs to the family of transfer learning. It transfers from both high resource neural machine translation model and pretrained language model to improve the quality of low resource machine translation. During the preparation for the shared task, we conducted additional experiments that supplement the original paper, including the choice of parent language, the validation of Transformer big model, and the usage of dual transfer along with iterative back-translation.

In addition, we also applied proven techniques to strengthen the quality of our system, including selected finetuning and ensemble. Our final submission achieves the top BLEU on the blind test sets for three translation directions: chv→ru, ru→chv, and hsb→de.

2 Approach

In this section, we describe the techniques used in our system. Interested readers are encouraged to check out the original papers for further details.

2.1 Dual Transfer

We reproduced the illustration of dual transfer from the original paper (Zhang et al., 2021), as shown in Figure 1. This illustration shows the case of general transfer, where the high resource translation direction is A→B, and the low resource translation direction is P→Q. As discussed in the original paper, in many cases, it is possible to use shared target transfer (B=Q) or shared source transfer (A=P). Taking chv→ru as an example, we can choose en→ru as the high resource translation direction, resulting in an instance of shared target transfer. In this shared task, when training the high resource translation model, we always initialize the shared language side with the pretrained language model BERT (Devlin et al., 2019).

2.2 Iterative Back-Translation

Iterative back-translation (Hoang et al., 2018) is an extension of back-translation (Sennrich et al., 2016a). It can exploit both sides of monolingual data of a language pair, and produces translation models for both directions, which is suitable for this shared task.

The initial models for generating synthetic parallel data are produced by using dual transfer with low resource authentic parallel data. In each iteration of iterative back-translation, we use the latest model to greedily decode a disjoint subset of 4m monolingual sentences[1] to generate synthetic parallel data. Then a new model is trained on a mixture of authentic and synthetic parallel data. With the use of dual transfer, model training can start from

[1] For chv and hsb, all monolingual sentences are used in each iteration.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1009–1013

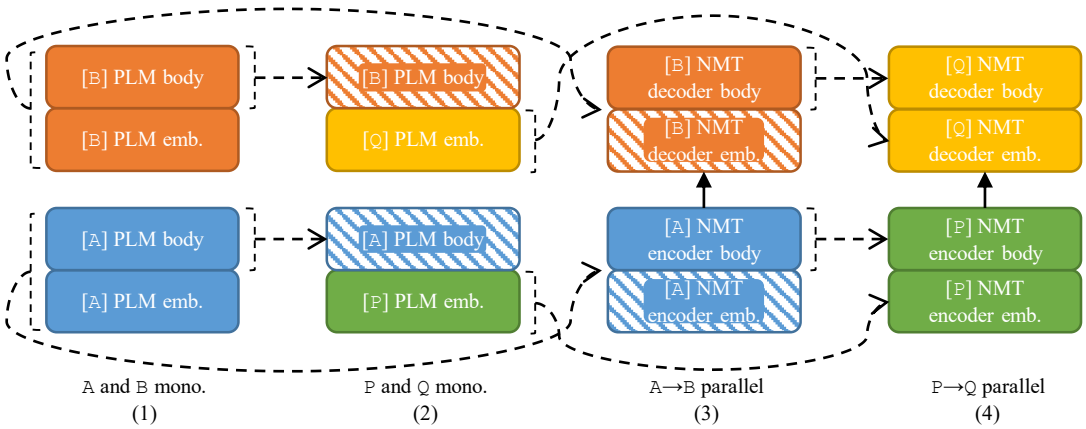

Figure 1: Dual transfer from pretrained language model and high resource A→B neural machine translation to low resource P→Q neural machine translation. Dashed lines represent initialization. Parameters in striped blocks are frozen in the corresponding step, while other parameters are trainable. Different colors represent different languages. Data used in each step is also listed.

language code	# sentence (pair)
cs-de	15m
hsb-de	0.1m
kk-ru	3.9m
en-ru	17m
chv-ru	0.7m
cs	90m
de	100m
hsb	0.8m
kk	17m
en	54m
ru	110m
chv	3m

Table 1: Training data statistics.

parent language	chv→ru BLEU
kk	18.47
en	18.61

the initial parameters as shown in Step (4) of Figure 1. This has the additional benefit of reducing training time, because convergence is faster than training from random initialization.

2.3 Selected Finetuning

Selected finetuning aims to deal with the domain difference that may exist between the test set and the training set. Given the source side of the test set, we try to select similar source sentences from the training set, and then finetune the translation model on the selected subset of training sentence pairs.

We use BM25 (Robertson and Zaragoza, 2009) to calculate the similarity between two sentences for retrieval. The BM25 score between a query sentence Q and a sentence D in the corpus for retrieval $\mathcal{C}$ is given by

$$s(D,Q) = \sum_{i=1}^{L_Q} \frac{\text{IDF}(q_i) \cdot (k+1) \cdot \text{TF}(q_i, D)}{k \cdot \left(1 - b + b \cdot \frac{L_D}{L_{\text{avg}}}\right) + \text{TF}(q_i, D)},$$

where the query sentence Q is a sequence of L_Q subwords $\{q_i\}_{i=1}^{L_Q}$, $\text{IDF}(q_i)$ is the Inverse Document Frequency for q_i in the corpus $\mathcal{C}$, $\text{TF}(q_i, D)$ is the Term Frequency for q_i in the sentence D, L_D is the length of the sentence D, L_{avg} is the average length of the corpus $\mathcal{C}$, k and b are hyperparameters, which are set as 1.5 and 0.75, respectively.

Based on the BM25 score, we calculate the similarity between a source test sentence (as the query sentence) and the source sentences in the training set to obtain the top 500 sentences. After performing the selection for all the source test sentences, we merge them and remove duplicates to obtain the set for finetuning.

model	chv→ru	ru→chv	hsb→de	de→hsb
Transformer base	18.61	16.18*	55.60	55.98
Transformer big	19.24	17.12	56.10	57.12

$\text{NMT}_{\text{chv}\rightarrow\text{ru}}$	14

Table 4: Runtime of each step in dual transfer for $\text{NMT}_{\text{chv}\rightarrow\text{ru}}$ with Transformer big.

3 Experimental Setup

3.1 Data

We collected allowed data for the involved languages and followed the same preprocessing pipeline of punctuation normalization and tokenization, using scripts from Moses[2]. The English monolingual data came from the English original side of ru-en back-translated news[3], but its automatic translation to Russian was discarded. The provided Chuvash-Russian dictionary was not used. Each language was encoded with byte pair encoding (BPE) (Sennrich et al., 2016b). The BPE codes and vocabularies were learned on each language's monolingual data, and then used to segment parallel data. We used 32k merge operations for all languages. After BPE segmentation, we discarded sentences with more than 128 subwords, and cleaned parallel data with length ratio 1.5. Training data statistics is provided in Table 1. Note that we experimented with Kazakh (kk) data (Section 4.1), but did not use it for our final submission. Evaluation on test sets is given by SacreBLEU[4] (Post, 2018), after BPE removal and detokenization.

3.2 Hyperparameters

We use Transformer (Vaswani et al., 2017) as our translation model, but with slight modifications that follow the implementation of BERT[5]. The absolute position embeddings are also learned as in BERT. The encoder and decoder embeddings are independent because each language manages its own vocabulary, but we tie the decoder input and output embeddings (Press and Wolf, 2017). We apply dropout with probability 0.1. We use LazyAdam as the optimizer. Learning rate warms up for 16,000 steps and then follows inverse square root decay. The peak learning rate is 5×10^{-4} for parent translation models, and 1×10^{-4} for child translation models. Early stopping occurs when the validation BLEU does not improve for 10 checkpoints. We set checkpoint frequency to 2,000 updates for parent translation models and 1,000 updates for child translation models. The batch size is 6,144 tokens per GPU and 8 NVIDIA V100 GPUs are used.

Hyperparameters for BERT are the same as in the original paper (Zhang et al., 2021).

For selected finetuning, we use stochastic gradient descent as the optimizer, and the learning rate is 1×10^{-5}. We finetune for 10,000 updates, and save a checkpoint every 100 updates. The checkpoint with the highest validation BLEU is kept.

4 Results

4.1 The Choice of Parent Language

In our preliminary experiments, we found it beneficial to use a closely related language as the parent language. It is clear that there are several factors that should be taken into account, such as the degree of closeness, and the amount of resource for training the parent model. For Upper Sorbian, Czech (cs) is closely related to it, and Czech-German has a good amount of parallel data, so we directly choose Czech as the parent language.

Chuvash, however, is a rather isolated language in the Turkic family. The closest language with usable data is Kazakh (kk), but the amount of parallel data for Kazakh-Russian is relatively small, and we found it to be quite noisy. Therefore, we considered

Table 7: Test set BLEU to show the effect of ensemble.

using English (en) as the parent language of Chuvash. Even though English is unrelated to Chuvash and they use different scripts, English-Russian has more parallel data that can guarantee the quality of the parent model.

We conducted an experiment with Transformer base. Results in Table 2 indicate that English can serve as an eligible parent for Chuvash. Considering that we plan to use Transformer big for which data amount is likely to play a more important role, we decided to use English as the parent language for Chuvash.

4.2 The Effect of Transformer Big

The original paper (Zhang et al., 2021) evaluated dual transfer only with Transformer base. In this shared task, we scale up to Transformer big. We also face a more realistic setting where the monolingual data for the low resource languages (chv and hsb) are quite scarce. Therefore it is worth testing the effect of scaling up. Results in Table 3 show that Transformer big brings consistent improvements. We also report the runtime of each step in dual transfer for $\text{NMT}_{\text{chv}\rightarrow\text{ru}}$ with Transformer big in Table 4 for reference, but the numbers can vary depending on implementation and data size. In the following experiments and our final submission, we use Transformer big models.

4.3 Iterative Back-Translation

We ran five iterations of iterative back-translation. Results are shown in Table 5. The best BLEU scores are attained with two or three iterations. Another observation is that iterative back-translation brings larger improvements for chv→ru and hsb→de than ru→chv and de→hsb. This is probably because the monolingual data for chv and hsb are small in quantity.

4.4 Selected Finetuning

We only use selected finetuning for the chv-ru pair because parallel data for hsb-de is scarce. In order to test the effect of selected finetuning, we start from the models of Iteration 2 in Table 5. Results in Table 6 indicate that selected finetuning gives modest improvements.

4.5 Ensemble

We validate the effectiveness of ensemble on hsb→de and de→hsb, by performing ensemble decoding from the five models from iterative back-translation. Results in Table 7 demonstrate that ensemble gives BLEU improvements of about 0.8.

4.6 Final Submission

For chv→ru and ru→chv, we perform selected finetuning starting from the best models from iterative back-translation (Iteration 2 for chv→ru, Iteration 3 for ru→chv). Note that the selected training subsets are different from those in Section 4.4 because the selection is based on the source side of the blind test sets. We finetune five times

with different random seeds for model ensemble. For hsb→de and de→hsb, we ensemble the five models from iterative back-translation.

5 Conclusion

In this paper, we describe a series of experiments that contribute to our submission to the WMT 2021 shared task of Very Low Resource Supervised Machine Translation. These experiments, as well as the good results of the final submission, show that dual transfer can work in synergy with several widely used techniques in realistic scenarios.

Abstract

Human evaluation has always been expensive while researchers struggle to trust the automatic metrics. To address this, we propose to customise traditional metrics by taking advantages of the pre-trained language models (PLMs) and the limited available human labelled scores. We first re-introduce the hLEPOR metric factors, followed by the Python version we developed (ported) which achieved the automatic tuning of the weighting parameters in hLEPOR metric. Then we present the customised hLEPOR (cushLEPOR) which uses Optuna hyper-parameter optimisation framework to fine-tune hLEPOR weighting parameters towards better agreement to pre-trained language models (using LaBSE) regarding the exact MT language pairs that cushLEPOR is deployed to. We also optimise cushLEPOR towards professional human evaluation data based on MQM and pSQM framework on English-German and Chinese-English language pairs. The experimental investigations show cushLEPOR boosts hLEPOR performances towards better agreements to PLMs like LaBSE with much lower cost, and better agreements to human evaluations including MQM and pSQM scores, and yields much better performances than BLEU (data available at https://github.com/poethan/cushLEPOR). Official results show that our submissions win three language pairs including **English-German** and **Chinese-English** on *News* domain via cushLEPOR(LM) and **English-Russian** on *TED* domain via hLEPOR.

1 Introduction

Machine Translation (MT) is a rapidly developing research field that plays an important role in NLP area. MT started from 1950s as one of the earliest artificial intelligence (AI) research topics and gained a large improvement in the output quality in large resourced language pairs after the introduction of Neural MT (NMT) in recent years (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Bahdanau et al., 2014). However, the challenge still remains in achieving human parity of MT output (Han et al., 2021a). Thus MT evaluation (MTE) continues to play an important role in aiding MT development from the aspects of timely and high quality evaluations, as well as reflecting the translation errors that MT systems can take advantages of for further improvement (Han et al., 2021b). On one hand, human evaluations have long been criticised as expensive and unrepeatable. Furthermore, the inter- and intra-agreement levels from Human raters may struggle to achieve a consistent and reliable score, unless done in rigour with highly trained and skilled evaluators (Alekseeva et al., 2021). On the other hand, even though researchers have claimed that the automatic evaluation metrics have reached much better performances in the category of system level evaluations of MT outputs, with high correlation to human judgements, the segment level performance is still a large gap from human experts' expectation (Freitag et al., 2021; Barrault et al., 2019, 2020; Han et al., 2013a; Macháček and Bojar, 2013).

In the meantime, many pre-trained language models have been proposed and developed in very recent years and showing big advantages in different NLP tasks, for instance, BERT (Devlin et al., 2019) and its further developed variants (Feng et al., 2020). In this work, we take the advantages of both high performing automatic metric and pre-trained language model, aiming at one step further towards higher quality performing automatic MT evaluation metric from both system level and segment level perspectives.

Among the evaluation metrics developed recent years, hLEPOR (Han et al., 2013b,a) is an augmented metric that include many evaluation factors with tunable weights assigned including precision, recall, word order (via position difference factor),

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1014–1023
November 10–11, 2021.

and sentence length. It has also been applied by researchers from different NLP fields including natural language generation (NLG) (Novikova et al., 2017; Gehrmann et al., 2021), natural language understanding (NLU) (Ruder et al., 2021), automatic text summarization (ATS) (Bhandari et al., 2020), and searching (Liu et al., 2021), in addition to MT evaluation (Marzouk, 2021).

However, original hLEPOR has disadvantage of the manual tuning of its parameter weights which take a lot of human efforts. We choose hLEPOR (Han et al., 2013b,a) as our baseline model, and use the very recent language model LaBSE (Feng et al., 2020) to achieve automatic tuning of its parameters thus aiming at reducing the evaluation cost and further boosting the performance. This system description paper is based on our earlier work, especially the training models (Erofeev et al., 2021).

The rest of the paper is organised as below: Section 2 revisits hLEPOR metric, its factors, advantages and disadvantages, Section 3 introduces our Python ported version of hLEPOR and the further customised hLEPOR (cushLEPOR) using language models, Section 4 presents our experimental development and evaluation that we carried out on cushLEPOR metric using WMT historical data, Section 5 reserves space for our submission to this year WMT21 metrics task, and Section 6 finishes this paper with discussions of our findings and possible future work.

2 Revisiting hLEPOR

hLEPOR is a further developed variant of LEPOR (Han et al., 2012) metric which was firstly proposed in 2013 including all evaluation factors from LEPOR but using harmonic mean for grouping factors to produce final calculation score (Han et al., 2013b). Its submission to WMT2013 metrics task achieved system level highest average correlating scores to human judgement on English-to-other (French, Spanish, Russian, German, Czech) language pairs by Pearson correlation coefficient (0.854) (Han, 2014; Macháček and Bojar, 2013). Other MT researchers also analysed LEPOR metric variant as one of the best performing segment level metric that was not significantly outperformed by other metrics using WMT shared task data (Graham et al., 2015). hLEPOR is calculated by:

$$\textit{h}\text{LEPOR} = Harmonic(w_{LP}LP, w_{NPosPenal}NPosPenal, w_{HPR}HPR)$$

where ***LP*** is a sentence length penalty factor which was extended from brevity penalty utilised in BLEU metric, ***NPosPenal*** is for n-gram position difference penalty which captures the word order information, as bellow, where $MatchN_{hyp}$ and $MatchN_{ref}$ indicate the position number of matched words in hypothesis and reference sentences:

$$\text{LP} = \begin{cases} e^{1-\frac{Length_{ref}}{Length_{hyp}}} \; if \; Length_{hyp} < Length_{ref} \\ 1 \; if \; Length_{hyp} = Length_{ref} \\ e^{1-\frac{Length_{hyp}}{Length_{ref}}} \; if \; Length_{hyp} > Length_{ref} \end{cases}$$

$$NPosPenal = e^{-NPD}$$

$$NPD = \frac{1}{Length_{hyp}} \sum_{i=1}^{Length_{hyp}} |PD_i|$$

$$|PD_i| = |MatchN_{hyp} - MatchN_{ref}|$$

The factor ***HPR*** is the harmonic mean of Precision and Recall values.

$$HPR = \frac{(\alpha+\beta)PrecisionxRecall}{\alpha Precision + \beta Recall}$$

$$Precision = \frac{Aligned_{num}}{Length_{hypothesis}}$$

$$Recall = \frac{Aligned_{num}}{Length_{reference}}$$

We refer the work (Han, 2014; Han et al., 2013a, 2012) for detailed factor calculation with examples there.

The basic version of hLEPOR carries out similarity calculation between MT system outputs and reference translations, in the same language setting, based on the *word surface level* tokens. The hybrid hLEPOR metric also carries out similarity calculation based on POS sequences from system-output and reference text. To do this, POS tagging is needed as the first step, then hLEPOR(POS) calculation uses the same algorithms used for the word level similarity score hLEPOR(word). Finally, hybrid hLEPOR is a combination of both word level and POS level score. In this system submission

work, with the time limitations, to make an easier to use customised hLEPOR, we take the basic version of hLEPOR, i.e. the word level similarity calculation and leave the hybrid hLEPOR into the future work.

The weighting parameters for the three main factors in original hLEPOR metric, i.e the (w_{LP}, $w_{NPosPenal}$, w_{HPR}) set, in addition to the other parameters inside each factor, were tuned by manual work based on development data (see *Appendix* for detailed parameter value sets on each language pair for word-surface level evaluation, en $\Leftrightarrow$ cs/fr/de/es/ru). This is very time consuming, tedious, and costly. In this work, we will introduce an automated tuning model for hLEPOR to customise it regarding deployed language pairs, which we name as cushLEPOR.

3 Proposed Model

3.1 Python port of hLEPOR

Original hLEPOR was published as Perl code [1], in a non-portable format, which is not very suitable for modern AI/NLP applications, since they are using almost exclusively Python. Python is a programming language of choice for AI and machine learning (ML) tasks, thanks to its amazing ecosystem of open source or simply free libraries available to researchers and developers. However, hLEPOR was not available in NLTK (Bird et al., 2009) or any other public Python libraries. We therefore took original published Perl code and ported it to Python, carefully comparing the logic of original paper and the Perl implementation. During this work we run both Perl code to reproduce the results of original code, and the new Python implementation. This work helped us to spot and fix at least three minor errors which did not significantly affected the score, but nevertheless we fixed the bugs of the Perl code.

While doing the porting we did also notice that hLEPOR parameter values were taken empirically and never explained in detail except for the suggested parameter setting table in the paper (Han et al., 2013b,a) for eight language pairs that were tested for the WMT2013 shared task, including EN-CZ/DE/FR/ES and the opposite direction. They were:

- **alpha**: the tunable weight for recall
- **beta**: the tunable weight for precision
- **n**: words count before and after matched word in npd calculation
- **weight_elp**: tunable weight of enhanced length penalty
- **weight_pos**: tunable weight of n-gram position difference penalty
- **weight_pr**: tunable weight of harmonic mean of precision and recall

The parameter values for hLEPOR as published in the publicly available Perl code were mannually tuned for *English-to-Czech/Russian (EN=>CS/RU) language pair* setting (Han et al., 2013b,a) as below:

- **alpha** = 9.0,
- **beta** = 1.0,
- **n** = 2,
- **weight_elp** = 2.0,
- **weight_pos** = 1.0,
- **weight_pr** = 7.0.

We refer to our **Appendix** for the manually tuned parameters for other language pairs available in the paper by (Han et al., 2013a,b) including English=>French/German (EN=>FR/DE) and Czech/Spanish/French/German=>English (CS/ES/FR/DE=>EN) and Russian=>English (RU=>EN) which was set up using CS=>EN without extra manual tuning. We came to the conclusion that we need to check whether these parameters are optimal, and find out whether better set of values exist to improve agreement with human judgement.

Because the different characteristics of each language, and language families, the evaluation of MT outputs would emphasis on different factors. For instance, word order factor reflected by n-gram position different penalty in hLEPOR (NPosPenal), can be with higher or lower weight for strict order languages and loose/flexible word order languages. Thus, we assumed that hLEPOR optimisation towards different languages will generate corresponding different set of parameter values. We call this step language-specific optimisation, and it will save much cost and time to achieve an automatic tuning process. The Python ported hLEPOR is available at Pypi https://pypi.org/project/hLepor/.

[1] https://github.com/poethan/LEPOR

3.2 Customised hLEPOR: cushLEPOR

With the recent development of pre-trained neural language models and their effective applications in different NLP tasks, including question answering, language inference and MT, it becomes a natural question that why do not we apply them in MT evaluation as well.

Very recent work from Google team verified that MQM (Multi-dimension quality metric) (Lommel et al., 2014) and SQM (Scalar Quality Metrics) (Freitag et al., 2021) have good agreement with each other when they were carried out both by professional translators. However, this does not correlate to Mechanical Turk based crowd-sourced human evaluation that was carried out by general researchers or untrained online workers with low professional linguistic skills. It also reflected that crowd-sourced evaluation tends to favour very literal translations instead of better translations with more diverse meaning equivalent lexical choices.

To customise hLEPOR (cushLEPOR) towards optimised parameter setting for deployed language pairs, we choose Optuna open source hyper-parameter optimisation framework (Akiba et al., 2019) to automate hyper-parameter search for best agreement between cushLEPOR and human experts evaluation wherever such data-set is available.

SQM (Freitag et al., 2021) borrows WMT shared task settings to collect segment-level scalar rating, but set the score scale from 0 to 6 instead of 0 to 100. Professional translator labelled scores using SQM is named as pSQM.

We aim at optimising cushLEPOR parameters to obtain best agreement with pSQM scores. However, in practical situation, human evaluations are not often feasible to obtain due to the constrains from both time and financial aspects.

We therefore propose to carry out an alternative optimisation model, i.e. customising cushLEPOR parameters towards pre-trained large scale language models, e.g. LaBSE (Language Agnostic BERT Sentence Embedding) model similarity score.

LaBSE model is built on BERT (Bidirectional Encoder Representations from Transformers) architecture and trained on monolingual (for dictionaries) and bilingual training data. LaBSE training data is filtered and processed. The resulting sentence embeddings achieve excellent performance on measures of sentence embedding quality such as the semantic textual similarity (STS) benchmark and sentence embedding based transfer learning (Feng et al., 2020).

LaBSE linguistic similarity score finds matching translations very well. The disadvantages, however, are high demand for computational resources (with GPUs), intensive application coding with requirement for ML skills, and slow performance.

The design of using optimised hLEPOR (cushLEPOR) in lieu of LaBSE similarity aims at developing a simple, high-performing, easy to run and not computationally demanding script to achieve results similar to high-end LaBSE similarity score, and hopefully towards human judgement. The cushLEPOR parameters can be optimised for agreement with any type of scores, such as pSQM, MQM, and LaBSE, etc.

Regarding the optimisation stage using Optuna, the task is to find the extremum values of continuous (not discrete) surface in a 6-dimensional space of six cushLEPOR parameters. The values of parameter set change continuously which means there's an infinite number of parameter values; however it is not a differentiable situation mathematically, and there are gaps. Generally we cannot presume that it is a smooth surface. Before Optuna, computational tools used to deploy a discrete mesh in such cases by using discretization method, which was less computationally intense than full scale continuous search on all possible values of parameter sets.

Optuna framework is currently one of the best Tree-structured Parzen Estimator (TPE) model implementations, which kind of estimators converges to optimal solution in 200-300 epochs, and the method can work with continuous (real) parameters (Bergstra et al., 2011).

4 Experimental Evaluations

The training and development data we used regarding MQM scores and pSQM labels is from the recent work by Google Research team on investigating into human evaluations based on WMT2020 shared task (Freitag et al., 2021) (data available at `https://github.com/google/wmt-mqm-human-evaluation`).

We first focus on English-to-German language (EN-DE) pair, which includes MQM and pSQM labels, acquired from 10 submission of WMT 2020, then take ZH-EN data-set. We refer to the paper (Freitag et al., 2021) for detailed MT system names and offering institutions.

Firstly, a multi-parameter optimisation against LaBSE for EN-DE language pair gave the following values for cushLEPOR parameters:

- **alpha** = 2.97,
- **beta** = 1.97,
- **n** = 4,
- **weight_elp** = 1.0,
- **weight_pos** = 14.97,
- **weight_pr** = 2.2.

This set of values reflected very different weighting systems in comparison to the original hLEPOR metric. For instance, 1) cushLEPOR assigned recall and precision much closer weight (2.97 vs 1.97) in comparison to hLEPOR (9.0 vs 1.0), 2) cushLEPOR chose 4-gram in chunk matching instead of bi-gram used in hLEPOR, 3) cushLEPOR assigned NPosPenal (n-gram position difference penalty) factor a very heavy weight against other two factors LP (length penalty) and HPR (harmonic mean of precision and recall) by (**14.97** vs 1.0 and 2.2) in comparison to hLEPOR which emphasised the weight on HPR (1.0 vs 2.0 and **7.0**). From these points of view, cushLEPOR trained on EN-DE language pair indicates the importance of the larger window context consideration during word matching, as well as the word order information reflected by n-gram (n value) and novel factor NPosPenal introduced by hLEPOR respectively.

This also reflected that LaBSE similarity is indeed a feasible goal for cushLEPOR optimisation. The correlations of hLEPOR and cushLEPOR to LaBSE are shown in Fig. 1 and 2.

However, we found out that we were not able to decrease much on RMSE (Root Mean Square Error) score for cushLEPOR towards pSQM , in comparison to original hLEPOR, (0.28 vs 0.29)which does indicate that original hLEPOR empirically shows very good fit for pSQM type human evaluation, using the suggested parameter settings for EN-DE (Han et al., 2013a,b) as bellow.

- **alpha** = 9.0,
- **beta** = 1.0,
- **n** = 2,
- **weight_elp** = 3.0,

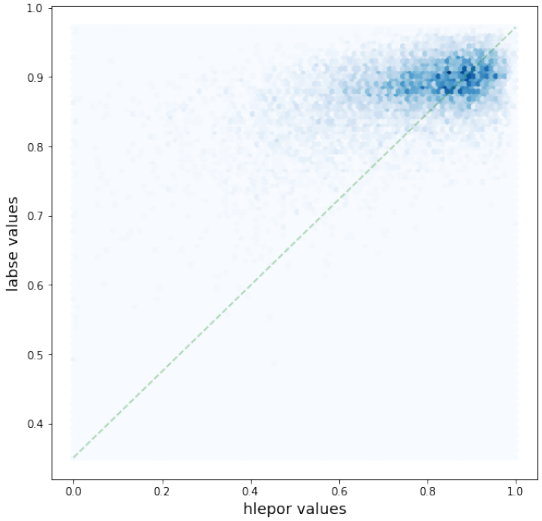

Figure 1: Agreement with LaBSE: hLEPOR

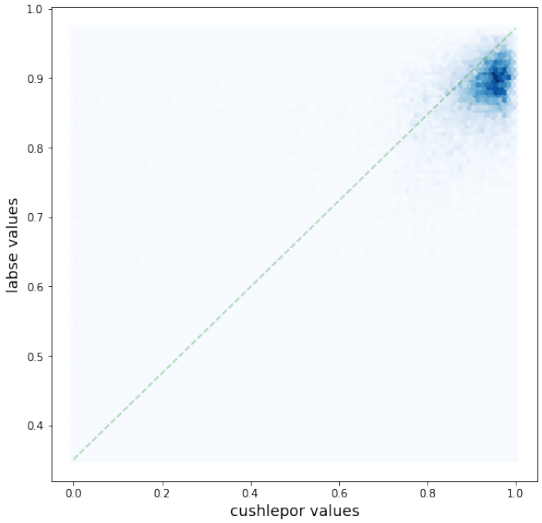

Figure 2: Agreement with LaBSE: cushLEPOR

- **weight_pos** = 7.0,
- **weight_pr** = 1.0.

The RMSE value between pSQM and hLEPOR, vs pSQM and cushLEPOR is shown in Fig. 3. However, it indeed shows much better performance then BLEU metric, as in Fig. 4 (0.28 vs 0.46).

Optuna did optimise cushLEPOR against LaBSE very well, halving the RMSE distance between LaBSE and cushLEPOR as compared to original hLEPOR, shown in Fig. 5.

The performances of tuning on LaBSE and pSQM are shown in Fig. 6 and 7 respectively. The horizontal axis is the score value (0, 1) and the vertical axis is the sentence number that falls into the corresponding score intervals.

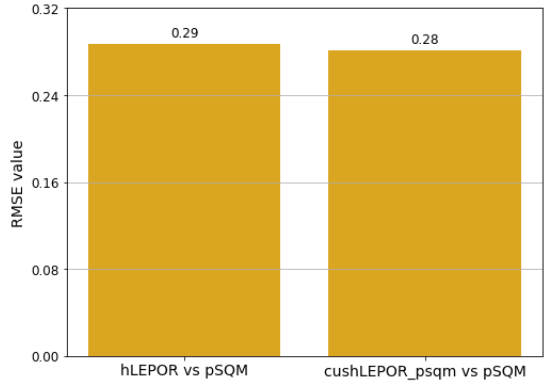

Figure 3: RMSE: hLEPOR vs cushLEPOR to pSQM (lower score is better)

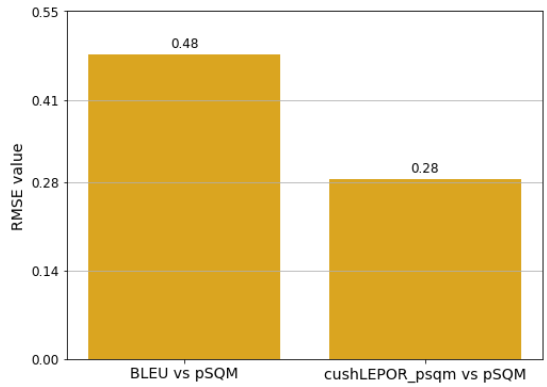

Figure 4: RMSE: BLEU vs cushLEPOR to pSQM (lower score is better)

Figure 5: RMSE: hLEPOR vs cushLEPOR to LaBSE (lower score is better)

From the score distribution visualisation, it reflects the tuning on pSQM has a larger covered error types while LaBSE is less sensitive to some errors that human experts would spot out. As shown on these charts, pSQM human rating shows much wider "tail" of "low score ratings", while LaBSE rating is much more focused. The reason is that LaBSE similarity model underestimates the severity of errors and error types, while humans analyse the meaning and assign proper error penalties in more diverse setting. As an example, the sentence "The comet did not struck the Earth this time." and "The comet did struck the Earth this time." has very close lexical similarity, but the meaning is very different, in this case “opposite”. LaBSE similarity score would not assign significant penalty to such difference, while human will treat it as a major error. This difference plays a crucial role for reliable translation quality evaluation.

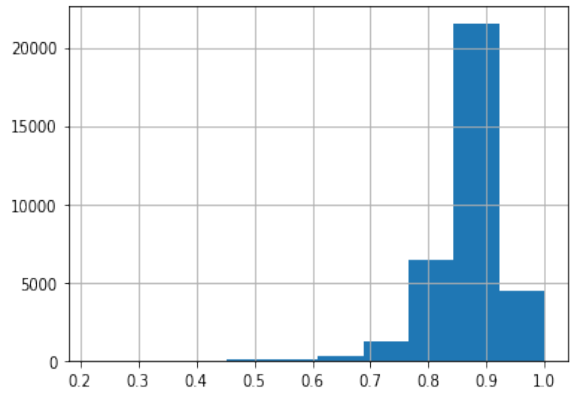

Figure 6: Score Distribution: tune on LaBSE

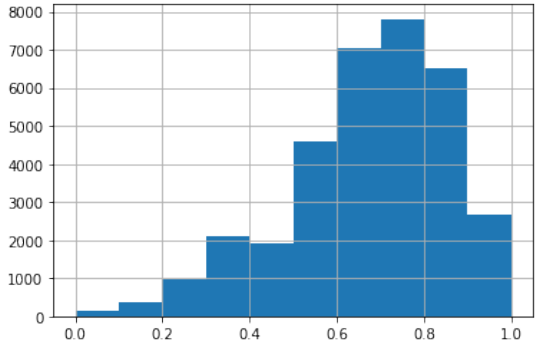

Figure 7: Score Distribution: tune on pSQM

5 Submission to WMT21

For WMT2021 Metrics Task, we submitted our cushLEPOR system scores for zh=>en and en=>de language pairs, both segment-level and system-level evaluation. The training and development set we used are exact the ones from last section (Section 4). We can not tune our cushLEPOR model parameters on en=>ru language pair from the WMT21 official data, because the human labelled MQM and pSQM scores as validation data that cushLEPOR requires do not exist from last year WMT20 set. Instead, we submitted hLEPOR metric for EN=>RU using the parameter settings in hLEPOR as men-

tioned in the last section. We carried out evaluation on all four official data-sets: **newstest2021** (traditional task), **florestest2021** (sentences translated as part of the WMT News translation task), **tedtalks** (additional sets of sentences translated by WMT21 translation systems in the TED talks domain), and **challengeset** (synthetic outputs generated specifically to challenge automatic metrics).

5.1 Submitted Parameter Setting

The optimised parameter values set for our zh=>en submission to WMT21 is displayed below.

For cushLEPOR(LM) using LaBSE training:

- **alpha** = 2.85,
- **beta** = 4.73,
- **n** = 1,
- **weight_elp** = 1.01,
- **weight_pos** = 11.13,
- **weight_pr** = 4.62

For cushLEPOR(pSQM) using professional translator labelled SQM training:

- **alpha** = 9.09,
- **beta** = 3.55,
- **n** = 3,
- **weight_elp** = 1.01,
- **weight_pos** = 14.98,
- **weight_pr** = 1.57

The optimised parameter values set for our en=>de submission to WMT21 is displayed below:

For cushLEPOR(LM) using LaBSE training:

- **alpha** = 2.95,
- **beta** = 2.68,
- **n** = 2,
- **weight_elp** = 1.0,
- **weight_pos** = 11.79,
- **weight_pr** = 1.87

For cushLEPOR(pSQM) using professional translator labelled SQM training:

- **alpha** = 1.13,
- **beta** = 1.71,
- **n** = 2,
- **weight_elp** = 1.06,
- **weight_pos** = 11.90,
- **weight_pr** = 1.01

5.2 Official Results from Metrics Task

The official results from WMT2021 Metrics task show that cushLEPOR(LM) ranks in the **first cluster** in performance on **News test** data with single reference evaluated on overall English-to-German, Chinese-to-English and English-to-Russian where professional human evaluation data is available (*Ref.* Table 8 "Metric rankings based on pairwise accuracy" in Findings paper (Freitag et al., 2021)). Furthermore, in the language specific ranking, cushLEPOR(LM) also wins **English-to-German** and **Chinese-to-English** language pairs, including TED data condition. Our hLEPOR baseline metric wins **English-to-Russian** TED domain language specific ranking (Ref. Table 12 "Summary of language-specific results" in the official findings paper (Freitag et al., 2021)). The official result on "System-level Pearson correlations for **English-to-German**" (Table 23 of findings) shows that cushLEPOR(LM) achieves score 0.938 in News domain, ranking *number 1 in Cluster 1 metrics*, out of overall 29 metric submissions.

6 Discussions and Future Work

In this work, we described cushLEPOR, a customised hLEPOR metric which can be automatically trained and optimised using both human labelled MQM scores, as well as large scale pre-trained language model (LM) LaBSE towards better agreement to human experts level judgements and distilled LM performance respectively, and reducing cost at the meantime, e.g. the manual tuning from hLEPOR and high computational demand from LMs.

We also optimised cushLEPOR towards human translators' evaluation scores, i.e. pSQM, which showed much improved performance than BLEU and original hLEPOR (with default parameters). Our research is in line with the MT evaluation guideline suggestions from the very recent work (Marie et al., 2021) that better evaluation metrics in

correlation to human judgement shall be tested and deployed. Or human judgements shall be carried out directly wherever possible.

We have some findings during the experimental investigation: 1) cushLEPOR trained on LaBSE can replace LaBSE to carry out similarity calculation task in MT evaluation, which is much more light weighted and low cost from computational power and complexity point of view. 2) we can choose alternative pre-trained language models (LMs) in the future to boost performance. 3) this cushLEPOR optimisation framework proves to be functional, offering high performance towards pre-trained LMs, much improved agreement of cushLEPOR to LaBSE scores in comparison to hLEPOR (as in Figure 1 and 2). 4) optimised cushLEPOR achieves better agreement towards professional translator's evaluation (pSQM).

Optuna, the hyper parameter optimisation toolkit we used, can generate different set of cushLEPOR parameter values in different runs, which could be an consistency issue. However, we believe it optimises the performance of cushLEPOR towards the highest agreement to the reference scoring (pre-trained LMs or human evaluations), but not to ensure the same set of parameter values to be generated, so this will not be a problem. We will carry out further analysis on this aspect in the future work.

The hybrid version of hLEPOR (Han et al., 2013b) use POS features to function as pseudo synonyms to capture alternative correct translations. However it relays on POS taggers for target language, which does not exist for newly proposed languages, and its tagging accuracy may be low, and it costs extra processing steps. In the future work, we plan to carry out integrated model which combine the POS tagging as a command function in data pre-processing for hybrid cushLEPOR.

Overall, cushLEPOR achieved the first cluster performances in *News* Domain data on *Chinese-English* and *English-German* in WMT2021 Metrics task, while hLEPOR wins *TED* domain data on *English-Russian* (Freitag et al., 2021). In the future work, we plan to carry out optimisation of cushLEPOR on more language pairs as well as more domains. We will keep our updated parameter set for extended languages and domains available on our cushLEPOR open-sourced platform.

Abstract

In this paper, we describe our submission to the WMT 2021 Metrics Shared Task. We use the automatically-generated questions and answers to evaluate the quality of Machine Translation (MT) systems. Our submission builds upon the recently proposed MTEQA framework. Experiments on WMT20 evaluation datasets show that at the system-level the MTEQA metric achieves performance comparable with other state-of-the-art solutions, while considering only a certain amount of information from the whole translation.

1 Introduction

The goal of automatic Machine Translation (MT) evaluation is to automatically evaluate the output quality produced by MT systems. Metrics used for this task assign a score by comparing the MT output to either a reference translation or to the source sentence. The main indicator that is used to assess the performance of a specific metric is the correlation with human judgement computed for outputs from several systems. It was recently shown that metrics based on contextualized embeddings, such as YISI (Lo, 2019) or ESIM (Mathur et al., 2019), are able to achieve better performance than the most common BLEU (Papineni et al., 2002).

In this paper, we describe application of the recently proposed metric – MTEQA (Krubiński et al., 2021) for the task of evaluating the quality of MT outputs in the context of the WMT21 Metric task.

The MTEQA[1] framework is inspired by previous works on evaluating abstractive summaries. It builds upon the fact that state-of-the-art (neural) MT systems tend to produce a fluent output but sometimes fail in adequacy of the translation. It leverages the recent progress in Question Generation (QG) and Question Answering (QA) to formulate and answer questions based on the MT output.

2 Related Work

2.1 MT Evaluation

Metrics that are most widely used for automatic evaluation of MT outputs produce a score by comparing surface-level forms of hypothesis and reference translation. The most common one, BLEU, is a modified version of n-gram precision calculated by averaging over different values of n with penalization for too short translations (brevity penalty). The recently proposed CHRF (Popović, 2015) considers the character-level n-grams, making it possible to reward partially matched tokens. Recently, various works (e.g., Lo, 2019; Mathur et al., 2019; Bawden et al., 2020) explored the usage of contextualized word- or sentence-level embeddings to compare the numerical representations of reference and hypothesis. Such metrics enable explicit regression towards the desired human-produced labels.

2.2 Question-based Evaluation

Previous works examined the usage of reading comprehension tests to measure the quality and "usefulness" of MT systems (Tomita et al., 1993; Fuji et al., 2001; Castilho and Guerberof Arenas, 2018). Berka et al. (2011) were the first to use the *yes/no* type of questions for manual evaluation of MT systems, examining the English-to-Czech direction. Scarton and Specia (2016) approached the problem of document-level Quality Estimation (QE) by extending the CREG corpus (Ott et al., 2012) of German documents designed for reading comprehension exercises.

More work on the questions-based evaluation was done in the context of text summarization. Eyal et al. (2019) proposed the APES metric for the task of evaluating abstractive text summarization. They used the reference summary to produce fill-in-the-blank type of questions, by finding all possible entities using a NER system. The APES score for a given summarization model is the percentage

of questions that were answered correctly (using a Question Answering system), averaged over the whole test-set. Scialom et al. (2019) extended their work into unsupervised settings by generating questions from the source document. The FEQA (Durmus et al., 2020) and QAGS (Wang et al., 2020) metrics further extend the idea by automatically generating human-readable questions.

2.3 MTEQA

MTEQA is the first MT metric based on the principles of question answering.

The automatically generated pairs of a question and its (gold-standard) answer from the reference translation are used by a question answering system to provide a new (test) answer given the question and the MT output (translation) used as the context.

The generated (test) answer is then compared to the gold-standard answer, using the string-comparison metric. The final score for a given MT output is the average taken over all of the question/answer pairs generated for a corresponding reference.

3 Experiments

Our implementation of the MTEQA metric is based on the state-of-the-art system capable of solving the initial three tasks of the procedure: answer extraction, question generation, question answering. It is the T5 model (Raffel et al., 2020) fine-tuned on the SQuADv1 dataset (Rajpurkar et al., 2016) by Patil (2020) and available from GitHub[2]. The limitation of the T5 model is that it was trained on English data and most importantly tuned on the SQuADv1 dataset which is in English. Thus, this model only allows evaluation of MT systems translating from any language to English.

To overcome that, we used the multilingual mT5 model (Xue et al., 2021) and fine-tuned it on machine translation of SQuADv1 dataset. We exploited the existing translations into German (Lewis et al., 2020) and into Czech (Macková and Straka, 2020) which allows score translations into German (xx-de) and into Czech (xx-cs) directions. Due to time constraints we were not able to train QA and QG systems in other languages.

Figure 1 presents examples of extracted answers and generated questions.

3.1 Baseline

The baseline implementation is based on the T5 model tuned on the SQuADv1 dataset and used to generate: 1) the gold-standard answers from the reference translations, 2) a question for each gold-standard answer, 3) a test answer for each question and MT output (context) pair. The test answers are compared by the word-level F1 score commonly used for QA evaluation (Rajpurkar et al., 2016; Trischler et al., 2017; Chen et al., 2019; Durmus et al., 2020).

For each of the MT systems participating in WMT20 News translation task (Barrault et al., 2020), we compute both segment-level scores and a single system-level score, an average of segment-level scores. We report the system-level Pearson correlation with a DA human assessment using the *newstest2020* references We report correlation for a English → German, English → Czech and a few to-English directions (see Table 1, row MTEQA F1). We also include an average over all of the

Table 1: System-level Pearson correlation for selected metrics used for measuring MT quality with DA human assessment over MT systems using the *newstest2020* references. Average (avg) is computed over all to-English directions available. Number below the language pair indicates the number of systems considered. Figures without * are taken from Mathur et al. (2020a).

to-English directions, which were part of WMT20 Metric Task (Mathur et al., 2020b) evaluation campaign[3]. Other metrics are included for a comparison. At the segment-level, we report the Kendall's Tau correlation of segment-level metric scores with DARR human assessment scores, see Table 2. We use the same Kendall's Tau-like formulation which was used by Mathur et al. (2020b) in WMT20 evaluation campaign.

On average, the baseline outperforms the traditional MT evaluation metrics (SENTBLEU, BLEU) as well as the recently proposed ones that performed very well in the WMT20 Metric Task (PRISM, YISI-2), though for some of the translation directions (e.g. cs-en) MTEQA F1 is much worse (but for cs-en YISI-2 also does not beat BLEU). The segment-level correlation is much lower, even negative for some directions (e.g. zh-en) .

3.2 Generating Additional Answers

Since the QG system generates a single question for each sub-sequence of words marked as an extracted answer, the limit factor is the number of gold-standard answers we extract. To generate more questions we need more keyphrases to be asked about.

Considering the whole predictive power of the MTEQA metric is based on questions, we used linguistic processing of the sentence based on Part-of-Speech (POS) pattern matching and Named Entity Recognition (NER) to extract more keyphrases.

Given a sentence as the input, first, we parse the sentence using UDPipe (Straka et al., 2016) to extract part of speech (POS) tags. Then, we extract phrases that are matched with one of the patterns in our POS pattern bank. The POS pattern bank is created by parsing the sentences from XQuAD (Artetxe et al., 2020) dataset, extracting the POS patterns corresponding to the gold-standard answers, and taking the most frequent patterns. This dataset contains professional translations of the development set of SQuADv1, translated into various languages from different language families and using different scripts. Second, we extract named entities mentioned in the input sentence using a combination of two multilingual NER models, POLYGLOT-NER (Al-Rfou et al., 2015), and Stanza (Qi et al., 2020). Finally, we output the union of the extracted phrases and named entities as the potential answers. At both system- and segment-level using the MTEQA F1 KEYPHRASE variant yields improvements for most of the translation directions.

3.2.1 Tuning the Answer Comparison Metric

The choice of the Answer Comparison Metric can have a considerable impact on the final performance. Using the word-level F1 metric, given the gold-standard answer *"Tchaikovsky"*, both the *"Tchaikovski"* and *"Beethoven"* would get the same score. In the context of MT, it may be worth to consider a more fine-grained comparison.

We decided to use the CHRF (Popović, 2015) metric, since it operates on the level of characters, and enables scoring even partial matches. Using the MTEQA CHRF KEYPHRASE variant yields further improvements at both system- and segment-level.

For the WMT21 Metrics Shared Task we submit this variant of the metric – the gold-standard answers are extracted by POS pattern matching and NER, and the chrF metric is used for answer comparison (MTEQA CHRF KEYPHRASE).

4 MQM scores

Recently, Freitag et al. (2021) demonstrated that the WMT DA method traditionally used for human evaluations has actually lower correlation with expert-based labels than the Multidimensional Quality Metrics (MQM) scoring method developed in the EU QTLaunchPad and QT21 projects. Following their findings, the WMT21 Metric Task will report the correlation with MQM labels in the official results.

To provide a more complete picture of the performance of the MTEQA metric, we also report correlation with the MQM assessments. Table 3 presents the system-level Pearson correlation of the metric with both the MQM and DA labels for 8 systems that were re-annotated by Freitag et al. (2021) and are available from GitHub[4].

The results are surprising and to a large extent unintuitive. Metrics performing well in comparison with MQM are often bad in comparison with DA.

5 Conclusions

In this paper we described our submission to the WMT21 Metrics Shared Task. We showed that the degree to which the MT output can be used to answer questions about the reference can be used as a proxy to evaluate the translation quality.

We showed a gradual improvement of our submission. We examined a linguistically motivated way of extracting keyphrases from the sentence, and showed that it boosts both the segment- and system-level correlation with DA human judgments. We were able to further boost the final performance by using the CHRF metric to compare the reference and test answers.

Finally, we examined the performance against the MQM labels and compared the performance against the DA labels.

Abstract

In this paper, we present the joint contribution of Unbabel and IST to the WMT 2021 Metrics Shared Task. With this year's focus on *Multidimensional Quality Metric* (MQM) as the ground-truth human assessment, our aim was to steer COMET towards higher correlations with MQM. We do so by first pretraining on *Direct Assessments* and then fine-tuning on z-normalized MQM scores. In our experiments we also show that reference-free COMET models are becoming competitive with reference-based models, even outperforming the best COMET model from 2020 on this year's development data. Additionally, we present COMETINHO, a light-weight COMET model that is 19x faster on CPU than the original model, while also achieving state-of-the-art correlations with MQM. Finally, in the "QE as a metric" track, we also participated with a QE model trained using the OPENKIWI framework leveraging MQM scores and word-level annotations.

1 Introduction

In this paper, we present the joint contribution of Unbabel and IST to the WMT 2021 Shared Task on Metrics. We participated in the segment-level and system-level tracks, as well as the "QE as a Metric" task.

Similar to our participation last year (Rei et al., 2020b), most of the models are based on the COMET framework[1] (Rei et al., 2020a). In last year's shared task (Mathur et al., 2020), COMET along with other trainable metrics such as PRISM (Thompson and Post, 2020) and BLEURT (Sellam et al., 2020) showed superior correlations with the *Direct Assessments* (DA) collected for the News Translation Shared Task. This year, we build on top of the models used last year to take into account that human assessments will be carried out using variants of the *Multidimensional Quality Metric* (MQM) (Lommel et al., 2014) framework and no longer based on DA (Graham et al., 2013). For this reason, we extended our training dataset to include DA evaluations from WMT ranging 2015 to 2020, with the exception of *en-de* and *zh-en* for which we do not include the 2020 data given that the same is included in the MQM development data (Freitag et al., 2021). Finally, we fine-tuned these new models on the z-normalized MQM scores provided for this year's shared task.

One of the remaining redeeming qualities of automated metrics such as BLEU (Papineni et al., 2002) is that they are incredibly light-weight. Despite the higher correlation with human judgement, trainable metrics tend to be slower to run. In an effort to close this gap we present COMETINHO, a light-weight model based on the COMET framework that replaces the original XLM-R large encoder with MiniLMv2 (Wang et al., 2020). This model is approximately 19x faster at inference time compared to the original COMET model (Rei et al., 2020a) and maintains state-of-the-art correlations with MQM in reference-based evaluations.

For the "QE as a metric" track, we show that reference-free evaluation models can reach surprisingly high correlations with human judgements and are competitive with their corresponding reference-based models. Last year we also participated with a similar model in the Metrics Shared Task, but here we elaborate in more detail on the primary differences between this model architecture and other COMET models.

Finally, and for the first time, we submit and describe a reference-free model that in addition to learning from MQM scores also makes use of word-level error annotations. This is possible this year given the shift in evaluation method from DA

This translation received an overall sentence score of 0.2 and the model was able to identify that the words "blind driving" are translation errors giving a good insight on why the sentence score is low.

to MQM. This model uses the OPENKIWI [2] architecture and its word-level tagging feature to predict OK/BAD word tags along with a sentence-level quality score.

2 The COMET Framework

For a more comprehensive description of the COMET architecture we direct the reader to the original paper (Rei et al., 2020a). Below we will highlight some relevant features that contrast with the COMET reference-free model (COMET-QE). In COMET we encode segment-level representations using the pretrained, cross-lingual, model XLM-RoBERTa (Conneau et al., 2020). Even though we encode the source, the hypothesis, and the reference (i.e. the human curated translation of the source) separately, their embeddings are mapped into a shared feature space. Subsequently, we obtain combined features using the three embeddings ($\boldsymbol{s}$, $\boldsymbol{h}$, and $\boldsymbol{r}$, for the source, hypothesis, and reference, respectively): $\boldsymbol{h} \odot \boldsymbol{s}$, $\boldsymbol{h} \odot \boldsymbol{r}$, $|\boldsymbol{h} - \boldsymbol{s}|$, and $|\boldsymbol{h} - \boldsymbol{r}|$. These features, concatenated to $\boldsymbol{r}$ and $\boldsymbol{h}$ and the resulting vector is the input to a feed-forward regressor.

2.1 Reference-free COMET

The architecture of the COMET model used in the "QE as a metric" task (COMET-QE) is very similar to the main COMET model (Rei et al., 2020a) briefly described above and RUSE (Shimanaka et al., 2018). The biggest difference being that in the COMET-QE model the reference is not used and, consequently, the combination of features used as input to the feed-forward regressor are also different from reference-based COMET. In this case, the combined features are simply: $\boldsymbol{h} \odot \boldsymbol{s}$ and $|\boldsymbol{h} - \boldsymbol{s}|$; the final vector to the feed-foward regressor being the concatenation of the latter features together with $\boldsymbol{h}$ and $\boldsymbol{s}$. A schematic representation is shown in Figure 1.

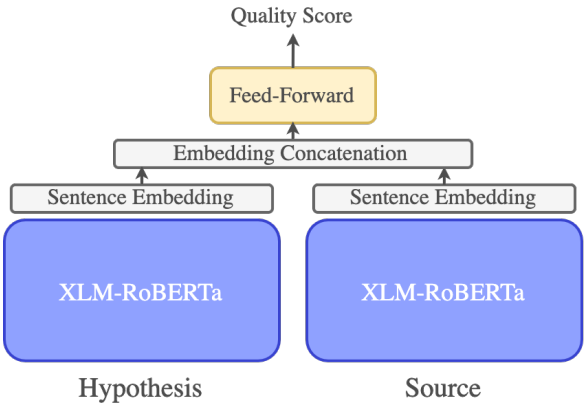

Figure 1: The COMET-QE model follows the dual encoder architecture proposed in RUSE (Shimanaka et al., 2018) but replacing the reference translation with the source sentence.

3 Lightweight COMET: COMETINHO

Our light-weight version of the original COMET model is almost an exact replica in terms of architecture save that we replaced the underlying pre-trained encoder with MiniLMv2 (Wang et al., 2020) which is a distilled version of XLM-R large (Conneau et al., 2020). This distilled model is made available by HuggingFace Transformers (Wolf et al., 2020): `nreimers/mMiniLMv2-L6-H384-distilled-from-XLMR-Large`

Our COMETINHO models are 19x faster on CPU and 14.3x times faster on GPU than COMET models based on XLM-R large. Also, in terms of disk footprint, these models are 5x smaller [3].

4 The OPENKIWI Framework

When using the MQM framework for the calculation of the quality score, human annotators seek to identify and annotate error spans at the word-level, as well as the severity of those errors. We

[2] **OpenKiwi** hosted at: https://github.com/Unbabel/OpenKiwi

[3] Contrastive inference times were tested using a 2.3 GHz Intel Core i5 for CPU, and using a Nvidia T4 for GPU.

leveraged these word-level annotations using the OpenKiwi framework (Kepler et al., 2019), by transforming each word into an OK or BAD tag. In the OpenKiwi architecture, in contrast with COMET-QE, source and hypothesis are jointly encoded. A sentence pair representation is then obtained using average pooling over the hypothesis word embeddings and then used as features to a feed-forward regression layer that learns to produce a sentence level score. At the same time, the word embeddings from the hypothesis are used to predict OK/BAD tags and therefore, the model is trained in a multitask setting (regression and sequence labelling).

5 Corpora

In this year's shared task the organisers provided a development set with MQM annotations for the *en-de* and *zh-en* participating systems on WMT20 (Freitag et al., 2021). Apart from the official development data we used all the Direct Assessments available from previous years.

5.1 Multi-dimensional Quality Metric Corpus

In this corpus, for each language pair, each translation was annotated by 3 raters from a pool of 6. Following what is a common practice for the DA's we convert the segment-level scores of each annotator into a z-normalized score and the final translation quality score is an average of the 3 z-scores. Also, because the sign of these MQM annotations is the opposite of the Direct Assessments we invert the score. Subsequently we generate a train and test split leaving 20% of the documents for each language pair for testing. This results in a total of 11230 *en-de* training samples and 15600 *zh-en* training samples, with testsets of 2950 and 4400 samples, respectively. All results reported in this paper are with respect to the above train and test split. The documents contained in each split are listed in the Appendix of this paper.

Annotators are not always consistent and the annotations of one annotator might differ from another (Graham et al., 2017). With this in mind, we decided to calculate the Kendall's Tau correlation between all annotators as a measure of inter-annotator agreement (Figure 2). The inter-annotator Kendall Tau can then be used as a ceiling effect for the developed metrics which ideally should behave as an additional annotator.

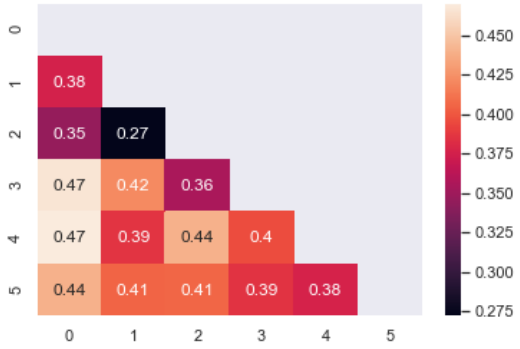

Figure 2: Kendall Tau Correlations between the *en-de* annotators used to develop the shared task development set (Freitag et al., 2021).

For training of the OpenKiwi model described herein we used proprietary MQM data from the customer support domain, covering several industries such as tech industry and travel industry. This data is composed by 1.1M (source, hypothesis) pairs with corresponding MQM annotations from 38 language pairs mostly out-of-english.

5.2 Direct Assessments

Each year, the WMT News Translation shared task organisers collect human judgements in the form of Direct Assessments. Those assessments are then used in the Metrics task to measure the correlation between metrics and therefore decide which metric works best. In recent years researchers have been using these annotations to create trainable metrics that regress on these scores (Shimanaka et al., 2018; Sellam et al., 2020; Rei et al., 2020a). We follow the same approach and use Direct Assessments ranging from 2015 to 2020 for training. The collective corpora contain a total of 33 language pairs including low-resource languages such as English-Tamil (*en-ta*) and a total of 795269 tuples with source, hypothesis, reference and direct assessment z-score. The only exception to this data is that we did not include the *en-de* and *zh-en* assessment from 2020 because they overlap with the MQM development data described in section 5.1.

6 Segment-level task

The COMET framework is highly flexible and easy to adapt to different types of human judgements (Rei et al., 2020a). This year we first pre-trained on the DA collected from 2015 to 2020 except for *en-de* and *zh-en* as described above. Like in Glushkova et al. (2021) we trained 5 models for 1 epoch each using 5 different seeds and created an ensembled

Table 2: Segment-level correlations on the *en-de* and *zh-en* testset.

model (COMET-DA). During our experiments we tested two ensembling techniques; averaging the different model predictions and averaging the parameters from the 5 models. Those two approaches had similar results but in the end we decided to use the later one for performance.

Subsequently, we fine-tuned each of the 5 models on the MQM data provided as development for another epoch. As before, we performed weight averaging to obtain an ensemble of those models (COMET-MQM). In both the pre-training and fine-tuning we only perform 1 training epoch in order to ensure that the final models are able to generalise to many language pairs and do not overfit to the News domain. This is especially important since the MQM dataset only contains *en-de* and *zh-en*.

For COMETINHO, as previously mentioned, we used the distilled version of XLM-R (MiniLMv2), available through Hugging Face, and we followed the same training recipe where we pre-train the model using DA's for 1 epoch and then we adapt the model to the MQM data for another epoch.

7 System-level task

For the System-level task we compute the system-level score for each system by averaging the segment-level scores obtained. This follows the same approach used to compute system-level scores based on segment-level human annotations such as DA's and MQM which means that a metric that achieves strong segment-level correlation should also achieve strong system-level performances.

8 QE as a Metric Task

We trained a reference-free model (COMET-QE) in the same way we did for reference-based COMET models described in section 6. As described in section 2.1, the primary difference between the two models is the inclusion or exclusion of the source as input.

9 Experimental Results

9.1 Segment-level task

Reference-based segment-level correlations on the *en-de* and *zh-en* testsets are shown in Table 2. We used both Pearson and Kendall Tau correlation metrics to evaluate our models. As baselines we used lexical metrics such as CHRF (Popović, 2015) and BLEU (Papineni et al., 2002), an embedding-based metric BERTSCORE (Zhang et al., 2020) and three trainable-metrics; BLEURT (Sellam et al., 2020), PRISM (Thompson and Post, 2020) and COMET-DA (2020) (Rei et al., 2020b).

The fact that the COMET-DA (2021) gives higher correlations than the COMET-DA (2020) shows that adding more training data and combining checkpoints trained on different seeds already provides a boost in performance. However, fine-

Table 3: System-level Kendall's Tau (τ) correlations for all system combinations (on the left) and Human vs MT (on the right).

tuning on the MQM development data was the most significant addition to previous work: the COMET-MQM (2021) model increased on average more than 0.1 Pearson correlation. This improvement is consistent with regard to the two COMETINHO models (with COMETINHO-MQM having notably higher correlations than COMETINHO-DA). Nevertheless, the fact that COMETINHO-DA has competitive or state-of-the-art performance with all the other metrics such as BLEURT, PRISM, and BERTSCORE, while also being much faster, presents an ideal opportunity for future work to investigate the incorporation of trainable metrics into the training objectives of MT systems.

For reference-free metrics, the fine-tuning on the MQM data, on average, gave a boost in performance (the only exception being the Pearson correlation for the *en-de* where COMET-QE-DA has a slightly higher correlation than COMET-QE-MQM). Overall, it is somewhat surprising that COMET-QE-* (2021) and COMET-* (2021) show relatively comparable correlations, suggesting that using the reference as input for MT evaluation might be less useful than expected and could feasibly become redundant. This surprising result was also reported by Kocmi et al. (2021) and is especially important since curating reference sentences is usually costly and time consuming and can introduce undesired bias in the evaluation (Freitag et al., 2020).

Finally, the OPENKIWI model has competitive correlations when looking to other trainable metrics and to COMET models that were not fine-tuned on the MQM development data. This add further weight to the suggestion above that references might not add substantial value to MT evaluation. Its performance is even more surprising when considering the fact that this model was train with data from a completely different domain.

It is worth highlighting that the Kendall's Tau correlations for all models (with exception of the two reference-based COMETINHO models) are in the range obtained for correlations between different annotators, for *en-de*, Figure 1. This further validates the value of our models.

9.2 System-level task

System-level results are presented in Table 3 where we report a Kendall Tau correlation defined as follows:

$$\tau = \frac{Concordant - Discordant}{Concordant + Discordant} \quad (1)$$

where *Concordant* defined as the number of times a metric agrees with humans that a given system x is better than a given system y and *Discordant* is the opposite. These decisions are the computed for all combinations of systems in the testset.

Due to the low number of systems and the relative proximity of the ground-truth MQM system scores we also compare metrics on their ability to distinguish human references from MT outputs. With reference to table 7 in the appendix we note that, for *zh-en*, all 8 MT systems demonstrate comparable performance but that there is a clear separation of human translations. For that reason Table 3 also presents the Kendall Tau correlations considering only "Human" systems against MT systems where we can observe that reference-free metrics achieve better performance. This results confirms the finding from last year's shared task (Mathur et al., 2020) where COMET-QE was highlighted as being the only metric able to differentiate human translations from MT.

10 Related work

Classic n-gram matching MT evaluation metrics such as BLEU (Papineni et al., 2002) have been adopted by the MT community as a primary form of MT evaluation, yet, in the recent years of the WMT Metrics shared task (Bojar et al., 2017; Ma et al., 2018, 2019; Mathur et al., 2020) these classic metrics have been outperformed first by embedding-based alternatives and more recently by trainable metrics based on pre-trained models.

With the rise of word embeddings (Pennington et al., 2014; Peters et al., 2018; Devlin et al., 2019), metrics such as BLEU2VEC (Tättar and Fishel, 2017) and MEANT 2.0 (Lo, 2017) replaced the typical word/n-gram matching by fuzzy matches based on distributional word representations. These metrics appeared for the first time at the WMT Metrics task in 2017 with MEANT 2.0-SRL achieving the highest results at segment-level. In 2018 and 2019 YISI-1 (Lo, 2019), a successor of MEANT 2.0 (Lo, 2017), was among the winners of the WMT Metrics task. YISI-1 (Lo, 2019) mostly takes advantage of BERT embeddings (Devlin et al., 2019) to create soft alignments between hypothesis and reference.

Trainable metrics started as simple regressions based on lexical features (e.g BLEND (Ma et al., 2017)) but nowadays these metrics also use embeddings to extract features that are then used to regress on quality assessments. The first of such metrics were RUSE (Shimanaka et al., 2018) and ESIM (Mathur et al., 2019) which were based on RNN encoders and worked mostly for English. In 2020, BLEURT (Sellam et al., 2020) and COMET (Rei et al., 2020a) were proposed. Both metrics used pre-trained transformer based encoders to extract sentence-level features that are then passed to a regression model; the difference is that COMET also extracts features for the source segment which was something overlooked by predecessor metrics. In the 2020 Metrics Shared task both COMET and BLEURT achieved some of the highest correlations with human judgements and shared the podium with PRISM (Thompson and Post, 2020)

11 Conclusions

In this paper we present the Unbabel-IST's contribution to the WMT 2021 Metrics shared task which for the first time, introduced evaluation using MQM. Our specific contributions include; the fine-tuning of Direct Assessment based models on MQM data which yields impressive gains on the described test sets and a new, lightweight COMET model which achieves comparable performance to its predecessors. Such a light model can provide interesting opportunities for future work into the incorporation of modern metrics into MT training. Finally, but perhaps our most important contributions; we further validate the observations in (Kocmi et al., 2021) that QE as a metric is becoming competitive as an alternative to reference-based evaluation, and, we show that a word-level QE system can be successfully trained on MQM annotations and be competitive with current trainable metrics while providing some intuition about "what" is wrong with a specific translation.

Acknowledgments

We are grateful to Fabio Kepler and José G. C. de Souza for their valuable feedback and discussions. This work was supported by the P2020 programs MAIA (contract 045909) and Unbabel4EU (contract 042671), by the European Research Council (ERC StG DeepSPIN 758969), and by the Fundação para a Ciência e Tecnologia through contract UIDB/50008/2020.

Regressive Ensemble for Machine Translation Quality Evaluation

Michal Štefánik and **Vít Novotný** and **Petr Sojka**
Masaryk University, Faculty of Informatics, MIR group https://mir.fi.muni.cz
{stefanik.m,witiko}@mail.muni.cz, sojka@fi.muni.cz

Abstract

This work introduces a simple regressive ensemble for evaluating machine translation quality based on a set of novel and established metrics. We evaluate the ensemble using a correlation to expert-based MQM scores of the WMT 2021 Metrics workshop. In both monolingual and zero-shot cross-lingual settings, we show a significant performance improvement over single metrics. In the cross-lingual settings, we also demonstrate that an ensemble approach is well-applicable to unseen languages. Furthermore, we identify a strong reference-free baseline that consistently outperforms the commonly-used *BLEU* and *METEOR* measures and significantly improves our ensemble's performance.

1 Introduction

Automated evaluation of text generation is challenging due to many orthogonal qualitative aspects that the user expects from a text generation system. In machine translation, we can observe errors of the so-called critical category (Wulczyn et al., 2017) such as hallucinating (Lee et al., 2019), omitting parts of the input from translation, or the negation of meaning (Matusov, 2019).

Consider an example of the last category:

- *Reference*: "I never wrote this article, I just edited it."
- *Hypothesis 1*: "It is not my article, I just edited it."
- *Hypothesis 2*: "I never wrote this article, I never edited it."

In this example, all *BERTScore* (Zhang et al., 2019), *BLEURt* (Sellam et al., 2020), and *Prism* (Thompson and Post, 2020b) metrics rank *Hypothesis 2* higher than *Hypothesis 1*. In *BLEURt* and *Prism*, this can be due to a known vulnerability of Transformers, which rely on a lexical intersection (McCoy et al., 2019) if such a heuristic fits the problem sufficiently well. Trivially, just counting the negations can easily remedy this specific problem. However, such a heuristic would fail in many other cases, such as when we adjust *Hypothesis 1* to "It is an article of somebody else, I just edited it.".

Such cases motivate our ensemble approach that aims to expose both surface and deeper semantic properties of texts and subsequently learn to utilize these for the specific task of translation evaluation. Even though the objective might constrain the particular metrics, data set, or systematically fail in some cases, another metric or their combination in the ensemble allows the flaw to be corrected.

2 Metrics for machine translation evaluation

This section reviews the related work, focusing on the metrics we used in our ensemble.

The standard and still widely-used surface-level metrics for the evaluation of machine translation quality are *BLEU* (Papineni et al., 2002), *ROUGE* (Lin, 2004), and *TER* (Snover et al., 2006). Surface-level metrics are not able to capture the proximity of meaning in cases where one text paraphrases the other, which is an ability commonly observed in deep neural language models (Lewis et al., 2020). One metric that addresses this flaw is *METEOR* (Banerjee and Lavie, 2005), which utilizes WordNet to account for synonymy, word inflection, or token-level paraphrasing.

Evaluation of semantic text equivalence is closely related to a problem of accurate textual representations (embeddings). The traditional method that we identify as relevant for the evaluation of segment-sized texts is FastText (Bojanowski et al., 2017). FastText learns representations of character n-grams from which it creates a unified representation of tokens by averaging. Additionally, a distance of a pair of texts can be computed directly from the token-level embeddings using methods such as the soft vector space model (the soft co-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1041–1048
November 10–11, 2021.

sine measure, *SCM*) (Novotný, 2018), or by solving a minimum-cost flow problem (the word mover's distance, *WMD*) (Kusner et al., 2015).

Similar matching is performed by *BERTScore* (Zhang et al., 2019), which uses internal token embeddings of a selected BERT layer optimal for the task. Although the token representations are multilingual in some models (Devlin et al., 2018), which makes *BERTScore* usable without references, we are not aware of prior work evaluating it as such. A possible drawback of cross-lingual alignment using a max-reference matching scheme of *BERTScore* lies in a possibility of a significant mismatch of sub-word tokens in source and target text. In contrast, the metric that we refer to as *WMD-contextual* uses the same embeddings as *BERTScore* but uses the network-flow optimization matching scheme of *WMD*.

Task-agnostic methods have recently been outperformed by methods that fine-tune a pre-trained model for a related objective: *BLEUrt* (Sellam et al., 2020) fine-tunes a *BERT* (Devlin et al., 2018) model directly on Direct Assessments of submissions to WMT to predict the judgements using a linear head over contextual embeddings of a classification *[CLS]* token. *Comet* (Rei et al., 2020) learns to predict Direct Assessments from tuples of source, reference, and translation texts with the triplet objective or the standard MSE objective.

Some of the most recent work incorporates latent objectives and/or data sets. For instance, *Prism* (Thompson and Post, 2020b,a) learns a language-agnostic representation from multilingual paraphrasing in 39 languages, thus being one of the few well-performing reference-free metrics. The orthogonality of its training objective might lower its correlation to other methods that use contextual embeddings.

3 Methodology

Our methodology aims to answer the following major question with additional supporting questions:

1. **Can an ensemble of surface, syntactic, and semantic-level metrics significantly improve the performance of single metrics?**

2. Can such an approach be applied cross-lingually, i.e., on languages that it has not been trained on?

3. Can surface-level metrics in reference-free configuration achieve results comparable to the reference-based ones?

4. Are contextual token representations important for evaluating semantic equivalence, or can these be replaced with pre-inferred token representations?

3.1 Experimental setup

We perform our primary evaluation on Multidimensional Quality Metrics (MQM) data set (Freitag et al., 2021), where we use averaged judgement scores as our gold standard. Where multiple judgements are available for the given pair of a source and a hypothesis, we average the scores over the judgements and consider this average as our gold standard. We split the samples into train (80%) and test (20%) subsets based on unique source texts.

In our experimental framework, which we release as an open-source Python library and Docker image for ease of reproduction[1][2], we implement a selected set of the metrics based on their guidelines, together with a bunch of novel metrics, introduced in Section 3.2 aiming to provide additional, orthogonal insight of textual equivalence.

Subsequently, we train a regressive ensemble on the *standardized* metric features of the whole train set, intending to predict the averaged MQM expert judgements. We evaluate the ensemble, together with all other selected metrics using pairwise Spearman's rank correlation (Spearman's ρ) with the MQM judgements on the held-out 20% test split.

In addition to our primary evaluation on the MQM data set, we perform our experiments on the Direct Assessments (DA) from WMT 2015 and 2016, and a dev set of Catastrophic errors from the Post-editing Dataset (Fomicheva et al., 2020a) of the Multilingual Quality Estimation Dataset (MLQE-PE) (Fomicheva et al., 2020b) used for evaluation at the Quality Estimation workshop of WMT 2021. Refer to Section 3.6 for a detailed description of our experiments on DA and MLQE-PE.

We performed all our evaluations on segment-level judgements. To minimize the impact of calibration for each of the specific metrics to evaluation, we report Spearman's rank correlation coefficient, reflecting the mutual qualitative ordering rather than particular values of the judgements.

[2] https://hub.docker.com/r/miratmu/regemt

3.2 Novel metrics

In addition to a selected set of metrics based on a literature review, we implement a set of novel metrics that allows our ensemble to reflect a wider variance of properties of the evaluated texts.

3.2.1 Soft Cosine Measure

The soft cosine measure (*SCM*) (Novotný, 2018) is the cosine similarity of texts in the soft vector space model, where the axes of terms are at an angle corresponding to their cosine similarity S in a token embedding space:

$$\text{SCM}(\vec{x}, \vec{y}) = \frac{\vec{x}^\mathsf{T} \cdot S \cdot \vec{y}}{\sqrt{\vec{x}^\mathsf{T} \cdot S \cdot \vec{x}} \cdot \sqrt{\vec{y}^\mathsf{T} \cdot S \cdot \vec{y}}} \quad (1)$$

where $\vec{x}$ is a weighted bag-of-words (BoW) vector of a reference (or a source in a reference-free setting), and $\vec{y}$ is a weighted BoW vector of a hypothesis.

We use *SCM* with two token representations:

1. We use the static token representations of FastText (Grave et al., 2018). We refer to the resulting metric as *SCM*.

2. We use the contextual token representations of *BERT* (Devlin et al., 2018) using the methodology of *BERTScore* (Zhang et al., 2019). We collect representations of all tokens segmented by the WordPiece (Wu et al., 2016) tokenizer, and we treat each unique (token, context) pair as a single term in our vocabulary.

   Subsequently, we *decontextualize* these representations as follows: For each WordPiece token, we average the representations of all (token, context) pairs in the training corpus. We refer to the resulting metric as *SCM-decontextualized*. Due to the multilingual character of the learned BERT token representations, this metric is applicable both in reference-based and source-based approaches.

In addition to two token representations, we also use two different SMART weighting schemes of Salton and Buckley (1988) for the BoW vectors $\vec{x}, \vec{y}$ and the construction of the term similarity matrix S:

1. We use raw term frequencies as *weights* in the BoW vectors, the `nnx` SMART weighting scheme, and we construct the term similarity matrix in the vocabulary order. We refer to the resulting metrics as *SCM* and *SCM-decontextualized*.

2. We use term frequencies discounted by inverse document frequencies as weights in the BoW vectors, the `nfx` SMART weighting scheme, and we construct the term similarity matrix in the decreasing order of inverse document frequencies (Novotný, 2018, Section 3). We refer to the resulting metrics as *SCM-tfidf* and *SCM-decontextualized-tfidf*.

3.2.2 Word Mover's Distance

The Word Mover's Distance (*WMD*) (Kusner et al., 2015) finds the minimum-cost flow F between vector space representations of two texts:

$$\text{WMD}(\vec{x}, \vec{y}) = \text{minimum cumulative cost } F^\mathsf{T} \cdot S$$
$$\text{subject to } \sum_j F_{ij} = x_i, \sum_i F_{ij} = y_j, \quad (2)$$

where $\vec{x}$ is an ℓ_1-normalized weighted BoW vector of a reference (or a source in reference-free setting), $\vec{y}$ is an ℓ_1-normalized weighted BoW vector of a hypothesis, and S is a term similarity matrix.

Similar to *SCM* described in the previous section, we experiment with two token representations: FastText embeddings of whole tokens (*WMD*) and decontextualized embeddings of WordPiece tokens (*WMD-decontextualized*). Additionally, we also use the contextual embeddings of WordPiece tokens (*WMD-contextual*) to show the impact of decontextualization on the metric performance: If the impact is negligible, future work could avoid the costly on-the-fly inference of BERT representation and significantly reduce the vocabulary size.

Similarly to *SCM*, we also use two different weighting schemes: raw term frequencies (*WMD-**) and term frequencies discounted by inverse document frequencies (*WMD-*-tfidf*).

3.2.3 Compositionality

Our custom metric that we refer to as Compositionality constructs a transition graph of an arbitrary text G_t based on directed, pairwise transitions of the tokens' part-of-speech (PoS) categories. As the models for PoS tagging are language-dependent, we use the compliant—though not always systematically aligned—schemes of tagging used for training the taggers in English (Weischedel et al., 2013), German (Brants et al., 2002), Chinese (Weischedel et al., 2013), and Norwegian (Unhammer and Trosterud, 2009).

Subsequently, we row-normalise the values of matrix G_t and we define a distance metric of *Compositionality* C for $x = G_{t_1}$ and $y = G_{t_2}$:

$$C(x, y) = \ell_1\text{-norm}(x_{ii} - y_{ii}), \quad (3)$$

where the PoS tags $i \in x$ and $i \in y$.

In our submission, we apply this metric only if the language belongs to a set of the languages for which we have a tagger: English, German, Chinese, or Norwegian. In reference-based evaluations, this constraint applies to the target language; in the case of reference-free evaluations, it applies to both source and target languages.

3.3 Ensemble

We ensemble the aforementioned metrics as predictors in a regression model, minimizing the residual between the average segment-level MQM scores and predicted targets.

We experiment with a wide range of simple regressors and observe a superior performance of simple approaches of fully connected, two-layer perceptron with 100-dimensional hidden layer and ReLu activation and linear regression with squared residuals. We report the results for *RegEMT* as the best-performing one of these classifiers picked on a 20% held-out validation subset of the train data set.

In addition to the ensemble of all available metrics, we evaluate a baseline regressive ensemble *Reg-base* using solemnly two surface-level features: character-level source and target length according to WordPiece (Wu et al., 2016) tokens.

3.4 Cross-lingual experiments

As expert judgments are incredibly costly to obtain, it is unrealistic to expect that the training data for the trained systems will be available in the future for a vast majority of language pairs containing under-resourced languages. To estimate the performance of all metrics on uncovered language pairs, we perform a cross-lingual evaluation on average MQM judgements of two available language pairs: ***zh-en*** and ***en-de***.

Where applicable, we fit the metric parameters on the train split of the non-reported language pair. Subsequently, we evaluate and report the results on a test split of the reported pair to MQM judgements.

3.5 Ablation study

To understand the impact of individual metrics in their roles as predictors for our ensemble, we use their pairwise correlations for systematic feature elimination.

In our ablation study, we iteratively select the metric with the highest Spearman's ρ to any other metric. We eliminate the selected metric from our ensemble by fitting a new regression model on the remaining features. We continue until all metrics are eliminated and evaluate the ensemble at each step of the process.

3.6 Additional evaluations

To allow for additional insight into the consistency of the results to other relevant evaluation sources, together with an evaluation of the metrics in the novel application of critical error recognition, we perform the experiments analogically on a DA data set of the WMT submissions from years 2015 and 2016, as well as to the Critical Errors dev set of MLQE-PE data set for reference-free metrics.

In the case of DA judgements, we use the assessments from the year 2015 as a training split and assessments from the year 2016 as a test split.

In the case of MLQE-PE, we split the data analogically to MQM by splitting the unique source texts in an 80:20 ratio. In this case, we consider as gold judgements the mean severity of error assigned by three annotators to each of the translations.

4 Results

Correlations to MQM judgements. Table 1 lists correlations to MQM for source-based, i.e., reference-free metrics (upper) and reference-based metrics (middle). Results reported for *RegEMT* fit a selected regression model on the estimates of all the other metrics available for a given evaluation scheme. As described in Section 3.3, we pick the evaluated regression model based on its performance on a held-out portion of the train set: a two-layer perceptron for the source-based ***zh-en*** pair and a simple linear regression in all other cases, with negligible mutual differences between regression models in performance on the validation set (below 2%). In the reports suffixed with ***X***, we fit the regression model on the other language pair than the one used for the evaluation.

The results suggest that a simple regressive ensemble can benefit from the variance of the predictors in a majority of the evaluated configurations, including the cross-lingual settings and other evaluated datasets. We observe the highest margins in correlations in the case of MQM judgements.

Table 1: Results for Spearman's correlations with selected gold standards. From top: correlation of source-based metrics (top) and reference-based metrics (middle) to averaged scores of MQM expert judgements for specified languages. Results suffixed with ***X*** are evaluated cross-lingually: both ensemble metrics are trained on other language pairs than evaluated. (Bottom): Results for other data sets: Direct assessments of WMT 2016 submissions and dev set of Catastrophic translations from MLQE-PE data set; reported values are an average of correlations over all available language pairs.

Baseline ensemble. Table 1 shows that *Reg-base*, using only the counts of reference and hypothesis Word-pieces, demonstrates its consistent superiority over the standard surface-level metrics of *BLEU* and *METEOR*, even in the cross-lingual vs. monolingual comparison. With respect to the MQM judgements, the correlations of *Reg-base* are reasonably consistent; hence, in the reference-free cases of ***en-de*** language pair, the correlation of *Reg-base* is very close to the correlations of *RegEMT*.

Importance of contextualization. The results in Table 1 are inconsistent concerning the importance of contextualization in token-level metrics (*WMD-cont** vs. *WMD-dec** and *SCM-cont** vs. *SCM-dec**). We observe a significant (15–16%) decrease of correlation between a contextualized and decontextualized versions of WMD in *all* cases of ***zh-en*** language pair. The situation differs in ***en-de*** pair, where for the reference-based case, the correlation of decontextualized version of WMD is superior by 7%.

Metrics correlations. Table 2 demonstrates mutual correlations of the evaluated metrics. We see the strong pairwise correlations among the metrics based on contextualized representations, such as between *Comet*, *Prism*, *BERTScore* and *BLEURt*; all of these are higher than 0.79. The situation is similar among the metrics based on static token representations of *SCM* and *WMD*, both with and without TF-IDF.

In contrast, we observe a low correlation of *BLEU* and *METEOR* to *Reg-base* forming a cluster of surface-level metrics.

Ablation study. Figure 1 displays performance development in Spearman's ρ of the regressive ensemble when we incrementally eliminate the metrics from the set of ensembled predictors. Following the methodology described in Section 3.5, the exact ordering of the metrics in ablation for ***zh-en*** pair is shown in Table 2, and we observe it to be similar also for the other language pair of MQM.

In ensembles of reference-based metrics (left), we observe a high consistency throughout the removal of most of the metrics. A longer consistency in ***zh-en*** case is attributed to a consistent performance in ensembling *BLEURt* (removed in step 14) and *METEOR* (removed in step 15). These metrics only reach the correlation of 0.48 and 0.28, respectively, when evaluated independently. In ***en-de*** case, the most significant drops can be attributed to a removal of the best-performing *Comet* (step 9) and *Prism* (step 11).

Ensemble of source-based metrics (right) shows significant drops in ***zh-en*** pair after removing *Prism* (step 3) and *WMD-contextual* (step 4). In ***en-de*** language pair, the correlation is relatively low throughout the whole ablation process. The least corre-

5 Discussion

Regressive ensemble. Following the objectives that we set in Section 3, we empirically confirm that an ensemble can push the quality of modeling the expert judgements in most of the configurations while performing close-to-the-best metrics on the others. Additionally, we demonstrate that such ensemble is transferable to new language pairs and that its use is motivated by qualitative gains even in cross-lingual settings.

At the same time, one must acknowledge the limitations that an ensemble system exposes compared to single and unsupervised metrics. An ensemble might inherit the systematic biases of each of its metrics. This problem is observable in the results of the source-based ***en-de*** pair of MQM in Table 1, where the ensemble follows the low correlations of its ensembled metrics. Further, relying entirely on the metrics' consistency, the ensemble will inevitably expose errors in domains where some metrics behave markedly out of their usual range.

On the other hand, we argue that this might rarely be the case with the surface-level metrics that are mainly unsupervised. We suspect it to be unlikely with learnable metrics, too, having their output space constrained by the range of their imitated metrics.

Values of correlations in Table 2 and partially also the threshold metrics in Figure 1 suggest that our ensemble relies primarily on trained contextualized metrics with regards to their correlation with the target as summarized in Table 1. We suspect that oversampling of under-represented categories of errors would increase the significance of other types of metrics, as the under-represented error categories would be the ones where the fine-tuned metrics perform worse.

Baseline ensemble. Surprisingly, our baseline ensemble *Reg-base* consistently outperforms other standard surface-based metrics such as *BLEU* (Papineni et al., 2002). This suggests possible applicability of surface-level metrics also in reference-free evaluation.

We suspect that the baseline features of length based on a multilingual WordPiece tokenizer (Wu et al., 2016) might reflect on the missing or inappropriately added segments more *strictly* than other surface-level metrics. At the same time, these errors are usually highly weighted in the overall score.

Table 2 shows considerable orthogonality of *Reg-base* to other metrics. This motivates the inclusion

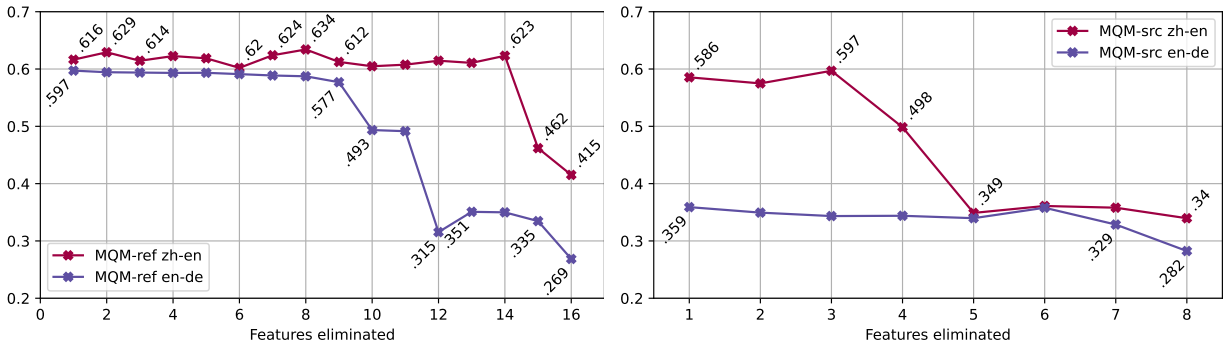

Figure 1: Ablation study: correlation of ensemble estimator to averaged MQM judgements during incremental elimination of the most-correlated metric from the ensembled predictors. Left: ablation of reference-based metrics, right: ablation of source-based metrics.

of the other weak surface metrics into the baseline ensemble to alleviate some of its apparent flaws.

Impact of contextualization. Based on the results of *WMD-** described in Section 3.2.2, one can not draw a consistent conclusion regarding the impact of contextualization. On average, decontextualization has decreased the performance of *WMD* by 8%, but the original motivation of a significant improvement in the usability of estimators might compensate. On the other hand, *WMD-decontextualized* and *WMD-decontextualized-tfidf* reached a considerable improvement of 16–18% as compared to *WMD* and *WMD-tfidf* using FastText embeddings, while losing none of their flexibility.

> "It is the harmony of the diverse parts, their symmetry, their happy balance; in a word it is all that introduces order, all that gives unity, that permits us to see clearly and to comprehend at once both the ensemble and the details."
>
> Henri Poincaré

6 Conclusion

This work evaluates the potential of ensembling multiple diverse metrics (*RegEMT*) for an evaluation of machine translation quality and offers a new simple baseline metric *Reg-base* that achieves better results than *BLEU* and *METEOR* by using just the source and reference lengths. We measure significant gains in Spearman's correlation to MQM with *RegEMT* compared to standalone metrics and we demonstrate that even simple linear estimators can benefit from the expressivity that the methods of all levels of representation provide. Additionally, as we demonstrate, the ensemble based on metrics supporting multilingualism can push the quality further even on unseen language pairs.

We recognize the inherent limitations of the regressive ensemble, which is inevitably slower, resource-heavier, and prone to inherit latent inductive biases of underlying metrics or their combinations. However, *RegEMT* shows the agility of the simple ensemble approach, which is in contrast to attempts to learn the full complexity of quality estimation through a single objective and allows the quality estimator to avoid the blind spots of particular metrics. We hope that our results will motivate future work in the ensemble evaluation.

Multilingual Machine Translation Evaluation Metrics Fine-tuned on Pseudo-Negative Examples for WMT 2021 Metrics Task

Abstract

This paper describes our submission to the WMT2021 shared metrics task. Our metric is operative to segment-level and system-level translations. Our belief toward a better metric is to detect a significant error that cannot be missed in the real practice cases of evaluation. For that reason, we used pseudo-negative examples in which attributes of some words are transferred to the reversed attribute words, and we build evaluation models to handle such serious mistakes of translations. We fine-tune a multilingual largely pre-trained model on the provided corpus of past years' metric task and fine-tune again further on the synthetic negative examples that are derived from the same fine-tune corpus. From the evaluation results of the WMT21's development corpus, fine-tuning on the pseudo-negatives using WMT15-17 and WMT18-20 metric corpus achieved a better Pearson's correlation score than the one fine-tuned without negative examples. Our submitted models are named C-SPEC (Cross-lingual Sentence Pair Embedding Concatenation) and C-SPECpn, are the plain model using WMT18-20 and the one additionally fine-tuned on negative samples, respectively.

1 Introduction

Recent studies of automatic evaluation is mostly based on the family models of BERT (Devlin et al., 2019). BERTscore (Zhang et al., 2020), BLEURT (Sellam et al., 2020), COMET (Rei et al., 2020) have shown a strong correlation with human judgement scores. However, we reported in our previous study (Takahashi et al., 2020), it is hard for BERT based metrics to correctly evaluate the translation errors that are annotated with low Direct Assessment (DA) score.

Upon the problems of evaluating poor quality translations, Sudoh et al. (2021) has attempted to solve the problem by creating a different human annotation set and corpus. Compared to DA, their idea is to make a clear definition of critical translation errors and let models learn the critical errors that can cause a serious misunderstanding.

Following the idea, we used pseudo-negative examples to train the evaluation model. Since, empirically, the cases of the evaluation failure happens frequently with the nouns translation errors, we generated pseudo-negative sentences by transferring the attribute of nouns with Word Attribute Transfer (Ishibashi et al., 2020). This system is based on our previous work (Takahashi et al., 2020), with an extension with fine-tuning with the pseudo-negative examples.

2 Related Work

BERTscore (Zhang et al., 2020), BERT regressor (Shimanaka et al., 2019), BLEURT (Sellam et al., 2020), and COMET (Rei et al., 2020) are applications of BERT to the machine translation evaluation. BERTscore measures the similarity of reference and hypothesis translation by the cosine-similarity of the token embeddings for each token in the reference and hypothesis. It uses a pre-trained BERT model without fine-tuning on evaluation data. Instead, BERT regressor and BLEURT are fully parameterized and require a human annotated evaluation corpus to fine-tune the models. Both metrics have the same model architecture; a linear layer is attached on top of the BERT encoder. They encode a paired reference and hypothesis sentence with BERT and predict the human evaluation score. Additionally, BLEURT conducts warm-up training of BERT before fine-tuning on an evaluation corpus. The model architecture of our submission is similar to BERT regressor and BLEURT, but its uniqueness comes from using the synthetic negative data to fine-tune the models to evaluate poor translations better.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1049–1052

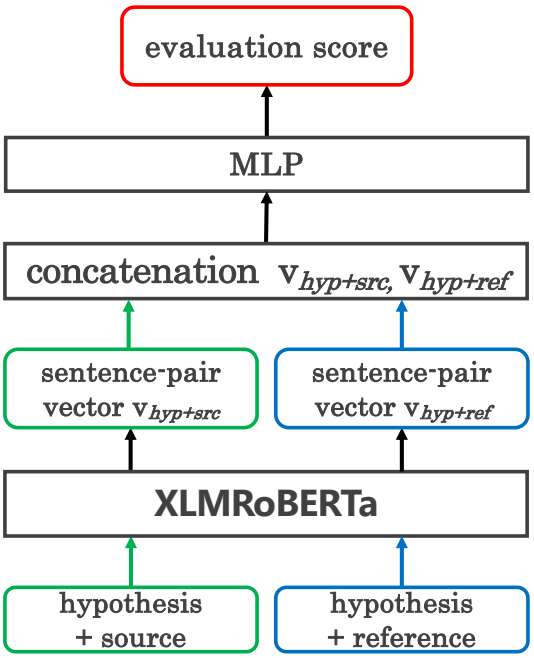

Figure 1: Architecture of C-SPEC

3 Our system

3.1 Model architecture

We extend the BERT regressor (Shimanaka et al., 2019) and use a cross-lingual language models, XLMRoBERTa (Conneau et al., 2020), to utilize a source sentence as a pseudo reference. In order to obtain a sentence-pair vector from source language and target language sentences together, our model encodes input sentences with a cross-lingual language model instead of monolingual BERT.

The model procedure is illustrated in the Figure 1. Our metric, called C-SPEC (Cross-lingual Sentence Pair Embedding Concatenation), uses paired inputs of hypothesis-source and hypothesis-reference. It introduces another vector for hypothesis-source ($v_{hyp+src}$) in addition to the standard one for hypothesis-reference pair ($v_{hyp+ref}$) to make an ensemble evaluation. Both sentence vectors are concatenated and used to predict the evaluation score in multi-layer perceptron (MLP). At first of the evaluation process, the cross-lingual language model encodes an input sentence into a sentence-pair vector. Then, using the sentence-pair vector, a MLP outputs the final evaluation score in regression manner. In training, we used standardized z score of DA (Direct Assessment; Graham et al. (2013)) as the ground truth and updated the model parameters by backpropagation (Rumelhart et al., 1986) with Mean Squared Error (MSE) Loss.

Our model was trained by the following steps. Firstly, in order to speed up and stabilize the training procedure, our models were trained on the corpus of WMT2015-2016's DA. Secondly, the models were additionally trained on WMT2015-2017's DA, WMT2018-2020's DA, or WMT2015-2020's DA. Thirdly, they were fine-tuned with the pseudo negative examples. Lastly, they were fine-tuned again on the WMT20's MQM segment-level corpus.

In each step of fine-tuning, we initialize the output-layer and only inherit the parameters of XLMRoBERTa. We tried three different conditions in the second step because DA corpus after WMT2018 is relatively noisy, and removing those data may play out well.

In the system-level evaluation, we simply averaged the segment-level evaluation scores for each system.

3.2 Word Attribute Transfer

We used the reflection-based word attribute transfer Ishibashi et al. (2020) for data augmentation. This transfer can make conversion of words into a certain word attribute, such as *queen* to *king*, using parameterized mirrors composed of two multi-layer perceptrons.

For the pseudo-negative hypothesis generation, we used two types of word attribute transfer in gender (male/female) and antonym. The word attribute transfer was applied onto all the words in an input sentence, and words having a target attribute were rewritten into their transferred counterparts while those that were not related to the target attribute were kept unchanged. For example, a sentence *"It is our duty to remain at his sides", he said, to applause* is transferred into *"It is our duty to change at his sides", he said, to whisper*, by the antonym transfer. Note that the word attribute transfer may not make any changes on an input sentence when all the words were identified as non-related words. We eliminated such sentences from our pseudo-negative examples.

3.3 Fine-tuning using pseudo-negative examples

Our pseudo-negative examples were obtained from the reference sentences in the training corpus of all-English that was used to firstly fine-tune a model, because the word attribute transfer model works only in English. However, we did not have any DA scores on these pseudo-negative examples. So, we used them to fine-tune the evaluation models

in classification manner. We introduced a different output layer on the top of the model illustrated in Figure 1 to classify an input example into the following categories:

1. A hypothesis is the same as its original system translation.
2. A hypothesis is the same as its reference.
3. A hypothesis is from the pseudo-negative examples

In the fine-tuning, we used three types of inputs corresponding to the classes above, and the models were trained to discriminate them. We expected such fine-tuned models to identify the serious word choice translation errors given in the pseudo-negative examples. We call the metric trained using the pseudo-negative examples C-SPECpn (pn:psuedo-negative).

4 Segment-level evaluation experiments

Our experiment was conducted on the development data for WMT21 metric task, which is randomly selected 10% of WMT20 MQM segement-level corpus. All the results were calculated by the Pearson's correlation with the MQM segment scores.

4.1 Results

The results of the WMT20 MQM segment-level corpus are shown in Table 1.

From the results, the models trained on negative examples of WMT15-17 and WMT18-20 overcame the plain models in Pearson's correlation. Among the models, the best score was archived by the one trained on WMT18-20 with the negative examples. Although WMT15-20 is a larger corpus than WMT18-20, the score of plain models was negligible at best, and the model trained on WMT18-20 and with negative examples did not overcome the plain one.

In order to figure out whether and how fine-tuning on the negative examples had impact on the evaluation performance, we calculated the Pearson's correlation for each small chunk of segment-level MQM scores and visualized the gap between models' outputs in Figure 2. Both the models trained on WMT15-17 and WMT18-20 with negative examples performed better in the MQM range of [-25.0, -5.0) and [-0.1, 0.0]. This suggests that using negative examples can improve the performance of evaluating high and critically low quality translations. However, the model trained on WMT15-20 with negative examples dropped its performance in the [-25.0, -5.0) range compared to the plain model. We assume the reason of the score drop is that the model was overly fine-tuned to the high quality translations, as it can be seen that the Pearson's correlation score in the [-0.1, 0.0] improved tremendously.

5 Conclusion

In this paper, we presented a BERT-based multilingual evaluation metric that is boosted by pseudo-negative examples to evaluate poor translations more precisely. Our model leverages our previous work Takahashi et al. (2020) and have shown an improvement of Pearson correlation when fine-tuning on the synthetic examples in the WMT15-17 and WMT18-20 corpus settings.

Abstract

In this paper, we present our submission to Shared Metrics Task: **RoBLEURT** (**R**obustly **O**ptimizing the training of **BLEURT**). After investigating the recent advances of trainable metrics, we conclude several aspects of vital importance to obtain a well-performed metric model by: 1) jointly leveraging the advantages of source-included model and reference-only model, 2) continuously pre-training the model with massive synthetic data pairs, and 3) fine-tuning the model with data denoising strategy. Experimental results show that our model reaching state-of-the-art correlations with the WMT2020 human annotations upon 8 out of 10 to-English language pairs.

1 Introduction

Automatically evaluating the adequacy of machine translation (MT) candidates is crucial for judging the quality of MT systems. N-gram-based metrics, such as BLEU (Papineni et al., 2002), TER (Snover et al., 2006) and chrF++ (Popovic, 2015, 2017), have dominated in the topic of MT metric. Despite the success, recent studies (Smith et al., 2016; Mathur et al., 2020a) also pointed out that, N-gram-based metrics often fail to robustly match paraphrases and capture distant dependencies. As MT systems become stronger in recent decades, these metrics show lower correlations with human judgements, leading the derived results unreliable.

One arising direction for metric task is using trainable model to evaluate the semantic consistency between candidates and golden references via predicting scores. BERTScore (Zhang et al., 2020), BLEURT (Sellam et al., 2020) and COMET (Rei et al., 2020) have shown higher correlations with human judgements than N-gram-based automatic metrics. Benefiting from the powerful pre-trained language models (LMs), e.g., BERT (Devlin et al., 2019), those fine-tuned metric models first derive the representation of each input, then introduce an extra linear regression module to give predicted score which describes to what degree the MT system output adequately expresses the semantic of source/reference contents. Furthermore, related work (Takahashi et al., 2020; Rei et al., 2020) reports that, metrics which additionally introduces source sentences into inputs can further boost the performance of metric model.

To push such "model as a metric" approach further, we present RoBLEURT – Robustly optimizing the training of BLEURT (Sellam et al., 2020), to achieve a better consistency between model predictions and human assessments. Specifically, for low-resource scenarios, using only hypotheses and references can give more accurate results, alleviating the sparsity of source-side language; for the high-resource language pairs, we format the model input as the combination of source, hypothesis and reference sentences, making model attending to both source input and target reference when evaluating the consistency of semantics. Then, we collect massive pseudo data from real MT engines tagged by pseudo scores with strong baselines for supervised model pre-training. As to the fine-tuning phase, we rescore the noisy WMT metric data of previous years with strong metric baselines, which are then utilized to fine-tune our model. Experimental results show that, following the setting of WMT2021 metric task, our RoBLEURT model outperforms the reported results of state-of-the-art metrics on multilingual-to-English language pairs.

2 RoBLEURT

2.1 Combining Multilingual and Monolingual Language Model

Same as previous years, translation tasks cover both low-resource and high-resource scenarios. To

[*]Work was done when Yu Wan was interning at DAMO Academy, Alibaba Group.
[†]Corresponding authors.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1053–1058

give higher reliable outputs, we believe our metric model can benefit from separately pre-trained and fine-tuned over each kind of scenarios:

- For low-resource multilingual-to-English language pairs, we can hardly obtain massive parallel data with high quality, nor access well-performed automatic translation systems to produce syntectic data for pre-training. We mainly consider model outputs and gold references as our model inputs. Thus we mainly consider the monolingual English language model (called RoBLEURT-NoSrc) in this scenario.

- As to high-resource language pairs, they do not suffer from limitations above, thus can benefit from the information of source input, model output and target reference. A multilingual version of pre-trained LM (called RoBLEURT-Src) can be used for this scenario.

The main architecture of our model is Transformer (Vaswani et al., 2017), which has been widely used in recent researches. As related studies point out that RoBERTa (Liu et al., 2019) outperforms conventional BERT (Devlin et al., 2019), we employ the well-trained model checkpoint from RoBERTa family. Besides, the conventional BLEURT model is trained based on uncased-BERT, which tokenizes the input sentences with the lower case format whereas RoBERTa uses case-sensitive tokenizer, which may be helpful to distinguish more information. Moreover, model with larger scale is generally related with better performance and higher capacity of available knowledges.

Recently, several approaches which further fine-tune RoBERTa model can give better performance over multiple natural language inference tasks. To make sure our model can also benefit from this, we finally use `RoBERTa-large-mnli`[1] and `RoBERTa-large-xnli`[2] (Conneau et al., 2020) for low-resouce and high-resource language pairs, respectively.

2.1.1 Model Combination

We are also interested in exploring whether we can boost the performance of combine RoBLEURT-NoSrc and RoBLEURT-Src. Combining the outputs from models trained with different settings is widely used in MT tasks (Barrault et al., 2020). In this paper, We simply use weighted combination of all available well-trained models.

2.1.2 Input Formatting

Our model consists of a well-trained RoBERTa model to obtain segment-level representations. Here we also try with two solutions: the model input includes source sentence (RoBLEURT-Src) or not (RoBLEURT-NoSrc). For the former, the model input is formatted as:

<s> hyp' </s> </s> ref </s>. (1)

As the latter, due to the number of input sentences is larger than RoBERTa predefined training format, we redesigned the input format as:

<s> src </s> </s> hyp' </s> </s> ref </s>. (2)

2.1.3 Prediction Module

To obtain a scalar value as predicted score, we directly derive the representation at the first position of input $\mathbf{X} \in \mathcal{R}^{1\times d}$ as the representation of input tuple, where d is the size of hidden states. It is then fed to projection layer, after which we yield a scalar for describing how adequately the hypothesis express the semantics:

$$s = \mathbf{W}\mathbf{X}^{\top} + b, \tag{3}$$

where $\mathbf{W} \in \mathcal{R}^{1\times d}, b \in \mathcal{R}^{1}$ are both trainable parameters.

During training, the learning objective is to reduce the mean squared error (MSE) between model prediction s and annotated score $score$:

$$\mathcal{L} = (s - score)^2. \tag{4}$$

2.2 Continuous Pre-training with Synthetic Data

Continuous Pre-training the model on synthetic data is proven helpful to improve the performance (Sellam et al., 2020), where BLEURT obtain the synthetic data by randomly perturbing 1.8 million segments from Wikipedia for this continuous pre-training (also called mid-training). However, we doubt that applying datasets out of MT domain, or even use learning signals tagged from non-reliable automatic metrics (e.g., BLEU), may harm the model learning during pre-training phase. As a consequence, we consider collecting synthetic data

[1] https://huggingface.co/roberta-large-mnli
[2] https://huggingface.co/joeddav/xlm-roberta-large-xnli

with real MT models over MT task datasets. To this end, we first collect the available translation outputs by using accessible engines[3] to generate MT hypotheses. Specifically, we collect high-quality cross-lingual parallel MT training data, including Czech (cs) / German (de) / Japanese (ja) / Russian (ru) / Chinese (zh) – English (en), from the WMT News translation track of each year. By taking the source side (cs/de/ja/ru/zh) as input for translation engines, we collect multiple triples formatted as (src, hyp, ref), where src, hyp, ref represent source, hypothesis, and reference respectively.

Adding Noise to Data As Sellam et al. (2020) demonstrated that, when collecting synthetic data for pre-training metric model, adding noise to data is helpful for model learning. Due to the high quality of automatically generated MT candidates in recent decades, such noise can smoothen the distribution of semantic consistency over whole dataset, which benefits the metric model learning. We thus follow their research, randomly select 30% of collected data to be added with noise at the hypothesis side. More specifically, we use the "word drop" noise – randomly dropping words with a randomized ratio for chosen sentence – to achieve such goal of quality reduction. Finally, we obtain a synthetic dataset formatted as (src, hyp', ref), where hyp' is the noisy hypothesis.

Data Pseudo Labeling As our model tends to be a regression model – predicting score for each inputted triplet, supervisedly guiding the model learning with given scores is essential. To give more adequate scores for each data item, we use COMET (Rei et al., 2020) for tagging each triplet, resulting into the data items formatting as quadruple $(src, hyp', ref, score)$. To make sure our model should be stably trained, we rescale the scores with Z-score format following Sellam et al. (2020).

2.3 Fine-tuning with Data Denoising Strategy

As reported in Sellam et al. (2020), Ma et al. (2019), and Mathur et al. (2020b), noisy data may give incorrect judgements on the reliability of one specific MT metric. After collecting the data from previous years, we find out that the DA datasets from year 2018-2019 are recognized as noisy ones, however they contribute a considerable portion to the available DA datasets. To give more accurate learning signals for training, we believe identifying the noisy data items is of vital importance. Specifically, we prepare the required metrics following two methods:

- RoBLEURT checkpoints. We first train several RoBLEURT models with different portions of training data, as well as multiple experiments by setting different random seeds. Here we use both RoBLEURT and RoBLEURT-NoSrc settings, and derives 4 checkpoints following each setting.
- Available well-performed checkpoints. We collect the officially released COMET[4] and BLEURT checkpoints[5].

After collecting the predictions with all checkpoints above, we identify the noisy data items by computing the variance of rankings within whole dataset. Finally, we rescore those noisy items with those models, tagging pseudo labels for fine-tuning. Besides, to guarantee the scores are unbiased, we re-normalize them within the dataset of each year by Z-score following Sellam et al. (2020).

3 Experiments

3.1 Settings of Continuous Pre-training

Synthetic Data Collection To continue pre-training the model, we simply collect parallel data from the previous WMT conferences, taking the training data from MT track cs/de/ja/ru/zh-en language pairs to obtain high-resource pseudo data. Finally, for each language pair, we collect 2.0 million quadruples for metric model pre-training. For low-resource scenarios, we reuse the datasets above, where the only difference is removing the source sentences.

As to development set, we directly collect the direct assessment (DA) dataset from the WMT2020 Metrics task track. We evaluate the model performance following DARR assessments (Ma et al., 2019; Rei et al., 2020), and choose the best checkpoint for fine-tuning.

Hyper-parameters During the continuous pre-training, we determine the maximum learning rate as $5 \cdot 10^{-6}$, training steps as 0.5M and warm-up steps as 50K. The learning rate first linearly warms up from 0 to maximum learning rate, then decays to

[3] We use own MT engines to obtain translation hypotheses.

0 till the end of training. To avoid over-fitting, we apply the dropout ratio as 0.1. We conduct the pre-training experiments with 8 Nvidia V100 GPUs, where each batch size for each GPU device contains 4 quadruplets. To avoid memory issues during pre-training, we simply reduce the number of total tokens, leaving 128 and 192 for ROBLEURT-NOSRC and ROBLEURT-SRC, respectively.

3.2 Settings of Fine-tuning

Data Collection We fine-tune our model with the WMT2015-2019 dataset as training set, where the WMT2018-2019 subsets are processed with our data denoising strategy as discussed in § 2.3. To directly confirm the effectiveness of our approach, we simply use WMT2020 dataset as dev set to compare reported results in WMT2020 metric task.

To select the model for participating the WMT2021 metric task, we divide the WMT2020 dataset into 4 folds, where the data items are firstly gathered with the identical source and reference sentence. For each fold, we select the corresponding fold of the WMT2020 subset as the dev set, and use the combination of the WMT2015-2019 dataset and the other unused WMT2020 subsets as the training set.

Hyper-parameters During fine-tuning, we set the training steps and warm-up steps as 20K and 2K, respectively. The other hyper-parameters are identical to those of pre-training phase. For each fine-tuning experiment, we determine the batch size as 16, and whole training process requires one single Nvidia V100 GPU.

Main Results We first testify the effectiveness of our approach by comparing with the results from the WMT2020 Metrics Task submissions. To be fairness, all of the model based metric baselines are trained on the WMT2015-2019 dataset. As shown in Table 1, comparing to baselines, our ROBLEURT achieves the best performance on cs/de/ja/ru/zh/iu/pl/ta-to-en settings, and achieves competitive results on km-to-en and ps-to-en.

4 Ablation Studies

4.1 Model Pedestal and Size

We first investigate the impact of model pedestal for metric task. As shown in Table 3, using RoBERTa-large instead of RoBERTa-base model as the base of ROBLEURT-SRC model gives a better performance. Furthermore, using the fine-tuned checkpoint RoBERTa-large-xnli can further improves the performance. This indicates our view, that powerful pre-trained LM, as well as the carefully re-optimized variants, can boost the performance of fine-tuned metric model.

4.2 Pre-training

To identify the improvement after introducing extra pre-training steps for metric model, we conduct the results in Table 4 for comparison. As seen, the performance drops significantly without pre-training phase. This caters to the previous findings (Sellam et al., 2020), where pre-training with pseudo data helps the supervised learning of metric model.

4.3 Data Denoising Strategy

As reported in (Sellam et al., 2020), the WMT2018-2019 DA subsets are bothered with noisy labels. We also investigate the impact of those data, whether introducing them into model training, or even clean them via rescoring with stronger metric. We thus arrange such ablation study during fine-tuning, and results are conducted in Table 5. Although the noisy portion contributes a great share

Model	cs	de	ja	ru	zh	iu	km	pl	ps	ta
RoBLEURT-NoSrc	13.5	46.9	27.4	10.8	14.8	28.2	30.6	8.3	14.7	25.0
RoBLEURT-Src	14.1	47.9	28.7	11.7	14.9	27.5	29.9	6.4	16.0	24.0

Table 2: DARR Kendall correlation (%) over WMT2020 data with model combination. For each setting, we present the averaged correlation with well-trained 3 models. Combining both RoBLEURT-Src and RoBLEURT-NoSrc models can give significant improvement.

Model	cs-en	de-en	ja-en	ru-en	zh-en
base	11.7	44.3	24.1	9.1	12.1
large	12.4	46.2	26.2	**12.0**	14.1
large-xnli	**14.1**	**47.9**	**28.7**	11.7	**14.9**

Table 3: DARR Kendall correlation (%) over WMT2020 data with different pedestals for RoBLEURT-Src setting. Larger model size can give better performance for metric model, and finetuned RoBERTa-large-xnli model can push the improvement further.

Model	cs-en	de-en	ja-en	ru-en	zh-en
w/o pretrain	10.6	44.8	21.4	6.1	10.2
w pretrain	**14.1**	**47.9**	**28.7**	**11.7**	**14.9**

Table 4: DARR Kendall correlation (%) over WMT2020 data with data filtering. We use RoBLEURT-Src model to conduct the results. Simply removing the noisy portion does not help the model training. However, reintroducing them into training set after rescoring them gives a significant improvement.

Model	cs-en	de-en	ja-en	ru-en	zh-en
full set	9.1	45.0	23.5	8.1	9.8
& remove	13.4	46.8	26.1	**11.7**	14.1
& rescoring	**14.1**	**47.9**	**28.7**	**11.7**	**14.9**

Table 5: DARR Kendall correlation (%) over WMT2020 data with data filtering. We use RoBLEURT-Src model to conduct the results. Simply removing the noisy portion does not help the model training. However, reintroducing them into training set after rescoring them gives a significant improvement.

of full training set (237K vs. 247K), the performance of RoBLEURT model trained without these noisy items does not diminish significantly. After rescoring with available checkpoints, these data segments further improves model performance.

4.4 Model Combination

We first identify whether introducing source side information to metric model helps training. As seen in Table 2, accepting source (row RoBLEURT-Src) than not (row RoBLEURT-NoSrc) as extra input significantly improves the correlation scores. However, for low-resource scenarios, experimental results show that source-side information does not help much for model training. This indicates that source information does not provide help for model training over low-resource scenarios, as the inadequacy of pre-training data may harms model training if source side is introduced. To derive better performance, one general idea is to combine several well-trained models during inference. We also explore whether combining both RoBLEURT-Src and RoBLEURT-NoSrc models can give better performance.

As shown in Table 2, directly averaging scores from multiple models lead to a significant performance drop. On the contrary, our model, which takes models over both RoBLEURT-NoSrc and RoBLEURT-Src settings can effectively leverage the predictions, achieving significant performance gain across all language pairs.

5 Conclusion

In this paper, we describe our submission metric – RoBLEURT, from the perspective of combining multilingual and monolingual language model, continuous pre-training with the massive synthetic data pairs, and fine-tuning with data denoising strategy. Experimental results confirms the effectiveness of our pipeline, demonstrating state-of-the-art correlations with the WMT2020 human annotations upon 8 out of 10 to-English language pairs.

Abstract

We are using a semi-automated test suite in order to provide a fine-grained linguistic evaluation for state-of-the-art machine translation systems. The evaluation includes 18 German to English and 18 English to German systems, submitted to the Translation Shared Task of the 2021 Conference on Machine Translation. Our submission adds up to the submissions of the previous years by creating and applying a wide-range test suite for English to German as a new language pair. The fine-grained evaluation allows spotting significant differences between systems that cannot be distinguished by the direct assessment of the human evaluation campaign. We find that most of the systems achieve good accuracies in the majority of linguistic phenomena but there are few phenomena with lower accuracy, such as the idioms, the modal pluperfect and the German resultative predicates. Two systems have significantly better test suite accuracy in macro-average in every language direction, Online-W and Facebook-AI for German to English and VolcTrans and Online-W for English to German. The systems show a steady improvement as compared to previous years.

1 Introduction

Evaluation in NLP and particularly in Machine Translation (MT) is an essential process for identifying flaws and leading further system improvements. Nevertheless, the exact method of evaluation to be used varies, given the quality requirements of the particular use case. Whereas the vast majority of the evaluation methods reside on metrics or direct assessment by humans to produce a single quality score given an entire test set, a recent trend has opted to evaluating the details of the produced translations, with major focus on their correctness from a linguistic perspective. For this reason, the translation systems are not tested based on generic test-sets, but they are given input which is particularly crafted to trial their performance. Most commonly, this is done with the help of a test suite (cf. Guillou and Hardmeier, 2016; Isabelle et al., 2017b; Burchardt et al., 2017).

The paper at hand describes the use of a test suite in order to evaluate 18 German to English and 18 English to German MT systems that participated at the Shared Task of the Sixth Conference on Machine Translation (WMT21)[1]. The evaluation is performed by an extensive test suite that tests a wide range of linguistically motivated phenomena. In addition to our contributions in the previous years, which focused only on German to English, this year we are presenting for the first time results with an extensive test suite with a similar logic for the opposite direction English to German. Our German to English test set contains 5,560 test sentences, covering 107 linguistic phenomena that are organized in 14 categories. The English to German test set contains 4,443 test sentences, covering 111 linguistic phenomena that are organized in 12 categories.

2 Related Work

Test suites have already been used since the beginnings of MT in the 1990s (King and Falkedal, 1990; Way, 1991; Heid and Hildenbrand, 1991). With the rise of deep learning, the quality of MT outputs has improved significantly, which in turn lead to a recent revival of test suites that focus on the evaluation of specific linguistic phenomena (e.g., pronoun translation (Guillou and Hardmeier, 2016), or on the comparison of different MT technologies (Isabelle et al., 2017a; Burchardt et al., 2017), and Quality Estimation methods (Avramidis et al., 2018).

Within the scope of the test suite track of the Conference on Machine Translation, several test suites for multiple language directions have

I have baked a cake.	fail
I baked Tim a cake.	pass

Table 1: Examples of passing and failing MT outputs

been introduced. These test suites focus on one or multiple different phenomena, such as conjunctions (Popović, 2019), grammatical contrasts (Cinkova and Bojar, 2018), discourse (Bojar et al., 2018; Rysová et al., 2019), domain-specific translations (Vojtěchová et al., 2019), gender coreference (Kocmi et al., 2020), markables (Zouhar et al., 2020), morphology (Burlot et al., 2018), pronouns (Guillou et al., 2018), or word sense disambiguation (Rios et al., 2018; Raganato et al., 2019; Scherrer et al., 2020). In contrast to the majority of these test suites, our test suite does not focus on a single phenomenon but performs a systematic evaluation of more than one hundred phenomena per language direction.

3 Methods

Our test suite consists of two test sets (one per language direction) that have been created manually with the aim of testing the performance of MT systems. They cover a wide variety of linguistic phenomena which are grouped in different categories. While there is a big overlap between the linguistic categories and phenomena in the two test sets, there are also many differences as the categories and phenomena are language-specific. Some exemplary test sentences can be seen in Table 1.[2] Each linguistic phenomenon in the test suite is represented by multiple test sentences. Each test sentence is tied to a number of rules that determine whether a translation of the sentence would be deemed correct or incorrect. The performance of an MT system with regard to the linguistic phenomena is then evaluated by observing the amount of test sentences that are translated correctly.

[2]A larger set of exemplary test sentences can be found in the GitHub repository: https://github.com/DFKI-NLP/TQ_AutoTest.

3.1 Application of the test suite

The construction of the test suite has been described in detail in the papers for the test suite track from the previous years. Figure 1 depicts the preparation and application of the test suite with steps *a* to *c* representing the construction. The application starts with step *d*: The test sentences are given as input to the MT systems. The MT outputs are then evaluated by the set of rules which define whether the phenomenon under inspection is translated correctly or not (step *e*). The rules consist of regular expressions and fixed strings. When the rules cannot be applied to a translation to automatically determine whether it is correct or incorrect, the test sentence is marked with a warning. Those warnings are consequently inspected manually by a human annotator with linguistic knowledge who decides on the correctness of the translation and adapts the set of rules accordingly (step *e*).

Thereafter, the phenomenon-specific translation accuracy is calculated by dividing the number of correctly translated test sentences of a phenomenon by the total number of test sentences of that phenomenon:

$$\text{accuracy} = \frac{\text{correct translations}}{\text{sum of test items}}$$

Since the aim of this evaluation is to compare the systems in a fair way, we include only the test items that do not contain any warnings for any of the systems in the calculation. Test items that have an unresolved warning for at least one system are excluded from the calculation. Unfortunately, this reduces the amount of the test items by removing properly validated ones, and this is where we see the importance of the extensive manual evaluation and the creation of rules with good coverage.

To define which systems perform better for a particular phenomenon (or category), we compare all systems to the one with the highest accuracy. When we compare the highest scoring system with the rest, we confirm the significance of the comparison with a one-tailed Z-test with $\alpha = 0.95$. The systems which do not differ significantly from the best system are considered to be in the first performance cluster and indicated with boldface in the tables. The boldfaces therefore have a meaning only for the respective row of the table.

The average scores are computed in three different ways, because each category or phenomenon has a different amount of test items. *Micro-average* aggregates the contributions of all test items to

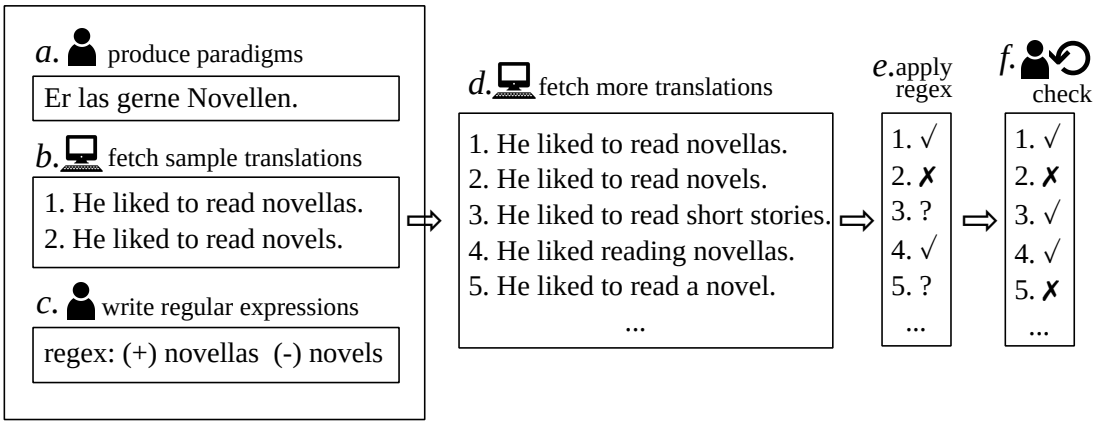

Figure 1: Example of the preparation and application of the test suite for one test sentence

compute the average percentages, *category macro-average* computes the percentages independently for each category and then averages them (i.e. treating all categories equally), and *phenomenon macro-average* computes the percentages independently for each phenomenon and then takes the average (i.e. treating all phenomena equally).

3.2 Experiment setup

In the evaluation presented in this paper, we obtained translations of our test suite by 36 systems that are part of the *news translation task* of the Sixth Conference on Machine Translation (WMT21). In previous years, we solely applied our test suite to the German to English MT outputs. However, this year, we did not only analyse the MT outputs from 18 German to English systems, but also from 18 English to German systems.

While there were already many rules for the evaluation of German to English MT output in our test suite, very few rules were available for the other language direction when we received the translations. Therefore, a significantly bigger amount of manual work was involved in the evaluation this year. For German to English there were on average 5.76% of warnings when we received the translations, while for English to German there were on average 84.21% of warnings. The manual evaluation process was conducted by three annotators with linguistic knowledge over the course of seven weeks and involved around 80 person hours. After the extensive manual evaluation, there were on average 3.04% of warnings for German to English and 4.87% for English to German.

As we explained previously, in order to have a fair comparison between the systems we excluded items where at least one system has an unresolved warning. Therefore, in the results that we are presenting in this paper we can only use 3,806 out of the 5,560 (68.4%) test items for German to English and 3,096 out of the 4,443 (69.7%) test items for English to German for the systems comparison.

4 Results

The accuracies resulting from the application of the test suite on the system outputs can be seen in the tables in the Appendix. We first present the results aggregated in categories (Tables 4 and 5) so one can have a broad overview of the systems performance, whereas afterwards a yearly comparison with last years (Table 6) and the detailed phenomenon-level results (Tables 7 and 8) are shown. The systems are ordered based on their macro-average accuracy, from high to low.[3]

4.1 Comparison between systems

For German to English, two systems have the highest category macro-averaged accuracy, Online-W and FacebookAI, whereas when considering the phenomenon macro-averaged accuracy, the significantly best systems are FacebookAI and Online-A. UEdin, Online-A and borderline compete with the best systems when the micro-average is considered, mainly because of their good accuracies on phenomena related to *verb tense/aspect/mood*, where there are many individual phenomena with a lot of test items in one category. Overall, the average accuracies are very high, with the lowest system (happyface) having a micro-average of 72.3%. Despite the high accuracies there is definitely room

[3]For German-English the two VolcTrans system variations appear as one system, since they delivered the same output. This is not the case for the English-German direction where they appear separately.

for improvement.

For English to German, based on the category macro-average, FacebookAI and VolcTransAT share the first position. Based on the micro-average and the phenomenon macro-average however, FacebookAI, Online-B and VolcTrans-GLAT share the first position. The accuracies for this language direction in overall are much higher on the micro-average, but not on the macro-average. However, due to the fact that the test items are different in their nature and in the amount, we cannot make a direct comparison between the two language directions.

4.2 Categories

For some categories, the accuracies have reached very high numbers, which is the case for *negation* and *punctuation*, both having a 100% for German to English. Concerning punctuation, in the previous years we had seen individual systems with considerable punctuation errors, which seem to not appear this year. However, the high scores do not necessarily mean that all problems for these phenomena are solved. It could rather mean that our test suite does not cover the current edge cases, a consideration that is subject to further research. Other categories such as *composition*, *subordination* and *named entities & terminology* reach an average of more than 90% accuracy in German to English. The worst performing category in German to English is *false friends*, where all systems perform 64-86%. *Ambiguity*, *verb tense/aspect/mood* and *multi-word expressions* (MWE) also perform relatively low, with accuracies less than 85%.

For English to German, there are no categories for which all systems reach an accuracy of 100%. However, there are several categories with average accuracies above 95%, that is *function words*, *negation*, *verb tense/aspect/mood*, and *subordination*. The category with the lowest average is *coordination & ellipsis*, with an average accuracy of only 70.8%. The individual systems reach a wide range of 58.6% to 81.6% accuracy for this category while for most other systems, the range is not as big for the systems. There are two more categories with a relatively low accuracy on average (below 85%), namely *verb valency* (81.4 % accuracy) and *ambiguity* (83.3% accuracy).

4.3 Phenomena

For **German to English**, the most difficult phenomena this year remain the *modal pluperfect* (*negated* and *non-negated*), the *resultative predicates* and the *idioms*. Online-W does impressively well with *idioms*, achieving almost 60%, with another two systems, FacebookAI and Online-A, reaching 33.3%. These numbers were significantly lower in the previous years, which indicates an improvement in this direction. There are some phenomena for which all systems reached 100% accuracy, such as *negation*, *internal possessor*, *comma*, *ditransitive perfect*, and *intransitive future I*.

Idiom	
Er redet um den heißen Brei herum.	
He's talking around the hot porridge.	fail
He's talking around the bush.	fail
He's beating around the bush.	pass
Modal pluperfect	
Sie hatten lesen wollen.	
They wanted to read.	fail
They had to read.	fail
They had wanted to read.	pass
Resultative predicate	
Lisa fuhr das Auto kaputt.	
Lisa drove the car broken.	fail
Lisa broke the car.	pass
Lisa crashed the car.	pass

Table 2: Examples of De-En linguistic phenomena with low accuracy with passing and failing MT outputs

Table 2 contains translation examples from linguistic phenomena with the lowest accuracy for German to English. *Idioms* are types of multiword expressions. The meaning of an idiom goes beyond the meanings of its individual elements. Most idioms are very language-specific and therefore difficult to translate. For the German idiom "um den heißen Brei herumreden", there is the equivalent English idiom "to beat about the bush". The first incorrect translation contains a direct translation of all the individual elements of the German idiom. The second incorrect translation, which was produced by several MT systems, is very interesting because it does indeed contain the "bush" of the English idiom. However, it still contains the wrong verb as the verb "is talking" is simply a translation of the German "redet". Therefore, the second translation is still incorrect. Only the third translation which contains the full English idiom is correct.

The second example contains a test sentence from the phenomenon *modal pluperfect*. Modal verbs can usually have several meanings which often leads to translation errors. Furthermore, the tense pluperfect is often mistranslated as preterite, as in the first incorrect translation. The second in-

Idiom	
The mafia boss has spilled the beans.	
Der Mafiaboss hat die Bohnen verschüttet.	fail
Der Mafiaboss hat sich verplappert.	pass
Der Mafiaboss hat es ausgeplaudert.	pass
Pseudogapping	
Jackie likes the doctor but she doesn't the nurse.	
Jackie mag den Arzt, aber sie nicht die Krankenschwester.	fail
Jackie mag den Arzt, aber sie ist nicht die Krankenschwester.	fail
Jackie mag den Arzt, aber nicht die Krankenschwester.	pass
Middle Voice	
This car drives easily.	
Dieses Auto fährt leicht.	fail
Dieses Auto fährt sich leicht.	pass
Das Auto ist leicht zu fahren.	pass

Table 3: Examples of En-De linguistic phenomena with low accuracy with passing and failing MT outputs

correct translation additionally leaves out the German modal verb "wollen" ("to want") which completely changes the meaning of the translation.

Resultative predicates contain a verb and an adjective which describes the result of the verb action. *Resultative predicates* do not exist that way in English, which makes them hard to translate. In the example at hand, the meaning of the German sentence is that Lena drove the car which resulted in the car being broken. A literal translation like in the first translation is ungrammatical. The second and third translation are possible correct translations – even though the "driving" part is left out, these translations are still deemed best options to translate this phenomenon.

In **English to German**, *idioms* show even more difficulties as in German to English (average accuracy only 14.6%, the lowest average accuracy on any phenomenon for this language direction). Here, 9 systems totally fail to translate any idiom, whereas the system with the highest accuracy is an unconstrained system, which may attributed to the fact that additional data led to better coverage of such cases. Furthermore, *middle voice* (45.9%), *pseudogapping* (60.5%), and *stripping* (57.0%) and also have a relatively low accuracy. On the other hand, there were also many phenomena which reached (nearly) 100% accuracy, such as *internal possessor*, *comma*, *indirect speech*, *infinitive clause*, *object clause*, *subject clause*, *passive voice*, and *ditransitive*, *intransitive* and *transitive verbs* in many tenses.

Table 3 covers example translation from low accuracy phenomena for English to German. The first example again contains an *idiom*. The English idiom "to spill the beans" does not have an equivalent idiomatic translation in German. Therefore, the first translation, which is a literal translation of the separate idiom elements, is incorrect. The second and third translation are possible correct translations.

The second example sentence is taken from the phenomenon *pseudogapping*. Put simply, in *pseudogapping*, part of the verb phrase is omitted. In the example at hand, the non-finite verb part "like" is omitted in the second conjunct of the construction. In the first incorrect German translation, the verb has been completely left out in the second conjunct (while the subject "sie" persists). In the second incorrect translation, the second conjunct contains the auxiliary verb 'ist" which also leads to ungrammaticality. The third translation leaves out the non-finite verb part "like" as well as the subject which results in a grammatical German construction.

The third example contains a sentence in *middle voice*. In middle voice, the subject of the verb is neither agent nor patient. A sentence in active voice would be: "I am driving the car.", with the subject ("I") being the agent. A sentence in passive voice would be: "The car is driven by me." with the subject ("the car") being the patient. The subject of the example sentence in Table 3 ("This car") is neither agent nor patient. As middle voice does not exist in German, such sentences have to be translated in other constructions. A literal translation like the first example translation is incorrect. Possible correct translations can be seen in the second and third translation.

5 Comparison with previous years

The progress of the systems performance through the last four years for German-English can be seen in Table 6. The calculation is done based on the common test items without warnings over all these years (4,366 test items), this is why the scores differ slightly from the ones in Table 4. In the first columns of Table 6 the best systems of every year are compared. One can see that the best system of 2021 has significantly better macro-averaged accuracy as compared to the best system of 2020, but when the micro-averaged accuracy is considered, there has been no significant improvement or deterioration. This year's best system also seems

to perform better in a few categories, with most impressive improvements at *false friends* (+14%) and the *non-verbal agreement* (+5%).

Individual systems show some small improvements in general, but the fine-grained evaluation is able to indicate some significant deterioration in particular categories. For example, Online-B, Online-G and VolcTrans, despite their overall improvement, show a significant deterioration regarding *verb tense/aspect/mood*, which reaches a -9% in the case of VolcTrans. Other deteriorations occur for several systems regarding *false friends* and *function words*. This shows that the overall improvement in translation quality may occur at the expense of particular qualitative aspects.

6 Conclusions and Further Work

We presented the result of applying a fine-grained linguistically motivated test suite on the outputs of 36 state-of-the-art machine translation systems, as submitted in the Sixth Conference on Machine Translation. We presented detailed accuracies of translations of 18 German to English as well as 18 English to German MT systems based on more than 3,000 test items each, organized in various linguistic categories and fine-grained phenomena. Additionally, we drew a comparison to previous years' evaluations.

In both language directions, the systems achieve good accuracies in most phenomena or categories and there is some advancement as compared to last year, although there is space for about 10% improvement on the average accuracy. A few phenomena still suffer considerably, such as the *idioms*, the *modal pluperfect* and the German *resultative predicates*, although there is notable improvement as compared to previous years.

As discussed, the very high accuracies for some categories or phenomena raise the question whether the difficulty of the respective test items should be increased. In future work, we plan to investigate this by constructing more test items. Further work includes the development of similar test suites for other language pairs.

Table 7: Accuracies (%) of successful translations on a phenomenon-level granularity for German-English, organized in categories. Boldface indicates the best scoring system in each row, including all systems which are not significantly inferior than the best scoring system. Grey rows average the accuracies of the phenomena per category.

Table 8: Accuracies (%) of successful translations on a phenomenon-level granularity for English-German, organized in categories. Boldface indicates the best scoring system in each row, including all systems which are not significantly inferior than the best scoring system. Grey rows average the accuracies of the phenomena per category.

Pruning Neural Machine Translation for Speed Using Group Lasso

Maximiliana Behnke

Kenneth Heafield
University of Edinburgh
kheafiel@inf.ed.ac.uk

Abstract

Unlike most work on pruning neural networks, we make inference faster. Group lasso regularisation enables pruning entire rows, columns or blocks of parameters that result in a smaller dense network. Because the network is still dense, efficient matrix multiply routines are still used and only minimal software changes are required to support variable layer sizes. Moreover, pruning is applied during training so there is no separate pruning step. Experiments on top of English→German models, which already have state-of-the-art speed and size, show that two-thirds of feedforward connections can be removed with 0.2 BLEU loss. With 6 decoder layers, the pruned model is 34% faster; with 2 tied decoder layers, the pruned model is 14% faster. Pruning entire heads and feedforward connections in a 12-1 encoder-decoder architecture gains an additional 51% speed-up. These push the Pareto frontier with respect to the trade-off between time and quality compared to strong baselines. In the WMT 2021 Efficiency Task, our pruned and quantised models are 1.9–2.7× faster at the cost 0.9–1.7 BLEU in comparison to the unoptimised baselines. Across language pairs, we see similar sparsity patterns: an ascending or U-shaped distribution in encoder feedforward and attention layers and an ascending distribution in the decoder.

1 Introduction

Making transformer-based machine translation models (Vaswani et al., 2017) faster and smaller is a common requirement for server and mobile deployment. We focus on pruning methods that actually improve speed upon strong baselines. There is a variety of work on pruning individual parameters (See et al., 2016; Brix et al., 2020), structures like attention heads (Voita et al., 2019; Behnke and Heafield, 2020), and even whole layers (Sajjad et al., 2020). Unfortunately, much of the prior work on pruning does not report speed or makes inference slower: Brix et al. (2020) achieved no speed-up while Yao et al. (2019) report a 87.5% sparse model took 1.6× as long using cuSPARSE. However, Gale et al. (2020) point out that coefficient-sparse kernels like cuSPARSE are highly unoptimised. Even block-sparse kernels are 1.8× slower at 70% sparsity (Gray et al., 2017) though they did eventually achieve a 1.4× speed-up with "balanced pruning". We propose pruning entire rows or columns and even whole submatrices of a tensor, resulting in a smaller dense matrix. Because the inference problem remains dense, we sidestep the need for sparse kernels to improve speed.

We use group lasso (Yuan and Lin, 2006) regularisation, which encourages groups to diminish together, during the usual training procedure. Murray et al. (2019) used group lasso to prune feedforward layers in their submission to the Efficient Translation Task at WNGT 2019 (Kim et al., 2019a). Their submissions, which "eliminate more than 25% of the model's parameters while suffering a decrease of only 1.1 BLEU" were at best 6% faster than their baseline. When tuned for the same quality loss, our method reduces size by 66% and translates 52% faster. Moreover, their submissions were slower than higher-quality competitors by an order of magnitude, whereas our baselines are state-of-the-art.

Too much work (Gu et al., 2018; Lee et al., 2020; Wang et al., 2020b) on efficiency compares a baseline unoptimized system with their optimized system, which is smaller or faster in exchange for some reduction in BLEU. What these papers fail to prove is that their method works better than existing methods that also make models smaller or faster in exchange for some reduction in BLEU like knowledge distillation (Kim and Rush, 2016), quantisation, reducing the number of layers, prior work on pruning, or simply training a smaller model. In other words, is the trade-off offered by their method any better than the trade-offs already available, regardless of the type of method? Stacking the exist-

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1074–1086
November 10–11, 2021.

ing methods produces a variety of data points with different speed and quality. The Pareto frontier is the set of data points that a practitioner would choose from: no other data point is simultaneously faster (or smaller) and of higher quality. We argue that a new method's empirical justification should advance the Pareto frontier. In this work, we build upon and compare to strong baselines to show the frontier advances.

To compare with the state-of-the-art in terms of speed and to investigate the impact this pruning makes on different languages, we build upon English→German, Spanish→English and Estonian→English student models trained with sequence-level knowledge distillation (Kim and Rush, 2016). We experiment with four architecture variations: a typical decoder with 6 layers and faster variations with shallow decoder of only 1–2 layers. We also include our experiments from the WMT 2021 Efficiency Shared Task.

Our key findings show that:

1. It is possible to prune entire nodes from feed-forward layers early during training, resulting in Pareto optimal architectures (quality vs speed). Similarly, pruning entire heads on the top of it results in even faster models.
2. Different language pairs exhibit similar structural sparsity patterns.
3. Pruning during training matches, and sometimes outperforms, retraining the pruned model from scratch.
4. Among the English→German Pareto optimal models, the notable examples include a model with a 6-layered decoder being 34% faster at the cost of 0.2 BLEU and a model with 12-1 encoder-decoder ratio gaining additional 51% speed-up costing 0.3 BLEU.
5. This type of pruning combined with quantisation gives a significant speed boost. Our models are 1.9–2.7× faster at the cost of 0.9–1.7 BLEU.

2 Related work

Extensive research to reduce workload, compress and speed-up neural machine translation models includes methods such as knowledge distillation (Kim and Rush, 2016), quantisation (Quinn and Ballesteros, 2018; Aji and Heafield, 2020), layer approximation (Kim et al., 2019b) and pruning. For the best results, they can be stacked together to train the efficient state-of-the-art model.

In their analysis, Dalvi et al. (2020) claim that 85% of transformer neurons are redundant across the network. Using transfer learning, they find the minimal set of neurons that achieve optimum performance given the task. However, that method requires a fully pretrained model to perform a brute-force search on it, making overall training time too long.

Pruning techniques are usually split into two groups: unstructured and structured. Unstructured removes individual coefficients. It is straightforward to apply and yields good quality results simultaneously, which makes it popular. Unstructured magnitude pruning, while successfully applied to NMT (See et al., 2016), often needs retraining to recover from quality damage. Moreover, it also requires an efficient matrix multiplication routine to get any speed-up besides size compression. The latest research on combining lottery ticket hypothesis with other methods (Brix et al., 2020) sparsified NMT models by 70 to 90% while losing between 0.6 to 3.3 BLEU points in quality. They used a sparse matrix representation for compression but did not report any speed gains.

On the other hand, structured pruning removes whole layers or groups of parameters, such as blocks (Narang et al., 2017), which makes it easier to optimise on hardware via a special block-sparse matrix multiply (Gray et al., 2017). We apply block sparsity, but the blocks are entire rows or columns so that the usual dense matrix multiply can be used with less overhead. Another line of work prunes entire attention heads from a model (Voita et al., 2019; Behnke and Heafield, 2020), which we also explore in our approach.

Yao et al. (2019) combine unstructured sparsity with a light structure that aims to balance parallel workloads. They introduce a specialised kernel for their structured sparsity. Our workloads are easier to balance because they retain density. The idea that different levels of coarseness can be combined may also extend to prune coefficients, rows, columns, and layers simultaneously in future work.

Wang et al. (2020c) parametrise weight matrices with low-rank factorisations and remove rank-1 components during training, which is said to better preserve linear transformation of uncompressed matrices. They report compressing a Transformer-XL language model by 90% with 1.6× speed-up during inference. Low-rank approximations preserve density, albeit at the cost of doing serial ma-

trix multiplications.

Fan et al. (2019) explored a structured dropout that allows users to prune models for inference. Unfortunately they fail short on NMT experiments. They call WMT14 en-de a 'competitive benchmark' which it has not been for many years. Most problematically, they use tokenised BLEU, which has been noted to be harmful and gives false 'boost' of multiple points on tokenised data. They do not specify the tokeniser or script they use either. Again, there do not include any report on speed or model sizes despite claiming to have much smaller models as a result.

Dodge et al. (2019) used group lasso to sparsify a variant of RNN for text classification, which is an easier task to learn than NMT. They have to train until convergence twice, which we avoid. They provide no speed or model size analysis, suggesting that there is no improvement or proper implementation.

Group lasso has also been previously used by Wuebker et al. (2018) to compress the delta between a base model and a domain adapted version of the model. They still have to run a full-size model in inference, so they have no overall speed gain. They also have to store the full base model; compression only refers to the delta. In contrast, our work makes the base model faster and smaller. The different goals also mean different groups: they focused on embeddings that update in domain adaptation while we focus on costly parts of the architecture.

Though we use the same algorithm of group lasso, our method differs in several ways from (Murray et al., 2019). We prune submatrices in addition to rows and columns, though experiments on just rows and columns show better performance than theirs. They pruned only feedforward layers; we see more speed-up from feedforward layers and additionally prune attention. Finally, we use the normal Adam optimiser (Kingma and Ba, 2014) instead of proximal gradient descent (Parikh and Boyd, 2014). Empirically, we find turning regularisation off after some training is important to quality. Overall, we achieve a much better trade-off between quality and speed/compression.

Most of the methods above need either tuning or retraining, often multiple times. They are usually treated as techniques to compress already existing models. Still, there are ongoing research efforts on training a reduced model from start to finish in one go. For example, Golub et al. (2018) pruned weights with the lowest total accumulated gradients and reduced the memory footprint to allow training much larger models than possible on available hardware. Some methods prune immediately after initialisation, in either unstructured (Lee et al., 2019) or structured (Wang et al., 2020a) way. Our method is orthogonal and is integrated into a training scheme instead.

Using regularisation to sparsify groups of parameters was introduced by Yuan and Lin (2006) and has been since then built upon in the machine learning field (Scardapane et al., 2017; Wen et al., 2016). In this paper, we use group lasso in its simplest form to achieve structural sparsity in transformer layers, focusing on inference speed of machine translation.

3 Methodology

To allow regularisation to remove parameters structurally, we need to define how we group parameters. Depending on which matrix it is, we treat parameters in its rows, columns or heads as one entity to be pruned together. Thus, we apply a group lasso over them. A bias term, if necessary, is treated as a part of regularised groups. We want such a sparsity pattern to emerge early into training so that there is no need to retrain or tune it later.

Group lasso regularisation

Given a matrix w split into non-overlapping groups of parameters G, the group lasso is defined as:

$$R(w) = \sum_{g=1}^{G} \gamma \left\| w_g \right\|_2 = \sum_{g=1}^{G} \gamma \sqrt{\sum_{j=1}^{|G_g|} \left(w_g^j \right)^2}. \quad (1)$$

This penalty term applies L_2 norm over the parameters in each group to force them to go towards 0 together, with L_1 on top of it to enforce overall sparsification. γ is a scalar that orthonormalises groups of different sizes (Simon and Tibshirani, 2012), scaling by the number of elements in a group $\sqrt{d_g}$. If regularising only rows and columns, all groups are of the same size. However, in later experiments, we also regularise whole attention heads alongside individual feedforward connections.

In the end, the penalty for each layer is added to the cost function and scaled by λ and averaged

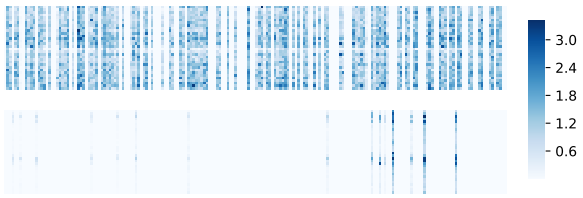

Figure 1: An example of block-sparse matrices in the first layer of decoder (top) and encoder (bottom) pruned by group lasso regularisation.

over words in a batch along with cross-entropy:

$$\frac{1}{|B|}(\sum_{x \in B} CE(x) + \lambda * \sum_{w \in W} R(w)) \,. \quad (2)$$

Initially we experimented with 8x8 blocks in group lasso. However, this approach removed entire rows and columns that correspond to pruning connections. Figure 1 shows an example of this effect on parameter matrices. When an entire row or column is zero, it can be deleted to form a smaller dense matrix. If an input connection is ignored and not used elsewhere, it can be removed from the upstream matrix. If an output connection is constant, the constant can be folded into downstream bias. These optimisations are typically discovered automatically by regularisation. We mainly focus on pruning feedforward layers, but later include experiments that prune attention heads as well.

4 Setup

4.1 Data & architectures

We concentrate on three language pairs: English→German, Spanish→English and Estonian→English. We use knowledge distillation (Kim and Rush, 2016) under teacher-student regime.

In English→German, we follow the Workshop on Neural Generation and Translation 2020 Efficiency shared task (WNGT2020) [1] under the WMT 2019 data condition (Barrault et al., 2019). As a teacher, we use a WMT 2019 system submitted by Microsoft to news translation task (Junczys-Dowmunt, 2019). It is an ensemble of four deep transformer-big models (Vaswani et al., 2017) with 12 layers in encoder and decoder, embedding size of 1024 and feedforward size 4096 and 8 attention heads. For Spanish→English and Estonian→English, we use teachers provided by the Bergamot,[2] which is an ensemble of two similar architectures but with 6 layers instead.

We start with strong student baselines, which are already very small and fast, closely following the latest trends set by WNGT2020.

Students for all language pairs have an embedding dimension of 256 and feedforward of 1536, based on "tiny" architecture from Kim et al. (2019a). The attention has 8 heads in each layer except for decoder self-attention, which is replaced by a faster SSRU (Simpler Simple Recurrent Unit) (Kim et al., 2019b). The models use a shared vocabulary of 32,000 subword units generated by SentencePiece (Kudo and Richardson, 2018) and translate using shortlists of top 50 words.

We tried different configurations of layers to investigate trade-offs between them and potential bottlenecks. We describe each architecture by layer number in encoder and decoder and whether the decoder layers are tied. Thus, we investigate the following architectures (chronologically): "6-2tied", "6-6", "12-1" and "6-2".

Other training hyperparameters were Marian defaults for training a transformer base model.[3] We used dynamic batching, filling a 10GB workspace on each of 4 GPUs, resulting in about 71,000 words per batch in a "6-2tied" student and about 46,000 words per batch in a "6-6" student. As is more effective in the teacher-student regime, we did not use dropout or label smoothing. We use the Adam optimiser (Kingma and Ba, 2014).

The English→German models were trained on 13M sentences of available parallel data, using the concatenated English-German WMT testsets from 2016–2018 as a development set. The Spanish→English students were trained on 242M sentences which included about 15M of mixed forward- and backtranslations. We used a WMT13 testset for development. Estonian→English students were trained on 132M sentences which included about 30M of mixed forward- and backtranslations, and WMT18/dev was used for development.

We trained and decoded all our models using the Marian NMT toolkit (Junczys-Dowmunt et al., 2018). We evaluate quality and speed on 1 CPU core. In order to expand beyond BLEU and incentivise others to do the same, we additionally

[3] Available via `--task transformer-base`.

evaluate with chrF (Popović, 2015) and COMET[4] (Rei et al., 2020) as well. We use SacreBLEU (Post, 2018) for BLEU and chrF. Training progressed until BLEU stopped improving for 20 consecutive validations. The checkpoint with the highest BLEU score was selected.

4.2 Training regime

Our training regime for all of ours models has three phases:

1. Pretrain for 25k batches.
2. Train with a regulariser for 250k batches.
3. Remove rows/columns with a sum less than $1e-5$, collapse a model and then train without regularisation until convergence.

It is well known that initial transformer training is problematic and sensitive to model hyperparameters (Nguyen and Salazar, 2019; Aji et al., 2019; Liu et al., 2020). A transformer starts training with 1–2 BLEU and quickly jumps over to 15–30 or more within a short training period, then slows down. Thus, we start pruning after BLEU improvement slowed down to be less than 1 BLEU point in a single checkpoint. This way, we avoid any potential damage to a model during the critical initial period. In this case, we pretrain for 25k batches.

Next, we had to decide how long to regularise our model to achieve a good trade-off between quality and sparsity levels. We started with regularising a model until convergence. As shown in Fig. 2, most of the parameters are already pruned in the first half of the training. Since students require significantly more updates to train than standard models, we want to give a model enough time to sparsify and converge without any constraints. For this reason, we split an average training time into two halves: the first with pruning, the second without it with normal convergence. We found that switching the regulariser off at some point is less aggressive and allows a model to recover some of its lost quality. We chose 250k updates as a pivot as it is about halfway to when the model has begun stalling in Fig. 2.

After each step, we copy the latest checkpoint and start a fresh training round. Thus, all training hyperparameters are reset. We checked and found no additional advantage to our baselines by refreshing learning rate scheduling or Adam optimiser. We do so to avoid partially retraining the same settings during our development phase, but Brix et al. (2020) found it beneficial in their pruning scheme.

[4]We used the default 'wmt20-comet-da' metric model.

5 Experiments

5.1 Pruning "6-2tied" models (English→German)

We begin our experiments with the state-of-the-art English→German student with a tied decoder (Bogoychev et al., 2020). This is their fastest architecture and we want to investigate how much further it can be pushed in that regard. In terms what is a typical difference in inference speed, a tiny distilled model is usually at least 20× faster than its teacher (Germann et al., 2020).

We investigate two scenarios: pruning both the encoder and decoder (Tab. 1a) or pruning only the encoder (Tab. 1b). The models were trained with the regularisation term $\lambda \in \{0.3, 0.4, 0.5, 0.7, 1.0\}$.

Since there is only one layer's worth of decoder parameters, the regularisation is reluctant to re-

move any parameters from it (Tab. 1a). A similar effect was observed by Behnke and Heafield (2020).

Because only the encoder was pruned, the speed-up is relatively small. Still, we successfully prune from half up to two-thirds of feedforward parameters with ± 0.2 BLEU change with 9–14% faster inference. In the most extreme case, it gains 42% speed-up at the cost of 1.5 BLEU.

To investigate whether this pruning just found a new type of architecture structure, we reinitialise and retrain the smaller pruned models from scratch with reduced dimensions. As seen in Tab. 2, the same models achieve noticeably worse translation quality when trained from the get-go in comparison to careful pruning.

Next, we concentrate on pruning encoder only (Tab. 1b). The model with about 50% of feedforward parameters removed is 14% faster with no change to the overall quality. The most aggressive pruning removes almost all feedforward layers in the encoder at the loss of 1.2 BLEU.

Table 5: The evaluation of Spanish→English "6-6" students pruned with group lasso on 1 CPU core averaged over WMT12–13.

In both cases, only one-third of feedforward parameters is required to perform within a small margin of BLEU loss (-0.2 to -0.3). Removing more than that results in progressively worse quality.

5.2 Pruning "6-6" models (English→German, Spanish→English)

The models with "6-6" architecture were trained with $\lambda = \{0.1, 0.15, 0.2, 0.3, 0.4, 0.5, 1.0\}$ pruning both encoder and decoder. The results are presented in Tab. 4. Additionally, we show the number of remaining rows/columns left in each layer, along with sparsity and inference speed-up.

The pruned models behave similarly to the smaller models in Tab. 1. The regularised models are of a better translation quality than the same architectures trained from scratch (Tab. 6). Similarly, it is possible to remove two-thirds of all feedforward parameters with -0.2 BLEU and +34% speed-up. Pruning more than that causes a notable step down in quality, which may not be worth aiming for since the "6-2tied" architectures outperform that loss. The sparsity pattern follows an ascending trend in both encoder and decoder layers.

We repeat the experiments but this time with Spanish→English using the same "6-6" architecture. The models were trained with regularisation $\lambda = \{0.1, 0.15, 0.2, 0.3, 0.4, 0.5, 1.0\}$. The results are presented in Tab 5.

Table 7: The evaluation of English→German "12-1" students pruned with group lasso on 1 CPU core.

The only differences between German and Spanish experiments are the languages involved and the scale of the training data: Spanish students trained on a 19× larger corpus. Experiments of such scale are still widely unexplored in machine translation, raising the question of whether known methods are beneficial in real-life scenarios. Most pruning papers use English→German models under WMT14 constraints (Bojar et al.), which is only 4.5M sentences (See et al., 2016; Brix et al., 2020; Hsu et al., 2020), sometimes branching into different languages such as Russian or French in a similar scope (Voita et al., 2019; Kasai et al., 2020). For that reason, we sampled 13M from 242M sentences (the same amount as English→German) and repeated the experiments. In the end, we came to similar conclusions, meaning that the Spanish subpar results are not related to architecture or data size. The reinitialised models (Tab. 6) on full dataset achieve comparable quality to their pruned counterparts. We conclude that in some cases, structural pruning serves as an architecture search method to find Pareto optimal quality-speed trade-off.

5.3 Pruning "12-1" models (English→German)

Kasai et al. (2020) argues that shifting layers from decoder to encoder makes a model much faster at almost no cost in translation quality. Their experiments have shown that 12-1 encoder-decoder layer proportions perform as good as 6-6. Pruning an already reduced decoder may cause a bottleneck that damages quality too much. However, if we shift most of the workload into an encoder, we can focus on pruning it exclusively.

This time we prune attention layers as well. Pruning attention structurally is more tricky — you cannot remove individual connections easily due to how matrix multiplications perform their routine. The only option is to remove respective heads or an entire layer. To keep it simple, we regularise individual connections and remove an entire attention head if at least half of its connections are dead (its rows/columns $< 1e-5$). The results are in Tab. 7, with an extended version of it in the appendix.

In terms of quality and speed-up, it outperforms other models presented so far. This type of pruning was not aggressive on attention, preferring to prune feedforward layers instead, indicating that attention connections perform more critical work in a model. At the small cost of 0.3 BLEU, the model is 51% faster than the baseline.

		Baseline		rc+heads		rc+rc

5.4 Pruning "6-2" models with head lasso (Estonian→English)

Finally, we train Estonian→English models, pruning both feedforward and attention layers across the whole model. We do not sweep parameters, choosing $\lambda = 0.3$. The results are in Tab. 8.

This time we try two options:

- regularising individual connections and then removing heads with more than half of con-

	BLEU		COMET		Sparsity

Table 9: 8-bit model performance. BLEU score is calculated from WMT20. Speed is measured on a single core CPU with a mini-batch of 32. We experimented with two types of pruning. Head pruning removes entire heads. Row and column pruning removes entire rows or columns of matrices, resulting in a smaller matrix.

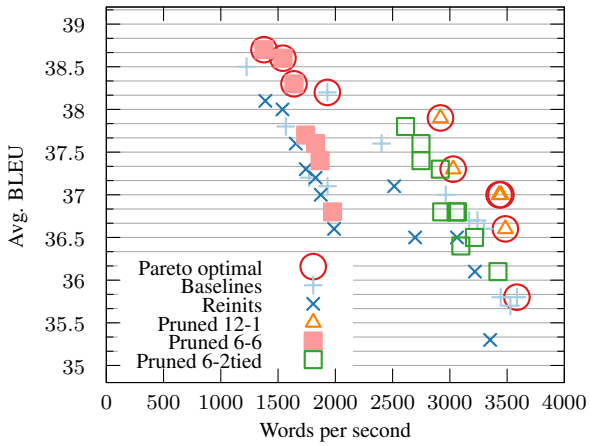

Figure 3: Pareto trade-off between average translation quality and average translation time for English→German students of different architectures.

nections inactive (rc+rc = rows/columns in FFN and attention both)

- regularising entire heads with group lasso (rc+heads = rows/columns in FFN, heads in attention)

Due to how the penalty is scaled with γ in Eq. 1, the regularisation of entire heads is much more aggressive towards them, removing some layers entirely, which we skip during inference. Both pruning methods perform within a -0.1 to -0.3 BLEU difference compared to the same architecture trained from scratch. However, despite only 0.1 BLEU difference, the same model loses 2.3 COMET points, further validating the fact that training from scratch is subpar. Those results show that there is a potential in regularising larger structures and even entire layers as a way of architecture searching. We leave the improvement of the method for future work.

6 Pareto trade-off (English→German)

In this section, we look at the Pareto trade-off between the translation quality and speed for all our English→German models (Fig. 3). To be fair in our comparison, we trained several simpler baselines with uniformly smaller feedforward dimensions set to $\{768, 384, 192, 96\}$. For"12-1" we additionally set heads per layer to 4 to roughly reflect sparsity percentages of pruned models.

We pit against each other the said baselines, the pruned models and their reinitialised counterparts. Naturally, the models with 6 decoder layers are slower but of a higher quality. However, it is better to switch to fewer decoder layers than to prune too far. Our experiments on "12-1" architecture show that its pruned models outperform all others (including all simpler baselines), being a leader in the Pareto frontier.

7 WMT2021 Efficiency Shared Task

To put our method to the final test, we participated in WMT2021 Efficiency Task[5] (Behnke et al., 2021). Under the task constraints, we trained, pruned and quantised 12–1.tiny and 12–1.micro architectures. We tried two pruning settings, following the directions set in Sect. 5.3 and 5.4: *rowcol-*

[5] http://www.statmt.org/wmt21/efficiency-task.html

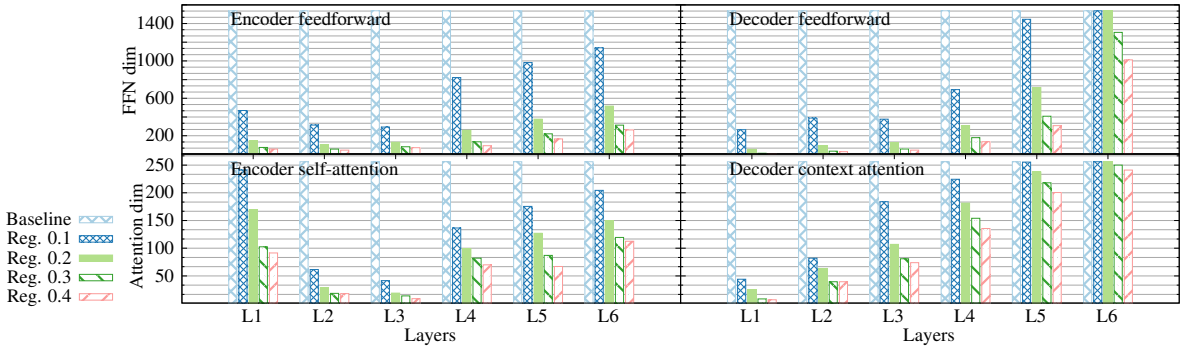

Figure 4: The distribution of feedforward and attention connections in Spanish→English "6-6" pruned students.

lasso and *head-lasso*. Both prune feedforward and attention layers in the encoder. *rowcol-lasso* regularised individual connections and removed an entire attention head if at least half of its connections are dead. *head-lasso* applied lasso to a whole head submatrix. Due to the scale of the task, we had no opportunity to grid-search for the best pruning hyperparameters, thus the experiments are as close to 'out-of-the-box' usage as they can be. We used $\lambda = 0.5$ for both methods. The models were pretrained for 50k updates and regularised for 150k, after which the models were sliced and trained until convergence. The results are presented in Tab. 9.

head-lasso left attention layers almost completely unpruned, focusing on removing connections from feedforward layers instead. *rowcol-lasso* was much more aggressive in both layers at the cost of quality. To further optimise the models, they were quantised to 8bit. However, we observe that the smaller a model is, the larger the quality drop after its quantisation. Additional finetuning allows us to recover at least partially from the quantisation damage. Evaluating on the latest testset WMT21, our pruned models are 1.2–1.7× faster at the cost of 0.6–1.3 BLEU. With quantisation, those models are 1.9–2.7× faster losing 0.9–1.7 BLEU in comparison to the unpruned and unquantised baselines.

8 Analysis

To analyse sparse architecture patterns, we experiment with Spanish→English models. We prune individual connections in all attention and feedforward layers. In Fig. 4, we present the distribution of remaining parameters for the baseline and the models regularised with $\lambda = \{0.1, 0.2, 0.3, 0.4\}$.

Since the decoder self-attention is replaced with SSRU (Kim et al., 2019b), we only show two "pairs" of parameters: encoder self-attention and decoder context attention, with their feedforward counterparts.

Both encoder layer types follow a similar sparsity pattern making a "U-shape", with the second and third ones being the most aggressively pruned. On the other hand, the decoder parameters are pruned less and less with each subsequent layer. This arrangement of parameters is identical to that exhibited by pruned attention heads in Behnke and Heafield (2020). In that paper, the attention in the encoder also prunes middle layers, and the context attention retains more heads in further layers. It strongly indicates that the decoder prefers to attend to itself first and confront context later.

The Estonian architectures, in which we pruned entire attention heads, exhibit a roughly similar structure. For us, this is a strong signal that structural pruning with its architecture search may have a broader generalisation.

9 Conclusions

This paper investigated the structural pruning of a transformer incorporated into a typical training routine. We focused on shredding nodes in feedforward layers and whole attention heads as training progresses. Our experiments on knowledge-distilled models with deep and shallow decoders have shown that this type of pruning leads to Pareto optimal architectures in quality and speed. Moreover, it converges in just one "pass" like a baseline since there is no need to repeat an entire or a part of the training. The resulting sparsity patterns are similar across different languages, with the first and middle layers being the most prioritised during pruning. On the other hand, our experiments on pruning both feedforward and attention layers reveal that some of them, such as the last context attention layer, distinctively avoid being pruned.

Phrase-level Active Learning for Neural Machine Translation

Abstract

Neural machine translation (NMT) is sensitive to domain shift. In this paper, we address this problem in an active learning setting where we can spend a given budget on translating in-domain data, and gradually fine-tune a pre-trained out-of-domain NMT model on the newly translated data. Existing active learning methods for NMT usually select sentences based on uncertainty scores, but these methods require costly translation of full sentences even when only one or two key phrases within the sentence are informative. To address this limitation, we re-examine previous work from the phrase-based machine translation (PBMT) era that selected not full sentences, but rather individual phrases. However, while incorporating these phrases into PBMT systems was relatively simple, it is less trivial for NMT systems, which need to be trained on full sequences to capture larger structural properties of sentences unique to the new domain. To overcome these hurdles, we propose to select *both* full sentences and individual phrases from unlabelled data in the new domain for routing to human translators. In a German-English translation task, our active learning approach achieves consistent improvements over uncertainty-based sentence selection methods, improving up to 1.2 BLEU score over strong active learning baselines.[1]

1 Introduction

Machine translation (MT) models are very sensitive to domain shift (Koehn and Knowles, 2017; Chu and Wang, 2018), and one typical way to address this problem is adding in-domain data to the MT training process (Luong and Manning, 2015; Chu et al., 2017). However, this data may not be available *a priori*, and hiring professional translators with knowledge of specific domains (such as medicine or law) is usually costly.

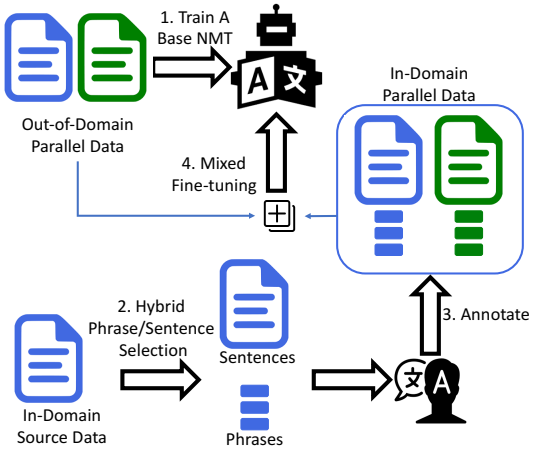

Figure 1: Overview of the active learning process

As a result, active learning approaches (Gangadharaiah et al., 2009; Haffari et al., 2009; Bloodgood and Callison-Burch, 2010) have been widely adopted to reduce the annotation cost by translating a smaller representative subset of the in-domain data, with the hope that models trained on this translated subset approximate those trained on a much larger labeled set. In general, active learning (AL) approaches iterate between two steps: *data selection/annotation*, and *model update*. With regards to data selection for machine translation, most existing works (Haffari et al., 2009; Peris and Casacuberta, 2018; Zeng et al., 2019) focus on selecting *sentences* that are most useful for training either phrase-based machine translation (PBMT) or neural machine translation (NMT) models.

However, even the most informative sentences inevitably involve segments that the MT system can already translate well, and asking the translator to also translate these segments is not cost-effective. There have been a few works used in conjunction with older PBMT models that ameliorate this problem through phrase-based selection techniques (Bloodgood and Callison-Burch, 2010; Daumé III and Jagarlamudi, 2011; Miura et al.,

November 10–11, 2021.

2016), which select only *individual phrases*, maximizing information gain. However, while these translated phrases can be easily integrated into PBMT by adding them to the existing phrase table, incorporating them into NMT models is less simple because NMT has no concept of a "phrase table" and must be trained on full sentences similar to those that must be translated.

In this paper, we propose a method for incorporating phrase-based active learning into NMT. Specifically, we first describe sentence-based and phrase-based selection strategies, then propose a hybrid strategy that combines both methods. We also describe several ways to incorporate this translated data into the training of NMT systems. We conduct experiments on German-English translation by adapting NMT models trained on WMT parallel data to the medicine and IT domains. Experimental results show that the hybrid selection strategy obtains more stable translation performance than either phrase-based or sentence-based selection strategy.

2 Problem Definition

In the setting of active learning for domain adaptation, we are given an out-of-domain labelled corpus $(x, y) \in \mathcal{L}$ and an in-domain unlabelled corpus $x \in \mathcal{U}$. We define a phrase as a contiguous sequence of words up to some length limit N, and denote a set of possible phrases in a sentence x by $\cup_{n\in[1,N]} n\text{-gram}(x)$, where we set $N = 4$ in all experiments below. To obtain translations of unlabelled data, we assume access to professional translators $\mathcal{O}(\cdot)$ who can translate source-side sentences $\mathcal{S}$ and/or phrases $\mathcal{P}$ selected from $\mathcal{U}$, i.e., $\mathcal{O}(x)\ \forall x \in \mathcal{S} \subset \mathcal{U}$, and $\mathcal{O}(p)\ \forall p \in \mathcal{P} \subset \mathcal{P}_{\mathcal{U}} = \cup_{x\in\mathcal{U}} \cup_{n\in[1,N]}\ n\text{-gram}(x)$. We assume that translating sentences or phrases requires cost $c(\cdot)$, and annotation must be performed within a fixed budget $B = \sum_{x\in\mathcal{S}} c(x) + \sum_{p\in\mathcal{P}} c(p)$. This active learning procedure consists of two main steps: selection/translation (§3) and fine-tuning (§4).

3 Active Selection Strategies

3.1 Sentence Selection Strategies

Existing sentence-based active learning methods usually define a sentence-level scoring function $\phi(x, \cdot)$, and select sentences with the top scores. Following Zeng et al. (2019), we categorize these methods into two classes: data-driven and model-driven methods. Data-driven methods only rely on the unlabeled data $\mathcal{U}$ and the labeled data $\mathcal{L}$, i.e., $\phi(x, \mathcal{U}, \mathcal{L})$, and usually score sentences based on the trade-off between the density and diversity of the selected sentences. In contrast, model-driven approaches usually estimate the prediction uncertainty of a source sentence given the current MT model θ, i.e., $\phi(x, \theta, \mathcal{U}, \mathcal{L})$, and select sentences with high uncertainty for training the model. Before getting to our proposed phrase-based strategies in §3.2 we highlight several existing sentence selection strategies.

Random Sampling: One easy strategy is randomly sampling sentences from the unlabeled data $\mathcal{U}$ for annotation. Although it is simple, this method is an unbiased approximation of the data distribution in $\mathcal{U}$. Therefore, this method remains a strong baseline in the active learning literature (Gangadharaiah et al., 2009; Miura et al., 2016; Zeng et al., 2019) if the annotation budget is sufficiently large.

Margin-based Ratio Score (MRS): Zhang et al. (2018) propose to measure the distance between sentence embeddings. This method takes each unlabeled sentence, estimates its distance in embedding space from the labeled sentences in the out-of-domain corpus, and iteratively selects sentences that are more distant from sentences in the labeled data. In our instantiation of this method, we leverage the pre-trained mBERT model (Devlin et al., 2019) to extract sentence representation $\mathbf{e}_x$ of a particular sentence x.[2] Instead of using a cosine similarity function, we measure a ratio-based score which is the ratio between the cosine similarity of $(\mathbf{e}_x, \mathbf{e}_{x'})$ and the average cosine similarity with their k nearest neighbors in Eq. (1), because the margin-based ratio score has been shown effective in sentence retrieval in (Artetxe and Schwenk, 2019).

$$\text{ratio}(\mathbf{e}_x, \mathbf{e}_{x'}) = \frac{\cos\left(\mathbf{e}_x, \mathbf{e}_{x'}\right)}{\sum\limits_{z\in \text{NN}_k(x)} \frac{\cos\left(\mathbf{e}_x, \mathbf{e}_z\right)}{2k} + \sum\limits_{z\in \text{NN}_k(x')} \frac{\cos\left(\mathbf{e}_{x'}, \mathbf{e}_z\right)}{2k}}, \quad (1)$$

where k is the number of nearest neighbors.

We then compute the distance between each in-domain sentence and its nearest out-of-domain

[2] We average the word representations from the 7th layer of the mBERT model as the sentence embedding, because the middle-layer representations have proven effective in cross-lingual retrieval tasks (Pires et al., 2019; Hu et al., 2020).

neighbor within a randomly sampled subset of labeled sentences $\mathcal{L}'$:

$$\phi(x, \cdot) = \text{dist}(x, \mathcal{L}') = 1 - \max_{x' \in \mathcal{L}'} \text{ratio}(\mathbf{e}_x, \mathbf{e}_{x'}).$$

We approximate the distance between x and out-of-domain corpus $\mathcal{L}$ using a subset $\mathcal{L}'$ for efficiency purposes, because the out-of-domain $\mathcal{L}$ is usually large. Next we use the distance $\text{dist}(x, \mathcal{L}')$ as our scoring function $\phi(x, \cdot)$, and select the unlabeled sentence with the largest distance from (subsampled) sentences in the out-of-domain corpus.

Round Trip Translation Likelihood (RTTL): One model-driven method is based on a method referred to as "round trip translation" (Haffari et al., 2009; Zeng et al., 2019). The labeled data $\mathcal{L}$ is used to train two MT models $\theta_{\text{src-tgt}}, \theta_{\text{tgt-src}}$ that translate between the source and target languages in two directions. Each unlabeled source sentence $x \in \mathcal{U}$ is first translated to $\hat{y}$ in the target language by $\theta_{\text{src-tgt}}$, and then $\hat{y}$ is translated to $\hat{x}$ by $\theta_{\text{tgt-src}}$. This method assumes that if this round-trip translation process fails to recover some of the content on the source side then this is an indication that the sentence may be difficult for the current model and is a good candidate for human annotation. Haffari et al. (2009) use a scoring function that computes the similarity between the original sentence x and $\hat{x}$ using the sentence-level BLEU score (Chen and Cherry, 2014), while Zeng et al. (2019) estimate the likelihood of the original source sentence x given $\hat{y}$ by the reverse MT model $\theta_{\text{tgt-src}}$.

$$\hat{y} \approx \underset{y}{\text{argmax}}\, P_{\theta_{\text{src-tgt}}}(y|x) \tag{2}$$

$$\phi(x, \cdot) = \log P_{\theta_{\text{tgt-src}}}(x|\hat{y}) \tag{3}$$

3.2 Phrase Selection Strategies

A few existing phrase-based active learning methods (Bloodgood and Callison-Burch, 2010; Miura et al., 2016) have been proposed to improve PBMT systems. These methods first determine the possible set of phrases in a sentence, select phrases to be translated according to a scoring metric, and incorporate these in the training of the PBMT system. In the following paragraphs, we introduce two phrase-based selection strategies, and discuss how to integrate this data into NMT in §4. Similar to the sentence selection strategies, we define a phrase-level scoring function $\phi(p, \cdot)$ and select phrases with the top scores.

n-gram Frequency (NGF) (Bloodgood and Callison-Burch, 2010): The most straightforward phrase selection strategy is to select the most frequent phrases in the unlabelled data that *do not* appear in the already labeled data. First we extract two sets of possible n-grams ($n \leq 4$) from sentences in $\mathcal{U}$ and $\mathcal{L}$, which are defined as $\mathcal{P}_\mathcal{U} = \cup_{x \in \mathcal{U}} \cup_{n \in [1,N]} n\text{-gram}(x)$, and $\mathcal{P}_\mathcal{L} = \cup_{(x,y) \in \mathcal{L}} \cup_{n \in [1,N]} n\text{-gram}(x)$. We then score each phrase as follows:

$$\phi(p, \cdot) = \begin{cases} occ(p, \mathcal{U}), & \text{if } p \in \mathcal{P}_\mathcal{U}, p \notin \mathcal{P}_\mathcal{L} \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

where $\text{occ}(p)$ counts the occurrences of p in $\mathcal{U}$. We then select the top frequent phrases until we use up the budget for annotating phrases.

Semi-Maximal Phrases (NGF-SMP): The two phrase sets $\mathcal{P}_\mathcal{U}, \mathcal{P}_\mathcal{L}$ extracted by the n-gram Frequency method contain many substrings that also occur in some longer strings. For example, p = "eines der" always co-occurs with the longer p' = "eines der besten" in the WMT14 German-English dataset. To identify the longer strings, Miura et al. (2016) proposed the following semi-order relation, which defines the relation between a phrase p' and its sub-string p satisfying the condition that p' occurs at least half the time of p in the corpus $\mathcal{U}$.

$$p \overset{*}{\preceq} p' \Leftrightarrow \exists \alpha, \beta : \ \alpha p \beta = p' \wedge \frac{\text{occ}(p, \mathcal{U})}{2} < \text{occ}(p', \mathcal{U}) \tag{5}$$

A phrase p is called a semi-maximal phrase if there does not exist a phrase p' in $\mathcal{U}$ such that $p \overset{*}{\preceq} p'$. Therefore, a compact subset of phrases $\mathcal{P}'_\mathcal{U}$ can be constructed by containing only semi-maximal phrases in the phrase set $\mathcal{P}_\mathcal{U}$ in $\mathcal{U}$:

$$\mathcal{P}'_\mathcal{U} = \{p | \nexists p' \in \mathcal{P}_\mathcal{U}, p \overset{*}{\preceq} p' \wedge p \in \mathcal{P}_\mathcal{U}\}. \tag{6}$$

By using semi-maximal phrases in $\mathcal{P}'_\mathcal{U}$ rather than all phrases in $\mathcal{P}_\mathcal{U}$, we remove a large number of phrases that are included in a longer phrase more than half the time, and reduce the redundancy of the selected phrases. Next we can select phrases similarly using Eq. (4) by replacing the original phrase set $\mathcal{P}_\mathcal{U}$ with the sub-set $\mathcal{P}'_\mathcal{U}$.

Notably, we select representative phrases by their occurrences instead of using a similarity function between phrase embeddings. Because it is easy to count the phrase occurrences by extract string-match while it is infeasible to do so for sentences.

As for sentence selection, measuring a similarity between sentence embeddings (e.g., MRS) provides an alternative way of matching sentences.

3.3 Hybrid Selection Strategy

Phrase-based selection has its benefits, such as efficient annotation of core vocabulary from the target domain. However, at the same time it lacks the ability to identify larger sentence structure that may nonetheless be unique to the target domain. Modeling this structure is particularly important for NMT (in constrast to PBMT), as NMT directly learns both lexical and syntactic transformations within the same model.

Because of this, we propose a simple yet novel hybrid selection strategy that leverages the benefits of both sentence-based and phrase-based selection strategies. Specifically, we allocate our budget in a way to annotate sentences with B_s words from our set of sentences and B_p words from our set of phrases. Depending on the specific sentence-based and phrase-based selection strategies chosen in the hybrid selection strategy, it is non-trivial to determine which selection strategy improves the in-domain translation performance more than the other one before actual finetuning. Therefore, in our implementation, we assume that we have no prior knowledge about which selection strategies will be most effective, and simply evenly distribute the annotation budget into the sentence-based and phrase-based strategies. We leave more sophisticated allocation strategies as future work, and we discuss some potential avenues briefly in §7.

4 Training with Sentences and Phrases

After data selection, we fine-tune the base NMT model on the newly translated data. This is essentially an extreme form of domain adaptation where we adapt a base NMT model trained on out-of-domain data to a new domain. Specifically, we adapt a strategy of *mixed fine-tuning* (Luong and Manning, 2015), which continues training a pre-trained out-of-domain model on both in-domain data and a certain amount of out-of-domain data to prevent overfitting to relatively small in-domain data. Compared to the standard domain adaptation setting where we have only a small number of in-domain sentences, our phrase-level active learning setting has the additional difficulty of having to use short translations of individual phrases. In the following, we describe both methods to choose which data to use in mixed fine-tuning, and how to incorporate phrasal translations.

4.1 Data Mixing

For data mixing, we sample a subset $\mathcal{L}_r$ of data directly from the labeled set $\mathcal{L}'$, and concatenate $\mathcal{L}_r$ with the newly annotated sentences $\mathcal{L}_s$ and phrases $\mathcal{L}_p$ for mixed fine-tuning (Line 8 in Algorithm 1). Specifically, we define a distribution function ψ over $\mathcal{L}'$, and either sample by $(x, y) \sim \psi$ or greedily take the most likely data by $(x, y) = \text{argmax}_{(x,y)\in\mathcal{L}'} \psi(x, y)$ iteratively for M times to obtain the subset $\mathcal{L}_r$ of M parallel data.

Random Sampling: The most simple way to select out-of-domain data is to randomly sample sentences from the out-of-domain corpus $\mathcal{L}'$, i.e., $(x, y) \sim \text{Uniform}(\mathcal{L}')$. Although it is simple, this has been popularly used in the literature of domain adaption for NMT (Chu and Wang, 2018).

Retrieve Similar Sentences: Recently, Aharoni and Goldberg (2020) showed that pre-trained language models implicitly learn sentence embeddings that cluster by domains, and proposed a data selection method that has proven more effective than methods based on the likelihood of an in-domain language model (Moore and Lewis, 2010). Since our base NMT model is pre-trained on out-of-domain corpus, we need to adapt the model to the domain of the unlabeled data. Instead of random sampling, we adopt the selection method in Aharoni and Goldberg (2020) to retrieve parallel sentences from $\mathcal{L}'$ that are close to the in-domain sentences in $\mathcal{U}$. To do so, we leverage the contextualized sentence representations, and measure the distance of a source sentence in $\mathcal{L}'$ w.r.t. the unlabeled corpus $\mathcal{U}$ by $\text{ratio}(x, \mathcal{U})$, $\forall x \in \mathcal{L}'$. Next, we iteratively retrieve labeled data from $\mathcal{L}'$ that have the smallest distance scores to their nearest neighbors, i.e., $(x, y) = \text{argmax}_{(x,y)\in\mathcal{L}'} \text{ratio}(x, \mathcal{U})$.

4.2 Incorporating Phrasal Translations

In addition to obtaining real parallel data from $\mathcal{L}'$ for mixed fine-tuning, we create synthetic parallel data $(\hat{x}, \hat{y})$ by incorporating phrasal translations into existing context from $\mathcal{L}'$. Specifically, for an unlabeled sentence $x \in \mathcal{U}$ containing a newly annotated phrase p_x, we retrieve the most similar sentence pair (x^*, y^*) from $\mathcal{L}'$ by

$$(x^*, y^*) = \underset{(x',y')\in\mathcal{L}'}{\text{argmax}} \text{ratio}(\mathbf{e}_x, \mathbf{e}_{x'}) \quad (7)$$

We then alter (x^*, y^*) with the newly annotated phrase pair (p_x, p_y) to create synthetic sentence pair $(\hat{x}, \hat{y})$. Similar to data mixing, we concatenate the set of synthetic data with the annotated sentences $\mathcal{L}_s$ and phrases $\mathcal{L}_p$ for mixed fine-tuning.

Switch Phrases: Inspired by existing data augmentation methods (Fadaee et al., 2017), we examine a data augmentation method that switches out phrases in the out-of-domain sentence pairs in $\mathcal{L}'$ by the newly annotated phrase pairs from $\mathcal{U}$. First, we define the following operation $\text{Switch}(x, p, i)$ that returns a new sentence by substituting the phrase at the i-th position in x^* by p_x.

$$\text{Switch}(x^*, p_x, i) = [x^*_{<i}; p_x; x^*_{\geq i+|p_x|}] \quad (8)$$

Next, we enumerate all possible positions in x^* for switching phrases, and then apply the in-domain language model trained on $\mathcal{U}$ to select the most probably synthetic sentence by

$$\hat{x} = \underset{\substack{x'=\text{Switch}(x^*,p_x,i) \\ \forall 0 \leq i < |x^*|-|p_x|, \\ p_x \in \cup_{n\in[1,N]} n\text{-gram}(x)}}{\text{argmax}} P_{\text{LM}}(x'), \quad (9)$$

where p_x is a phrase in the unlabeled sentence x. Notably, we use a 4-gram language model implemented in `KenLM`[3]. Since sentences are usually short (average length of 10-25 words), creating a synthetic sentence takes $O(|x^*||x|)$ scoring operations by the language model.

To synthesize the corresponding $\hat{y}$ from the retrieved target sentence y^*, we apply a word alignment model trained on $\mathcal{L}$ to find the index j for the translation of the replaced phrase $x^*_{i:i+|p_x|}$ in y^*, and substitute the phrase at the j-th position in y^* by p_y to obtain $\hat{y} = \text{Switch}(y^*, p_y, j)$.

Contextualized Phrases: The other idea is to augment the context of a newly annotated phrase pair (p_x, p_y), since a phrase p_x lacks larger sentence structure. Specifically, we define the contextualized operation that augments a phrase p_x in x by appending it to the retrieved sentence x^*.

$$\text{Contextualize}(x^*, p_x) = [x^*, p_x] \quad (10)$$

We then enumerate all annotated phrases in x, and apply an in-domain language model to find the most probable annotated phrase pair (p_x, p_y) that synthesizes $\hat{x}$. The corresponding $\hat{y}$ can be obtained by $\text{Contextualize}(y^*, p_y)$.

$$\hat{x} = \underset{\substack{x'=[x^*,p_x] \\ \forall p_x \in \cup_{n\in[1,N]} n\text{-gram}(x)}}{\text{argmax}} P_{\text{LM}}(x') \quad (11)$$

5 Experiments

5.1 Experimental Setting

We use the WMT14 German-English data as the out-of-domain labeled data for training our base NMT model, and take the source sentences of two parallel corpora in the medicine and IT domains (Koehn and Knowles, 2017) as the unlabeled data. More details can be found in Appendix B.1.

As our NMT model, we use a 6-layer 512-unit Transformer (Vaswani et al., 2017) implemented in `Fairseq`,[4] and use a subword vocabulary of 50,000 for both languages constructed by Byte Pair Encoding (Sennrich et al., 2016). We train the base model with Adam for 10 epochs with 4K warmup steps and a peak learning rate of 1e-3, and decay the learning rate based on the inverse square root of the number of update steps (Vaswani et al., 2017).

For active learning, we set our annotation budgets by number of words translated (following the prevailing translation market practice to charge for jobs by the word), and investigate the budgets from 2.5K words up to 40K words.[5] After data selection (§3), we obtain a set $\mathcal{L}_r$ of M parallel sentences (§4), and set the size $M = |\mathcal{L}_p|$ where $\mathcal{L}_p$ is selected by NGF-SMP. We then fix $\mathcal{L}_r$ for mixed fine-tuning in all experiments, and continue fine-tuning the base model on a mixture of the newly-translated data and $\mathcal{L}_r$ for 5 more epochs.

5.2 Word-level Translation Accuracy

Since our selection and mixed fine-tuning methods focus on leveraging phrasal translations for domain adaptation, we perform a fine-grained analysis on the word-level translation accuracy of the NMT systems due to the domain shift. A source word is defined as an unseen in-domain word when it never appears in the out-of-domain corpus. If phrase selection strategies select more in-domain words, we would expect a higher translation accuracy of such in-domain words by the adapted NMT systems using phrase selection. As a result, we compare the

translation accuracy of in-domain words by the NMT models using different selection strategies in Figure 3. As shown in the figure, NGF-SMP significantly improves the translation accuracy of the in-domain words with a small annotation budget. In contrast, MRS falls short of the other compared methods when the annotation budget is less than 80K words. Moreover, we find that the hybrid selection strategy of NGF-SMP and MRS can combine the merits of both methods, and obtain an even higher accuracy when the budget is greater than 40K annotated words. Qualitatively, the example in Table 1 shows the translations for a source sentence with all words appearing in the medical domain. The NMT model adapted by MRS translates the first half of the source sentence by picking the correct word "exercised", while the NMT model adapted by NGF-SMP generates the correction translation "somnolence" in the second half of the output. The NMT model using the hybrid of NGF-SMP and MRS strategies translates both words correctly (more examples in Appendix B.2).

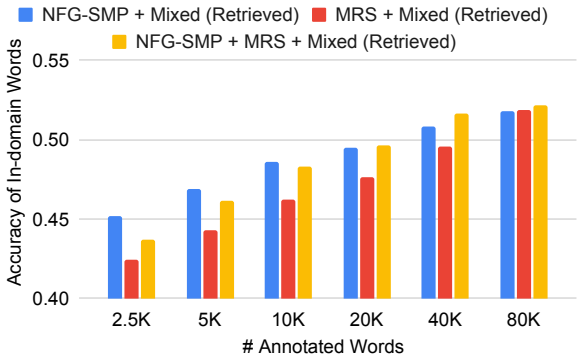

Figure 3: Translation accuracy of in-domain words in the test set from the medicine domain

5.3 How Does Each Selection Strategy Help?

We examine the question of which selection strategy (§3) best improves accuracy on in-domain test data. For mixed fine-tuning, in this section we use the retrieved out-of-domain parallel data for a fair comparison among all active selection strategies. Figure 2 shows the average BLEU score and the standard deviation of the adapted MT systems to two new domains over 3 independent runs.[6]

Comparing among sentence selection strategies in Figure 2, MRS performs slightly better than the random sentence selection baseline on adapting the NMT model to the IT domain with smaller standard deviation values, and performs comparably on adapting to the medicine domain. However, we observe that RTTL performs worst, and we conjecture that this is due to the usage of the base NMT models that are trained on the out-of-domain parallel data in both directions. The errors accumulated from the round trip translation process lead to an inaccurate estimation of the uncertainty score for a source sentence. Table 2 shows the top 5 sentences selected by RTTL. The selected sentences in the medicine domain are short phrases rather than complete sentences, and those selected in the IT domain contain duplicate phrases such as "bewerten mitâ".

[6]To obtain a stable result, we independently run the active learning procedure with different selection strategies 3 times, collect new translation data, and concatenate them with the same data retrieved from out-of-domain labeled data

Table 2: Top 5 sentences selected by RTTL

For phrase-based selection methods, NGF-SMP significantly outperforms the random phrase selection strategy. Further, NGF-SMP even outperforms sentence selection methods when the annotation budget is small (less than 20k words) for adaption to the medicine domain. As we increase the annotation budget to 40K annotated words, sentence selection strategies outperform phrase selection strategies. This indicates that if we keep training NMT systems on shorter phrase pairs when the annotation budget is sufficient, the NMT systems would be limited by lack of longer sentence structures. In Figure 2b, we also find that NMT models trained with phrasal translations fall short of those trained with sentence translations when adapting to the IT domain. It is hard to train the NMT systems to translate certain phrases correctly without the sentence context. For example, "Persönlichen Ordner" in the IT domain is translated to "home directory" rather than "personal folder" in the sentence "jedes Skript dieses Dialogs hat Schreib-Zugriff auf Ihren Persönlichen Ordner ".

Finally, the hybrid selection of NGF-SMP and MRS strategies outperforms the individual selection strategies over every budget in our set of budgets, i.e., 2.5K, 5K, 10K, 20K, 40K annotated words, improving the best phrase selection strategy NGF-SMP by 0.49 average BLEU points, and the best sentence selection strategy MRS by 1.11 average BLEU points in the medicine domain. Notably, the phrase-based selection strategy especially helps in the scenario where the context is not required to translate domain-specific words, for example, the name of a medicine or a disease in the medicine domain (See the first example in Appendix B.2). For the adaptation scenario that requires a longer context in some domains such as IT, the hybrid strategy can also significantly outperforms the best phrase-based strategy NGF-SMP by 1.2 average BLEU points, and the best sentence selection strategy MRS by 0.15 BLEU points. Overall, our hybrid selection strategy is effective to combine the merits of both sentence and phrase selection strategies in the domain adaptation setting.

5.4 How Representative Are the Selected Data?

If the selected data has a significant overlap of segments with the in-domain test data, we would expect a better adaptation performance of the NMT trained on the selected data. Therefore we investigate the n-gram overlap between the selected data and the test data when we annotate 5K words from the medicine corpus, and report the average BLEU score of the adapted NMT models trained on the selected data in Table 3. Interestingly, we find that there exists a high correlation ($\rho \approx 0.8$) between the n-gram overlap and the average BLEU score, which indicates that the n-gram overlap with the test set can be used as a good measure of whether the selected data is useful for improving the NMT model in the new domain. Compared to the random phrase selection, NGF-SMP selects phrases with a high overlap with the test data. We also observe that sentence selection strategies cover fewer phrases in the test data than phrase selection strategies. This also corroborates our assumption that asking translators to annotate phrases that the MT system can already translate well is not cost-effective to improve the in-domain translation performance.

5.5 How Redundant Are the Selected Data?

To answer this question, we first define "in-domain words" as words that only appear in the in-domain test set but do not exist in the out-of-domain data. We report the statistics of the in-domain word types word counts in the selected data with 10K annotated words in Table 5. We find that phrase selection strategies select more unique in-domain word types and counts than the sentence selection strategies. This indicates that phrase selection strategies leverage the same amount of budget effectively to annotate more diverse in-domain words than sentence selection strategies.

5.6 How Do Phrasal Translations Help in Mixed Fine-tuning?

We further investigate the effect of mixed fine-tuning using the newly annotated in-domain data and sub-sampled out-of-domain data when comparing with fine-tuning only on the newly annotated data. Table 4 shows the average BLEU score and the standard deviation values over 3 independent runs. Compared to fine-tuning on only annotated data, adding randomly sampled sentence pairs from the out-of-domain data helps when the annotation budget is less than 5K annotated words, but hurts when we increase the budget. In contrast, adding sentences retrieved by the similarity in the sentence embedding space not only outperforms fine-tuning only on annotated data and mixed fine-tuning with randomly sampled sentences, but also achieves smaller standard deviation values. On the other hand, mixed fine-tuning on synthetic data by switching phrases performs slightly worse than the mixed fine-tuning on real retrieved data, but outperforms the fine-tuning without any out-of-domain data, especially when the annotation budget is small, e.g., 5K annotated words. Combining synthetic data by switching phrase and real retrieved data for mixed fine-tuning also improves the translation performance over the training only on synthetic data. However, the contextualized method performs worst among all mixed fine-tuning methods, which indicates that simply appending existing sentence context to phrasal translations might potentially introduce noise to the training data.

6 Related Work

Active Learning for Machine Translation Pioneering works on active learning for machine translation focus on selecting sentences that are most useful for training PBMT. This includes sentence selection strategies based on maximizing the percentage of unseen n-gram (Eck et al., 2005), n-gram frequency, lexical diversity (Haffari et al., 2009), or in-domain coverage (Ananthakrishnan et al., 2010). These sentence selection strategies have been used in active learning algorithms to deal with static data in the batch mode (Ananthakrishnan et al., 2010), or steaming data in the interactive setting (González-Rubio et al., 2012; Peris and Casacuberta, 2018; Lam et al., 2019).

For phrase-level annotations, there have been a few works applying phrase-based selection (Bloodgood and Callison-Burch, 2010; Miura et al., 2016) to PBMT. While the annotated phrases can be easily integrated by adding them with estimated translation probability to the existing phrase table in PBMT, it it less trivial to integrate these phrase-level annotations in NMT. Arthur et al. (2016) integrated the word-level translations to NMT by interpolating the probability of the NMT decoder with the estimated lexical probability. However, this approach requires a modification of the NMT model. Our paper investigates data-driven approaches that augment the training data by leveraging annotated phrases and existing parallel data.

Word/Phrase-based Data Augmentation The other line of research investigates data augmentation methods that leverage word or phrase translations to create synthetic parallel data for training MT models. This includes augmentation methods that replace a word in the existing parallel data with a low-frequency word sampled from the frequency distribution of the vocabulary (Xie et al., 2017) or from the probability of language models in both directions (Fadaee et al., 2017; Kobayashi, 2018). Wang et al. (2018) proposed an effective method

that randomly replaces words in parallel sentences with other random words from the in-domain vocabulary. A more recent work on dictionary-based data augmentation (Peng et al., 2020) proposed to use an existing high-quality in-domain dictionary, and replaced a source word in the existing parallel data by the most similar word in the dictionary according to the cosine similarity metric in the embedding space. In contrast, we select noisy in-domain phrases using different phrase-based selection strategies (§3.2) to ensure the selection quality in an active learning process.

7 Discussion and Future Work

In this paper, we investigate ways to incorporating phrasal translations into training NMT for domain adaptation in the active learning setting. We find that phrasal translation is particularly useful in the adaptation scenario where longer sentence context is not necessarily required to translate in-domain words correctly. In contrast, NMT systems can benefit from learning sentence structure with sentence-based selection strategies. The hybrid selection strategies can combine the merits of both sentence-based and phrase-based selection strategies. Nonetheless, there are several future directions. (1) It is worth exploring how different annotation strategies may result in a difference in cost or time. (2) Although several findings could be generalized to other language pairs, testing our methods on morphologically rich languages is our next step. (3) Our current hybrid strategy simply allocates the annotation budget evenly without assuming any prior knowledge of the strategies and the translation performance. Techniques in multi-armed bandit problems (Gittins et al., 2011) can be used to learn a good allocation strategy.

Appendix

A Pseudo code

Algorithm 1 shows the active learning procedure for machine translation, which consists of two main steps: selection/translation (§3) and fine-tuning (§4).

Algorithm 1 Active Learning for Domain Adaptation of Machine Translation

procedure ACTIVEADAPTATION($\mathcal{U}, \mathcal{L}, B$)
  Inputs: the unlabelled set $\mathcal{U}$, the labelled set $\mathcal{L}$, and a budget B.
  Train a MT model θ on $\mathcal{L}$.
  $\mathcal{S}, \mathcal{P} \leftarrow$ **SELECTION**($\mathcal{U}, \mathcal{L}, B$)
  Translate $\mathcal{S}$ by $\mathcal{L}_s = \{(x, \mathcal{O}(x)) | x \in \mathcal{S}\}$
  Translate $\mathcal{P}$ by $\mathcal{L}_p = \{(p, \mathcal{O}(p)) | p \in \mathcal{P}\}$
  $\mathcal{L}_r \leftarrow$ **Obtain parallel data from $\mathcal{L}$ (§4)**
  Fine-tune θ on $\mathcal{L}_s \cup \mathcal{L}_p \cup \mathcal{L}_r$
return θ

Algorithm 2 Hybrid Phrase/Sentence Selection

procedure SELECTION($\mathcal{U}, \mathcal{L}, B$)
  Inputs: the unlabelled set $\mathcal{U}$, the labelled set $\mathcal{L}$, and a budget B.
  Initialize $\mathcal{S} = \{\}$, $\mathcal{P} = \{\}$
  Allocate the budget: $B_s, B_p \leftarrow B$
  while $\sum_{x \in \mathcal{S}} c(x) < B_s$ **do**
    $x \leftarrow \text{argmax}_{x \in \mathcal{U}} \phi(x, \cdot)$
    $\mathcal{U} = \mathcal{U} \setminus \{x\}$
    $\mathcal{S} = \mathcal{S} \cup \{x\}$
  Construct $\mathcal{P}_\mathcal{U}, \mathcal{P}_\mathcal{L}$ by strategies (§3.2)
  while $\sum_{p \in \mathcal{P}} c(p) < B_p$ **do**
    $p \leftarrow \text{argmax}_{p \in \mathcal{P}_\mathcal{U}}$ **occ**$(p, \mathcal{U})$
    $\mathcal{P}_\mathcal{U} = \mathcal{P}_\mathcal{U} \setminus \{p\}$
    $\mathcal{P} = \mathcal{P} \cup \{p\}$
  return $\mathcal{S}, \mathcal{P}$

B Experiments

B.1 Experimental Details for Reproducibility

Dataset: As pointed out in Aharoni and Goldberg (2020), there is overlap between the training data and the test data in the original split of the two corpora provided by Koehn and Knowles (2017), so we follow them in removing the duplicated sentences in the in-domain data, and re-splitting two new test sets in order to prevent the model from memorizing the selected in-domain training data that could potentially be included in the test data. Table 6 shows the data statistics.

Data	Domain	Lang	#Sentences	#Words	Vocab	Avg Len
$\mathcal{L}$	WMT14	De	4.4M	108.0M	1.9M	24.4
		En		114.5M	955.3K	25.8
$\mathcal{U}$	Medicine	De	227.2K	3.8M	114.3K	16.8
	IT	De	190.6K	2.1M	114.6K	11.5

Table 6: Data statistics of the out-of-domain labeled data in WMT14 and the in-domain unlabeled data in the medicine and IT domains.

Model: As our NMT model, we use a 6-layer 512-unit Transformer (Vaswani et al., 2017) implemented in `Fairseq`,[7] and use a subword vocabulary of 5,000 for both languages constructed by Byte Pair Encoding (Sennrich et al., 2016). The model has 45M parameters.

Training: We train the base model with Adam for 10 epochs with 4K warmup steps and a peak learning rate of 1e-3, and decay the learning rate based on the inverse square root of the number of update steps (Vaswani et al., 2017). We save the last checkpoint as our base model, and continue fine-tuning the base model on a mixture of the newly-translated data and the retrieved out-of-domain data for 5 more epochs.

Training/Inference Time: We train each model on one NVIDIA RTX 2080Ti GPU for all our experiments. Training the base NMT model takes less than 1 days, and fine-tuning the base NMT model on selected data takes less than 4hours. The decoding of 2000 sentences can be finished within 5 minutes.

B.2 Qualitative Analysis

In the first example of Table 7, the NMT model adapted by NGF-SMP can predict most words correctly while the NMT model adapted by MRS generate a random sentence.

B.3 Do Phrasal Annotations Bias NMT?

Since phrasal annotations are short and do not contain complex sentence structure, we hypothesis that NMT systems trained on phrasal annotations would be biased towards generating shorter sentences or sentences in different grammatical order w.r.t. the reference sentence. To understand this question, we analyze the length ratio between the translation outputs and the reference sentences in Figure 4.

[7] https://github.com/pytorch/fairseq

	Output	S-BLEU
Source	Schwindel, Parästhesie, Geschmacksstörung	
Reference	Dizziness, paraesthesiae, taste disorder	
NGF-SMP	Dizziness, paraesthesia, taste disturbance	23.27
MRS	The room was very small and the bathroom was very small.	0.00
NGF-SMP+MRS	Dizziness, paraesthesia, taste disturbance	23.27
Source	Über Hospitalisierung oder Todesfälle in Verbindung mit Infektionen wurde berichtet.	
Reference	Hospitalisation or fatal outcomes associated with infections have been reported.	
NGF-SMP	There have been reports of Hospitalisation or death associated with infections.	29.79
MRS	Hospitals or deaths associated with infections have been reported.	54.63
NGF-SMP+MRS	There have been reports of Hospitalisation or fatality associated with infections.	29.79

Table 7: Translations generated by NMT models using different selection strategies. The last column shows the sentence BLEU score of the translations. Translation errors are highlighted in red.

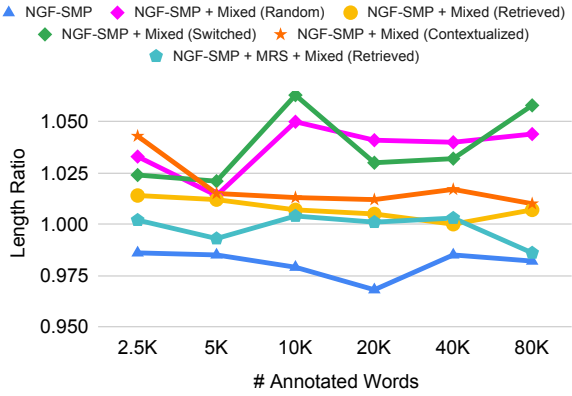

Figure 4: Length ratio between the NMT outputs and the reference sentences.

We find that the NMT model trained only on annotated phrases selected by NGF-SMP generates shorter sentences than reference sentences. In contrast, adding sentences randomly sampled from the labeled corpus $\mathcal{L}$ make the NMT model generate longer sentences than the reference sentences, while retrieving sentences from $\mathcal{L}$ that are similar to the sentences in $\mathcal{U}$ makes the model produces translation outputs with closed lengths as the reference sentences. Qualitatively, we also show the problem of generating sentences with different structures as the reference sentences in the third example in Table 1. In the third example, the NMT model trained with NGF-SMP produces a translation in an active voice, while the reference sentence uses a passive voice.

Learning Feature Weights using Reward Modeling for Denoising Parallel Corpora

Gaurav Kumar, Philipp Koehn, Sanjeev Khudanpur
Center for Language and Speech Processing
Johns Hopkins University
gkumar@cs.jhu.edu, {phi, khudanpur}@jhu.edu

Abstract

Large web-crawled corpora represent an excellent resource for improving the performance of Neural Machine Translation (NMT) systems across several language pairs. However, since these corpora are typically extremely noisy, their use is fairly limited. Current approaches to deal with this problem mainly focus on filtering using heuristics or single features such as language model scores or bilingual similarity. This work presents an alternative approach which learns weights for multiple sentence-level features. These feature weights which are optimized directly for the task of improving translation performance, are used to score and filter sentences in the noisy corpora more effectively. We provide results of applying this technique to building NMT systems using the Paracrawl corpus for Estonian-English and show that it beats strong single feature baselines and hand designed combinations. Additionally, we analyze the sensitivity of this method to different types of noise and explore if the learned weights generalize to other language pairs using the Maltese-English Paracrawl corpus.

1 Introduction

Large parallel corpora such as Paracrawl (Bañón et al., 2020) which have been crawled from online resources hold the potential to drastically improve performance of neural machine translation systems across both low and high resource language pairs. However, since these extraction efforts mostly rely on automatic language identification and document/sentence alignment methods, the resulting corpora are extremely noisy. The most frequent noise types encountered are sentence alignment errors, wrong language in source or target, and untranslated sentences. As outlined by Khayrallah and Koehn (2018), training algorithms for neural machine translation systems are particularly vulnerable to these noise types. As such, these web-crawled corpora have seen limited use in training large NMT systems.

This paper proposes a method for denoising and filtering noisy corpora which explores and searches over weighted combinations of features. During NMT training, we score sentences and create batches using random weight vectors. These batches are use to train the system and measure improvement over the validation set (reward). Finally, by modeling the weight-*reward* function, we learn the set of weights which maximize reward and are used to score and filter the noisy dataset. At a high level, this method (i) allows the use of multiple sentence level features, (ii) learns a set of interpolation weights for the features which directly maximize translation performance, (iii) requires no prior knowledge about which features are informative or even if they are mutually redundant, and (iv) trains within the NMT pipeline and does not require any special infrastructure.

We include experiments which apply this method to building NMT systems for the noisy Estonian-English Paracrawl dataset and show that it beats strong single feature filtering-baselines and hand-designed feature interpolation. Additionally, we analyze the robustness of this method in the presence of specific kinds of noise (Khayrallah and Koehn, 2018) via a controlled experiment on the Europarl datasets. Finally, we look at the impact of transferring the learned weights from one language pair (Estonian-English) to a noisy dataset of another language pair (Maltese-English Paracrawl).

We present related work in Section 2. Section 3 describes the procedure we use to model and search over the weight-feature-*reward* space to estimate feature weights which maximize translation performance. Our experiment design, datasets and features, appear in Section 4. Section 5 includes our primary results where we compare the performance of the proposed method to strong single feature filtering baselines and hand-design feature weights.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1100–1109
November 10–11, 2021.

We conclude in section 6 with an analysis of this method's performance at filtering specific kinds of noise and the application of learned weights to a different language pair.

2 Related Work

Existing efforts towards filtering and denoising noisy corpora focus on pre-filtering using hand-crafted rules and by using sentence pair scoring and filtering methods. Deterministic hand-crafted rules (Hangya and Fraser, 2018; Kurfalı and Östling, 2019) remove sentence pairs with extreme lengths, unusual sentence length ratios and exact source-target copies, and are extremely effective in removing most of the obvious automatic extraction errors. Automatic sentence pair scoring functions have been used successfully to filter noisy corpora as well. This includes the use of language models (Rossenbach et al., 2018), neural language models trained on trusted data (Junczys-Dowmunt, 2018) and lexical translation scores (González-Rubio, 2019). Chaudhary et al. (2019) propose the use of cross-lingual sentence embeddings for determining sentence pair quality while several efforts (Kurfalı and Östling, 2019; Soares and Costa-jussà, 2019; Bernier-Colborne and Lo, 2019) have focused on the use of monolingual word embeddings. Parcheta et al. (2019) use a machine translation system trained on clean data to translate the source sentences of the noisy corpus and evaluate the translation against the original target sentences using BLEU scores. Erdmann and Gwinnup (2019) and Sen et al. (2019) propose similar methods using METEOR scores and Levenshtein distance respectively. Rarrick et al. (2011), Venugopal et al. (2011) and Antonova and Misyurev (2011) present techniques for detecting machine translated sentence pairs in corpora. Tools such as LASER (Schwenk and Douze, 2017), BiCleaner (Sánchez-Cartagena et al., 2018) and Zipporah (Xu and Koehn, 2017) have been used (Chaudhary et al., 2019) for noisy corpus filtering. Curriculum learning has been used to obtain policies for data selection which can expose the model to noisy samples less often during training (Wang et al., 2018; Kumar et al., 2019). More recently, ElNokrashy et al. (2020) and Esplà Gomis et al. (2020) have used classifier based approaches to filtering noisy parallel data.

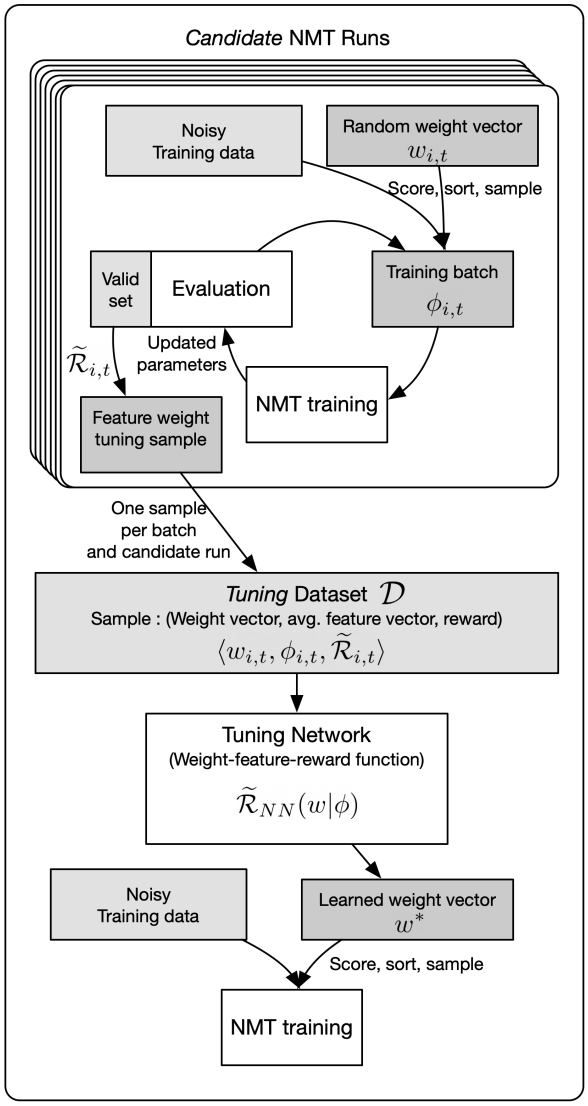

Figure 1: Overview of the proposed method for learning weights for sentence-level features to filter noisy parallel data and improve translation performance.

3 Method

The proposed method centres around finding weights for combining sentence-level features, which are then used to compute sentence-level scores and filter the noisy corpus. While the choice of features can be arbitrary, this method's performance will eventually depend on their quality, and we would ideally want them to be informative and decorrelated.

Figure 1 provides an overview of the proposed method. We first train a number of *candidate* neural machine translation (NMT) systems. During training for each candidate system, we repeatedly (i) generate a random weight vector, (ii) sample a batch of sentences from the noisy corpus based on sentence-level scores computed using this weight

vector, (iii) update NMT system parameters using this batch, and (iv) measure the improvement in translation quality on a validation set following this update. The weight vector w, the average feature vector ϕ of the batch, and the improvement $\mathcal{R}$ on the validation set (*reward*) are recorded for each batch t during the training of each candidate NMT system i, and $\langle w_{i,t}, \phi_{i,t}, \mathcal{R}_{i,t} \rangle$ becomes a sample in new data set $\mathcal{D}$, called the *tuning* data set[1], for learning feature weights to maximize reward. Hence, even though the parameters of the *candidate* systems are not used directly, they are used to gather noisy *candidate* evaluations of the latent weight-feature-reward function.

Once we have $\mathcal{D}$, we use a feed-forward network to learn the weight vector that maximizes the reward. The learned weight vector w^* is then used to compute sentence-level scores and filter the noisy data set. The *final* NMT system is trained using this *clean* data set.

Some subtleties in normalizing the observed rewards and learning weights are explained below.

3.1 Candidate NMT runs

Note from the bottom of Figure 1 that the learned weight vector w^* is used to sort all the sentences in the noisy training data, and the top-scoring ones are used for final NMT training. The purpose of the candidate NMT training runs is to generate the *tuning* data set $\mathcal{D}$ from which w^* is learned. Therefore, the setup for the candidate runs mimics typical NMT training, but for the following differences.

1. **Selecting batches**: For selecting sentences to constitute a batch, we first sample a random weight vector w of dimension $|\phi|$, the number of sentence-level features, uniformly[2] from $[-2.5, 2.5]^{|\phi|}$. Ideally, we would score *all* sentences in the noisy data set and then filter the top sentences to create a batch. However, this is prohibitively slow to do for every batch. Hence, we randomly sample twice the number of sentences required to constitute the batch, score them, and select the top half. For the i^{th} sentence, the score s_i is a dot product of its feature vectors with the weight vector:

$$s_i = \sum_{i=1}^{|\phi|} w_i \phi_i \tag{1}$$

   The selected sentences are removed from the training pool for this epoch. This method of batch selection ensures that the sampled weight vector determines which sentences are selected and that their average feature vector is significantly different from one obtained using unbiased/random selection.

2. **Reward computation**: The reward must represent how the choice of w (through the sentences selected to form the batch) impacts translation performance. This is approximated by computing the perplexity of a validation set following a parameter update with the selected batch. However, since perplexity naturally decays in standard NMT training, batches at the beginning of the training will naturally receive larger rewards, obscuring the impact of sentence selection. We mitigate this effect by using delta-perplexity, i.e. the change in perplexity of the validation set over a window of updates.

3. **Accumulating training samples**: For each batch t of candidate run i, we collect the random weight vector $w_{i,t}$, the batch feature vector $\phi_{i.t}$, defined as the average of the feature vectors of all sentences in the batch, and the reward $\mathcal{R}_{i,t}$. These triples are gathered from all batches during training, across all candidate training runs, to form the data set $\mathcal{D}$ for learning the feature weights.

3.2 Reward Normalization

As a further way to make the rewards time-invariant with respect to NMT training, the observed rewards $\mathcal{R}_{i.t}$ are normalized with respect to an expected reward estimated from a set of *baseline* NMT runs. Specifically, at each time step t, we compute the rewards $\mathcal{R}^b_{j,t}$ of $j = 1, \ldots, J$ concurrent training runs—whose batches selected in the standard manner—and, for each of the candidate NMT runs, we set

$$\widetilde{\mathcal{R}}_{i,t} = \mathcal{R}_{i,t} - \frac{1}{J} \sum_{j=1}^{J} \mathcal{R}^b_{j,t}, \tag{2}$$

[1] Not to be confused with the validation set which contains sentence pairs, this dataset is solely used to model the weight-reward function and contains no sentence identity beyond feature vectors.

[2] The range of the uniform distribution represents the plausible range of weights given the features.

where J is the number of baseline systems used.

Going forward, we do not need to track the identity of the update which led to a training sample, t, or the candidate system c_i which produced it.

3.3 Learning Feature Weights

The i^{th} sample $\langle w_i, \phi_i, \widetilde{\mathcal{R}}_i \rangle$ in $\mathcal{D}$ may be viewed as a (noisy) evaluation of an unknown function $\mathcal{R}(w|\phi)$. This function maps a vector w to final NMT quality, given a fixed sentence-level feature function ϕ and the stipulation that sentences are selected for training based on a weighted combination of their feature values using weights w. Furthermore, if we learn this function using $\mathcal{D}$, we may use the w^* that maximizes the learned function $\widetilde{\mathcal{R}}_{NN}(w|\phi)$ for our final denoising and NMT training. Specifically, we propose to use

$$\begin{aligned} w^* &= \arg\max_w \mathcal{R}(w|\phi) \\ &\approx \arg\max_w \widetilde{\mathcal{R}}_{NN}(w|\phi) \end{aligned} \tag{3}$$

We propose learning $\widetilde{\mathcal{R}}_{NN}(w|\phi)$ via a simple feed-forward neural network that maps the weights w_i to the observed reward $\widetilde{\mathcal{R}}_i$. We consider two ways of providing input to this neural network, one that uses only the w_i, and another that modulates w_i with batch quality, represented by ϕ_i.

1. **Weight-based**: We use a feed-forward network with the weight vectors w_i as input and learn to predict the observed reward $\widetilde{\mathcal{R}}_i$. Since the weight vectors interact directly with the feature vectors to determine which sentences are sampled to create a batch, we hypothesize that maximizing this weight-reward function will produce feature weights which will lead to better sentence sampling.

2. **Feature-based**: Since the *tuning* samples are noisy evaluations of the function $\mathcal{R}(w|\phi)$, we often encounter samples where weight vectors are close in weight space but have different rewards. To counter this problem, when using a feed-forward network to learn $\widetilde{\mathcal{R}}_{NN}(w|\phi)$, we scale the weight vector input w_i by the sum of the corresponding feature vector ϕ_i. This has the effect of keeping weight vectors which have similar feature vectors close in input space and moving apart those with significantly different feature vectors.

Once this neural network is learned from $\mathcal{D}$, we perform a grid search over its input space, as defined in Section 3.1, to find the maximizer of (3).

3.4 Re-sampling and training

The weight vector w^* learned from the previous section is used to score all sentences from the original noisy data set. We sort the sentences by these scores and sample the top candidates to form the *clean* training data set and use it to train a standard NMT system.

4 Experiment Setup

We use Fairseq (Ott et al., 2019) for our neural machine translation systems configured to be identical to the systems described in Ng et al. (2019). The feed-forward network used to tune weights has two 512-dimensional layers and is trained using standard SGD using a learning rate of 0.1. The grid search for the weights was done on the range $[-2.5, 2.5]$ with 5000 points uniformly distributed per dimension. The number of samples used for reward normalization was 3 and the window for computing the delta-perplexity reward was set to 3.

4.1 Corpora

We use the Paracrawl Benchmarks (Bañón et al., 2020) data set in Estonian-English for all our experiments. These consist of documents where sentences were aligned using Vecalign (Thompson and Koehn, 2019) and then de-duplicated so that each sentence pair only occurs once in the data set. The test and validation sets for our experiments in Estonian-English are *newstest2018* and *newsdev2018* respectively. Statistics of these corpora appear in Table 1.

	train	**valid**	**test**
Sentence Pairs	22.8m	2k	2k
Source Tokens	190m	29k	31k
Target Tokens	207m	38k	40k
Avg. Len (src)	9.8	14.5	15.3
Avg. Len (tgt)	10.7	19.1	20.1

Table 1: Statistics for the processed Estonian-Engligh (Es-En) Paracrawl data set and its corresponding validation and test sets. The training corpus was filtered using Vecalign scores; the raw corpus contains about 168m sentence pairs.

4.2 Features

We use five sentence-level features for all our filtering experiments. They are, (i) IBM Model 1 alignment scores (Brown et al., 1993), (ii and iii) source and target language model scores, (iv) dual conditional cross entropy (Junczys-Dowmunt, 2018) and (v) sentence length ratio. We experimented with aggregate features such as Zipporah (Xu and Koehn, 2017), BiCleaner (Sánchez-Cartagena et al., 2018) and bilingual features such as LASER (Schwenk and Douze, 2017) and these were used to replicate the baselines from Bañón et al. (2020) for our dataset. The IBM Model 1 scores were obtained using the Moses (Koehn et al., 2007) pipeline. The Estonian and English language models were trained on their respective NewsCrawl data sets[3]. The *clean* machine translation model for computing the conditional dual-cross entropy scores is trained on the *Europarl*v8 data set[4]. All features are gaussianized using the Yeo-Johnson power transformation and then normalized to have zero mean and unit variance.

5 Results

For our experiments, we scored all sentences in the noisy corpus, sorted and sampled the top parallel sentences to form subsets with 10, 15 and 20 million English words. These filtered data sets were used to train standard NMT systems and performance was evaluated on the test set described in the previous section. The results of these filtering experiments appear in Table 2.

First, we evaluate the efficacy of all the features we use for our interpolation task by filtering the data set on these features alone. Additionally, to include some strong baselines, we use three out-of-the-box, scoring features which provided strong results in the WMT 2020 parallel corpus filtering task[5] (Bañón et al., 2020; Chaudhary et al., 2019). These are BiCleaner, Zipporah and LASER. Of these, LASER provides the strongest filtering and translation results beating the other two by 0.3 to 0.9 BLEU points. Of the five features we use for our experiments, dual cross-entropy (Junczys-Dowmunt, 2018) is the strongest feature and matches the performance of LASER. Using source or target language model scores in isolation leads to the weakest translation performance while IBM Model 1 scores perform only slightly better than them. Surprisingly, the simple sentence length ratio feature beats all other features except dual cross-entropy by 1.4 to 1.6 BLEU points. This is a strong indicator of the type of noise in the data set and that bilingual features (even simple ones) perform better than monolingual features such as language model scores.

	10m	**15m**	**20m**
1-Feature Filtering Baselines			
Zipporah	20.4	21.3	21.3
BiCleaner	19.8	20.9	21.2
LASER	21.7	22.4	22.5
IBM Model 1	18.1	19.9	20.8
Target LM	17.6	19.5	20.4
Source LM	17.4	19.4	20.4
Dual Cross-Entropy	21.5	22.4	22.6
Sentence Length Ratio	19.7	20.2	21.2
Filtering using Feature Weights			
Uniform weight baseline	20.9	21.5	21.6
Weight based (14)	22.1	**23.1**	**23.5**
Feature based (15)	**22.4**	**23.1**	**23.6**

Table 2: BLEU scores for the Estonian-English NMT systems where the training data was filtered using single features or a learned weighted combination of features. Feature weights were learned using the proposed method. The number of candidate runs which produced the best results appear in parentheses.

Next, we look at interpolation of features using weights learned using the proposed method. As a baseline, we also include an experiment which filters based on a uniform interpolation of the five features we use. This baseline performs worse than the strongest single feature filtering experiments by 0.5 to 1 BLEU points. For both the weight-based and feature-based methods of learning interpolation weights for the features, a significant number of *candidate* runs are required before adequate performance is achieved. This is not surprising, since we are searching for an optimal weight vector in a fairly large weight space and we need a large number of samples before a good representation of the weight-reward function can be learned. Figure 2 shows the improvement in BLEU scores for the weight-based approach as data from more *candidate* runs in added to the *tuning* stage for learning weights and filtering the data set. The performance

[3] statmt.org/wmt18/translation-task.html

[4] statmt.org/europarl/

[5] statmt.org/wmt20/parallel-corpus-filtering.html

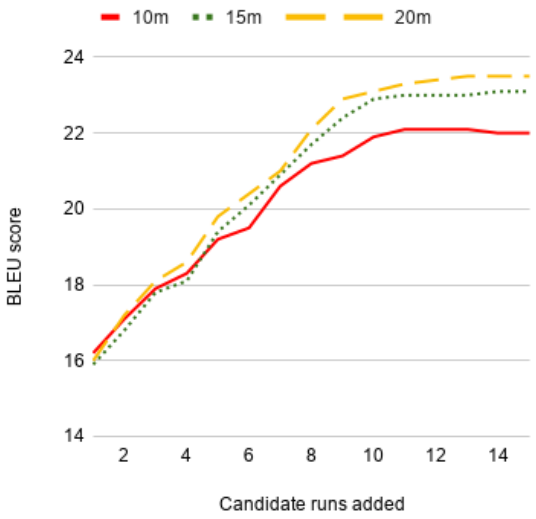

Figure 2: Improvement in BLEU scores of the final NMT system as data from additional 'candidate' training runs is added to the tuning stage to learn weights. Training data was filtered using the learned weights.

of the final NMT system steadily improves as more data from more systems is added and eventually converges.

Our strongest result was achieved with 14 *candidate* runs for the weight-based approach for the 10, 15 and 20m setting respectively. This beat the uniform weight baseline by 1.5 to 2 BLEU points and the strongest single feature (LASER) baseline by 1 BLEU point. The feature based approach performed slightly better with 15 candidate runs and beat the strongest single feature baseline (LASER) by 1.3 BLEU points.

6 Analysis

The following sections examine the learned weights, the effect of transferring them to noisy corpora of a different language pair and the method's performance when exposed to specific kinds of noise.

6.1 Learned Weights

Table 3 shows the weights learned using the *tuning* network, normalized to sum to one. Unsurprisingly, the strongest feature (dual cross-entropy) has the highest weight, with the sentence length ratio and IBM Model 1 (weak multi-lingual features) drawn for the next place while source and target LM have relatively low weights.

Feature	Weight	Feature
IBM Model 1	0.07	0.12
Source LM	0.03	0.02
Target LM	0.02	0.02
Dual xent	0.81	0.76
Sen. Length Ratio	0.07	0.08

Table 3: Feature weights learned post-tuning with the weight-based and the feature-based approaches. The weights have been normalized to sum to 1 (column).

6.2 Weight Transfer

Since the feature functions we use for our experiments are reasonably language-independent, a reasonable experiment is to see if the feature weights learned on one language-pair can be transferred to a noisy corpus of another another language pair. However, we hypothesize that unless the feature distributions (proxy for noise profile of the dataset) of the datasets are similar, this transfer will have limited success.

We test this hypothesis using the Maltese-English Paracrawl corpus. The training corpus contains 26.9 million sentence pairs and was sentence aligned using Vecalign and de-duplicated in a manner similar to our primary experiments. The validation and the test sets for these experiments are from the EUbookshop[6] dataset and contain 3k and 2.2k sentences respectively. The sentence level features were computed using the procedure described in section 4.2 and we use the DGT corpus[7] (about 1.6 million parallel sentences) to the train the clean translation models, the source and the target language models.

1-Feature Filtering Baselines	
Target LM	28.3
Source LM	27.1
Dual Cross-Entropy	**32.5**
Filtering using Transfer Weights	
Uniform weight baseline	30.5
Weight based	31.6
Feature based	31.3

Table 4: BLEU scores for the Maltese-English Paracrawl NMT systems where the training data was filtered using single features or a *transferred* (from Estonian-English) weighted combination of features.

[6] opus.nlpl.eu/EUbookshop.php
[7] data.europa.eu/euodp/en/data/dataset/dgt-translation-memory

The results of these experiments appear in Table 4. Even though filtering with the transferred weights beats the simpler single feature baselines, it fails to beat the strongest one, dual cross-entropy. It is worth noting that the reason filtering with the learned weights does this well is because the dual cross-entropy feature has the highest weight from our previous experiments. These experiments suggest that some form of feature distribution matching across corpora is required before weight transfer becomes viable.

6.3 Sensitivity to Noise Types

Inspired by Khayrallah and Koehn (2018), we look at how the most common noisy types in the Paracrawl data set affect the performance of the proposed method. For the purpose of these experiments, we use the *Europarl* v8 [8] Estonian-English data set. The training data set consists of about 651k parallel sentences, 11.2m source and 15.7m target tokens. We only use the feature-based method for this analysis and each experiment tunes weights based on 5 *candidate* runs.

We add synthetic noise to this data set by replacing 50% of the sentences in the data set to contain a specific kind of noise. The noise types we looked at and their perturbation methods are described below:

1. Misaligned sentences: Since parallel corpora extraction efforts use automated document and sentence alignment methods, noise includes source sentences which are not aligned to the correct target sentence. To emulate this, we randomly shuffle the source sentences of half the sentences in the clean data set.

2. Misordered words: A result of automatic or imperfect human translation, we add this noise to the clean data set by randomly shuffling the words within the source sentences.

3. Wrong language: This is a very common noise type in web-crawled corpora. We emulate it by performing lexical replacements (from Estonian to French).

4. Untranslated words: This other common noise type is added to our data set by copying the source sentence to the target.

[8] www.statmt.org/europarl

Noise Type	% Retained
Misaligned sentences	92
Misordered words	81
Wrong language	89
Untranslated words	78

Table 5: The portion of the clean sentences retained after perturbing 50% of the data set with specific noise types, learning feature weights and resampling the top 50% samples.

For each type of noise, we perform the following experiment: perturb 50% of the clean data with the chosen noise type, compute feature values for the sentences in the full data set, learn feature weights using the weight-based method described in section 3, filter out the top 50% of the data set and measure the percentage of *clean* (non-perturbed) sentences which were retained.[9] The results of this analysis appears in Table 5. The method performs significantly better than chance in all noise categories, but given our choice of features, it is better at filtering out misaligned sentences and sentences with tokens in the wrong language and is slightly less effective at dealing with misordered and untranslated words.

7 Future Work

The validation set based delta-perplexity is expensive to compute per update and replacing it with a more stable or time invariant reward (Wang et al., 2019) may help improve the performance of this method. Additionally, we plan to replace grid search with a more granular search procedure over the weight space with respect to the weight-feature-reward function. The tuning network can also be modified to include sentence-quality modulated loss functions (via feature values). An alternative to searching for feature weights is to instead search for the prototypical feature vector which maximizes translation performance and then use it to filter the closest sentence pairs from the noisy dataset. Finally, as discussed in Section 6.2, transferring learned weights has the potential to dramatically reduce the cost of applying to this method to new language pairs and may help with performance on low-resource language pairs where good feature weights cannot be learned.

[9] We note that the performance of this analysis depends on the chosen features. As an extreme example, if we perturb the source sentences and only consider a target-side feature (such as target language model scores), we will have no way of discriminating bad noisy samples from the clean ones.

8 Conclusion

We present a method for denoising and filtering noisy parallel data for improving the performance of neural machine translation systems. We learn interpolation weights for sentence-level features by modeling and searching over the weight-reward space. These are used to score and filter sentences in the noisy corpora. Our experiments with Estonian-English Paracrawl show gains of over a BLEU point over the strongest single feature filtering and uniform weight baselines. Analysis also shows that this method is effective at addressing the most common noise types in web-crawled corpora.

Monotonic Simultaneous Translation with Chunk-wise Reordering and Refinement

Abstract

Recent work in simultaneous machine translation is often trained with conventional full sentence translation corpora, leading to either excessive latency or necessity to anticipate as-yet-unarrived words, when dealing with a language pair whose word orders significantly differ. This is unlike human simultaneous interpreters who produce largely monotonic translations at the expense of the grammaticality of a sentence being translated. In this paper, we thus propose an algorithm to reorder and refine the target side of a full sentence translation corpus, so that the words/phrases between the source and target sentences are aligned largely monotonically, using word alignment and non-autoregressive neural machine translation. We then train a widely used wait-k simultaneous translation model on this reordered-and-refined corpus. The proposed approach improves BLEU scores and resulting translations exhibit enhanced monotonicity with source sentences.

1 Introduction

Simultaneous interpretation is widely used in various scenarios such as cross-lingual communication between international speakers, international summits, and streaming translation of a live video. Simultaneous interpretation has a latency advantage over conventional full-sentence translation, i.e. offline translation, as it requires only partial sequence to start translating. However, as the source and target languages differ in word orders, there is a difficulty in simultaneous interpretation that does not exist in offline translation which translates only after the whole source sentence is received. For example, when dealing with language pairs that significantly differ in word order (e.g., between SOV language and SVO language), an interpreter may not receive sufficient information with partial sequence to start generating a translation that respects the natural order of the target language. One of the approaches to address this problem is to perform *anticipation*[1]. Note that the nature of anticipation relies on interpreters' assumptions and the anticipation may provide incorrect translations. Alternatively, human interpreters strategically resort to producing *monotonic translations* that follow the word order of the source sequence (Cai et al., 2020).

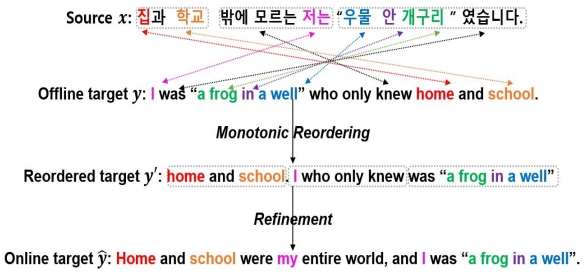

Figure 1: An example illustration of monotonic reordering and refinement for simultaneous translation

To illustrate the differences between the two strategies, the example in Figure 1 may be referred to. Of the two targets, offline target $\mathbf{y}$ respects the target language order and an online target $\hat{\mathbf{y}}$ roughly follows the source word ordering. Successful anticipation in Figure 1's case would be to predict the initial words in $\mathbf{y}$ (I was a "frog in a well") before receiving the full $\mathbf{x}$. This would pose difficulty even to professional translators as all the relevant information is in the latter part of the $\mathbf{x}$ (저는$_{I}$ /"우물$_{a\ well}$ / 안$_{in}$ / 개구리$_{a\ frog}$" 였습니다$_{was}$.). Bartłomiejczyk (2008) reports the success rate of human interpreters' anticipation attempts to be as low as 38.1% even though they make predictions based on pre-acquired domain knowledge. On the other hand, a monotonic approach would be to gen-

[1]A simultaneous interpretation strategy where the interpreter says information that is not yet said by the speaker.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1110–1123
November 10–11, 2021.

erate an $\hat{y}$ style translation - the grammaticality in the resulting sequence is sacrificed to translate only the received information.

A similar case applies to Simultaneous Machine Translation (SimulMT) models, which start translating before a whole sentence is given. Several studies (Ma et al., 2019; Arivazhagan et al., 2019; Ma et al., 2020) often utilize offline full-sentence translation corpora to train SimulMT models. Offline full-sentence parallel corpora are expected to follow the natural order of languages and mostly contain source to offline-target pairs. Naturally, when SimulMT models are trained on these corpora, the models inevitably learn to perform anticipation. Recent SimulMT studies are focused on reducing anticipation (Zhang et al., 2020a) or performing better anticipation (Zhang et al., 2020b). On the contrary, studies on enabling monotonic translation in SimulMT are scarcely available. Recently, Chen et al. (2020) suggest utilizing pseudo-references for monotonic translation.

In this paper, we propose a paraphrasing method to generate a monotonic parallel corpus to allow a monotonic interpretation strategy in SimulMT. Our method consists of two stages. The method first chunks source and target sequences into segments and monotonically *reorders* the target segments based on source-target word alignment information (Section 3.1). Then, the reordered targets are *refined* to enhance fluency and syntactic correctness (Section 3.2). To show the effectiveness of our method, we train wait-k models (Ma et al., 2019) on the resulting monotonic parallel corpus of reordering-and-refinement. Results show improvements in BLEU scores over baselines and models producing monotonic translations. Our main contributions are as follows:

- We propose a method to reorder and refine the target side in an offline corpus to build a monotonically aligned parallel corpus for SimulMT.
- We investigate the monotonicity in different language pairs, and show monotonicity can be improved after the reordering-and-refinement process.
- We train widely used wait-k models on generated monotonic parallel corpora in multiple language pairs. The results show improvements over baselines in both translation quality and monotonicity.

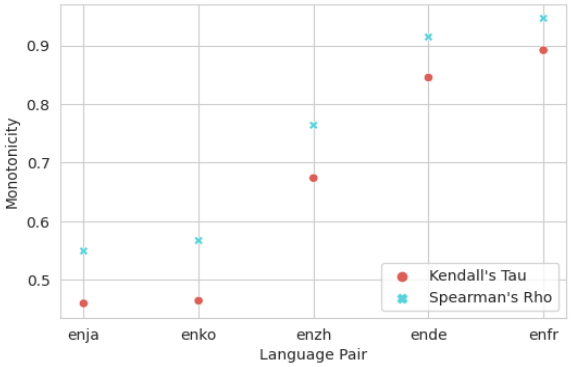

Figure 2: Monotonicity measured on offline trainsets. Utilized data is described in Section 4.1. As Kendall's τ and Spearsman's ρ show similar patterns, we only report Kendall's τ measurements in the rest of the paper.

2 Monotonicity Analysis

In this section, we analyze the degree of word order differences in multiple language pairs, i.e., the monotonicity in different language pairs. To measure the monotonicity, two rank correlation statistics are utilized: Kendall's τ and Spearman's ρ. The analyzed language pairs are: English-{Korean, Japanese, Chinese, German, French}.

According to Polinsky (2012), English is a head-initial language and Korean and Japanese are rigid head-final languages; Korean and Japanese are likely to exhibit extreme word order differences with English. German and Chinese are considered a mixture of head-final and head-initial languages; they are likely to have word differences with English, but not as severe as Korean or Japanese. French is also head-initial, so English and French pair is likely to have similar word order.

Figure 2 show monotonicity measurements between English and five different languages which vary in monotonicity: English-German and English-French pairs show high monotonicity, while English-Japanese and English-Korean pairs show low monotonicity.

Lower monotonicity in language pairs presents higher difficulties for SimulMT tasks. For example, wait-k algorithm only sees $k + t$ source tokens to generate a target token at step t which could lead to unwanted anticipation. To avoid such anticipation, as we mentioned in Section 1, human interpreters often provide a monotonic translation. In the same sense, we conjecture that promoting monotonicity in training corpora is beneficial for translation quality in SimulMT.

3 Monotonic Reordering and Refinement

In this section, we describe our proposed paraphrasing method of chunk-wise reordering and refinement to generate monotonic corpus for SimulMT. Given source $\mathbf{x} = \{x_1, x_2, \cdots, x_{|\mathbf{x}|}\}$ and offline full sentence target $\mathbf{y} = \{y_1, y_2, \cdots, y_{|\mathbf{y}|}\}$, an alignment $\mathbf{a}$ is defined as a set of position pairs of $\mathbf{x}$ and $\mathbf{y}$.

$$\mathbf{a} = \{(s, t) : s \in \{1, \cdots, |\mathbf{x}|\}, t \in \{1, \cdots, |\mathbf{y}|\}\}$$

First, in chunk-wise reordering phase, we generate source chunk set $\mathcal{C}^X$

$$\mathcal{C}^X = \{(x_{1:p_1}), (x_{p_1+1:p_2}), \cdots, (x_{p_{k-1}+1:p_k})\},$$

where $0 < p_1 < p_2 < \cdots < p_k = |\mathbf{x}|$ and reordered target chunk set $\mathcal{C}^Y$

$$\mathcal{C}^Y = \{(y'_{1:q_1}), (y'_{q_1+1:q_2}), \cdots, (y'_{q_{k-1}+1:q_k})\},$$

where $0 < q_1 < q_2 < \cdots < q_k = |\mathbf{y}|$, and $y'_i \in \mathbf{y}'$ is reordered target token from offline target $\mathbf{y}$. The elements of a reordered target chunk $\mathcal{C}^Y_i$ are corresponding target tokens of a source chunk $\mathcal{C}^X_i$ based on given alignment information $\mathbf{a}$. Also, we preserve the original target order within each $\mathcal{C}^Y_i$. For example, offline and reordered target in Figure 1 correspond to $\mathbf{y}$ and $\mathbf{y}'$ respectively, and both sequences are only different in token orders. The number of source chunks in one sentence is the same as the number of reordered target chunks ($|\mathcal{C}^X| = |\mathcal{C}^Y|$), while the number of tokens in $|\mathcal{C}^X_i|$ and $|\mathcal{C}^Y_i|$ could vary. We experiment two chunking methods; fixed-size chunking and alignment-aware adaptive size chunking.

Given chunked sets $\mathcal{C}^X$ and $\mathcal{C}^Y$, we refine reordered target tokens to generate more natural and fluent sentence with a Non-Autoregressive Translation (NAT) model. In the refinement algorithm, final paraphrased sentence $\hat{\mathbf{y}}$ is generated from reordered sequence $\mathbf{y}'$. Furthermore, we incorporate an Autoregressive Translation (AT) model into our refinement process. The more detailed steps for each phase will be explained in the following subsections.

3.1 Chunk-wise Reordering

3.1.1 Fixed-size Chunk Reordering

In the fixed-size chunk reordering method, we simply chunk a sequence of tokens into fixed size segments. The source chunk set $\mathcal{C}^X$ in this chunking method is as follows:

$$\mathcal{C}^X = \{(x_{1:K}), (x_{K+1:2K}), \cdots, (x_{[|\mathbf{x}|/K]:|\mathbf{x}|})\},$$

where $K \in [1, |\mathbf{x}|]$ is chunk size. If $k = 1$, $\mathcal{C}^X$ is identical with $\mathbf{x}$. We conduct subword operation such as sentencepiece or BPE after chunking process in order to avoid subword separation.

3.1.2 Alignment-Aware Chunk Reordering

In the alignment-aware chunking method, we segment a sentence adaptively by leveraging alignment information $\mathbf{a}$, as described in Algorithm 1. The left grid in Figure 3 presents the subword alignment between source and target sentence. We run aligner on subword over word because the alignment performance is consistently better Zenkel et al. (2020) when using GIZA++ (Och and Ney, 2003) , which we use in our experiments. Based on this alignment information, we initialize a list of chunks $\mathcal{C}$. As observable, there are some tokens which have no alignment information. To avoid omission, we assign the same alignment as the previous token; if a token is at the head, it follows the next token's alignment. To ensure subwords can be properly detokenized after reordering, we merge mid-splitted subwords. The middle grid in Figure 3 presents the result of these initialization steps. After initialization, we generate consistent chunks by merging all the inconsistent ones, following the definition of consistency in Zens et al. (2002). In a consistent chunk, tokens are only aligned to each other, not to tokens in other chunks. If any chunk in $\mathcal{C}$ has size smaller than a minimum size threshold δ, we merge a chunk pair that are adjacent in both source and target side and have the shortest target distance between them. If the distances are the same between multiple candidate pairs, we choose the pair of chunks that makes the smallest size after merging. We additionally merge the chunks adjacent to the merged one if they are arranged monotonically. Merging is repeated until all chunks meet the size requirements. An example of final result is the right grid in Figure 3. Phrase extraction method used in statistical machine translation Koehn (2004) also makes phrase level alignments from word alignments using heuristics like ours, but it tends to choose shorter phrases since the number of co-occurrences decrease drastically as the phrase size grows, which makes it difficult to generate larger chunks to prevent hurting grammatical correctness while reordering phase.

3.2 Refinement

Reordered target results from previous phase inevitably entail irregularities mainly for two rea-

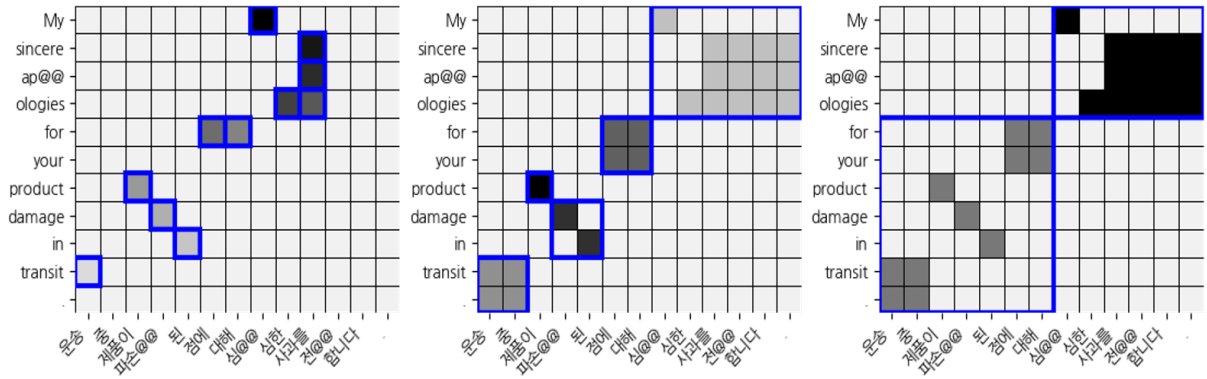

Figure 3: Example of alignment-aware reordering process. **Left**: Original alignments. **Center**: (Initialization) After filling align vacancy, merging mid-split subwords and enforcing the consistency requirement. **Right**: After merging all the chunks shorter than length thresholds.

Algorithm 1: Alignment-Aware reordering

Input: Source sentence $\mathbf{x}$ and target sentence $\mathbf{y}$
Output: Monotonically aligned chunks $\mathcal{C}'$

$\mathbf{a}$ = Alignment between $\mathbf{x}$ and $\mathbf{y}$
$\mathcal{C}$ = Initialize chunks $\mathcal{C}$
$\mathcal{C}$ = Merge all the inconsistent chunks in $\mathcal{C}$
while $|C_i^X| < \delta_{src}$ **or** $|C_i^Y| < \delta_{tgt}$ **for any** $\mathcal{C}_i$ **in** $\mathcal{C}$ **do**
  $\mathcal{C}_k$ = The smaller of the chunks adjacent to $\mathcal{C}_i$
  Merge $\mathcal{C}_i$ and $\mathcal{C}_k$
  Merge monotonic chunks adjacent to $\mathcal{C}_i$
end
$\mathcal{C}'$ = Reorder target side of $\mathcal{C}$ monotonically

Algorithm 2: Chunk-wise Refinement

Input: Source and target chunks $\mathcal{C}^X, \mathcal{C}^Y$
Output: Paraphrased target $\hat{\mathbf{y}}$

$i = 1$
$\hat{Y}_0 = []$
while $i \leq |\mathcal{C}^X|$ **do**
  $X_i = \mathcal{C}^X_{1:i}$ and $Y'_i = [\hat{Y}_{i-1}; \mathcal{C}^Y_i]$
  $\hat{Y}_i = \arg\max_Y \log p^{\mathcal{R}}(Y|X_i, Y'_i)$
  $i = i + 1$
end
Return: $\hat{Y}_{|\mathcal{C}^X|}$

sons. One could be broken connectivity of collocations in segmentation process. The other would be disfluently missing or containing words of endings and preposition as the position of chunk has been changed, thus requiring an addition of new words or clearing unnecessary words. In this part, we focus on refining aforementioned anormalities in order to enhance fluency, while preserving the monotonicity at the same time.

3.2.1 Refinement with NAT

We iteratively decode partial source $\mathcal{C}^X$ with pretrained translation model, given partial reordered target $\mathcal{C}^Y$ as a guidance in order to generate corresponding online target $\hat{Y}$. More specific process is explained in Algorithm 2. As the model refines given $[\hat{Y}_{i-1}; \mathcal{C}_i^Y]$, previous refined output $\hat{Y}_{i-1}$ could be altered as the model re-generates the entire sequence from scratch. Similarly in translation (Arivazhagan et al., 2020; Han et al., 2020b), we set an option of fixed or alterable prefix to force the model whether to generate same target prefix of $\hat{Y}_{i-1}$ or to allow the model to modify the prefix. As we limit the visibility of source information and iteratively generate target tokens with increasing source chunks, we expect the refinement model to generate monotonically aligned and paraphrased targets $\hat{\mathbf{y}}$ with enhanced fluency.

We use NAT architecture as the core refinement model $\mathcal{R}$. In NAT inference, the model's decoder is first given source features and fed an empty target sequence. Then the NAT decoder develops the empty sequence into a translation of the source sequence. This development is often iterative. Note that at every iteration step, the target sequence is refined - closer to the source sequence in meaning and become more fluent. This motivates us to utilize NAT architecture in our refinement process for monotonic-yet-disfluent sequences. In our approach, the NAT model starts refinement iteration with initialized tokens of previous output and

reordered target chunk Y_i', instead of an empty sequence. This target initialization act as a weak supervision to generate monotonically aligned target, which allow model to focus only on the fluency the reordered targets.

3.2.2 Incorporation of AT

Despite the aptness of NAT structure to our refinement phase, NAT model entails a performance degradation compared to AT model in the expense of speedup. Also, there exists repetition problem in NAT (Lee et al., 2018; Gu and Kong, 2021) which is generated in the process of multiple chunk-wise iterative refinement. In order to complement the aforementioned weaknesses of NAT decoding, we incorporate AT into our refinement process with NAT model.The final probability is computed jointly with the probability of AT and NAT model:

$$p^{\mathcal{R}}(Y|X_i, Y_i') \propto p^{AT}(Y|X_i)^{\alpha} \cdot p^{NAT}(Y|X_i, Y_i')^{(1-\alpha)}, \quad (1)$$

where $\alpha \in [0, 1]$ is hyper-parameter deciding the ratio between AT and NAT probability.

Size/L_{avg}	EnKo	EnJa	DeEn	EnZh
Train	3.4M/22	3.9M/12	4M/28	15.9M/27
Valid	800/19	4451/17	3000/25	4000/30
Test	1429/21	1194/17	2169/25	4000/30
AlignAw	3.1M	1.7M	2.2M	6.5M
er	0.85	1.15	0.98	1.12

Table 1: Data statistics and average of En token length L_{avg} of used corpus. AlignAw denotes number of pairs processed with alignment aware refinement. er denotes emission rates used in wait-k decoding. Token lengths and er are measured base on subwords counts.

4 Experiments

4.1 Dataset

In this section, we describe the utilized datasets. Detailed statistics are presented in Table 1. Utilized EnKo trainset and devset are created using in-house translation corpora while test scores are reported on IWSLT17 (Cettolo et al., 2017) EnKo testset. The DeEn trainset of WMT15 translation task (Bojar et al., 2015) is utilized. *newstest2013* is utilized as devset and *newstest2015* is used as testset. The EnJa trainset and validset are respectively the combination trainsets and validsets of KFTT (Neubig, 2011), JESC (Pryzant et al., 2018), TED (Cettolo et al., 2012). The trainset and validset are used as preprocessed and provided by the MTNT authors[2] (Michel and Neubig, 2018). Only the TED portion of testsets is used. For EnZh training UN Corpus v1.0 (Ziemski et al., 2016) is used. Trainset, devset, and testset follow the original splits. Monotonicity of EnFr in Figure 2 is measured on the WMT14 (Bojar et al., 2014) trainset. Additional details regarding utilized tokenization and vocabulary training are listed in Appendix A.

4.2 Metric

All the BLEU scores are cased-BLEU measured using sacreBLEU (Post, 2018). Test scores are measured using models that report best BLEU on their respective devsets. All references and translations of each Korean, Japanese, and Chinese languages are tokenized prior to BLEU evaluation. Tokenizers utilized are mecab-ko[3], KyTea [4], and jieba for Korean, Japanese and Chinese respectively. We report detokenized BLEU on DeEn results. To measure monotoniticy, we use Kendal's τ rank correlation coefficient.

4.3 Implementation Details

The default setting for NMT and SimulMT models follow the base configuration of transformer (Vaswani et al., 2017). SimulMT models are trained using wait-k algorithm, where $k \in \{4, 6, 8, 10, 12\}$, with uni-directional encoder similarly to Han et al. (2020a). The base NMT and SimulMT models are trained up to 300k train steps on a single GPU - each step is performed on a batch of approximately 12288 tokens. For refinement, we utilize NAT models of Levenshtein transformer architecture (Gu et al., 2019) with maximum iteration of 1. The NAT models are trained using sequence-level knowledge distillation (Kim and Rush, 2016) - the references of trainset pairs are replaced with beam search results ($beam = 5$) of NMT teachers. The NAT models follow base configurations and teacher NMT models follow big configuration. Both types of models are trained up to 300k steps on 8 GPUs. In each training step, a 8192 tokens batch is used per GPU. Additional implementation details can be found in the Appendix B.

Table 2: BLEU scores and monotonicity measurements of EnKo wait-k models trained on offline and reordered-and-refined corpora. Note that monotonicity is measured between the model translations and testset references.

4.4 Corpus Generation and Training

We demonstrate the effectiveness of our reordering-and-refinement method by training wait-k models on the resulting datasets. The wait-k models are trained on the combination of the monotonically aligned training pairs and offline trainset. AlignAw + NAT + AT denotes monotonically aligned corpora using alignment-aware reordering and refinement using joint probability of NAT and AT models. And Offline refers to the offline full-sentence corpus.

4.4.1 Reordering

Fixed: For fixed-size reordering, we experiment with chunk sizes $K \in \{4, 6, 8, 10, 12\}$. In wait-$k$ training, k and K are matched. All fixed-size reordered-and-refined corpora have the same size as corresponding offline corpus.

AlignAw: For each corpus, we generate four variations of alignment-aware reordering with source and target minimum chunk size of $2, 3$. Alignment-aware reordering is not applicable on the already-monotonic cases and the sentence pairs which are locally non-monotonic inside a chunk and globally monotonic among chunks within a single pair - typically, the reordering method is applicable to 20% to 50% of offline corpus.

We gather unique pairs from the created four variations to generate the final reordered pairs. The statistics of reordered set for each translation direction is in Table 1. The resulting pairs are refined and combined with corresponding offline corpus to train wait-k models. Here, same set of reordered pairs are utilized for all k settings.

seq-rep-n	Offline	NAT	NAT + AT
1-gram	0.036	0.076	0.072
2-gram	0.008	0.022	0.018
3-gram	0.003	0.009	0.006
4-gram	0.001	0.004	0.002

Table 3: N-gram repetition rate measured on offline and reordered-and-refined EnKo corpora. $\alpha = 0.25$ is set to for NAT + AT

4.4.2 Refinement

NAT: NAT models are utilized to refine the reordered pairs. Both the fixed prefix and alterable prefix refinement is performed and combined. BertScore (Zhang et al., 2020c) is measured and used to discard refinement results that show below average scores. The size of the resulting set is the same as the corresponding offline corpus.

NAT + AT: NAT and AT models can both be utilized to jointly compute token probability in refinement (Section 3.2.2). The AT models utilized are the baseline wait-k models trained on offline corpora. We experiment with $\alpha \in \{0.25, 0.5\}$. The examples of reordered-and-refined sequences can be found in Appendix E.

5 Results and Analysis

5.1 Experimental Results on EnKo

Table 2 shows BLEU scores and Kendal's τs of wait-k models trained using original offline corpus and variations of reordered-and-refined corpus. We observe that the models trained on monotonically

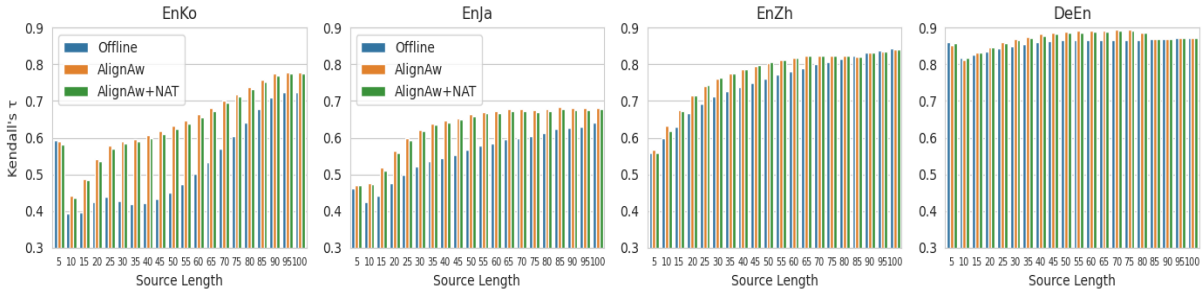

Figure 4: Monotonicity of offline pairs and pairs processed with reordering-and-refinement. AlignAw indicate that targets are alignment-aware reordering (Section 3.1.2, and AlignAw + NAT show monotonicity after NAT refinement (Section 3.2.1) is applied to AlignAw pairs.)

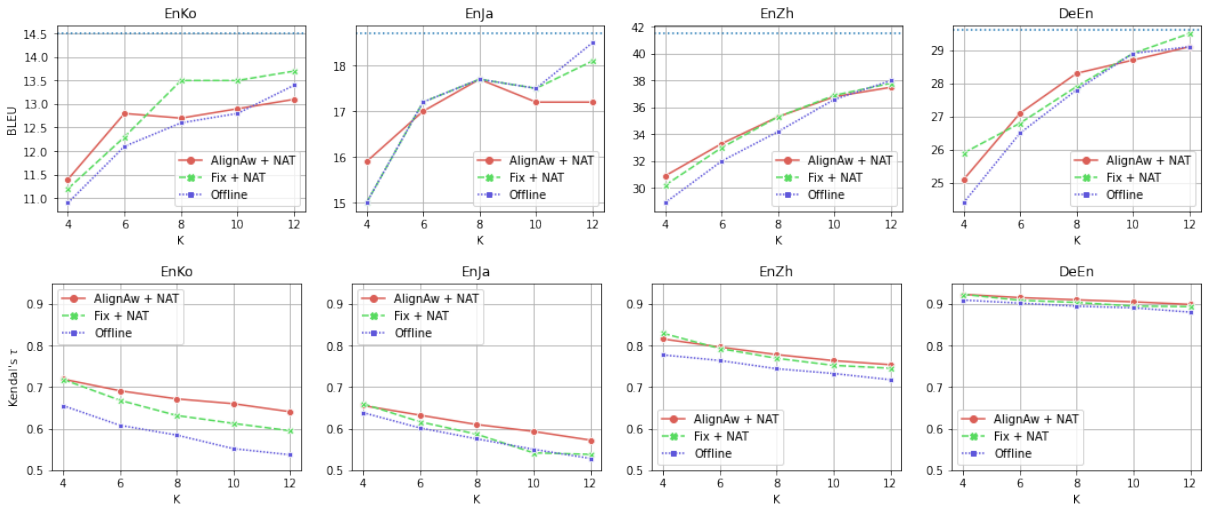

Figure 5: BLEU scores and monotonicity measurements presented by wait-k models trained on offline translation corpora and variations of reordered-and-refined corpora.

reordered-and-refined corpora show higher BLEU scores and monotonicity.

Reordering: Of the variations, corpora including AlignAw chunking process generally show better BLEU scores over Fixed + NAT when $k \leq 6$. This could be the benefit of the semantically plausible way to split sentences provided by AlignAw chunking. On the other hand, models trained with Fixed + NAT corpora show higher BLEU when $k \geq 8$.

Refinement: Experiments on utilizing AT probabilities show degraded BLEU scores in $k \in 6, 8, 10$. On the contrary, the models trained on AlignAw + NAT + AT corpora show enhanced monotonicity. The α value may be adjusted to make trade-off between promoting monotonicity in translation or enhancing translation quality in terms of BLEU.

Repetition Reduction with AT: Following (Welleck et al., 2020), we report n-gram repetition rate, seq-rep-n, on each generated corpus in Table 3. We observe from seq-rep-n in all of the tested n values, that employing AT models in refinement help alleviating the repetition problem of posed by NAT models.

5.2 Language Pairs Comparison

Figure 4 shows the difference in monotonicity between different language pairs: EnKo, EnJa, EnZh, and DeEn. It is observable in Figure 4 that the overall monotonicity in EnKo and EnJa pairs is enhanced after paraphrasing, while monotonicity scores of DeEn remain almost the same, only showing slight improvement. The extent of monotonicity enhancement in EnZh is between that of EnKo/Ja and DeEn. In all language pairs, the enhancements are generally lower in long or very short sequences. In the case of long sequence pairs, a pair may contain multiple sequences and be already aligned at the sequence level, thus resulting in marginal monotonicity enhancement. In the case of shorter length sequences, the whole sentence

may be merged into a single chunk, less benefiting from our process. After the reordered sets are refined, monotonicity marginally decreases. This is expected as forcibly aligned tokens are refined to augment the fluency in the resulting sentence.

To present the effectiveness of generated monotonic corpus in different language pairs, we train wait-k models on EnKo, EnJa, EnZh, and DeEn, and report BLEU and Kendal's τ of the models in Figure 5. The horizontal dotted line presents the BLEU of unidirectional offline model. The important observation we can find is that the monotonicity increment of wait-k model in Figure 5 is proportional to that of generated monotonic corpus in Figure 4, suggesting that promoting monotonicity in training corpus is beneficial for SimulMT models to generate monotonic output, especially in language pairs with differing word orders.

Within two paraphrasing methods, Fixed + NAT and AlignAw + NAT , we can see that the monotonicity of Fixed + NAT is always in between that of Offline and AlignAw + NAT in Figure 5, and the gap increases as the k value get higher.

While our methods are effective in EnKo, the performance of suggested method is similar or lower than that of baseline in EnJa. We presume that the ineffectiveness in EnJa is due to its short average sentence length with highest emission rate, as shown in Table 1. A short sentence often cannot preserve semantic properties while being split into chunks and reordered. For example, Fixed-length reordering always chunks all sentences ignores such feature and only increases disfluency in the chunked result. Also, even though AlignAw enforces the consistency requirement on the chunks, adjustment of such requirement like changing minimum chunk size may be required considering the high emission rate.

Based on the highest performance at $k = 8$, there is about 8% BLEU improvement over Offline in EnKo whereas there is about 3% improvement in EnZh and about 2% improvement in DeEn. It is roughly proportional to the monotonicity improvements shown in Figure 4.

5.3 Evaluation on Online References

We test wait-k models on our in-house EnKo online and offline testsets of 150 lines. We choose EnKo because the impact of reordering-and-refinement is the greatest in that pair. The source sentences of both testsets are identical. The online references

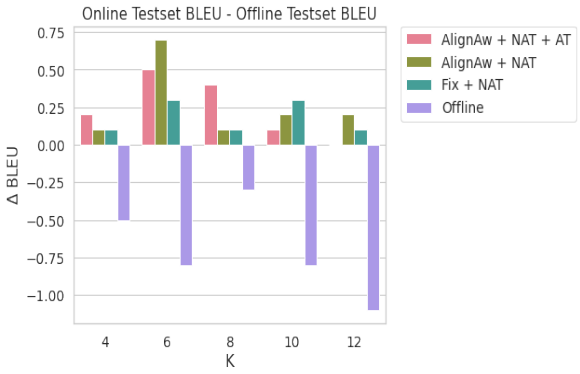

Figure 6: Differences of BLEU score between online and offline of EnKo wait-k models.

are constructed by a professional interpreter under a simulated simultaneous interpretation scenario and the offline references are constructed by the same interpreter assuming a typical translation scenario. In construction of online references interpreter was encouraged to perform monotonic interpretation rather than anticipation. BLEU scores are computed with both online and offline references for each trained model. Figure 6 plot the subtraction of BLEU scores on offline references from BLEU scores on online references. It is noticeable that the wait-k models trained on offline corpus have negative value while all the models trained on generated corpus present positive values, which implies the effectiveness of our approach. Overall, the substantial differences at $k = 6$ may suggest that the chunk size utilized by human interpreter has comparable value.

6 Related Work

Due to word order differences between languages, SimulMT training often face situations where anticipation is required. Note that word order difference is observed to be problematic even for human interpreters (Al-Rubai'i, 2004; Tohyama and Matsubara, 2006). Chen et al. (2020) suggest using pseudo-references which involve utilizing wait-k inference output to limit "future anticipation" in training. Zhang et al. (2020b) utilize NMT teachers to implicitly embed future information in their SimulMT students for better anticipation performance. Zhang et al. (2020a) study adaptive policy to tackle this problem - authors suggest an adaptive SimulMT policy that dictate READ/WRITE actions based on whether "meaningful units" are fully formed with consumed input tokens.

Related work in the broader SimulMT and para-

phrasing domain is presented in Appendix F.

7 Conclusion

Most of SimulMT models are trained on offline translation corpora, which could lead to limitation in translation quality and achievable latency, especially in non-monotonic language pairs. To address this problem, we propose a reordering-and-refinement algorithm to generate monotonically aligned online target with NAT model. We then train widely used wait-k SimulMT models on this newly generated corpus. Resulting models show BLEU score improvement and significant enhancement on monotonicity in multiple language pairs.

A Dataset Details

All utilized texts regarding English-to-Korean and German-to-English directions are first tokenized with Moses (Koehn et al., 2007), then per-language BPE vocabularies are learned on the moses-tokenized trainset. The sizes of the vocabularies are 29k BPE English vocabulary and 44k BPE Korean vocabulary for English-to-Korean and 16k BPE German vocabulary and 16k BPE English vocabulary for German-to-English. The English-to-Japanese texts are first moses-tokenized. And KyTea[5] is applied to additionally tokenize Japanese texts. Separate English and Japanese vocabulary of size 32K is trained on tokenized training data using Sentencepiece (Kudo and Richardson, 2018). For English-to-Chinese training, no moses-tokenization is applied and Chinese sentences are tokenized using Jieba[6]. Separate English and Chinese vocabulary of size 32K is trained on training pairs using sentencepiece. The in-house EnKo data consists mainly of the AIHub EnKo offline translation corpus[7], news domain translation data, in-house proprietary patent data, and translated dialogue data of general domain.

B Additional Implementation Details

Our implementation is based on fairseq (Ott et al., 2019), and all GPUs used are V100s. The alignment information used in reordering process is extracted with GIZA++ (Och and Ney, 2003). The alignment information used to evaluate monotonicity is extracted using fast-align (Dyer et al., 2013). The alignments are measured in subword level. Embedding weights are separately learned for source and target languages, while transposed target language embedding weights also works as linear projection layers at the top of transformer decoders.

C Reporting AlignAw + NAT Scores

The AlignAw + NAT wait-k models are trained on different variations of AlignAw + NAT corpora - AlignAw + NAT corpora generated with prefixes fixed (**b0**), and with alterable prefixes (**b1**), and combination of **b0** and **b1** filtered using BertScore (**b0b1**). The reported AlignAw + NAT testset BLEU scores are of the wait-k models that show highest BLEU score on validset regardless of the dataset variations.

EnKo Wait-k	k=4	k=6	k=8	k=10
Offline	10.9/18	12.1/12	12.6/7	12.8/4
Pseudo Refs	11.2/19	11.6/13	12.2/9	13.3/5
Fixed + NAT	11.2/12	12.3/8	13.5/5	13.7/3
AlignAw + NAT	11.4/9	12.8/6	12.7/3	12.9/2

Table 4: BLEU scores/k-AR% of EnKo wait-k models.

D Comparison with Test Time wait-k Refs

In recent work, Chen et al. (2020) propose a method of pseudo-references generated with test time wait-k decoding. We apply their method in EnKo to create pseudo references for $k \in \{4, 6, 8, 10\}$ and train wait-k model. The results are presented in Table 4. Similar to our monotonicity metric, this work also suggest k-anticipation rate (k-AR) as a metric of parallel corpora. We also measure and report our generated corpus with this metric. Compare to Offline and Pseudo Refs , we see that our AlignAw + NAT corpus significantly decrease k-AR and the models trained with AlignAw + NAT also show enhanced BLEU score in general.

E Examples of Paraphrased Targets

Figure 7 presents an example sentence of English to Korean in whole pipeline process. We first represent the source sentence and its two different target sentences, online and offline translation. As results of the reordering phase, for each method (i.e., fixed chunking and AlignAw chunking), we provide only one case: $k = 8$ in fixed chunking and $\delta_{src} = 2$ and $\delta_{tgt} = 2$ in AlignAw chunking. Figure 8 shows the final grid of AlignAw chunking in this example. We conduct the MOS evaluation with the result of refinement phase. MOS is the average of human-evaluated score by professional interpreters. In this evaluation, AlignAW + NAT shows the best performance than others. Moreover, we present the inference outputs of SimulMT models which are trained on generated monotonic corpus. In this case, results of our methods are better than the result of offline model. We also provide DeEn example in Figure 9.

F More Related Work

Simultaneous Translation: A fixed policy is used in (Dalvi et al., 2018) and (Ma et al., 2019) which train SimulMT models according to the predefined policy. In particular, the Wait-k strategy

proposed by (Ma et al., 2019) waits for k sub-words and alternates READ/WRITE based on the emission rate. Due to the deterministic feature of this schedule, the model can be easily implemented and trained. On the downside, anticipation from missing contents often fails to predict correct target tokens, and a fixed schedule could impede the model from speeding up or slowing down flexibly for source inputs. There are several works of SimulMT with many variants of the Wait-k approach. For example, (Caglayan et al., 2020) explores whether additional visual context can complement missing source information. Furthermore, in (Zheng et al., 2020b), the opportunistic decoding technique is introduced which allows partial (certain length of suffix) corrections in a timely fashion. Finally, (Zheng et al., 2020a) extended the wait-k to an adaptive one by composing a set of fixed policies heuristically.

Upon the proposal by (Cho and Esipova, 2016), various adaptive policies have been suggested by several works including (Gu et al., 2017; Zheng et al., 2019a,b; Arivazhagan et al., 2019; Ma et al., 2020). SimulMT proposed by (Cho and Esipova, 2016) use greedy decoding with heuristic waiting criteria to decide whether the model should read or emit, while (Gu et al., 2017) utilize a pre-trained model with a reinforcement learning agent that maximizes quality and minimizes latency. Advancing this work, (Alinejad et al., 2018) proposes to add a new action PREDICT that anticipate future source words. Recently, (Arivazhagan et al., 2019) use hard attention to schedule the policy and introduced new differentiable average lagging metrics which can be integrated into training losses, and (Ma et al., 2020) incorporate this work into the multi-headed Transformer model. Furthermore, (Zhang et al., 2020a) proposes an adaptive policy which learns to segment source input considering possible target output. Other researches including (Zheng et al., 2019a) use separately trained oracles in the supervision of extracted action sequence.

Paraphrase: Translation is one of more common approaches for paraphrase generation. Mallinson et al. (2017) explore pivoting (translating a source sequence to a pivot language, then to a target language) to generate paraphrases and assess correlation between original and paraphrased sentences. Back-translation has also been explored for paraphrase generation (Wieting et al., 2017; Iyyer et al., 2018). Other techniques, such as translating with oversampling strategy have also bee studied (Chada, 2020).

On the other hand, various NMT research employ paraphrased data to overcome data limitation. Edunov et al. (2018) show that source-paraphrased corpus generated with back-translation can significantly improve BLEU scores in NMT tasks. Similarly, Khayrallah et al. (2020) directly implements paraphrasers in NMT training to improve translation quality.

Simultaneous Neural Machine Translation with Constituent Label Prediction

Abstract

Simultaneous translation is a task in which translation begins before the speaker has finished speaking, so it is important to decide when to start the translation process. However, deciding whether to read more input words or start to translate is difficult for language pairs with different word orders such as English and Japanese. Motivated by the concept of pre-reordering, we propose a couple of simple decision rules using the label of the next constituent predicted by incremental constituent label prediction. In experiments on English-to-Japanese simultaneous translation, the proposed method outperformed baselines in the quality-latency trade-off.

1 Introduction

Simultaneous machine translation is a task in which the machine starts outputting a translation before reading the entire input sentence. This task is more difficult than full-sentence translation because it translates the initial part of a sentence without the context of the latter part. This involves a trade-off between delay and quality of the translation; using a longer context should improve translation quality at the cost of a longer delay, and vice versa. In practice, we should control the latency so that it's not too large, but we may also need to allow a long latency depending on the situation.

Most of the recent simultaneous translation models (Ma et al., 2019; Arivazhagan et al., 2019; Raffel et al., 2017; Arivazhagan et al., 2019; Ma et al., 2020b; Dalvi et al., 2018; Gu et al., 2017; Alinejad et al., 2018; Cho and Esipova, 2016; Zheng et al., 2020, 2019; Zhang et al., 2020) are based on neural machine translation (NMT), although earlier studies were based on statistical machine translation (Rangarajan Sridhar et al., 2013; Grissom II et al., 2014; Oda et al., 2014, 2015). In simultaneous NMT, there are two major approaches: those in which a latency hyperparameter is given before the training and those in which it is given at the time of inference.

The former approach requires training a model individually for each pre-defined latency setting, while the latter approach uses a single model for different latency conditions. Most human simultaneous interpreters would not need such long training to slightly adjust latency, while it takes much more time to learn other languages to develop their translation skill. Therefore, the latter approach is closer to the learning process of human simultaneous interpreters.

wait-k (Ma et al., 2019) is a simple simultaneous NMT method of the former approach that waits k tokens before starting to translate. It also has variants within the latter approach called test-time wait-k, in which k is determined at the inference time. wait-k had better performance than test-time wait-k in that study's experiments.

There is another method in the latter approach that uses Meaningful Unit (Zhang et al., 2020). In this model, chunk-based incremental decoding is done at inference time by segmentation with a boundary predictor. This model outperformed baselines of the former approach. They refined their basic boundary predictor to deal with sentence pairs in which full-sentence translation needs long-distance reordering. However, its training process is very complicated: It first generates monotonic translations, fine-tunes the NMT model with them, then generates an oracle boundary with the model, and finally fine-tunes a boundary-prediction model based on BERT (Devlin et al., 2019).

Simultaneous translation is still difficult for language pairs such as English-Japanese, which often require long-distance reordering. To tackle the reordering problem, we propose an input-segmentation method for simultaneous translation, using a couple of simple rules and incremental prediction of the label of a syntactic constituent coming immediately after the input existing so far. This

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1124–1134

Source sentence	I **bought** *a pen*.
Monotonic translation	watashi wa **katta** *pen wo*.
Full-sentence translation	watashi wa *pen wo* **katta**.

Table 1: Translation from English (SVO) to Japanese (SOV)

Boundary prediction	I / **bought** *a pen*.
Simultaneous translation	watashi wa / *pen wo* **katta**.

Table 2: Example of English-to-Japanese translation using proposed method with segment-boundary prediction

is not dependent on the trained NMT. Therefore, once we create it, it is reusable for other models.

Our proposed method is inspired by Head Finalization (Isozaki et al., 2010). Head Finalization reorders words of the source sentence before translating from an SVO (Subject-Verb-Object) language to an SOV language in full-sentence statistical machine translation. This method moves a syntactic head into a later position so that the word order of the source language (e.g., English) becomes similar to that of the target language (e.g., Japanese). This enables us to monotonically translate from English, which is a typical SVO language, to Japanese, a typical SOV language.

Recent NMT models like Transformer (Vaswani et al., 2017) works well on reordering in general, so this kind of pre-reordering is not usually used. However, simultaneous translation monotonically reads input words one by one, and therefore the difference in word order remains a problem. As shown in Table 1, monotonic translation often becomes unnatural compared to full-sentence translation. The part "bought a pen" should be translated to *pen wo katta* by reversing the word order. Therefore, after reading the word "bought," it is important to wait for future words without starting to translate it. In this case, "I" is the last word that does not require reordering. This word is regarded as a segment boundary to start a partial translation.

Table 2 shows an example of our proposed segmentation. Suppose we predict the next constituent label as a verb phrase (VP) after reading an input word "I." This shows the possibility that the next words should be reordered, so the "I" becomes the boundary. Once detecting the boundary, NMT model starts to translate "I" into "watashi wa." After that, the model restarts to read the remaining input words, then translates "bought a pen" into "pen wo katta." The total output of simultaneous translation based on the proposed segmentation is the same as that of full-translation in this simple example. By ensuring that the Verb and its Object of the source sentence are included in a single segment, it is possible to output translation while maintaining the SOV-like structure of the target language.

In experiments on English-to-Japanese simultaneous translation, the proposed method outperformed baselines in the quality-latency trade-off.

2 Related work

In statistical machine translation, there are several approaches to finding boundaries of segments for simultaneous translation. Oda et al. (2014) proposed a method to choose segment boundaries that maximize the BLEU score. Rangarajan Sridhar et al. (2013) proposed segmentation strategies based on lexical cues.

In NMT, there have been many studies on simultaneous translation. The amount of latency is decided either before training or at inference time. wait-k (Ma et al., 2019) is the simplest variant using fixed latency: It simply waits for k tokens before starting translation (Ma et al., 2019). The latency policy can be learned from a parallel corpus together with an NMT model. MILk (Arivazhagan et al., 2019) and other approaches (Raffel et al., 2017; Ma et al., 2020b) used a latency-augmented loss function in training to balance latency and accuracy.

In contrast, the latency policy can be learned with a pre-trained NMT model, such as test-time wait-k (Ma et al., 2019) and STATIC-RW (Dalvi et al., 2018). These have fixed policies that wait for the fixed number of tokens before translation, but there are other models that learn a more flexible policy for a given pre-trained NMT model. Some studies use reinforcement learning to learn an adaptive READ/WRITE policy (Grissom II et al., 2014; Satija and Pineau, 2016; Gu et al., 2017; Alinejad et al., 2018). Training by reinforcement learning can be unstable depending on the condition. One

method that does not use reinforcement learning is wait-if-* (Cho and Esipova, 2016), which translates and segments jointly to maximize the translation quality. Zheng et al. (2020) extended wait-k to an adaptive policy by adaptively choosing the strategy at inference. There is another method that generates oracle READ/WRITE actions by a pre-trained NMT model and predicts actions using a neural network model (Zheng et al., 2019). Meaningful Unit (Zhang et al., 2020) works along the same lines and has outperformed baselines such as MILk and wait-k.

With respect to the use of syntactic clues for simultaneous translation, Oda et al. (2015) proposed a method to incrementally parse an incomplete sentence by predicting unseen syntactic constituents on the right and left side of each segment. They concatenated the predicted constituents and the words in a segment and then input the result into tree2string translation. They decided to wait for more tokens or output the translation depending on where the constituents appear in the translation result.

Our proposed method is based on chunk-based simultaneous translation using chunk boundary detection with simple rules on next-constituent labels. It basically segments an input before a verb phrase. This is much simpler and easier to implement than the work by Zhang et al. (2020) and Oda et al. (2015).

3 Proposed Method

Figure 1 shows a step-by-step example of our proposed method described in this section.

3.1 Standard Simultaneous Translation

A standard NMT for full sentences is represented by the following equation:

$$p_{full}(Y|X) = \prod_{t=1}^{|Y|} P(y_t|X, y_{<t}), \quad (1)$$

where $X = x_1, x_2, ..., x_n$ is an input sentence consisting of n tokens and $Y = y_1, y_2, ..., y_m$ is a predicted target language sentence consisting of m tokens.

A simultaneous NMT uses only a prefix of the input to predict a target language token:

$$p_{simul}(Y|X) = \prod_{t=1}^{|Y|} P(y_t|x_{g(t)}, y_{<t}), \quad (2)$$

where $g(t)$ is a monotonic non-decreasing function representing the number of read source tokens to output the tth target token.

3.2 Chunk-based Simultaneous Translation

We use chunk-based incremental decoding for our simultaneous translation model and a full-sentence NMT model trained in a standard manner. However, at the time of inference, we translate the current prefix upon chunk segmentation while keeping the previously translated output unchanged.

Suppose we have already translated input chunks $\boldsymbol{X}^{i-1} = X_1, X_2, ..., X_{i-1}$ into an output prefix also represented by chunks: $\widetilde{\boldsymbol{Y}}^{i-1} = \widetilde{Y}_1, \widetilde{Y}_2, ..., \widetilde{Y}_{i-1}$, while translating the next input chunk X_i into $\widetilde{Y}_i$. We restart the translation from the beginning using all of the available input chunks X_1^i. This is similar to an approach called *re-translation* that generates translations from scratch for every new input word (Niehues et al., 2016; Arivazhagan et al., 2020), but we apply forced decoding to $\widetilde{\boldsymbol{Y}}^{i-1}$ in the output prefix. The probability of the prefix $\widetilde{\boldsymbol{Y}}^{i}$ can be denoted as follows:

$$p_{prefix}(\widetilde{\boldsymbol{Y}}^i|\boldsymbol{X}^i) = p_{full}(\widetilde{\boldsymbol{Y}}^{i-1}|\boldsymbol{X}^i) \times p_{chunk}(\widetilde{Y}_i|\boldsymbol{X}^i, \widetilde{\boldsymbol{Y}}^{i-1}). \quad (3)$$

The first term is calculated in the same way as the standard full-sentence NMT in Eq. (1) through forced decoding, and the second term is decomposed as follows, letting $\widetilde{Y}_i = y_1^i, y_2^i, ..., y_{|\widetilde{Y}_i|}^i$:

$$p_{chunk}(\widetilde{Y}_i|\boldsymbol{X}^i, \widetilde{\boldsymbol{Y}}^{i-1}) = \prod_{t=1}^{|\widetilde{Y}_i|} P(y_t^i|\boldsymbol{X}^i, \widetilde{\boldsymbol{Y}}^{i-1}, y_{<t}^i). \quad (4)$$

This can be more efficient than an incremental Transformer (Ma et al., 2019) that refreshes the encoder for every input word, since our chunk-based translation refreshes the encoder for every input *chunk*, which usually consists of multiple words.

3.3 Chunk Segmentation

We use constituent labels for our rule-based chunk segmentation as follows.

3.3.1 Incremental Constituent Label Prediction

We predict the label of a syntactic constituent coming after a sentence prefix at the current time-step. We call this process *Incremental Constituent Label Prediction* (ICLP). Here, we define this *next*

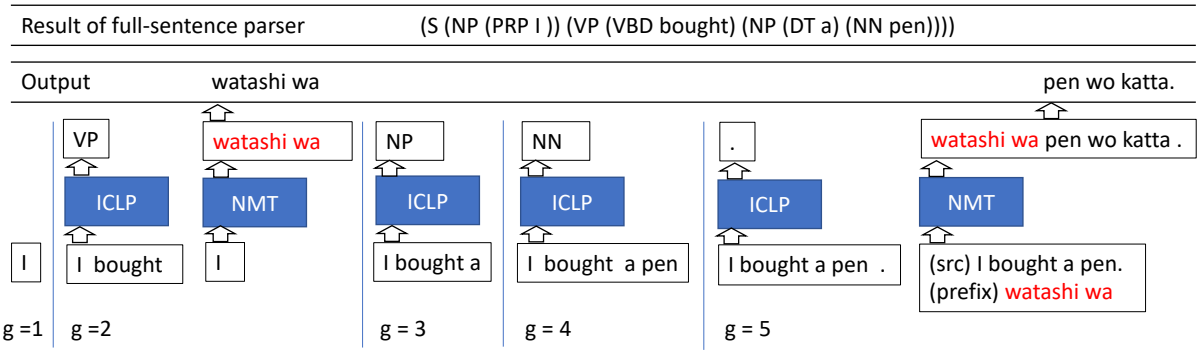

Figure 1: One look-ahead ICLP gives constituent labels. When a boundary is detected based on the label and rules, NMT starts to translate the source subsequence. The previous translation, which is red in the figure, is used as prefix words for the next translation. EOS is omitted for simplicity in the figure.

segmentation	You	/ can	save	time	by	/ doing	this	.
constituent label		VP	VP	NP	PP	S	NP	.
syntax tree	(S (NP (PRP You)) (VP (MD can) (VP (VB save) (NP (NN time)) (PP (IN by) (S (VP (VBG doing) (NP (DT this))))))) (. .))							

Table 3: Example result of one look-ahead ICLP with a minimum segment size of one.

constituent as the one coming next to the sentence prefix in pre-order tree traversal. However, this label prediction is not easy without observations on the next constituent. In this work, we allow one look-ahead, where we read one more word and predict the label of the constituent starting from that word. This causes an additional delay by one word but improves the prediction accuracy. Suppose we have an input sequence $W = [w_1, w_2, ..., w_{|W|}]$. The one look-ahead ICLP predicts the constituent label c_i upon the observation of w_i, as follows:

$$c_i = \underset{c' \in C}{\operatorname{argmax}}\, p(c' | w_{\leq i}), \quad (5)$$

where C is a set of constituent labels. Only a prefix word subsequence is fed into the ICLP, so previous label predictions do not affect later ones.

We can train the ICLP model as a multi-class classifier using a set of training instances in the form of prefix-label pairs. One sentence generates several instances for training data: (w_1, c_1), (w_1, w_2, c_2), (w_1, w_2, w_3, c_3), $(w_1, w_2, w_3, w_4, c_4)$, and so on. We implemented the ICLP model in two different ways using LSTM (Hochreiter and Schmidhuber, 1997) and BERT (Devlin et al., 2019).

3.3.2 Segmentation Rules

Table 3 shows an example of a result by the one look-ahead ICLP. We use one basic and two supplemental rules for chunk segmentation as follows.

- Segment the input coming just before constituents labeled `S` and `VP`.
- If the previous label is `S` or `VP`, do not segment the input.
- If the chunk is shorter than the minimum length, do not segment the input.

In incremental translation from *Subject-Verb-Object* to *Subject-Object-Verb*, the subject can be translated before observing the verb coming next, but the verb should be translated after observing the object. Therefore, the chunk boundary should be between the subject and verb, not between verb and object. To achieve this, we employ a simple rule to segment a chunk just before `VP`. We also include `S` in the rule just as with `VP` because `S` (simple declarative clause) often appears in the form of a unary branch "(`S` (`VP` ...))" as shown in Table 3.

However, in cases such as "can save" in the example, `VP` occurs again immediately after the segmentation before "can." The basic rule suggests segmentation before "save," but it does not seem appropriate. Therefore, we introduce the minimum segment size to avoid such over-segmentation as a hyperparameter to control the accuracy-latency trade-off. If the hyperparameter is larger than one, the chunk segmentation after "You" in the example does not occur.

4 Experimental setup

4.1 Dataset and preprocessing

We conducted experiments on English-Japanese (En-Ja) translation. We also tried English-German (En-De) translation to investigate the difference in language pairs.

For En-Ja, the model was trained on 17.9 M sentence pairs from WMT2020 and fine-tuned on 223 K sentence pairs from IWSLT2017. We used 5312 sentence pairs for the development set from dev2010, tst2011, tst2012, and tst2013 of IWSLT. We evaluated the model on 1442 sentence pairs from dev2021 of IWSLT.

For En-De, the model was trained on 4.5 M sentence pairs from WMT2014 and fine-tuned on 206 K sentence pairs from IWSLT2017. We used 5589 sentence pairs for the development set from dev2010, tst2011, tst2012, and tst2013 of IWSLT. We evaluated the model on 1,080 sentence pairs from tst2015 of IWSLT.

We tokenized English and German sentences with `tokenizer.perl` in Moses (Koehn et al., 2007) and Japanese sentences with MeCab (Kudo, 2005). For each language pair, we used subwords based on Byte Pair Encoding (BPE) (Sennrich et al., 2016) with a shared vocabulary of 16 K entries. To develop the subword vocabulary, we used all of the in-domain training sentences (IWSLT) and one million out-of-domain sentences (WMT).

We trained the ICLP models using Penn Treebank 3 (Marcus et al., 1993) for training, excluding a randomly selected one percent of sentences reserved for the development set. We used NAIST-NTT TED Talk Treebank (Neubig et al., 2014) for the evaluation set. The number of training, development, and test instances (e.g., the number of labels to be predicted) were 2.8 M, 27.9 K, and 21.9 K, respectively. Note that multiple ICLP instances are induced from what a single parse tree generates.

4.2 Model settings

We compared the following four models. All of them were based on the Transformer-base (Vaswani et al., 2017).

wait-k
: The range of `k` is [2, 4, 6,..., 30].

Meaningful Unit
: The hyperparameter is `p`, which is the threshold of the probability of a boundary. The ranges of `p` are [0.5, 0.1, 0.15,..., 0.95], [0.99, 0.991, 0.992,..., 0.999], and [0.9991, 0.9992,..., 0.9999]. Monotonic translation of Meaningful Unit was generated from the fine-tuning dataset by the fine-tuned NMT model. We used their refined Meaningful Unit method, which improved the translation quality at low latency (Zhang et al., 2020)[1]. They used a two look-ahead boundary predictor in their experiments. We additionally tried a one look-ahead predictor because it is not certain how many future words should be used for the predictor.

Fixed-size segmentation
: This simply segments an input with a fixed length specified by a hyperparameter `f`, which means the boundary comes every `f` subwords or words. The range of `f` is [2, 4, 6,..., 30] for words and [4, 8, 12,..., 60] for subwords.

ICLP
: The hyperparameter is `m`, which means the minimum number of words in one segment. The range of `m` is [1, 2, 3, . . . , 29].

We controlled hyperparameters to adapt to a wide range of latency. The hyperparameter is given both in the training and at the inference time for wait-k, but it is given only at the inference time for other models. Therefore, we trained the wait-k model for each `k` while in other approaches a single NMT model is commonly used.

We used fairseq (Ott et al., 2019) to implement these models and basically followed the official baseline for IWSLT 2021[2,3] to set the hyperparameters. We saved checkpoints every 5000 updates for pre-training and every 200 updates for fine-tuning. Other hyperparameters were the same for pre-training and fine-tuning. We stopped training early with patience 4. The max-tokens for the mini batch size was 4096, and weights were updated

[1] Zhang et al. (2020) removed the monotonic translations with a lower score than full-sentence translation. However, it is rare for a monotonic translation to have a higher score than full-sentence translation. Consequently, few sentences remained in our setting. Therefore, we improved the translation quality by preventing over-translation instead of removing it. Once the same words are output four times continuously or the target length becomes four times longer than the source length, we expand the source prefix.

[2] https://github.com/pytorch/fairseq/blob/master/examples/simultaneous_translation/docs/enja-waitk.md

[3] https://github.com/pytorch/fairseq/issues/346

every 4 mini batches. We set the learning rate to 0.0007 and trained the model on a single GPU. The last three models used the same NMT model. We used beam search within chunks in a standard way and chose 1-best hypotheses at the end of chunk translation. The beam size was four for the chunk-based and full-sentence models. We used greedy decoding for wait-k.

We implemented two types of ICLP models as mentioned earlier. For the LSTM-based ICLP, we used two-layered unidirectional LSTMs to encode an input sentence with a fully connected layer for the constituent label prediction. The numbers of dimensions for embedding and hidden states are 512. We tokenized English sentences using `tokenizer.perl` in Moses and Byte Pair Encoding (Sennrich et al., 2016) with a vocabulary of 16 K entries. For the BERT-based ICLP, we used a BERT-based classifier with an additional fully connected layer over the `[CLS]` token, implemented using Huggingface transformers (Wolf et al., 2020) with a pre-trained model `bert-base-uncased` and the corresponding subword tokenizer. For both models, the input was a subword sequence, so the constituent label prediction was made upon the observation of an *end-of-word* subword. The following training conditions were commonly applied to both models: learning rate of 5e-5, training batch size of 512 instances, checkpoints saved at the end of every epoch, and early stopping with the patience of three epochs.

4.3 Evaluation

We used SimulEval (Ma et al., 2020a) to evaluate the quality and latency of simultaneous translation. BLEU (Papineni et al., 2002) was used to evaluate quality. We used Average Lagging (AL) (Ma et al., 2019) to evaluate the latency. AL is widely used and defined by the following equation:

$$AL_g(X, Y) = \frac{1}{\tau_g(|X|)} \sum_{t=1}^{\tau_g(|X|)} g(t) - \frac{t-1}{\gamma}. \quad (6)$$

$\tau_g(|X|)$ is the decoding step when the source sentence finishes. It counts latency up to the $\tau_g(|X|)$ th target token predicted just after reading the final source token. γ is defined as $|Y|/|X|$. When the source length $|X|$ equals target length $|Y|$, AL of wait-k equals its k. In this experiment, the latency was calculated on character level for En-Ja, and word level for En-De.

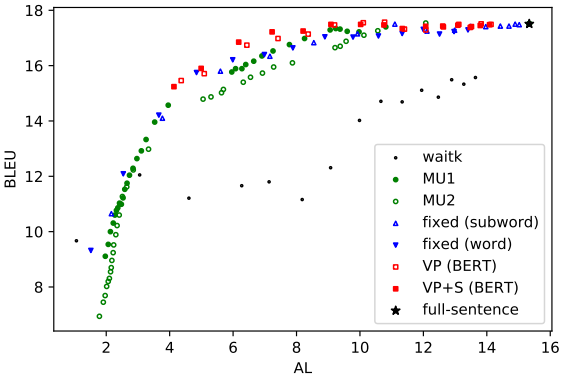

Figure 2: Scatter plot of BLEU and AL (En-Ja). MU1 and MU2 correspond to Meaningful Unit with one and two look-ahead respectively.

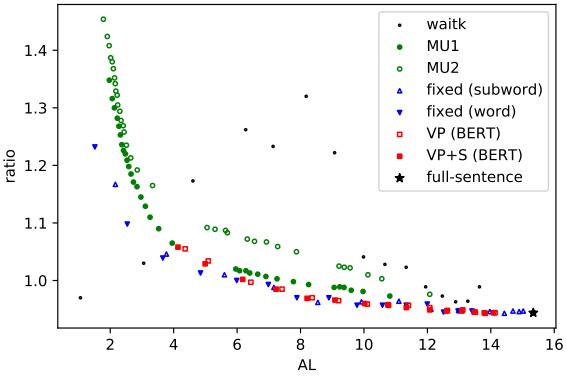

Figure 3: Scatter plot of length ratio and AL (En-Ja)

4.4 Results

We illustrate the results of English-Japanese translation in Figure 2. Our proposed method outperformed baselines in a wide range of AL. Most of the points of the proposed method appear to the upper-left of the other methods, thus showing the best performance. We compared the use of segmentation rules based on `VP` and `VP+S`. The points shifted to the left by adding `S` as boundary because it increased the number of boundaries and decreased latency. Although we tried the different look-ahead lengths of one and two for the boundary predictor of Meaningful Unit, our proposed model outperformed both of these models in a wide range of latency.

The difference between wait-k and the models using the full-sentence translation model was large in the quality-latency trade-off. Surprisingly, the fixed-size segmentation was also effective. When the segment size was fixed, it did not make a large

difference in the result, regardless of whether the unit was a subword or a word.

5 Analysis

5.1 Length ratio

Figure 3 shows the length ratios of translation hypotheses and references with different latency parameters. Too large a ratio decreases the BLEU score and makes the content delivery difficult both in text (subtitles) and speech (text-to-speech).

The length ratio of wait-k was unstable compared to other models because it was trained individually for each k.

Except for wait-k, the length ratios were large in the range of small latency, probably due to the condition mismatch between training and inference. These NMT models were trained on full sentences, but they were used to translate short segments in the inference. Therefore, they tend to output longer segment translations than expected. Their ratios gradually decrease as AL increases and the length of segments becomes closer to the length of full sentences.

5.2 Segment length distribution

Figures 4,5 and 6 show the distributions of source segment length in the En-Ja test set for which AL is close to 7.2. Table 4 shows their corresponding AL and BLEU of each model. The length was calculated as the number of subwords in a segment, and the previous segment was concatenated to the next segment when the previous segment has no translation output.

Segmentation with fixed size 16 has some segments shorter than size 16 because the sentence length is not always a multiple of 16.

Compared with ICLP model, Meaningful Unit has wider distribution, and the most segments consist of two subwords. These short segments have less context information and can output longer segment translation than expected. This would be one of the reason why our proposed method outperformed Meaningful Unit.

5.3 Controlling latency

In Figures 7 and 8, each plot is labeled by the corresponding value of the hyperparameter of inference. It is difficult to control latency for Meaningful Unit as shown in the figure. BLEU scores of hyperpa-

S	0.77	0.62	0.69

Table 7: Results of label prediction (BERT) without look-ahead

rameters from 0.9996 to 0.9999 were also the same as that of a full-sentence translation model.

In contrast, our proposed method can easily control latency because it uses the minimum chunk length as an intuitive hyperparameter to adjust it.

5.4 How many words to wait

Compared with the fixed-size segmentation model, our proposed model and Meaningful Unit have a disadvantage in AL, which is caused by the look-ahead approach. Despite this disadvantage, our proposed approach outperformed the fixed-size segmentation in a wide range of AL. This means the benefit of looking at the future words and finding a better boundary outweighed the above disadvantage.

5.5 Performance of ICLP

Tables 5 and 6 show the results in precision and recall of the one look-ahead ICLP models. The LSTM-based ICLP was better in precision, but the BERT-based ICLP was better in recall for `VP`. Figure 9 compares them in the downstream simultaneous translation. The lines connected by dots nearly overlapped, so there was no large difference in BLEU score. LSTM is more efficient than BERT in incremental processes, so it is suitable for practical usage.

Table 7 shows the results by the ICLP model without one look-ahead approach. Compared with Table 5, the scores are much lower. One look-ahead approach was important to improve its performance.

5.6 En-De translation

We conducted additional experiments in En-De translation to investigate the performance in a different language. German is another language with different word order from English especially in verbs and also suffers from the reordering problem. Figure 10 shows the results. This is almost the opposite of the results of the En-Ja translation. The

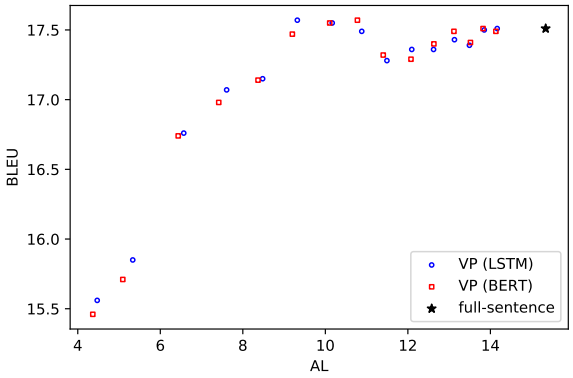

Figure 9: Comparison between the use of LSTM- and BERT-based ICLP

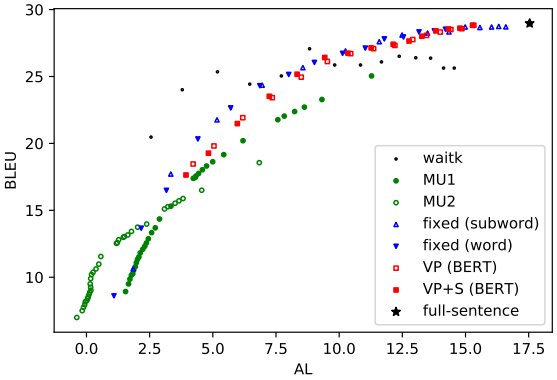

Figure 10: Scatter plot of BLEU and AL (En-De)

proposed boundary decision rules used for En-Ja translation were not so effective for En-De translation, so we need to find other rules to detect boundaries in En-De translation.

6 Conclusion

We proposed a novel segmentation method for simultaneous translation that uses simple rules and ICLP. Our proposed method is simple, and it outperformed the baselines in the quality-latency trade-off in En-Ja translation. On the other hand, the proposed method did not work effectively in En-De translation due to the smaller word order differences than those in En-Ja translation.

In future work, we expect to extract segmentation rules automatically and apply these rules to other language pairs as well.

Abstract

Context-aware neural machine translation (NMT) incorporates contextual information of surrounding texts, that can improve the translation quality of document-level machine translation. Many existing works on context-aware NMT have focused on developing new model architectures for incorporating additional contexts and have shown some promising results. However, most existing works rely on cross-entropy loss, resulting in limited use of contextual information. In this paper, we propose CorefCL, a novel data augmentation and contrastive learning scheme based on coreference between the source and contextual sentences. By corrupting automatically detected coreference mentions in the contextual sentence, CorefCL can train the model to be sensitive to coreference inconsistency. We experimented with our method on common context-aware NMT models and two document-level translation tasks. In the experiments, our method consistently improved BLEU of compared models on English-German and English-Korean tasks. We also show that our method significantly improves coreference resolution in the English-German contrastive test suite.

1 Introduction

Neural machine translation (NMT) has achieved impressive performances on translation quality, due to the introduction of novel deep neural network (DNN) architectures such as encoder-decoder model (Cho et al., 2014; Sutskever et al., 2014), and self-attentional networks like Transformer (Vaswani et al., 2017). The state-of-the-art NMT systems are now even comparable with human translators in sentence-level performance.

However, there are a number of issues on document-level translation (Läubli et al., 2018). These include pronoun resolution across sentences (Guillou et al., 2018), which needs cross-sentential contexts. To incorporate such document-level contextual information, several methods for context-aware NMT have been recently proposed. Many of the works have focused on introducing new model architectures like multi-encoder models (Voita et al., 2018) for encompassing contextual texts of the source language. These works have shown significant improvement in addressing discourse phenomena such as anaphora resolution mentioned above, as well as moderate improvements in overall translation quality (Lopes et al., 2020).

Despite some promising results, most of the existing works have trained the model by minimizing cross-entropy loss, making the model rather exploit contextual information implicitly such as a form of regularization (Kim et al., 2019; Li et al., 2020). Data augmentation for context-aware NMT is also an important issue, despite that recent works have focused on back-translation (Huo et al., 2020).

In this paper, we propose a Coreference-based Contrastive Learning for context-aware NMT (CorefCL), a novel data augmentation and contrastive learning scheme leveraging coreference information. Cross-sentential coreference between the source and target sentence can be a good source of training signal for context-aware NMT since it occurs when one or more expressions refer to the same entity, thus reflects dependencies between the source and contextual sentences.

CorefCL starts by conducting automatic annotation of coreference between the source and contextual sentences. Then, the referred mentions on contextual sentences are corrupted by removing and/or replacing tokens to generate contrastive examples. With those contrastive examples, we introduce a contrastive learning scheme equipped with a max-margin loss which encourages the model to discriminate between the original examples and the contrastive ones. By doing so, CorefCL makes the model more sensitive to cross-sentential contextual information.

Proceedings of the Sixth Conference on Machine Translation (WMT), pages 1135–1144
November 10–11, 2021.

We experimented with CorefCL on three English-German corpora and one English-Korean document-level corpus, including WMT, IWSLT TED talk, and OpenSubtitles'18 English-German subtitles translation task, and a web-crawled English-Korean subtitles translation. In all translation tasks, CorefCL consistently improves overall BLEU over baseline models without CorefCL. On experiments with three common context-aware model settings, we show that improvements by CorefCL are also model-agnostic. Finally, we show that the proposed method significantly improved the performance on ContraPro (Müller et al., 2018), an English-German contrastive coreference benchmark.

2 Related Works

2.1 Context-aware NMT

Context-aware machine translation has been vigorously studied to exploit the crucial context information in surrounding sentences. Recent works have shown that contextual information can help the model to generate not only more consistent but also more accurate translation (Smith, 2017; Voita et al., 2018; Müller et al., 2018; Kim et al., 2019).

In particular, Voita et al. (2018) introduced a context-aware Transformer model which is able to induce anaphora relations, Miculicich et al. (2018) showed that a model using cross-sentential contextual information significantly outperforms in document-level translation tasks, and Yun et al. (2020) insisted that context-aware models record the best performance especially in spoken language translation tasks where mandatory information tend to be sparse over multiple sentences.

The simplest method for context-aware machine translation is to concatenate all surrounding sentences and treat the concatenated sequence as a single sentence (Tiedemann and Scherrer, 2017). Although the concatenation strategy boosted Transformer architectures in multiple tasks (Tiedemann and Scherrer, 2017; Voita et al., 2018; Yun et al., 2020), it lagged behind efficiency as the Transformer architecture has limited long-range dependency (Tang et al., 2018).

To improve the efficiency, an additional encoder module is introduced to encode only the context sentences (Libovický and Helcl, 2017; Jean et al., 2017; Voita et al., 2018). Additionally, hierarchical structures also have been introduced because the context sentences do not have the same significance as the input sentences (Miculicich et al., 2018; Yun et al., 2020).

2.2 Coreference and NMT

The difference in coreference expressions among languages (Zinsmeister et al., 2017; Lapshinova-Koltunski et al., 2020) gives MT systems a challenge on pronoun translation (Bawden et al., 2018). Several recent works have attempted to incorporate coreference information (Ohtani et al., 2019). The closest work to ours is (Stojanovski and Fraser, 2018) which also adds noise on creating a coreference-augmented dataset, while we do not add oracle coreference information directly to the training data.

2.3 Data augmentation for NMT

One of the most common methods for data augmentation in NMT is back-translation that generates pseudo-parallel data from monolingual corpora using intermediate NMT models (Sennrich et al., 2016a). Generally, back-translation is conducted at sentence-level, however, several works have proposed document-level back-translation (Sugiyama and Yoshinaga, 2019; Huo et al., 2020).

On the other hand, sentence corruption by removing or replacing word(s) has also been widely used for improving model performance and robustness (Lample et al., 2018; Voita et al., 2019). Inspired by these works, we choose sentence corruption for contrastive learning.

2.4 Contrastive Learning

Contrastive learning is to learn a representation by contrasting positive and negative (contrastive) examples. It has succeed in various machine learning fields including computer vision (Chen et al., 2020) and natural language processing (Mikolov et al., 2013; Wu et al., 2020; Lee et al., 2021).

Recently, several approaches to contrastive learning for NMT have also been studied. Yang et al. (2019) proposed strategies for generating word-omitted contrastive examples and leveraging contrastive learning for reducing word omission errors in NMT. Pan et al. (2021) applied contrastive learning for multilingual MT and employed data augmentation for obtaining both the positive and negative training examples.

While these works have been conducted in sentence-level NMT settings, we focus on extending contrastive learning in context-aware NMT.

3 Context-aware NMT models

In this section, we briefly overview context-aware NMT methods and describe our baseline models which are also commonly adopted in recent works.

Generally, a sentence-level (context-agnostic) NMT model takes an input sentence in a source language and returns an output sentence in a target language. On the other hand, a context-aware NMT model is designed to handle surrounding contextual sentences of source and/or target sentences. We focus on leveraging the contextual sentences of the source language.

Throughout this work, we consider the Transformer (Vaswani et al., 2017) as a base model architecture by following the majority of the recent works on context-aware NMT. Transformer consists of a stack of self-attentional layers in which a self-attention module is followed by a feed-forward module for each layer. Here we list four Transformer-based configurations that we used in the experiments:

- **sent-level**: As a baseline, we have experimented with the basic Transformer model which does not use any contextual sentences.
- **concat**: This is a straightforward approach to incorporate contextual sentences without modifying the Transformer model (Tiedemann and Scherrer, 2017). This concatenates all contextual sentences and an input sentence with special tokens between sentences.
- **multi-enc**: This has an extra encoder for encoding contextual sentences separately. We follow the model introduced in (Voita et al., 2018) which obtain a hidden representation of contextual sentences by weight-shared Transformer encoder. The model combines the encoded source and context representations using a source-to-context attention mechanism and a gated summation.
- **multi-enc-hier**: To represent multiple contextual sentences effectively, hierarchical encoders for contextual sentences have been proposed (Miculicich et al., 2018; Yun et al., 2020). In this configuration, the context representation is calculated in token-level first, then finally processed in sentence-level. We experimented with the model of (Yun et al., 2020) in this paper.

All the model structures are described in Figure 1.

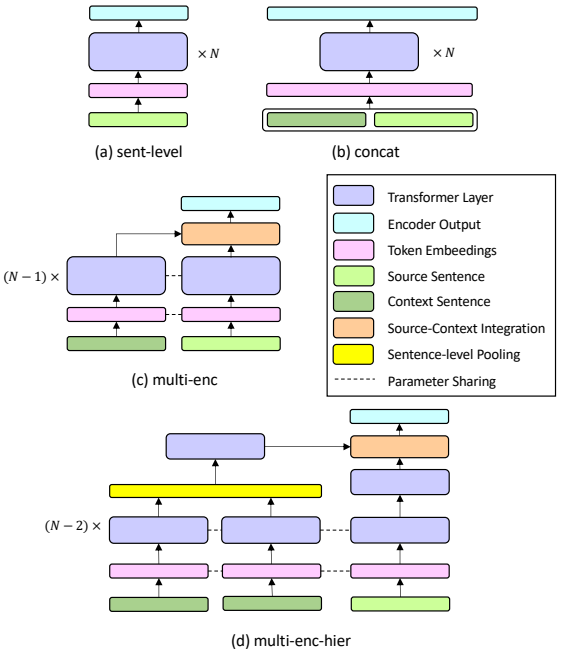

Figure 1: The structure of compared context-aware NMT models.

4 Our Method: CorefCL

In this section, we explain the main idea of CorefCL, a data augmentation and contrastive learning scheme leveraging coreference between the source and contextual sentences.

4.1 Data Augmentation Using Coreference

Generally, constrastive learning encourages a model to discriminate ground-truth and contrastive (negative) examples. In existing works, a number of approaches have been studied for obtaining contrastive examples:

- Corrupting the sentence by randomly removing or replacing one or more tokens in the sentence. (Yang et al., 2019)
- Choosing an irrelevant example in the batch or dataset. (Pan et al., 2021)
- Perturbations on representation space. Usually output vector of encoder or decoder is used. (Lee et al., 2021)

CorefCL basically takes a similar approach to the first one, by the sentence corruption. However, unlike previous works that modify the source sentence, CorefCL modifies the contextual sentences to form contrastive examples. Specifically, we corrupt cross-sentential coreference mentions which

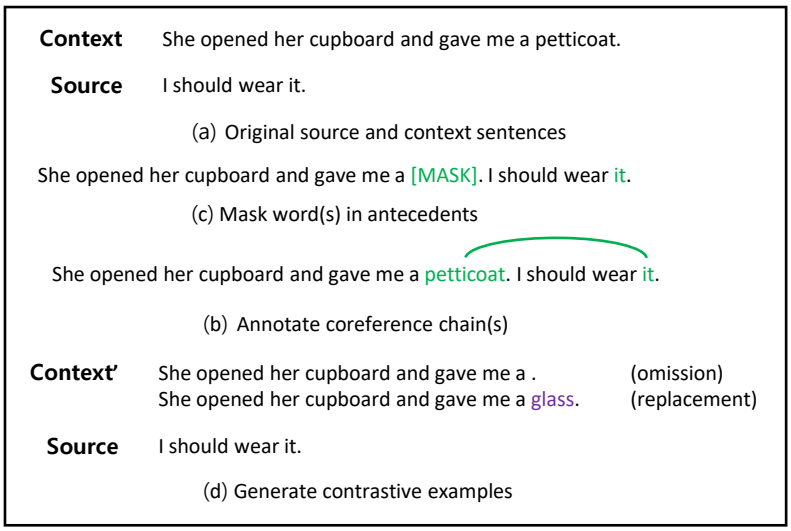

Figure 2: Data augmentation process of CorefCL.

occur between the source and its contextual sentences. This is based on the intuition that coreference is one of the core components of coherent translation.

More formally, steps to forming contrastive examples in CorefCL are as follows (see also Figure 2):

1. Annotate the source documents automatically. We use NeuralCoref[1] to identify the coreference mentions between the source and its previous sentences as contextual sentences

2. Filter the examples with cross-sentential coreference chain(s) between the source and contextual sentences. Around 20 to 30% of the training corpus is annotated in this way. See Section 5.1 for details

3. For each coreference chain, mask every word in the antecedents with a special token. We also keep the original examples for training

4. Masked words are replaced randomly with other words in vocabulary (*word replacement*), or omitted (*word omission*)

In the experiments, we take both of the corruption strategies. Precisely, the masked words are removed with a probability of 0.5, or randomly replaced otherwise. We found that this method is more effective compared to the methods using only one of the two corruption strategies. Please refer to the ablation study in Section 5.5 for more details.

[1]https://github.com/huggingface/neuralcoref

4.2 Contrastive Learning for Context-aware NMT

Context-aware NMT models can implicitly capture dependencies between the source and contextual sentences. CorefCL introduces a max-margin contrastive learning loss to train the model to explicitly discriminate inconsistent contexts. This contrastive loss also encourages a model to be more sensitive to the contents of contextual sentences.

Formally, given the source $\mathbf{x}$, target $\mathbf{y}$, n contextual sentences $C = [\mathbf{c}_1, \cdots, \mathbf{c}_n]$ in the data $\mathcal{D}$, we first train the model by minimizing a negative log-likelihood loss, which is a common MT loss:

$$\mathcal{L}_{MT} = \sum_{(\mathbf{x},\mathbf{y},C)\in\mathcal{D}} -\log P(\mathbf{y}|\mathbf{x}, C).$$

Once the model is trained with MT loss, we fine-tune the model with a contrastive loss. With a contrastive version of context $\tilde{C}$, our contrastive learning objective is minimizing a max-margin loss (Huang et al., 2018; Yang et al., 2019):

$$\mathcal{L}_{CL} = \sum_{(\mathbf{x},\mathbf{y},C,\tilde{C})\in\mathcal{D}} \max\{\eta + \log P(\mathbf{y}|\mathbf{x}, \tilde{C}) - \log P(\mathbf{y}|\mathbf{x}, C), 0\}.$$

Minimizing $\mathcal{L}_{CL}$ encourages the log-likelihood of the ground-truth to be at least η larger than that of the contrastive examples. In our formulation, we want the model to be more sensitive to the subtle changes in the contextual sentences.

The contrastive loss is jointly optimized with MT loss since we empirically found that the joint

optimization has yielded better performance than minimizing CL loss only as similar to (Yu et al., 2020):

$$\mathcal{L} = (1-\alpha)\mathcal{L}_{MT} + \alpha\mathcal{L}_{CL},$$

where $\alpha \in [0, 1]$ is a weight for balancing between contrastive learning and MT loss. For simplicity, we fixed α during fine-tuning.

5 Experiments

5.1 Datasets

We experimented with CorefCL on various document-level parallel datasets: i) 3 English-German datasets including WMT document-level news translation[2] (Barrault et al., 2019), IWSLT TED talk [3] (Cettolo et al., 2017), OpenSubtitles'18[4] (Lison et al., 2018), and ii) our web-crawled English-Korean subtitles corpus.

For all tasks, we take every 2 preceding sentences as contextual sentences and we only consider sentences within the same document (article, talk, movie, one episode of TV programs, etc.) of the source sentence. If split of the validation and the test set is not presented in the data, we apply document-based split to ensure that training and validation/test data is well-separated. Details of datasets are listed as follows:

WMT We use a set of parallel corpora annotated with document boundaries which is released in WMT'19 news translation task. Specifically, we combine Europarl v9, News Commentary v14, and MODEL-RAPID to form a training set containing $3.7M$ examples and $0.85M$ with cross-sentential coreferences. For validation and test sets, we used newstest2013 and newstest2019 which contain $3.05k$ and $2.14k$ examples respectively.

IWSLT The IWSLT dataset consists of transcriptions of TED talks in a variety of languages. We used the 2017 version of the training set, a combination of dev2010, tst2010, tst2015 as a validation set, and tst2017 as a test set. The resulting dataset consists of $232k$ ($50.3k$ with cross-sentential coreferences), $3.5k$, $1.2k$ examples of train, dev, test sets respectively.

OpenSubtitles We also choose the English-German pair of OpenSubtitles2018 corpora. The raw corpus contains $24.4M$ parallel sentences. We follow the filtering methods in (Voita et al., 2019) by removing pairs that have a time overlap of subtitle frames less than 0.9. We also use separate documents for validation / test sets, resulting in $3.9M$ ($1.01M$ with cross-sentential coreferences), $40.7k$, $40.5k$ examples for train / validation / test sets respectively.

En-Ko Subtitles For English-Korean experiments, we first crawled approximately $6.1k$ bilingual subtitle files from websites such as GomLab.com. Since sentence pairs of these subtitles are already soft-aligned by the creators so we applied a simple time-code based heuristics to filter examples. The final data contains $1.6M$ ($0.24M$ with cross-sentential coreferences), $155.6k$, and $18.1k$ examples of consecutive sentences in the training, validation, and test sets respectively.

For preprocessing, all English and German corpus is tokenized first with Moses (Koehn et al., 2007) tokenizer[5]. We then apply the BPE (Sennrich et al., 2016b) using SentencePiece[6], and the size of the merge operation is approximately $16.5k$. We also put a special token [BOC] at the beginning of contextual sentences to differentiate them from the source sentences.

5.2 Settings

We use model hyperparameters, such as the size of hidden dimensions and the number of hidden layers as same the `transformer-base` (Vaswani et al., 2017), since all of the compared models are based on Transformer. Specifically, we set 512 as the hidden dimension, the number of layers is 6, the number of attention heads is 8, and the dropout rate is set to 0.1.

All models are trained with ADAM (Kingma and Ba, 2014) with different learning rates for each dataset. We employ early stopping of the training when the MT loss on the validation set does not improve. We start training each baseline model from scratch with random initialization and document-level dataset. Note that all the baseline models are not trained using iterative training as (Zhang et al., 2018; Huo et al., 2020) which first trains the model from sentence-level task first, then document-level task. All the evaluated models are implemented on top of the transformers[7] framework.

We measure the translation quality by the BLEU score (Papineni et al., 2002). For scoring BLEU,

System	WMT	OpenSubtitles	IWSLT	En-Ko Subtitles	
				detok.	char.
sent-level	22.7	27.6	29.3	8.6	19.2
concat	22.4	28.3	29.7	9.3	22.1
+ CorefCL	23.5 (+1.1)	29.1 (+0.8)	30.9 (+1.3)	10.9 (+1.6)	24.9 (+2.8)
multi-enc	23.1	28.6	29.8	9.2	21.7
+ CorefCL	24.3 (+1.2)	29.8 (+1.4)	31.1 (+1.3)	10.8 (+1.6)	24.4 (+2.7)
multi-enc-hier	24.4	29.1	30.0	10.3	23.1
+ CorefCL	25.4 (+1.0)	30.2 (+1.1)	31.1 (+1.2)	11.7 (+1.4)	25.7 (+2.6)

Table 1: Corpus-level BLEU scores of compared models on different tasks. For the En-Ko subtitles task, we list both detokenized (detok.) and character-level (char.) scores. Improvements by CorefCL are denoted in (). Underlined score means that the model has the largest BLEU improvements among models in the same task.

we use the sacreBLEU (Post, 2018) case-sensitive, detokenized scores for En-De, and case-insensitive scores with `intl` tokenizer for En-Ko task. We also report case-insensitive char-level scores on En-Ko for comparison.

5.3 Overall BLEU Evaluation

We display the corpus-level test BLEU scores of all compared models on different tasks in Table 1. Among the baseline systems, all context-aware models show moderate improvements over the sentence-level (sent-level) baseline. These results are comparable to that of Huo et al. (2020) on the IWSLT task except for multi-enc-hier, and Yun et al. (2020) on OpenSubtitles task. One exception is a single-encoder model (concat) on WMT task, which seems due to the longer average sentence length.

We evaluated CorefCL by fine-tuning the context-aware models. Results show that models with CorefCL outperformed their vanilla counterparts, with the BLEU gain of up to 1.4 in En-De tasks, and 1.6/2.8 (detokenized/char-level BLEU) in the En-Ko subtitles task.

We observed that while CorefCL consistently improves BLEU on all tasks, it achieves better results on IWSLT and En-Ko subtitles tasks. Since improvements on much larger datasets like WMT and OpenSubtitles are smaller, we suggest that CorefCL also works as a regularization.

5.4 Results on English-German Contrastive Evaluation Set

To assess how CorefCL improves the ability to deal with pronoun-related translations more in detail, we experiment our method with ContraPro.[8] ContraPro is a contrastive test suit for En-De pronoun translation introduced by Müller et al. (2018). The evaluation is done by letting the model scores the German sentence with correct and incorrect pronoun translation, given the source and contextual English sentence. The accuracy is calculated by counting the number of correctly scored examples (i.e. correct examples that received a higher score than their incorrect counterpart).

System	Trained on			
	WMT		OpenSubtitles	
	BLEU	Acc.	BLEU	Acc.
sent-level	19.3	47.9	29.6	48.4
concat	19.9	49.7	30.5	54.4
+ CorefCL	20.3	51.2	32.3	57.9
multi-enc-hier	20.4	50.9	31.7	57.3
+ CorefCL	21.9	52.4	33.6	60.5

Table 2: BLEU and pronoun resolution accuracies on ContraPro (Müller et al., 2018) En-De contrastive test set.

We evaluate the models trained with WMT and OpenSubtitles tasks. We also list BLEU scores of En-De translation using the English source text in ContraPro. As shown in Table 2, CorefCL significantly improves the baselines in scoring accuracy for all models by up to 5.5%, as well as slight improvements in BLEU scores.

One interesting finding is that CorefCL also achieved substantial accuracy gain on the models trained on WMT. Since the ContraPro is created from OpenSubtitles, WMT-trained models would yield lower performance because of domain shift between training and testing. Table2 clearly shows the performance drop in BLEU, nevertheless, moderate improvements in accuracy can also be ob-

[8] https://github.com/ZurichNLP/ContraPro

served on WMT-trained models.

5.5 Analysis

System	BLEU	Accuracy
multi-enc-hier	31.7	57.3
+ CorefCL	33.6	60.5
- Word omission	32.4	59.4
- Word replacement	32.3	58.6

Table 3: Ablation study on coreference corruption strategy. All systems are trained on OpenSubtitles English-German dataset and evaluated on ContraPro.

Ablation Study CorefCL uses the two corruption strategies for generating contrastive coreference mentions; word omission and word replacement. To make a better understanding of influence of these strategies, we evaluate CorefCL of different settings of these strategies.

As shown in Table.3, using both types of corruptions results in better performance. Removing one of the two strategies slightly degrades both the pronoun resolution accuracy and BLEU. Although not being significant, removing the word replacement has more impact on accuracy. This suggests that a standard context-aware model, at least for multi-enc-hier is less sensitive to word substitution. The word replacement strategy can complement this behavior as resulted in better performance.

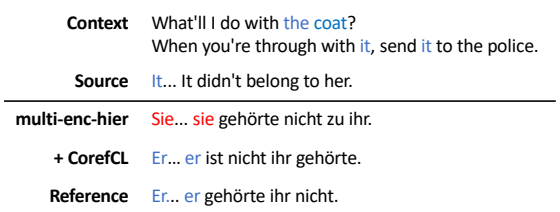

Figure 3: Example translation with and without CorefCL.

Qualitative Example We display a sample from ContraPro corpus and its translations made by multi-enc-hier model trained with OpenSubtitle task. In this example, since "coat" is translated as *Mantel* which is a masculine noun thus *Er* would be adequate translation of "It" instead of *Sie* which is feminine. While multi-enc-hier incorrectly translated "It" as *Sie*, the model fine-tuned with CorefCL correctly resolved it as *Er*.

In practice, context-aware models that do not leverage target-side contexts struggle to maintain these kinds of coreference consistency (Müller et al., 2018; Lapshinova-Koltunski et al., 2019) because of the asymmetric nature of grammatical components and data distributions. Results show that CorefCL can complement the limitation of source-only context-aware models.

6 Conclusions and Future Work

We have presented a data augmentation and contrastive learning scheme based on coreference for context-aware NMT. By leveraging coreference mentions between the source and target sentence, CorefCL effectively generates contrastive examples for applying contrastive learning on context-aware NMT models. In the experiments, CorefCL consistently improves the translation quality and pronoun resolution accuracy.

As future work, we plan to extend CorefCL to target contexts since maintaining coreference consistency needs both the source and the target contexts. It would be also interesting that applying CorefCL for fine-tuning pre-trained big language models like BART (Lewis et al., 2020) or T5 (Raffel et al., 2020) for downstream document-level MT tasks.
