tions of our models, and since we do not have access to the true labels in the test set, we report our best results on the dev set. As can be seen in Table 4, we have produced our best results using DeBERTa-V3$_{large}$. We have noticed two important factors that influence the final performance of the models. The first factor is batch size. Our best results were obtained on lower batch sizes of 8 and 16. The choice of rounded or floored numbers for subtask B is also a significant factor. The reason for this is that the distribution of labels changes depending on the normalisation method used.

6 Conclusion

In this work we developed a set of transformer-based models powered with ordinal regression to tackle an NLP cloze task as part of the SemEval 2022 shared task 7. The goal was to assign suitability scores or labels to several different provided fillers given each context and masked span.

Using a combined architecture based on ordinal regression that used training labels from both subtasks, we developed and trained models with a multi-task learning objective. The proposed system was ranked 4th out of 21 teams in both tracks of the shared task. In the subsequent analyses in the post evaluation phase, we have showed the effectiveness of this architecture in addressing this task. We compared different variations of our models and explored the effects of hyperparameters on model performance. The code and analyses are going to be publicly available.

A Appendix

In this section, we are going to share the details of the hyperparameters used for the fine-tuning of our models and the final training procedure used for the submission.

A.1 Hyperparameters

We fine-tuned all models for 5 epochs while keeping the embedding layers of all models frozen. We used the AdamW as our optimizer with a cosine learning rate schedular from the Hugging Face library and a weight decay of 0.00123974 and an initial learning rate of $1.90323e - 05$. Also, the λ_l and λ_r (as mentioned in 3.6) are set to 0.5 in all of the reported experiments as shown in Table 6.

Hyperparamters	
Epochs	5
Optimizer	AdamW
Learaning Rate Scheduler	Cosine
Initial Learning Rate	1.90323e-05
Weight Decay	0.00123974
λ_l	0.5
λ_r	0.5

Table 6: Details of the Hyperparamters used for fine-tuning

A.2 Training Procedure for Submission

Once we found the best hyperparameters and models using Dev dataset, We used a combination of Training and Dev data to train our final models for submission. With this approach, we have been able to achieve a 3% improvement on accuracy and up to 0.05 improvement on Spearman's rank correlation. Additionally, we found that combining Train and Dev data is noticeably less effective in the smaller models such as Bert$_{base}$ or RoBERTa$_{base}$, however, this is a better strategy when it comes to larger models such as RoBERTa$_{large}$ or T5$_{large}$. Based on this, we suppose that with further tuning. DeBERTa-V3$_{large}$ can potentially surpass the state-of-the-art if it has access to the combination of Train and Dev data.

X-PuDu at SemEval-2022 Task 7: A Replaced Token Detection Task Pre-trained Model with Pattern-aware Ensembling for Identifying Plausible Clarifications

Abstract

This paper describes our winning system on SemEval 2022 Task 7: *Identifying Plausible Clarifications of Implicit and Underspecified Phrases in Instructional Texts*. A replaced token detection pre-trained model is utilized with minorly different task-specific heads for SubTask-A: *Multi-class Classification* and SubTask-B: *Ranking*. Incorporating a pattern-aware ensemble method, our system achieves a 68.90% accuracy score and 0.8070 spearman's rank correlation score surpassing the 2nd place with a large margin by 2.7 and 2.2 percent points for SubTask-A and SubTask-B, respectively. Our approach is simple and easy to implement, and we conducted ablation studies and qualitative and quantitative analyses for the working strategies used in our system.

1 Introduction

The Internet's ever-increasing size has made it easy to find instructional texts such as articles in wikiHow[1], on almost any topic or activity. Regular revisions of these how-to manuals are necessary to ensure that instructions communicate the procedures required to attain a certain goal precisely. This shared task is introduced by Roth et al. (2022), whose intention is to find ways to improve instructional texts, evaluate to what extent current NLP systems are able to handle implicit, ambiguous, and underspecified language, and go beyond the surface form of a text and take multiple plausible interpretations into account. Thus, the proposed NLP systems should be capable of distinguishing between plausible and implausible clarifications of an instruction shown in Figure. 1.

The shared task consists of two subtasks:

- **SubTask-A: Multi-Class Classification**. The goal is to predict a class label (IMPLAUSIBLE, NEUTRAL, PLAUSIBLE) given the clarification[2] and its context.
- **SubTask-B: Ranking**. The goal is to predict the plausibility score on a scale from 1 to 5 given the clarification and its context.

Figure 1: An example randomly chosen from the dev set. Each sample is associated with five clarifications labeled (PLAUSIBLE, NEUTRAL or IMPLAUSIBLE) and scored on a scale from 1.0 to 5.0.

In this paper, we describe our winning system for both subtasks. We built our system based on a replaced token detection (RTD) task pre-training model. The idea is that the replaced token detection task is similar to this shared task which focuses on distinguishing semantically similar words/phrases. To close the gap the model trained between the pre-training phase and fine-tuning phase, we reused the pre-trained language modeling head during fine-tuning on Task 7. Then, two-layers MLPs are applied on the mean-pooled hidden states of a clarification (filler) given the context. For subtask A, we utilized the cross-entropy loss for the multi-class classification. For subtask B, a sigmoid function was used to impose restrictions on the output of the system on a scale from 1 to 5. Finally, we

[1]https://www.wikihow.com/Main-Page

[2]A clarification is a word/phrase that was inserted to specify information in the instruction.

trained multiple models and aggregated the predictions with a pattern-aware ensemble strategy. Our system achieved the best overall performance in the shared task with a 68.9% accuracy score (subtask A) and 0.807 Spearman's rank correlation score (subtask B). The outcomes are promising for improving the clarification of instructional texts.

2 Background

Pre-trained models (Devlin et al., 2018; Liu et al., 2019; Sun et al., 2019; Clark et al., 2020) have achieved state-of-the-art results in various Natural Language Processing (NLP) tasks. Recent works (Raffel et al., 2019; Brown et al., 2020; Sun et al., 2021) have shown that more generalization ability and superior performance can be achieved by pre-training models with billion or trillion parameters. Thus, we pursued the competitive pre-trained models such as DeBERTa (He et al., 2020) and large-scale pre-trained models ERNIE (Sun et al., 2021) whose effectiveness has been validated in the standard GLUE (Wang et al., 2018) and SuperGLUE benchmark (Wang et al., 2019).

However, in our initial experiment, we found that the aforementioned models, though have promising results on sentence-level or paragraph-level tasks, failed to distinguish the word/phrase-level semantically similar clarifications (fillers) in a given context. We believe the failure is due to the way these models were trained using a masked language modeling (MLM) task in the pre-training phase. MLM aims to map tokens with similar semantics to the embedding space that are close to each other instead of distinguishing them.

Based on the above finding, we believe what we need is a discriminator (Clark et al., 2020; He et al., 2021) pre-trained via a replaced token detection (RTD) task which is more aligned with this shared task. In RTD, the discriminator needs to determine if a corresponding token is either an original token or a token replaced by the generator. Formally, the loss function for the discriminator is as follows:

$$\mathcal{L}_{RTD} = -\sum_i \log p\left(\mathbb{1}\left(\tilde{x}_i = x_i\right) \mid \tilde{\mathbf{X}}, i\right) \quad (1)$$

where $\tilde{\mathbf{X}}$ is the input sequence constructed by replacing masked tokens with plausible tokens sampled from a generator, and the indicator function $\mathbb{1}(\cdot)$ distinguishes whether the plausible tokens are generated or the original ones.

3 Method

In this section, we will describe the strategies we used in our system in detail. In Section. 3.1, the system is presented on how we formalize the data as input, basic modules, and task-specific design for each subtask. Then, we describe the optimization object for each subtask (see Section. 3.2). Finally, we introduce a pattern-aware ensemble strategy to further boost the performance beyond a normal ensembled model in Section. 3.3.

3.1 System Description

As illustrated in Figure. 2, the framework for both tasks is nearly the same which consists of 4 parts, namely the input, a basic model, a pre-trained head, and a task-specific head.

The input sequence. Each sample is constructed by joining the *Pattern*, *Title*, *Section Header*, *Previous Sentence*, *Target Sentence* and *Follow-up Sentence* in order demonstrated in Figure. 1. Each candidate phase is filled in in its original position in the *Target Sentence*. When modeling the filled target sentence independently, the training set will be 5 times larger than the original since each target phrase has five candidates.

Basic Model. The pre-trained transformer is our starting point. The basic model takes as input the sequence $\tilde{x}$ and outputs the contextual representation of each token as follows:

$$\mathbf{H}_b = \text{Transformer}(\tilde{x}) \quad (2)$$

where $\mathbf{H}_b \in \mathbb{R}^{n\times d}$ with n tokens and d dimension.

Pre-trained Head. During the pre-training phase, a language modeling head is appended for a language modeling task. The head is usually discarded in the fine-tuning phase. However, in our experiment, we found better performance can be achieved when reusing the pre-trained head. Formally, the language modeling head takes as the input $\mathbf{H}_b$ and output representations for task-specific head as follows:

$$\mathbf{H}_p = \text{LN}(\text{Act}(\mathbf{H}_b\mathbf{W}_1 + \mathbf{b}_1)) \quad (3)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d\times d}, \mathbf{b}_1 \in \mathbb{R}^d$ is the weight and bias, $\text{Act}(\cdot)$ and $\text{LN}(\cdot)$ are the activation function and the layernorm layer (Ba et al., 2016) respectively.

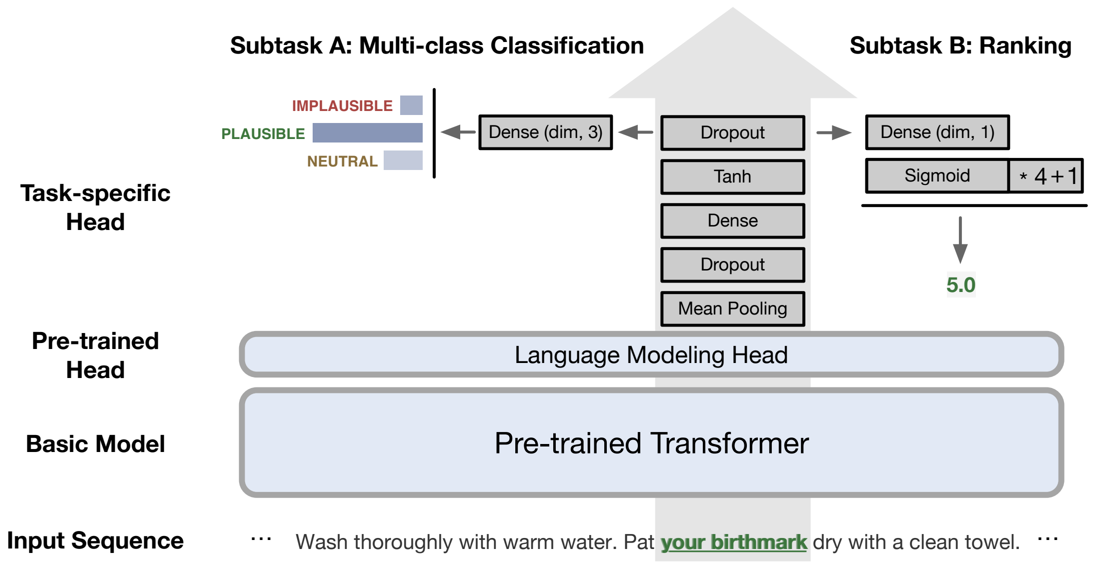

Figure 2: The illustration of our system.

Task-specfic Head. As there are several tokens after tokenizing the target phrase, we apply a mean pooing layer for the hidden states of the target phrase denoted as $\mathbf{H}_{p,i:j}$ as follows:

$$\mathbf{h}_t = \frac{\sum_i^j \mathbf{H}_{p,i}}{j-i} \tag{4}$$

where $\mathbf{h}_t \in \mathbb{R}^{1\times d}$ is the mean embedding of the target phase, i, j are the start and end token index of the tokenized target phrase respectively. Then, we sequentially appended a dropout layer, a dense layer with a Tanh activation function and a dropout layer for $\mathbf{h}_t$ as follows:

$$\tilde{\mathbf{h}}_t = \text{Dropout}(\text{Tanh}(\text{Dropout}(\mathbf{h}_t)\mathbf{W}_2 + \mathbf{b}_2)) \tag{5}$$

where $\tilde{\mathbf{h}}_t \in \mathbb{R}^{1\times d}, \mathbf{W}_2 \in \mathbb{R}^{d\times d}, \mathbf{b}_2 \in \mathbb{R}^d$ are the enhanced embedding of the target phase, learnable weight and bias respectively. Finally, the $\tilde{\mathbf{h}}_t$ is transformed to fit the three-class classification task and regression task as follows:

$$\tilde{\mathbf{y}}_c = \text{Softmax}(\tilde{\mathbf{h}}_t\mathbf{W}_3 + \mathbf{b}_3) \tag{6}$$

$$\tilde{y}_r = \text{Sigmoid}(\tilde{\mathbf{h}}_t\mathbf{W}_4 + \mathbf{b}_4) * 4 + 1 \tag{7}$$

where $\tilde{\mathbf{y}}_c \in \mathbb{R}^{1\times 3}, \mathbf{W}_3 \in \mathbb{R}^{d\times 3}, \mathbf{b}_3 \in \mathbb{R}^3$ are the probabilty distribution, learnable weight and bias for subtask A, and $\tilde{y}_r \in \mathbb{R}^1, \mathbf{W}_3 \in \mathbb{R}^{d\times 1}, \mathbf{b}_3 \in \mathbb{R}^1$ are the regression score, learnable weight and bias for subtask B. The Sigmoid function restricts the range of output space between 0 to 1, then we shift the number by multiplying four and adding one. The above method successfully restrict the regression score within the golden score on a scale of 1 to 5.

3.2 Optimazation Object

For subtask A, we utilized the cross-entropy loss for multi-class classification as follows:

$$\mathcal{L}_{ce} = -\sum_i^N \log(\tilde{\mathbf{y}}_c^i[y_c^i]) \tag{8}$$

where N is the number of training samples, y_c^i is the golden label for i-th sample, $\tilde{\mathbf{y}}_c^i[y_c^i]$ means the predicted probability of the golden label.

For subtask B, we used the mean squared error loss for regression as follows:

$$\mathcal{L}_{reg} = \frac{1}{N}\sum_i^N (\tilde{y}_r^i - y_r^i)^2 \tag{9}$$

3.3 Pattern-aware Ensembling

Ensemble is the commonly used technique where multiple diverse models are trained to predict an outcome, then aggregates the prediction of each model resulting in the final prediction. In our experiment, we observed that the model fine-tuned with different hyper-parameters have different preference on the *Resolved Pattern*[3]. Thus, we aggregates the prediction of each model seperately based on the performance on a subset split by the given *Resolved Pattern* attribute.

[3]Descriptions of the resolved pattern can be found in https://competitions.codalab.org/competitions/35210#participate

4 Experiment

4.1 Data

We use the training, validation and test data provided for SemEval 2022 Task 7 without introducing extra data. The data statistic is summarized in Table. 1 where there is a balanced distribution among different patterns.

4.2 Experimental Setup

DeBERTa (He et al., 2020, 2021), XLMR (Conneau et al., 2019) and ERNIE (Sun et al., 2021) are used as the pre-trained language model. We fine-tune the models using the AdamW optimizer (Kingma and Ba, 2014) with the default hyper-parameter, and additional fine-tuning hyper-parameters are listed in Table. 2. Experiments are carried out using eight Nvidia A100 GPUs.

4.3 Evaluation Method

For subtask A, the evaluation metric is the accuracy score. The model must predict one of the following labels: {IMPLAUSIBLE, NEUTRAL, PLAUSIBLE}.

For subtask B, the submission will be scored using Spearman's rank correlation coefficient, which compares the predicted plausibility ranking over all test samples to the gold ranking.

Task	**SubTask-A**		**SubTask-B**	
	Dev	Test	Dev	Test
2nd Place	-	66.10	-	0.7850
Ensembled Model	71.08	66.50	0.8260	0.7950

#	**Models**	**SubTask-A**
	MLM-based Models	
1	XLMR-Large	61.14
2	ERNIE	61.73
	RTD-based Models	
3	DeBERTa-V3-Large	**67.25**
4	#3 without pre-trained head	65.96

Table 4: Ablation studies on SubTask A with respect to the accuracy score on the dev set. (We reported the mean results with at least three runs.)

4.4 Results

Our ensembled prediction on test set placed first in the competition, with a 68.9% accuracy score for subtask A and a 0.8070 Spearman's rank correlation coefficient for subtask B. As shown in Table. 3. Our system outperforms the second-place system by 2.8 and 2.2 percent points respectively. The organizers predict an upper bound of 77.1% accuracy score and 0.89 ranking correlation based on the manual annotations. As a result, there's still a lot of room for growth.

4.5 Ablation Studies

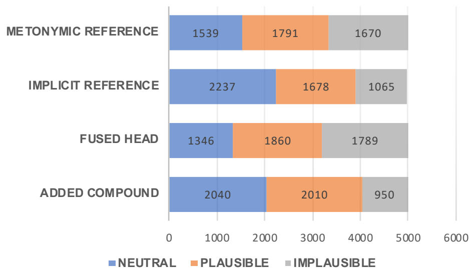

Figure 3: The label distribution of different pattern on training dataset.

The effectiveness of using a replaced token detection task pre-trained model and recovering the pre-train language modeling head in the task-specific

Pattern	IMPLICIT REFERENCE		METONYMIC REFERENCE		FUSED HEAD		ADDED COMPOUND

LR:1e-5, BSZ:32	65.12	0.8321	67.36	**0.8427**	67.68	0.8400	64.64	**0.8272**
LR:9e-6, BSZ:32	64.96	**0.8340**	**69.60**	0.8408	**71.84**	**0.8418**	63.20	0.8251
LR:1e-5, BSZ:64	71.84	0.8286	69.28	0.8382	65.12	0.8347	68.96	0.8134
LR:9e-6, BSZ:64	**72.32**	0.8265	**69.60**	0.8424	64.96	0.8325	**69.28**	0.8142

Table 5: Performance of the DeBERTa-V3-Large with different fine-tuning hyperparameters on the dev set. A model can't win all the subtasks on a subset split by the given pattern attribute. (LR and BSZ are abbreviations for learning rate and batch size.)

head have been revealed in Table. 4. The hypothesis that utilizing a model pre-trained by a similar task aligned with SemEval-2022 Task 7 contributes a lot is supported by comparing #1,#2 and #3. The performance of the model improved even more after reusing the pre-trained LM head (#3 and #4). The assumption is that the hidden states from the pre-trained head contain more information learned during the pre-training phase for distinguishing semantically similar tokens.

The effectiveness of the pattern-aware ensembling has been shown in Table.3. On subtasks A and B, pattern-aware ensembling outperformed the standard ensemble technique by 2.4 and 1.2 percent points, respectively, compared to the standard ensemble method.

The model trained with different hyperparameters may perform better on one pattern but not on another, as seen in Table. 5. For example, on the `FUSED HEAD` pattern, the model (LR:9e-6, BSZ:32) has the highest accuracy score of 71.84% but the lowest accuracy scores of 64.96% and 63.20% on `ADDED COMPOUND` and `IMPLICIT REFERENCE` pattern, respectively. The model (LR:9e-6, BSZ:64), on the other hand, has the lowest score on `FUSED HEAD` pattern but the best result on `ADDED COMPOUND` and `IMPLICIT REFERENCE` pattern. By visualizing the label distribution in Figure. 3, we infer that the phenomenon is related to a distribution difference in which `FUSED HEAD` pattern contains the lowest number of the label *NEUTRAL*, and the label `PLAUSIBLE` dominates the `ADDED COMPOUND` and `IMPLICIT REFERENCE` patterns.

5 Conclusion

We built a system for identifying plausible clarifications of implicit and underspecified phrases in instructional texts which is useful for improving the clarification of instructional texts. The system leverages the strength of a replaced token detection pre-trained discriminator and therefore performs extremely well on this shared task with the same goal to distinguish semantically similar tokens. In particular, we proposed a pattern-aware ensembling strategy to aggregate multiple predictions separately based on the pattern when there is a label distribution difference among patterns. On SemEval-2022 Task 7, the system achieved the best performance in both subtasks.

In future work, it's promising to incorporate the replace token detection task in a large-scale pre-trained model with billion, or even trillion parameters.

Abstract

This paper describes our system used in the SemEval-2022 Task 7(Roth et al.): Identifying Plausible Clarifications of Implicit and Underspecified Phrases. Semeval Task7 is an more complex cloze task, different than normal cloze task, only requiring NLP system could find the best fillers for sentence. In Semeval Task7, NLP system not only need to choose the best fillers for each input instance, but also evaluate the quality of all possible fillers and give them a relative score according to context semantic information. We propose an ensemble of different state-of-the-art transformer-based language models(i.e., RoBERTa and Deberta) with some plug-and-play tricks, such as Grouped Layerwise Learning Rate Decay (GLLRD) strategy, contrastive learning loss, different pooling head and an external input data prepreccess block before the information came into pretrained language models, which improve performance significantly. The main contributions of our system are 1) revealing the performance discrepancy of different transformer-based pretraining models on the downstream task; 2) presenting an efficient learning-rate and parameter attenuation strategy when fintuning pretrained language models; 3) adding different constrative learning loss to improve model performance; 4) showing the useful of the different pooling head structure. Our system achieves a test accuracy of 0.654 on subtask1(ranking 4th on the leaderboard) and a test Spearman's rank correlation coefficient of 0.785 on subtask2(ranking 2nd on the leaderboard).

1 Introduction

Cloze tasks have become a standard framework for evaluating various discourse-level phenomena in NLP. Some prominent examples include the narrative cloze test(Hoshino and Nakagawa, 2007), the story cloze test (Xie et al., 2020), and the LAMBADA word prediction task(Paperno et al., 2016). In these tasks, NLP systems are required to make a prediction about the filler of a cloze that is most likely to continue the discourse. However, these existing cloze tasks focus on the accuray of choosen fillers, ignore evaluating the absolute quality of all possible predictions.

The goal of Semeval 2022 Task7 is to evaluate the ability of NLP systems to distinguish between plausible and implausible clarifications of an instruction. The task is formulated as a complex cloze task, which involve two sub tasks. In Sub task 1, for each(sentence, filler) pair, NLP system need to classify four fillers into plausible, implausible or neutral and the evaluating indicator is accuracy. In Sub task 2, for each pair, NLP system need to predict scores for five fillers and the evaluating indicator is Spearman's rank correlation coefficient.

Since 2018, NLP models have adopted the concept of pre-training on a diverse corpus of unlabelled text, followed by supervised finetuning on specific tasks. Pretrained models are built to simulate anthropomorphic learning, wherein existing knowledge can be adapted to new tasks without doing any training on these tasks from scratch - a requirement of traditional machine learning models. By now, these pre-trained large language models such as Bert(Devlin et al., 2018), Roberta(Liu et al., 2019),Xlm-roberta (Conneau et al., 2019), Deberta(He et al., 2021) has been widely used to solve all kinds of language understanding tasks. Additionally, fine-tuning self-supervised pre-trained models has significantly boosted state-of-the-art performance on natural language processing (NLP) tasks. Many evidence showing models with pretrained commonsense knowledge can be well applied in the field of cloze task(Cui et al., 2020), because cloze task needs commonsense language knowledge and genera language knowledge.

Additionally, there are many training tricks can be used to improve the performance and generalization ability of the large pre-trained language models. First, adding contrastive learning loss in supervised task, such as Ntxent loss(Chen et al., 2020). Second, in case of pretrained language models' catastrophic forgetting in funtuning period, we set different learning rate and weight decay rate for different pre-trained language model layers(Zhang et al., 2021). Third in order to get the best sentence embedding, trying different pooling head is necessary. Inspired by these discoveries, we designed two NLP system for sub-task1 and sub-task2.

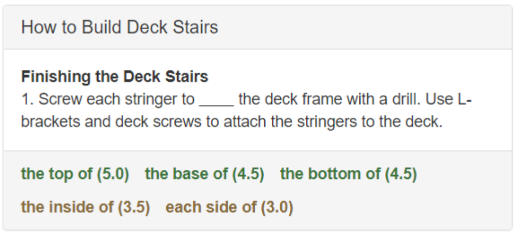
2 Task Setup

Formally, each instance in dataset is composed of 5 sentences, 5 fillers, 1 clarification phenomena and 1 score:

- $Article\ title$: title of the wikiHow article in which the sentence occurs.
- $Section\ header$: heading of the section which the sentence is part of.
- $Previous\ context$: a couple of sentences that occur before the sentence in question - omissions are marked by "(...)".
- $Sentence$: the sentence with a placeholder "..." that marks where the fillers should be inserted.
- $Follow-up\ context$: a couple of sentences that occur after the sentence in question - omissions are marked by "(...)".
- $Filler1 - Filler5$: the five different fillers.
- $Score$: is the quality score of each candidate word, range from 1 to 5.
- $Resolved\ pattern$: name of the clarification phenomenon (cf. list above: implicit reference, fused head, added noun, metonymic reference.)

As showing in figure 1, this task is a cloze task, using fillers(Filler1 to Filler5) to insert a blank at the position in the text(e.g. Screw each stringer to ___ the deck frame with a drill, use L-brackets and deck screws to attach the stringers to the deck.). Additional, article title(), section header,previous and fellow-up sentence, resolved pattern are given.

Sub-task 1 is a classification sub-task, the evaluation metrics is overall accuracy. According to rules, converting each real-valued gold score to a class label as follows:



How to Build Deck Stairs

Finishing the Deck Stairs
1. Screw each stringer to ____ the deck frame with a drill. Use L-brackets and deck screws to attach the stringers to the deck.

the top of (5.0) the base of (4.5) the bottom of (4.5)
the inside of (3.5) each side of (3.0)

Figure 1: Data Instance.

- $score <= 2.5$: IMPLAUSIBLE
- $2.5 < score < 4$: NEUTRAL
- $score >= 4$: PLAUSIBLE

Subtask2 is a regression subtask, our system need to predict each instance's gold plausibility score. The submissions will be scored based on Spearman's rank correlation coefficient which compares the predicted plausibility ranking over all test instances with the gold ranking.

3 Data Summary and Analysis

3.1 Data Construction

We try two different methods to preprocess input data.

Strategy One: We simply concatenate resolved pattern, article title, section header, previous context, sentence and follow-up context first. And then fill the blank spaces with 5 fillers separately. Finally in order to highlight fillers information, we add special symbols "<e>" before and after fillers.

Strategy Two: Since Resolved pattern is kind of category feature which is different than the other text features, We first replace resolved pattern with their explanations. And then connecting explanations to the other information. Finally, adding special symbols "<e>" before and after fillers. The explanation of resolved pattern showing below:

MPLICIT REFERENCE: In the original version of a sentence, there is an implicit reference to a previously mentioned entity. The revision makes this reference explicit.

FUSED HEAD: In the original version, there is a noun phrase where the head noun is missing. The revision adds that noun.

ADDED NOUN: The revision adds a compound modifier to a noun to make its meaning more specific.

METONYMIC REFERENCE: In the original version, a noun is used in a metonymy. The revision

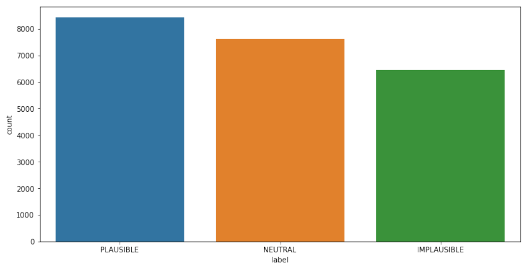


Figure 2: Label Distribution.

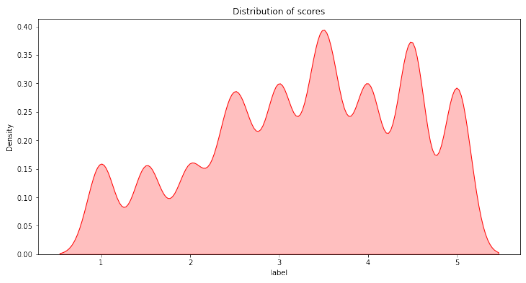

Figure 3: Score Distribution.

makes the particular component or aspect of a noun explicit that is meant.

We adopt two kinds of preprocess methods in our experiment and Strategy Two showing a better performance.

3.2 Data Analysis

We can see the label distribution and score distribution in Figure 2 and Figure 3. The largest number of labels is a plausible and the average score is near 3.5.

4 Methodology

For this task, we have tried a variety of modeling, optimization methods, learning rate schedule and different constrative learning loss. Details are described below.

4.1 Model Design

We design same model architectures for this two sub-task. Our model is based on different pre-trained models, such as roberta, xlmroberta and deberta. After these pre-trained block, we set different pooling head to replace cls head in order to get better sentence information. We try 3 different head, mean-max pooling head, cls head and lstm + attention head, and all the pooling structures showing good performance in our experiments.

CLS Pooling Head: CLS Pooling Head is the last layer hidden-state of the first token of the sequence (classification token) further processed by a Linear layer and a Tanh activation function. The Linear layer weights are trained from the next sentence prediction (classification) objective during pretraining. We reset cls top linear layer weights in finetuning. We believe this weights are over fitting NSP task that have a bad effect on further finetuning.

Mean-Max Pooling Head: We consider the last hidden state [batch, maxlen, hidden_state], then take max across maxlen dimensions to get max pooling embeddings. For mean pooling, we also consider the last hidden state, the average across max length dimensions to get averaged/mean embedding. Finally we concatenate this two embedding and further processed by a Linear layer.

LSTM plus Attention Pooling Head: Since LSTM network is inherently suitable for processing sequential information, we can use a LSTM network to connect all token of last hidden state [batch, maxlen, hidden_state], and the output of the all LSTM cell [batch, nums_LSTM_cell, LSTM_hidden_state] is used as input of next dot-product attention module. After dot-product attention module, we pass the pooled output to a fully connected layer for label prediction.

4.2 Training Details

Our system adopt grouped layer-wise learning rate decay(GLLRD)(Ginsburg et al., 2018) as main learning rate and weight decay strategy. GLLRD is a method that applies higher learning rates for top layers and lower learning rates for bottom layers. This is accomplished by setting the learning rate of the top layer and using a multiplicative decay rate to decrease the learning rate layer-by-layer from top to bottom.

In our experiment, We set 3 parameter group for 24-layers pretrained large language models, first group include 0 to 7 pretrained layers; second group include 8 to 15 pretrained layers; third group include 16-23 pretrained layers. We design a base learning rate 1e-5 for group 2(8-15 pretrained layers); A lower learning rate 1e-5/1.6 for group 1; A higher learning rate 1e-5 * 1.6 for group3; And a much higher learning rate(2e-4) for top layers.

The goal is to modify the lower layers that encode more general information less than the top layers that are more specific to the pre-training task. This method is adopted in fine-tuning several recent pre-trained models, including Roberta, Xlm-roberta and Deberta-v3(Zhang et al., 2021). Additionally, we adopt cosine_warmup in our learning rate scheduler and we adopt AdamW with opening bias correction. For task7 dataset, if not open bias correction, will lead to huge fluctuations in model performance.

4.3 Loss Function Design

Our system involve 3 kinds of loss, Classification loss(CrossEntropy loss), regression loss(MSE loss) and contrastive loss(NTXent loss). Inspired by recent contrastive learning algorithms, our system adopt NTXent loss as sencond loss which is proposed in SimCLR. Contrastive loss learns representations to maximize agreement between differently augmented views of the same data example in the latent space.In this task, our system need to evaluate the quality of all possible fillers, NTXent loss can help system get more robust sentence representation to classify all fillers.

For NTXent loss, We randomly sample a minibatch of N examples and define the contrastive prediction task on pairs of augmented examples derived from the minibatch, resulting in 2N data points.We do not sample negative examples explicitly. Instead, given a positive pair, similar to (Chen et al., 2017), we treat the other 2(N − 1) augmented examples within a minibatch as negative examples. Let $sim(u, v) = \mathbf{u}^\top v/||u||||v||$ denote the dot product between ℓ_2 normalized u and v (i.e.cosine similarity). Then the loss function for a positive pair of examples (i, j) is defined as (Chen et al., 2020):

$$\ell_{i,j} = -\log \frac{\exp\left(\operatorname{sim}\left(\boldsymbol{z}_i, \boldsymbol{z}_j\right)/\tau\right)}{\sum_{k=1}^{2N} \mathbb{1}_{[k\neq i]} \exp\left(\operatorname{sim}\left(\boldsymbol{z}_i, \boldsymbol{z}_k\right)/\tau\right)} \tag{1}$$

where $\mathbb{1}_{[k\neq i]} \in (0, 1)$ is an indicator function evaluating to 1 iff $[k \neq i]$ and τ denotes a temperature parameter. The final loss is computed across all positive pairs, both (i, j) and (j, i), in a minibatch.

In subtask 1, we adopt the weighted average method to obtain the final loss between CrossEntropy loss and NTXent loss. The method is as follows:

$$Loss_{total} = Loss_{CE} + \alpha Loss_{NTX}, \tag{2}$$

where $Loss_{CE}$ is CrossEntropy loss,$Loss_{NTX}$ is NTXent loss, $\alpha = 0.1$

In subtask 2, we adopt the final weighted average method to obtain the final loss between MSE loss and NTXent loss. The method is as follows:

$$Loss_{total} = Loss_{MSE} + \alpha Loss_{NTX} \tag{3}$$

where $Loss_{MSE}$ is MSE loss,$Loss_{NTX}$ is NTXent loss, $\alpha = 0.1$.

5 Experiments

5.1 Experiment Settings

In order to get better performance in this few-sample dataset, We apply AdamW as an optimization algorithm with 10% steps of warmup and open the the correct_bias item (Zhang et al., 2021). For hyperparamete, we fine-tune the uncased, 24-layer $Roberta_{Large}$, $Xlm - Roberta_{Large}$ and $Deberta_{Large}$ model with batch size 40, dropout 0.2, cosine_warmup 1e-2. Additionally we adopt grouped layer-wise learning rate decay strategy with base learning rate 1e-5, weight-ratio 1.6 and a much higher learning 2e-4 for top pooling layers, mentioned in 4.2 Training Details. We used stratified k-fold method to split training data into 5 folds.

5.2 Experimental Results

We separate trained our system for sub-task1 and sub-task2. In both sub-task, we adopt sentence embedding to settle the further classification and regression works. As showing in Table 1, for each method, the score we report here is the average score of the experiment results. From Table 1, we see that the deberta-v3 model showing the best overall performance on both sub-task1 and sub-task2. In sub-task1, we can find deberta model is at least 2% higher than roberta model and 1.8% higher than xlm-roberta model. On sub-task2, deberta model's improvement is much higher, compared with roberta and xlm-robera, deberta has an improvement of more than 4.5% and 3.1% respectively. More important, data construction method 2 replacing resolved pattern with their explanations also provided a performance boost, around 0.7% in both sub-task. GLLRD strategy and contrastive loss bring a great improvement, neary 1% and 0.5%. Different pooling head also bring different influence in final score, Lstm + Attention head showing the best performance, which can reach 0.649 in sub-task1 and 0.782 in sub-task2 . Totally, after trying different method and model fusion, our system

Pretrained model	Data Construction Method	Pooling head	GLLRD	Contrastive loss	ACC @ subtask1	Spearman coefficient @ subtask2
roberta-large	Strategy One	CLS Pooling	False	—	0.602	0.696
	Strategy Two	CLS Pooling	False	—	0.608	0.704
	Strategy Two	CLS Pooling	True	—	0.619	0.714
	Strategy Two	CLS Pooling	True	NTXent	0.624	0.718
	Strategy Two	Mean-Max Pooling	True	NTXent	0.626	0.717
	Strategy Two	LSTM plus Attention Pooling	True	NTXent	0.628	0.725
xlm-roberta-large	Strategy Two	CLS Pooling	True	NTXent	0.626	0.738
	Strategy Two	Mean-Max Pooling	True	NTXent	0.625	0.736
	Strategy Two	LSTM plus Attention Pooling	True	NTXent	0.629	0.740
deberta-v3-large	Strategy Two	CLS Pooling	True	NTXent	0.647	0.771
	Strategy Two	Mean-Max Pooling	True	NTXent	0.645	0.773
	Strategy Two	LSTM plus Attention Pooling	True	NTXent	0.649	0.782
Multi model Fusion	—	—	—	—	0.654	0.785

Table 1: Experiment results for sub-task1 and sub-task2

reach a test accuracy of 0.654 on sub-task1 and a test Spear-man coefficient of 0.785 on sub-task2.

6 Conclusion

This paper propose a complex system with GLLRD strategy, contrastive loss, input data construction block, different pretrained models and different pooling head structure. It solves the problem of how to evaluate the quality of all possible fillers in cloze task. Experiments on SemEval task 7 datasets demonstrate that using our system can advance the normal cloze task models.

niksss at SemEval-2022 Task 7: Transformers for Grading the Clarifications on Instructional Texts

Nikhil Singh
Manipal University Jaipur
`nikhil3198@gmail.com`

Abstract

This paper describes the 9th place system description for SemEval-2022 Task 7. The goal of this shared task was to develop computational models to predict how plausible a clarification made on an instructional text is. This shared task was divided into two Subtasks A and B. We attempted to solve these using various transformers-based architecture under different regime. We initially treated this as a text2text generation problem but comparing it with our recent approach we dropped it and treated this as a text-sequence classification and regression depending on the Subtask.

1 Introduction

Instructional texts which are in the form of step-by-step instruction to achieve a particular goal are sometimes ambiguous to make out what is being talked about. To ensure that instructions describe clearly enough what steps must be followed, some clarifications are made in the places of ambiguity. This task (Roth et al., 2022) revolves around automating the grading of a particular clarification made on the instructions into plausible implausible and neutral (SubTask A) and on a finer scale where it is required to rank potential clarifications from 1 to 5 (SubTask B).

Previous work, related to this involves a Shared Task (Roth and Anthonio, 2021) which was a binary classification task, in which systems had to predict whether a given sentence in context requires clarification or not. This shared task uses the same dataset that is the wikiHowToImprove dataset (Anthonio et al., 2020) but with some variations. Instead of a binary classification task, this task is shaped as a cloze task in which, clarifications are presented as possible fillers and systems have to score how well each filler plausibly fits in a given context. A data instance can be seen in Figure 1.

Seeing the performance of BERT over BiLSTMs in (Bhat et al., 2020), we decided to build upon that and explore the use of other transformers-based models.

2 System Overview

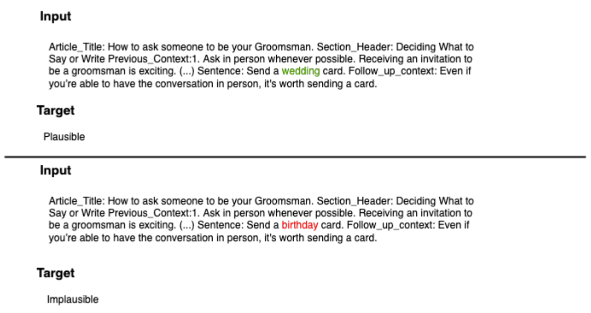
Data Pre-Processing

In order to convert the provided data into the form required for a text sequence classification model, we filled the blanks in the provided text with the provided potential fillers and associated their respective labels as shown in Figure 2. The resulting data were then divided into three parts training(80 %), validating(10 %), and testing(10 %).

2.1 Subtask A

For this task, we mainly experiment with two transformers-based models that differ fundamentally in the manner they were trained. Initially, we treated this as a text to text generation task using T5 (Raffel et al., 2019). The detailed steps involved in this experiment is present below.

- The Article title, previous context, the sentence (with filler), and the follow-up context was sequentially laid out one after the other.



Input

Article_Title: How to ask someone to be your Groomsman. Section_Header: Deciding What to Say or Write Previous_Context:1. Ask in person whenever possible. Receiving an invitation to be a groomsman is exciting. (...) Sentence: Send a wedding card. Follow_up_context: Even if you're able to have the conversation in person, it's worth sending a card.

Target

Plausible

Input

Article_Title: How to ask someone to be your Groomsman. Section_Header: Deciding What to Say or Write Previous_Context:1. Ask in person whenever possible. Receiving an invitation to be a groomsman is exciting. (...) Sentence: Send a birthday card. Follow_up_context: Even if you're able to have the conversation in person, it's worth sending a card.

Target

Implausible

Figure 2: Data input for both T5 and BERT

- Keywords such as Article Title,Section Header,Previous Context,Sentence and Follow up context were included in the input string to indicate the respective content for the T5 model.
- The model was trained in a supervised manner using Cross-Entropy for 2 Epochs with a batch size of 2 and gradient accumulation steps of 8 making an effective batch size of 16. The rest of the Hyper-parameters were as follows:max seq length=512,learning rate=3e-4,adam epsilon=1e-8 and a seed value of 42 to keep the model deterministic.
- The model took approximately 1.5 hours to train on Nvidia's P100 GPU with a memory of 16Gb.
- The complete experiment was done on Google Colab Pro.
- The model architecture can be seen in Figure 3.

The second model used was a BERT (Devlin et al., 2018) based model.

The detailed steps involved in this experiment is present below.

- The pre-processing of the data was the same as T5 but with all the instruction constituents clubbed into a single text, i.e. all the keywords such as Article Title,Section Header,Previous Context,Sentence and Follow up context were dropped and the resulting sequence was a continuous text sequence.
- The resulting input sequence was tokenized using a BertTokenizer from Huggingface and is passed through the bert-base-uncased model to embed it into a 768 dimensional feature vector containing the syntactical information of the input string.
- The feature vector is then passed through a dropout layer to increase the regularization which in-turn increases the generalizability of the model.
- The model was trained in a supervised manner in a multiclass classification regime for 5 Epochs with a batch size of 32. Rest of the Hyper-parameters are shown in Table 2. A seed value of 42 to keep the model deterministic.
- The model took approximately 25 minutes to train on Nvidia's P100 GPU with a memory of 16Gb.
- The complete experiment was done on Google Colab Pro.
- The model architecture can be seen in Figure 4

Model	**Accuracy(%)**
T5-base	40.28
bert-base-uncased	44.40

Table 1: Result on the hold-out test set for Subtask A

When compared to the T5 model the BERT-based model was not just effective but also more efficient and took lower time for training and inference and therefore became our official submission for this subtask. See Table 1 for results on the hold-out test set.

The Experiment setup has been shown in Table 2. All the Experiments were performed using Huggingface Transformers Library. [1]

2.2 Subtask B

Seeing the success of BERT over T5, we make necessary changes to convert the model used for Subtask A into a regression model. See Figure 5. See Table 3 for results on the hold-out test set. The experiment setup can be seen in Table 4.

3 Results

3.1 Subtask A

The submitted systems were evaluated using the Accuracy metric(Sklearn footnote). We were officially ranked 7th in Subtask A with an accuracy

score of 44.200% which is substantially above a naive majority class baseline of 39% and comparable to the baseline presented by the task organizers.

3.2 Subtask B

For Subtask B, the submissions were evaluated using Spearman's rank correlation coefficient(SRCC) which compares the predicted plausibility ranking overall test instances with the gold ranking. We ranked 5th with an SRCC of 0.25200.

4 Error Analysis

After examining the predictions from the submitted model, we saw that the model struggled significantly in distinguishing between neutral and either of plausible/implausible clarifications as there's a very slight difference between them. This problem increases further when we created a feature vector from the same sentence with changed filler word as it leads to a very slight change in the vector, hence leading the model confused to distinguish between individual classes having almost similar feature distribution. The performance can also be attributed to the distribution of the labels in development set and our submitted model might have overfitted to the development set, leading to a further decrease in performance in the test set.

5 Conclusion

We developed a system to classify the clarification made on instructional text into varying levels of plausibility using a transformer based language model with a limited attention span only taking a limited context around the filler. The recent advancement in transformer based models, such as BigBird (Zaheer et al., 2020) and Longformer (Beltagy et al., 2020) which can take up longer context into consideration are more preferred for a task like this.

Abstract

Thousands of new news articles appear daily in outlets in different languages. Understanding which articles refer to the same story can not only improve applications like news aggregation but enable cross-linguistic analysis of media consumption and attention. However, assessing the similarity of stories in news articles is challenging due to the different dimensions in which a story might vary, e.g., two articles may have substantial textual overlap but describe similar events that happened years apart. To address this challenge, we introduce a new dataset of nearly 10,000 news article pairs spanning 18 language combinations annotated for seven dimensions of similarity as SemEval 2022 Task 8. Here, we present an overview of the task, the best performing submissions, and the frontiers and challenges for measuring multilingual news article similarity. While the participants of this SemEval task contributed very strong models, achieving up to 0.818 correlation with gold standard labels across languages, human annotators are capable of reaching higher correlations, suggesting space for further progress.

1 Introduction

Consider the following question: Given a pair of "hard" news articles,[1] are they covering the same news story? Answering this question likely requires knowing specific aspects of the events covered: what happened, where and when it happened, who was involved, and why and how it happened (Pan and Kosicki, 1993; Klein and Martínez, 2009; Dijk, 1988).

Effectively modeling the similarity of news stories holds substantial practical benefits in structuring the content of the hundreds of thousands of news articles generated every day.[2] Given the volume of articles, an effective measure of news story similarity enables clustering and identification of event coverage in news media (Rupnik et al., 2016; Bisandu et al., 2018). Commercial news aggregation services, as provided by, e.g., Google News or Apple News, perform a similar clustering approach, yet are primarily monolingual and have not been made openly available or extensively researched beyond proprietary solutions. In addition, quantifying news article similarity allows the comparison of news outlets in terms of their coverage, understanding which stories consume much of the media agenda, as well as tracking the diffusion of news stories through a media ecosystem and over time. Being able to measure these aspects is important for a host of research questions in media and communication studies including, for example, agenda setting (McCombs, 2005). Another highly desirable property of such methods is to be applicable in multilingual settings, to detect news stories covered across languages in an increasingly globalized news ecosystem (Rupnik et al., 2016).

Assessing the similarity of two news articles introduces new challenges not found in traditional semantic textual similarity. Most importantly, methods for semantic textual similarity typically measure the extent to which two arbitrary documents are "the same," without concretely specifying the meaning of this similarity, or only do so in broad strokes (cf. Agirre et al., 2012; Lee et al., 2005; Nguyen et al., 2014). One byproduct of this vague application domain and under-specification is that

[1]"Hard news" is characterized as having a high level of newsworthiness demanding immediate publication (Tuchman, 1972). In our use, we aim to exclude opinion, features, and other forms of journalistic pieces not mainly concerned with covering current events as in Flaxman et al. (2016).

[2]For example, the source we use for metadata, Media Cloud, collects 629K articles per day.

agreeing on gold labels is notoriously difficult, at least at the full-length document level (Nguyen et al., 2014; Westerman et al., 2010), as even human labelers are dependent on specific instructions and/or knowledge of the absolute space of documents to label, to understand the relative concept of "similar" (Bär et al., 2011). News article similarity is thus more related to attempts to compare narratives (Chambers and Jurafsky, 2009; Miller et al., 2015; Chaturvedi et al., 2018), which require understanding the structure and content to assess similarity.

Here, we introduce SemEval 2022 Task 8 for the task of quantifying news similarity, a hard discourse-level task. Stories often include a variety of descriptions, people, and entities that may appear in another, dissimilar story. Further, the temporal nature of news means that as real-life events evolve, stories describing the same event may include new details or entities—possibly becoming a new news story altogether. For this task, we create a high-quality dataset by annotating pairs of news article for similarity in 10 different languages on several dimensions, e.g, geographic, temporal, and narrative similarity. Participants in this task were given a large collection of news articles, with 4,918 pairs receiving ground-truth similarity labels, and were asked to estimate the overall similarity of 4,902 news article pairs given to participants without labels for any dimension. The task is also challenging due to its large language diversity: the training data consists of 8 language combinations, while the evaluation dataset has 18 language combinations including three languages not appearing at all in the training data.

2 Data

2.1 Data Collection

The metadata and full text of news articles was collected from Media Cloud, an open-source platform aggregating millions of stories published online (Roberts et al., 2021). We collected the metadata and full text of all news articles from January 1, 2020 to June 30, 2020 in 10 languages, thanks to white-listing by Media Cloud. Overall, this collection includes news articles in the following languages: English (31M articles), Spanish (8.2M), Russian (7.2M), German (3.2M), French (3.2M), Arabic (2.9M), Italian (2.4M), Turkish (1.1M), Polish (595K), and Mandarin Chinese (342K). We hired and trained annotators with fluency in these languages. The total dataset consists of about 60M articles. Article metadata includes dates, headlines, and URLs of articles. To filter, match, and sample pairs of news articles for annotation, we apply a series of processing steps to the dataset (Figure 1), described below. The annotated data is available on Zenodo while the full text of most webpages annotated is available in a special collection at the Internet Archive. We have also created a Python package to crawl and process the webpages.

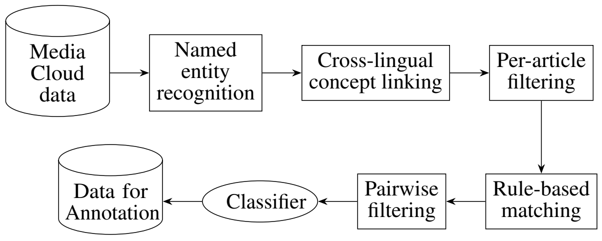

Figure 1: Filtering and pair matching pipeline.

Filtering. We applied a series of filtering steps to clean the data. First, we filtered out articles that miss one of basic metadata attributes: story ID, URL, title, or text. Second, we dropped data points that do *not* correspond to news articles of social or political importance[3] and very short articles whose word count is less than 100. Third, we filtered out articles that have titles or URLs that exactly match a newer news article. After applying these filtering steps, the numbers of articles per language are: English (10M articles), Spanish (4.6M), Russian (1.8M), German (1.3M), French (1.2M), Arabic (1.8M), Italian (1.5M), Turkish (655K), Polish (369K), and Mandarin Chinese (205K).

Matching and Sampling of News Pairs. Randomly sampled pairs of news articles are unlikely to be related. Therefore, a major design point in our pilot work was to identify meaningful candidate pairs. We experimented with document embeddings (Cr5: Josifoski et al., 2019), sentence embeddings (Sentence BERT: Reimers and Gurevych, 2019) applied to headlines and lead paragraphs, and named entities (spaCy, polyglot, and Babelfy; Moro et al., 2014) to identify similar articles. With extensive pilot study, we devised an efficient sampling pipeline (Figure 1). First, the named entities of each article are extracted using spaCy and

[3]Irrelevant websites include: "reddit.com," "facebook.com," "twitter.com," "fb.com," "wikipedia.org," "epochtimes.com," "youtube.com," "slideshare.net". We also dropped any url with 'sport' in it.

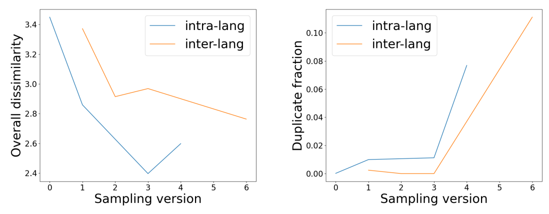

Figure 2: The average dissimilarity of news article pairs (left) and the fraction of duplicates (right) per sampling version.

polyglot.[4] For monolingual pairs, we select pairs of articles having high Jaccard similarity of these named entities. For cross-lingual pairs, we attempt to match the named entities to Wikipedia article titles and store the Wikidata concept ids of matching Wikipedia articles, which are language agnostic. We then select cross-lingual pairs of articles having high Jaccard similarity of these Wikidata concept ids.

To remove duplicate articles (i.e., articles that have the same or nearly the same text, but are published with different titles and URLs), we drop all pairs of articles that share one or more long sentences (of 40 or more characters) or where the Jaccard similarity of article text is higher than a certain threshold. Once the training set of news article pairs was annotated, we trained a logistic regression classifier that was used for further sampling. The features included in the classifier are: the word counts of both articles, the number of common words, the number of common named entities, cosine similarity of the named entities with BM25 embeddings (Robertson and Zaragoza, 2009), text Jaccard similarity, and an exponentially decaying function of publication date difference.

The pipeline was updated over time to increase the fraction of OVERALL similar pairs among samples (Figure 2, left). Version 1 of our sampling pipeline selects pairs based solely on the Jaccard similarity of named entities without any classifier, since initially no labeled data was unavailable. Version 2 introduces a temporal window where only articles published within a few days from each other are considered. Version 3 introduces a minimal threshold for Jaccard similarity of named entities. Versions 4 and 5 count the reappearance of words for Jaccard similarity and implement a more efficient similarity computation in Cython, respectively. Version 6 removes the word reappearance counts after an evaluation of its effectiveness. We note that while improvements to matching and sampling increased the fraction of similar news articles, we also experienced a small increase in the fraction of duplicate news articles (Figure 2, right).

[4]To scale the pipeline to tens of millions of articles, we use the efficient, simple language models rather than the transformer models in spaCy version 3.

2.2 Annotation

Annotation guidelines were developed through an iterative process, grounded in media studies literature on news. After several pilot annotation rounds, we formed a detailed codebook for seven dimensions of similarity. The questions were:

GEO How similar is the geographic focus (places, cities, countries, etc.) of the two articles?

ENT How similar are the named entities (e.g., people, companies, organizations, products, named living beings), excluding previously considered locations appearing in the two articles?

TIME Are the two articles relevant to similar time periods or describing similar time periods?

NAR How similar are the narrative schemas presented in the two articles?

OVERALL Overall, are the two articles covering the same substantive news story? (excluding style, framing, and tone)

STYLE Do the articles have similar writing styles?

TONE Do the articles have similar tones?

Annotators answered each question using a four-point Likert scale with the options, “Very Dissimilar,” “Somewhat Dissimilar,” “Somewhat Similar,” and “Very Similar.” In this paper, we represent these ordinal labels as numbers from 4 (Very Dissimilar) to 1 (Very Similar). In addition, each question can be answered with the option “Other”, which is used mainly for marking pairs of duplicate news articles and unavailable articles, e.g., due to a paywall or take-down (annotators were asked to report such cases via a free-text comment). The annotation codebook defines each dimension and gives examples with explanations of labeled news article pairs (e.g., Table 1).

To achieve the desired linguistic diversity and magnitude of news annotation we trained 25 annotators hired across 3 institutions (GESIS, UMass, UMich), out of which 10 labeled over 1,000 news article pairs during the course of roughly six months (Table 2). Annotators were compensated €12 per hour at GESIS and $15 per hour at UMass and UMich.

We implemented a custom annotation interface in Ruby and MongoDB that assigns news articles pairs at random within the language abilities of

Article 1	Article 2	GEO	ENT	TIME	NAR	STY	TONE	OVERALL

Table 1: Example annotated pairs. The pairs were annotated based on the full-text of the articles. Each of the seven dimension is annotated with a Likert scale with four options: Very Similar (VS), Somewhat Similar (SS), Somewhat Dissimilar (SD), and Very Dissimilar (VD). The articles in the first pair released very similar information about two people tested Coronavirus positive at New York City. The second pair is very dissimilar since one article described the violence against a women while the other one reported the rating improvement of a restaurant. They shared nothing in common. The final pair overlapped somewhat in terms of GEO (India), ENT (Indian Council of Medical Research, ILI, severe acute resparatory illness), and TIME. The two articles, however, still refer to different events.

15	1,076	716	71	0.77

Table 2: Annotators and their statistics: the number of labeled items (news article pairs), the number of shared items (also annotated by another annotator), median number of seconds to label an item, and Pearson correlation of their OVERALL labels with the mean labels of other annotators. Only annotators with at least 100 labels are shown.

each annotator. To engage and motivate annotators, the interface also provides feedback to annotators in the form of basic statistics such as the number of annotations, and the inter-rater agreement of the top annotators. The interface also shows past annotations and highlights disagreements, which were discussed at biweekly video conference meetings.

Codebook, Training, & Annotation. The annotation process has multiple stages (Figure 3). All annotators read the codebook and attended a training session at which the codebook and annotations of example pairs were discussed. The annotators then completed 30 practice annotation pairs independently. After completing each practice pair, annotators were able to view the gold standard labels that had been agreed by all of the SemEval task authors. Each gold standard label was accompanied by a written explanation of why the label was assigned. Question and answer sessions were held at which the annotations were discussed as well.

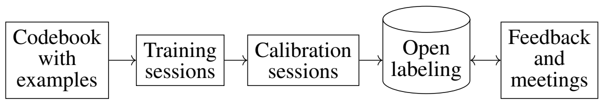

Figure 3: Annotator workplan.

Annotators then labeled another 30 gold standard pairs having detailed explanations, which we used to calibrate annotators' understanding of the codebook. Any disagreements were discussed until agreement was reached. The practice and calibration pairs were all English-language articles, which was a shared language ability between all our annotators. All news article pairs with gold standard labels and explanations, as well as the codebook, are released on Zenodo.

After these practice and calibration activities, pairs were annotated by a variable number of annotators, usually 1, 2, or 3, in the "open labeling" phase, where news article pairs were served to annotators continuously. Annotators were given feedback in the annotation interface on their agreement

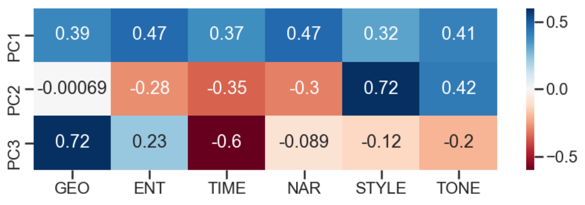

Figure 5: Heatmap showing the coefficients of the first three principal components of variation in the scores.

with other annotators, met regularly to discuss disagreements, and had an open channel for communication on a shared Slack instance. After annotating English-language pairs, non-English pairs were introduced and discussed with annotators. Finally, cross-language pairs were also introduced. The total number of annotations and average OVERALL label per each language pair is shown in Table 3.

Inter-annotator Agreement. The inter-rater agreement on the OVERALL similarity dimension is very high, with a Krippendorff's α of 0.77. We note that the distribution over labels is generally not uniform, e.g., the labeled news article pairs are skewed towards "Very Similar" in TIME, STYLE, and TONE (Figure 4). Gwet's AC_1 is known to be less sensitive to non-uniform marginal label distributions (Gwet, 2008), and it suggests a good agreement in all dimensions (Table 4).

Annotators vary in terms of the quantity and quality of the provided annotations. To compare the performance of annotators to the performance of models, we measure the inter-rater agreement of each annotator in a way that corresponds to the score of models, i.e., as a Pearson correlation between the labels of that annotator and a series of average labels from other annotators. Note, however, that this correlation is measured over labels contributed by the given annotator to both training and evaluation datasets, it is biased by the language-abilities of the annotator, and the mean label does not include the ego annotator. Our top 5 annotators consistently reach very high agreement scores of 0.85–0.88, whereas bottom 5 annotators reach agreement scores of 0.73–0.80 (Table 2).

2.3 Statistics of the Labeled Dataset

Figure 4 illustrates the relationship between the multiple similarity dimensions in the annotated dataset. The bar charts on the diagonal represent the distribution of annotations, from 1 (Very Similar) to 4 (Very Dissimilar). Panels below the diagonal represent two-dimensional histograms, and panels above the diagonal report the Pearson correlation between different dimensions, namely GEO, ENT, TIME, NAR, STYLE, TONE, and OVERALL.

Totals	4,918	4,902	2.62

Table 5: The number of news article pairs in the training and evaluation datasets by language and the mean OVERALL label (the higher, the more dissimilar).

NAR and ENT show the highest correlation with OVERALL (0.88 and 0.79 respectively). These two dimensions also provide the largest contributions to the variation in annotations, as indicated by the first component of the PCA shown in Figure 5.

There is no significant difference between the training and evaluation datasets with respect to the labels of any similarity dimension, and these results are also found when the dataset is disaggregated by language pair.

3 Task

3.1 Task Description & Rules

The Task was created on CodaLab.org[5] and advertised with alongside the other SemEval 2022 tasks. Participants were told, "The task is: Given a pair of news articles, are they covering the same news story? This SemEval task aims to develop systems that identify multilingual news articles that provide similar information. This is a document-level similarity task in the applied domain of news articles, rating them pairwise on a 4-point scale from most to least similar."

Participants were given 60 English-language pairs for trial data in August 2021. The training data was released to participants in two batches: the first batch was released on September 15, 2021, and the second was released on November 4, 2021. The training data consisted of article pairs in 8 different language combinations (Table 5).

Due to copyright restrictions, we were unable to release the raw text of the news articles included in the training data. In lieu of this, we developed and shared a Python package to download the text of news articles. For the training data, the downloader tries to fetch the articles from the Internet Archive or the live web and parse them with `newspaper3k`.[6] This mirrored the actions of annotators who were given links to the articles on the Internet Archive and live web.

The evaluation data was released on January 10, 2022, and consists of 4,902 pairs of news articles across 18 languages. For the evaluation data, we only included pairs of articles where both news articles were available on the Internet Archive.[7]

For both the training and evaluation datasets, we removed any article pairs where one or more annotators labeled the OVERALL similarity as "Other". This usually indicated that the pair was unavailable or not a news article.

The evaluation period ran from January 10 to February 3, 2022. This date reflected the extra time needed to download the articles as well as a short extension due to technical issues with the Codalab system. Participants were allowed to submit up to 5 submissions per day and 1,000 submissions overall.

3.2 Baselines

Our baseline models use SVC with linear kernel, logistic regression, random forest, and XGBoost (Chen and Guestrin, 2016). For feature selection, we found positive correlation between the fraction of "Very Similar" news article pairs and their Jaccard similarity in terms of named entities, as well as full text (Figure 6). Thus we evaluate three sets of features in the baseline models: set-A (Jaccard similarity of named entities), set-B (set-A and text Jaccard similarity), and set-C (set-B and word count difference).

3.3 Evaluation and Ranking

The teams were evaluated using Pearson's r correlation with the mean OVERALL labels on the

[5]`https://competitions.codalab.org/competitions/33835`

[6]Some participants found better success at parsing the articles using `trafilatura` (Barbaresi, 2021)

[7]A special collection on the Internet Archive now includes most webpages.

evaluation data. In ranking teams, we were inspired by recent work (e.g., Dodge et al., 2019) on estimating model performance while recognizing that not all systems solving a task are on equal footing. Specifically, some teams may have submitted more or fewer submissions due to time, computational budget, or model performance. Having varied numbers of submissions for each team/system creates an opportunity for rethinking how to estimate how well the system actually does.

Our approach ranks teams by bootstrapping their expected rank under certain constraints. We assume that for most teams, submissions are an exploration of the hyperparameter/model configuration space of their system. Each submission's score is then informative of the distribution of its expected performance. To create the official Task rankings, we bootstrap the expected rank from all teams' submissions. Specifically, we bootstrap rankings by sampling an equal number of submissions (n=5) from the most-recent 50 submissions of each team and then use the maximum score from each team's sampled submissions to compute one ranking of all teams. To get our final ranking, we repeat this process to sample n=10,000 rankings and take the average rank for each team across these samples. In essence, this process measures the expected ranking if each team was given the same number of hyperparameter/configuration searches.

In practice, our new ranking approach largely does not change the ranking from simply ordering teams by their highest-performing submission. However, a handful of teams did shift positions. The relative stability suggests that models were not affected by different hyperparameter/configuration selections.

4 Results

The task received over 500 public submissions from over 30 participants. Next, we provide an overview of the baselines and the approaches that have been adopted by the 19 teams who participated in the competition's leaderboard and submitted a description of their systems.

4.1 Summary of the Approaches

The teams explored a staggering range of approaches, including multimodal systems that encode the articles' images and knowledge-based features (Zosa et al., 2022). Systems were evaluated on their ability to assess news similarity of pairs of

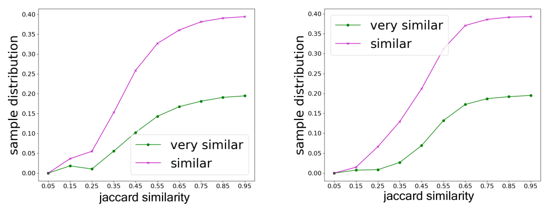

Figure 6: Sample distribution within different Jaccard similarity of named entities (left) and text (right). The "Similar" class includes both the "Very Similar" and "Somewhat Similar" labels

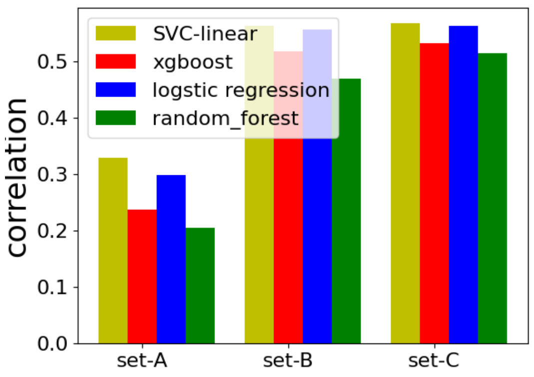

Figure 7: Baseline performances for feature sets.

cross-lingual news articles, and on a secondary task involving only pairs of articles in English. While some teams developed dedicated systems for the two evaluations, cross-lingual and English-only, the great majority of such systems were variations of a single design. For the sake of conciseness, in the remainder of the section we will restrict discussion to the cross-lingual news similarity task and to the best-performing systems. Table 6 reports salient characteristics of these systems, in order of their ranking using Pearson's correlation coefficient. The participant describe each system in finer detail and offer valuable insights on adapting them to the English-only subtask and on negative results (Nai et al., 2022; Wangsadirdja et al., 2022; Pisarevskaya and Zubiaga, 2022; Zosa et al., 2022; Singh et al., 2022; Giovanni et al., 2022; Hajjar et al., 2022; Chen et al., 2022; Joshi et al., 2022; Heil et al., 2022; Sandeep et al., 2022; Xu et al., 2022; Kuimov et al., 2022; Ishihara and Shirai, 2022; Luo et al., 2022; Jobanputra and Rodriguez, 2022; Dufour et al., 2022; Bhavsar et al., 2022; Stefanovitch, 2022).

Table 6: A summary of submitted models ordered by their performance. For each TEAM, the table reports common choices in terms of TRANSFORMER architecture, approaches for tackling CROSS-LINGUAL input, DATA HANDLING such as feature engineering and augmentation, and learning TECHNIQUE. Legend: T = title, B = body, D = description, K = keywords, P = publication date, * = sentiment, topics, geocoding, ** = 6 subdimensions, *** = semantic similarity, hyperpartisan news, **** = 3 subdimensions

4.2 Rankings and Variation Across Languages

The final rankings for the multilingual task as well as the English-language only subset are shown in Supplemental Table A1. Overall performance on the multilingual task (as measured with Pearson's r) ranged from 0.35 to 0.82 with a mean of 0.66 and a median of 0.72.

The highest single-language performance was achieved on French (median 0.84, max 0.87) and French–Polish (median 0.82, max 0.95) pairs. The worst performance was on German–French pairs (median 0.60, max 0.72). Supplemental Figure A1 shows the distribution of the best scores achieved by each team in each language.

Among the baseline models, we find that the SVC performs best, while the Jaccard similarities of named entities and text matter more than word count difference (Figure 7). However, the majority of submitted models perform significantly better than the baseline models.

4.3 Nuanced Inputs: Multiple Fields, Fine-tuning, & Feature Engineering

In addition to the main body of the articles, most systems leveraged information from multiple fields such as their titles and descriptions. All systems involved deep neural embeddings of those fields, with all but one team using Transformer-based architectures. The top-ranking system used several techniques to optimize an XLM-RoBERTa-based model without further feature engineering. *Accurately embedding multiple fields of the articles appears a crucial source of performance. Systems that engaged in fine-tuning or continued pre-training the embeddings scored higher on average.* Yet, there was no clear pattern on which architecture would produce performant representations for the task. In particular, the teams offered mixed evidence on the superiority of bi-embedding over cross-embedding approaches for the task. For example, teams Nikkei and SkoltechNLP found bi-encoders to outperform cross-encoders, whereas team HFL found the opposite (Ishihara and Shirai, 2022; Kuimov et al., 2022; Xu et al., 2022).

To improve upon the baseline of the sole embeddings (albeit often marginally), 10 teams experimented with additional feature engineering. Several teams explored forms of keyword and named-entity extraction. These approaches were arguably promising in that they mirrored the process of sampling,[8] though the results offer no conclusive ev-

[8]The sampling process was not shared with teams.

idence. Similarly, teams also tested strategies to focus the input around the most informative parts of the articles. This was due to multiple factors: first, the limitations of Transformer-based architectures which can only handle limited-length input; second, a small but consistent number of errors in automatically parsing the articles adding noise to the text; and last, the nature of the task: according to the "inverted pyramid" writing style, the start of a news article often summarizes the most important information. Thus, participants experimented with splicing the article body, which led to performance improvements.

4.4 Tackling Generalization: Multilingual, Augmentation, & Learning Strategies

A challenging characteristic of the task is the presence of cross-lingual pairs of articles—with several new language combinations introduced first in the evaluation data. The teams approached the challenge by resorting to multilingual embeddings or machine translating the articles to a high-resource language. *The best-performing systems employed a combination of both approaches, multilingual embeddings and translation, as part of a broader strategy for data augmentation.* Furthermore, the best-performing systems *resorted to forms of ensemble learning* such as stacking, which offered a further way to improve the generalization of the models (with the exceptions of teams TCU and dina (Luo et al., 2022; Pisarevskaya and Zubiaga, 2022)). With few exceptions (see Jobanputra and Rodriguez, 2022), optimizing for multiple tasks also seems to improve performance—e.g., the top-ranking system jointly learns all seven dimensions of similarity provided in the training data.

4.5 Simplicity–Performance Trade-Offs

While the best-performing systems explore sophisticated designs and techniques, the teams also suggested simpler methods that prove surprisingly effective. In fact, several teams found that simple systems outperformed more complex approaches in their experiments. A system that relies on pretrained embeddings without fine-tuning achieved a performance of 0.759 Pearson's correlation coefficient (Wangsadirdja et al., 2022) vis-à-vis the top score of 0.818 (Xu et al., 2022). Similarly, a baseline regressing over two features—shared named entities and cosine similarity between the article embeddings—scored as high as 0.677 (Sandeep et al., 2022). Finally, several teams reported performance improvement by using lexical features without particular adaptation to the cross-lingual settings of this task (e.g., teams Nikkei & TMA: Ishihara and Shirai, 2022; Stefanovitch, 2022). In a nutshell, carefully reflecting the characteristics of the task into the system design can lead to good performance even with simpler models.

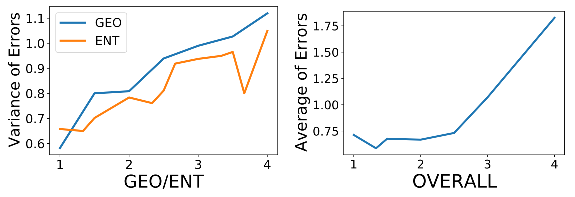

Figure 8: The variance of models' error against pairs with the same GEO/ENT as a function of GEO/ENT (left) and an average of models' error against pairs that were at least somewhat similar in GEO, ENT, TIME, and NAR (right).

4.6 Error Analysis

In this section, we analyze the errors of submitted models. Twenty-one teams achieved an accuracy of at least 0.70, and we focus our error analysis on these teams.

First, we compute the correlation between each model's error (absolute difference between the predicted OVERALL and the OVERALL reported by the annotators) and the sub-dimensions (GEO, ENT, TIME, and NAR) for each pair. We find a strong Pearson correlation between the variance of errors and the GEO and ENT sub-dimensions: the correlation for GEO is 0.97, while for ENT it is 0.88 (Figure 8, left).

We hypothesized that if there is a pair with high similarity in terms of GEO, ENT, TIME, and NAR but dissimilar in terms of the OVERALL label, then models will have difficulties against this pair. To test this hypothesis, we select only pairs that are Somewhat/Very Similar in terms of GEO, ENT, TIME, *and* NAR dimensions. Then, we report how the average error of models varies for different OVERALL ratings. We expect that the average error will be higher for pairs with higher OVERALL values (i.e., pairs that are more dissimilar overall). Figure 8 (right) shows the result of this analysis. We can see that there is a strong correlation between the average of error and the OVERALL label. The Pearson correlation between the error and OVERALL for the selected pairs is 0.88.

5 Discussion

Multilingual news article similarity is a challenging problem despite sharing some characteristics with Semantic Text Similarity. Participants in this SemEval task tried a number of innovative approaches to the problem. Systems that used multiple parts of the article (headline, body, publication date) and systems that fine-tuned or otherwise trained embeddings generally performed better than those that did not. The best-performing systems generally combined multilingual embeddings and translation. Nonetheless, there was no clear consensus as to the best architectures, embedding models, or preprocessing to perform on the data.

There were clear variations across languages, and more work is needed to create multilingual systems that work across diverse language combinations. Errors were particularly common when the news articles shared some similarity in terms of their geographic focus, temporal focus, named entities, and narratives but were nonetheless dissimilar overall. While the best-submitted model achieved a very high correlation of 0.82 with gold standard labels, the best human annotator reached 0.88 correlation, which suggests ample space for further progress.[9]

Our dataset is drawn from the first half of 2020 and covers several geopolitical events (e.g., BlackLivesMatter) as well as the first wave of the COVID-19 pandemic. The nearly 10,000 annotated pairs of news articles across 18 combinations of 10 different languages will enable exciting developments in natural language processing methods as well as social science studies of how the global media reported on this unique period.

Acknowledgments

This research has received funding through the Volkswagen Foundation. We thank Media Cloud for data access. We thank the Internet Archive which made it possible for participants to all have access to the same data. We are deeply grateful to the annotators and task participants: thank you.

Abstract

In this paper, we present the participation of the EMBEDDIA team in the SemEval-2022 Task 8 (*Multilingual News Article Similarity*). We cover several techniques and propose different methods for finding the multilingual news article similarity by exploring the dataset in its entirety. We take advantage of the textual content of the articles, the provided metadata (e.g., titles, keywords, topics), the translated articles, the images (those that were available), and knowledge graph-based representations for entities and relations present in the articles. We, then, compute the semantic similarity between the different features and predict through regression the similarity scores. Our findings show that, while our proposed methods obtained promising results, exploiting the semantic textual similarity with sentence representations is unbeatable. Finally, in the official SemEval-2022 Task 8, we ranked fifth in the overall team ranking cross-lingual results, and second in the English-only results.

1 Introduction

Detecting news stories related to a single theme and combining them into news clusters has been an increasing interest in the creation of news aggregators that consolidate thousands of articles from different publishers and websites (Pranjić et al., 2020). Tracking similarity of news coverage between different outlets or regions has also been urgent and challenging. For example, whether previously with Ebola or recently with the COVID-19 pandemic, monitoring and containment of infectious disease outbreaks has remained a key component of public health strategy to contain the diseases. The ability to track disease outbreaks in an accurate manner is critical in the deployment of efficient intervention measures. As such reports may not only be in English, there is also a need for effective multilingual systems. Hence, recent research has been focused on the area of identifying similarities between documents, phrases, stories, etc.

Semantic textual similarity (STS) deals with determining how similar two groups of sentences are by measuring their semantic similarity. Over the years, several solutions were proposed to assess STS. The most general approach is pre-training on massive datasets before fine-tuning on subsequent downstream tasks (Jiang et al., 2020; Raffel et al., 2019; Lan et al., 2019; Yang et al., 2019; Liu et al., 2019; Sanh et al., 2019). Other works considered finding the similarity by classifying texts using BERT-based models (Devlin et al., 2019) with a pair of sentences packed together as input (Yang et al., 2019; Liu et al., 2019; Sanh et al., 2019; Wang et al., 2019).

The SemEval-2022 Task 8 (*Multilingual News Article Similarity*) (Chen et al., 2022) aimed at developing systems that identify multilingual news articles that provide similar information by rating them on a real-valued $[1-4]$ scale, from most to least similar.

In this paper, we cover several techniques and propose different methods for finding the multilingual news article similarity by exploring different aspects of the dataset. We consider that the textual content, the provided metadata (e.g. title, keywords, topics), representative images corresponding to the news articles, and knowledge graph-based representations for entities and relations present in the articles, would draw on a multiplicity of modes, all of which contribute to the meaning and the main story

[*] Equal contribution from all the authors.

of the news articles. Moreover, we also translate the articles to a high-resource language (English) in order to assess the ability of our models in an English-only context. Therefore, we investigate the multimodality of the data by experimenting with sentence, image, and knowledge graph embeddings in two scenarios: (1) by directly computing the semantic similarity between the different features and (2) by learning through regression and predicting the similarity scores.

2 Data

The training data has 4,964 article pairs from seven languages (English, German, Spanish, Arabic, Polish, Turkish, and French) and gold standard similarity scores for six dimensions (*Geography, Entities, Time, Narrative, Style, Tone*), plus the *Overall* score. The final evaluation data has 4,902 pairs and three "surprise" languages that were not present in the training data (Chinese, Italian, and Russian)[1].

	Train	**Eval**
Monolingual pairs	4,387	3,462
Cross-lingual pairs	577	1,440
Unseen language pairs	NA	2,000
Total	4,964	4,902
Top image	6,755	7,569

Table 1: Training and evaluation data statistics.

Moreover, the metadata includes the article titles, several specific topics and keywords, and links to representative images. The statistics of the training and final evaluation data are in Table 1. Since some of our methods use images, we also report in the table a total number of images we were able to download for the datasets. We use only images from the URL specified as *top_image* in the JSON files of the articles.

3 Experiments

Next, we detail all our approaches and perform a detailed error analysis[2]. The evaluation is performed in terms of Pearson correlation. Our results are presented in Table 2. Each type of approach is detailed with the corresponding pre-trained models[3]. Also, each type of model has an id corresponding to the subsection number is detailed (1a, 2b, etc.).

3.1 Semantic Textual Similarity

A straightforward solution for finding the similarity between two texts is approaching it with sentence embeddings. Thus, we start our experimental setup by encoding the articles with Sentence-BERT (SBERT) (Reimers and Gurevych, 2019), a modified pre-trained BERT (Devlin et al., 2019) that uses a siamese and triplet network structure to derive semantically meaningful sentence embeddings that can be compared using cosine similarity. We explore this approach by encoding the articles with SBERT and and using the cosine similarity of articles pairs as the predicted *Overall* score. For these experiments, we used the default hyperparameters provided by Reimers and Gurevych (2019).

Similarity based We first concatenate the title and the textual content of each article, and due to the multilingual characteristic of the data, we encode the textual sequence with a pre-trained multilingual SBERT model and compute the Pearson correlation between the cosine similarity of these sentence embeddings and the gold labels, results presented in Table 2 (1a). Then, we experiment with machine translating all the non-English articles to English using Google Translate and use an English SBERT model. The results are presented in Table 2 (1b).

Regression based We fine-tune the SBERT model on the multilingual pairs, results presented in Table 2 (1c) and on the machine-translated articles, results presented in Table 2 (1d). For fine-tuning, we use only the *Overall* score as the target similarity score. Since the similarity scores provided in the training data are in the range [1-4] from *most to least* similar, we normalize the *Overall* scores (the scores provided by cosine similarity are in the $[0, 1]$ range from *least to most* similar.

3.2 Image Similarity & Regression

We download the images from the *top_image*, and as we can see in Table 1, out of 9,928 articles (4,964 pairs) in the train set, only 6,755 articles (68%) had a viable image. Out of 9,804 articles in the evaluation set, only 7,569 had a viable image (77%). For both, only around 60% of the articles had an image that could be used. Moreover, only around half of the pairs in both sets have representative images for both articles. Nonetheless, we attempt using

[1]For both sets, we were able to download around 98% of the articles.

Table 2: Correlation between similarity scores from the proposed models and the *Overall* score.

them in our approaches. We experiment with two recent pre-trained models, CLIP (Radford et al., 2021) and ViT (Dosovitskiy et al., 2020).

Similarity based We obtain the image embeddings with CLIP, compute the cosine similarity between the paired images, and report the Pearson correlation between the obtained similarities and the gold labels. The results are presented in Table 2 (2a). For the missing images, we assign the default cosine similarity of 0.5. We also experiment with an alternative strategy, which takes advantage of the fact that CLIP is a multimodal model and produces images and text embeddings in the same space, *Cross-images*. In this strategy, we compute all possible similarities between data points: image-to-image, text-to-text, and image-to-text. In the best case, when both images are available, this results in a total of four similarity values. In the worst case scenario, when no images are present, only the similarity between texts is used. If only one image is available, the strategy results in two similarities: text-to-image and text-to-text. The final score is obtained by averaging the similarities available. Surprisingly, this strategy works slightly worse than an approach based solely on images, as can be seen in Table 2 (2b).

Regression based This method is detailed in Section 3.4. The results are presented in Table 2 (2c and 2d).

3.3 Knowledge Graph Similarity & Regression

We use the Wikidata5m (Wang et al., 2021) knowledge graph (KG) to retrieve knowledge-based features as used by Koloski et al. (2022). Similarly, we exploit six different knowledge graph embeddings: transE (Bordes et al., 2013), rotatE (Sun et al., 2019), complEx (Trouillon et al., 2016), distmult (Yang et al., 2015), simplE (Kazemi and Poole, 2018), and quate (Zhang et al., 2019). We use GraphVite (Zhu et al., 2019), a system for training node embeddings, pre-trained on aforementioned embeddings of the Wikidata KG. For these experiments, we use the translated articles. We concatenate the title and text of the articles to search n-grams of sizes 1, 2, and 3, as potential concepts appearing in the KG. After extracting potential candidates, we extract the embeddings of the candidates from the KG. In addition, we generate latent semantic analysis (LSA), SBERT and stats representations as done by Koloski et al. (2021). The results are in Table 2 (3a and 3b).

Similarity based First, we generate all ten feature spaces. Next, we generate combinations of feature spaces (1,024 combinations in total), we concatenate and normalize them (KGm). Finally, we find thresholds to estimate the similarity scores, with respect to the *Overall* label. Our best results are presented in Table 2 (3a).

Regression based We utilize all six of the aforementioned KG representations, LSA and DistilBERT (Sanh et al., 2019) SBERT representations. Next, we use a singular value decomposition (SVD) to generate a new latent space of the devised features and we proceed to train a feed-forward neural network on the whole target space. Our best results are presented in Table 2 (3b).

3.4 Text & Image Regression Models

We also propose a classical approach that considers the task of finding the similarity between two articles by considering it as a regression task, and by predicting the similarity for the *Overall* score. This approach consists of a pre-trained and fine-tuned language model (BERT (Devlin et al., 2019) pre-trained on multilingual data). Because these models expect input data in a specific format, we need a special token, [SEP] or <sep>, to mark the end of a sentence or the separation between two sentences, and [CLS] or </s>, at the beginning of a text generally used for classification or regression tasks.

Regression based After the pair of articles are tokenized and together encoded with [CLS] at the start and then separated by [SEP], they are passed through the encoder. Similarly, images are passed through a ViT encoder. For the missing images, we generate a *fake* white image. The BERT output token representations are afterward concatenated with the [CLS] representation and Vit output image representation followed by a linear layer for regression. The learning of the model is conducted end-to-end by optimizing an objective corresponding to *Overall* prediction. For these experiments, we utilized AdamW (Kingma and Ba, 2014) with a learning rate of 1×10^{-5} for 2 epochs with mean squared error (MSE) loss. We also consider a maximum sentence length of 512 (the maximum possible accepted by BERT or RoBERTa). These results are presented in Table 2 (from 4a to 4d).

4 Error Analysis

Semantic Textual Similarity We can substantially improve the English-only model (1d) for STS by fine-tuning not just with monolingual English pairs from the training data but by using all the machine-translated pairs. However, we observe some cases where our best performing fine-tuned model is misled by similar turns of phrase even if the article pair covers different events. We show extracts from an article pair in Table 3 that covers a fire and a traffic accident, respectively. The gold *Overall* score for this pair is 4.0 (very dissimilar) but our best-performing model scores it at 3.1 (somewhat dissimilar) due to the similar phrasing that opens the articles and the mention of the same named entities.

Article1	**Article2**

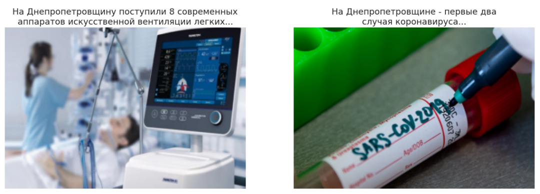
Figure 1: Two pairs of similar English articles (gold score of 1.0 for both) correctly predicted by the image-based model (1.28 & 1.0), and incorrectly predicted by SBERT (1.83 & 1.63).



На Днепропетровщину поступили 8 современных аппаратов искусственной вентиляции легких...
На Днепропетровщине - первые два случая коронавируса...
SARS-CoV-2019

Figure 2: A pair of marginally similar Russian articles (gold score of 2.0), which is an unseen language during training, correctly predicted by the image-based model (1.64), and incorrectly predicted by SBERT (2.94).

Image Similarity & Regression We analyze the scores predicted by two textual-based methods, (1d) SBERT with the best scores when using only images (2a). Out of 4,902 pairs in the evaluation

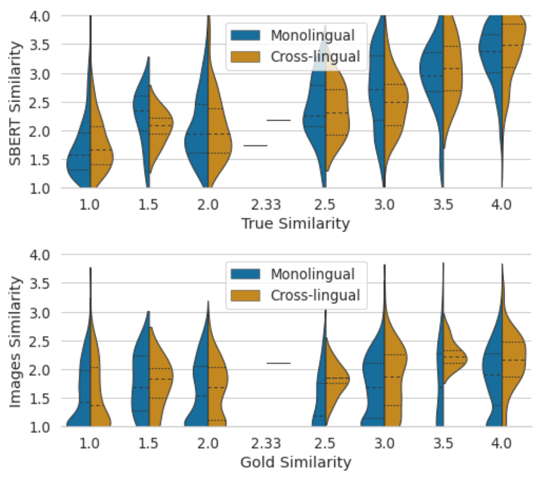


Figure 3: Similarity scores for the article pairs with available images for the image-based model, Images (2a) and Text+metadata (4c).

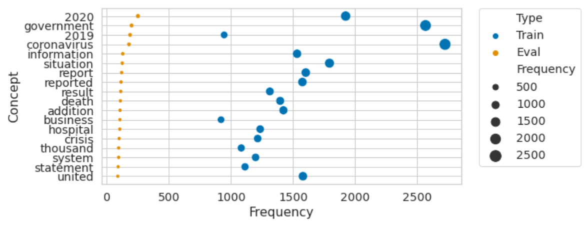

Figure 4: Distribution of KG concepts in the train and evaluation sets.

set (Table 1), only 2,009 have representative images for both news articles. Thus, we look closer at the predictions for these pairs and notice that 13% of them (262 pairs) are correctly predicted by (2a), and not by (1d), all of these being images with either faces or clearly identifiable texts or text boxes, as shown in Figure 1 for two pairs of English articles. We also give an example where this model is able to better distinguish the similarity between two articles in an unseen language (Russian) in Figure 2, where the articles discuss the same topic but describe different events.

Knowledge Graph Similarity & Regression We analyze the representations of articles based on the number of concepts retrieved from the WikiData5m. The most frequent concepts include entities such as *government, coronavirus, epidemic, report, information, death*, and *economy*, showing us that most of the articles report about the COVID-19 pandemic. The distribution of concepts per document is shown in Figure 4. Originally, the Wikidata5m KG is based only on English concepts. We notice a performance drop for the non-English articles, due to the translation to English, some original concepts are lost and replaced with another. For the training set, we retrieved an average of 55 concepts per article, while for the evaluation set we obtained 54 concepts per article. The lowest amount of retrieved concepts was one and the highest was 757.

Text & Image Regression Figure 3 presents the Images (2a) similarity scores in comparison with Text+metadata (4b) and Text+metadata+images (4d) similarity scores. First, the results for Text+metadata (4a) seem to be rather similarly distributed to those provided by SBERT, with a slight difference in the monolingual pairs with a gold score of 1.5, while SBERT generally predicts a similarity of 2.5. When using image representations, not surprisingly, we notice that the results for Images (2a) generally stay around an average of 2.0. This shows that having only around half of the train and evaluation sets with images is not enough to help distinguish between news articles.

SemEval-2022 Task 8 In the official SemEval-2022 Task 8, we ranked fifth in the overall team ranking for multilingual and cross-lingual results, and second in the English-only results. Our best performing model for both is SBERT finetuned on the STS task.

5 Conclusions

In this paper, we covered several techniques for assessing the similarity between multilingual and monolingual news articles in the context of SemEval-2022 Task 8 *Multilingual News Article Similarity*. We notice that, even if using images and knowledge graph representations give promising results, approaching STS with sentence embeddings is still unbeatable. However, images, being a language-agnostic medium, could be helpful if they depict people or text boxes. Future work could include an adaptable inclusion of images (for handling missing images) and the usage of multilingual knowledge graph representations.

Abstract

This paper describes our system designed for SemEval-2022 Task 8: Multilingual News Article Similarity. We proposed a linguistics-inspired model trained with a few task-specific strategies. The main techniques of our system are: 1) data augmentation, 2) multi-label loss, 3) adapted R-Drop, 4) samples reconstruction with the head-tail combination. We also present a brief analysis of some negative methods like two-tower architecture. Our system ranked 1st on the leaderboard while achieving a Pearson's Correlation Coefficient of 0.818 on the official evaluation set.

1 Introduction

In Task 8 (Chen et al., 2022), we are expected to assess the similarity of pairs of multilingual news articles as shown in Table 1. Ten different languages are covered in this task, including Spanish, Italian, German, English, Chinese, Arabic, Polish, French, Turkish and Russian. Task 8 emphasizes more the events themselves described in the news rather than the style of writing or other subjective characteristics. Therefore, it is beneficial to improve the quality of clustering of news articles and to explore similar news coverage across different outlets or regions.

The foundation model (Bommasani et al., 2021) we choose is XLM-RoBERTa (XLM-R) (Conneau et al., 2019) which has been proved to be a powerful multilingual pre-trained language model compared with other models like mBERT (Devlin et al., 2018) and it can process all the languages existing in Task 8. Based on that, a great variety of strategies have been tested along with our exploration like data augmentation (DA), head-tail combination, multi-label loss, adapted R-Drop, etc.

Through this task, we realized the importance of data quality and efficient training schemes in such a cross-lingual setting. By struggling to improve the richness of the data and find out what methods are effective when training such a similarity assessment model, our system[1] ranked 1st in this competition.

2 Background

2.1 Dataset Description

There are 4,964 samples with 8 language pairs in the training set and the test set contains 4,593 samples in 18 different language pairs, the details of which are presented in Table 2. Due to some inaccessible URLs, the training set is slightly smaller than it should be (22 samples missing in total).

The similarity scores of pairs of articles in the provided dataset are rated on a 4-point scale (between 1 and 4) from most to least similar in 7 subdimensions, including *Geography*, *Entities*, *Time*, *Narrative*, *Overall*, *Style* and *Tone* (an example is provided in Appendix). However, only the predictions for *Overall* will be used to evaluate the performance of our systems.

2.2 Related Work

Research on text similarity always attracts people's eyes as it acts as the basis of quite a few NLP downstream tasks like information retrieval (Ponte and Croft, 2017). Previously, some methods based on statistics like BM25 (Trotman et al., 2014) and Edit Distance (Ristad and Yianilos, 1998) are used to evaluate the relevance between two texts but they do not work anymore in cross-lingual settings. Then, after dense word embedding in low dimensions like Word2Vec (Mikolov et al., 2013) was put forward, methods like calculating the cosine similarity (Rahutomo et al., 2012) with the sentence embedding based on each word embedding came into use. However, it is hard for these approaches to capture the latent meaning of the whole article precisely. Nowadays, depending on transformer-based

Data Extraction and Cleansing

Figure 1: The overall framework of our system proposed for SemEval-2022 Task 8.

general pre-trained models are becoming the new paradigm and plenty of models for multilingual and cross-lingual settings have been proposed like mBERT (Devlin et al., 2018), ERNIE-M (Ouyang et al., 2020) and XLM-R (Conneau et al., 2019).

3 System Overview

Our baseline system is simply providing a pair of articles to XLM-R and regressing its output from [CLS] token to the manually annotated similarity score by training with Mean Squared Error (MSE). All the optimization methods discussed below are applied based on this architecture and the overall framework of our final system is illustrated in Figure 1. After training with all the positive strategies, we then made an ensemble of the best models on each fold for the final prediction.

3.1 Data Augmentation

In this task, we augmented the training data in two different ways and they will be introduced respectively in the following subsections.

3.1.1 Back Translation

It is clear from Table 2 that the original training set is not sufficient to train XLM-R, so we made use of back-translation to enrich it. As the English pairs account for the largest, we only paid attention to the non-English samples in this stage. Take the French samples for example, by calling Google Translation API[2], we translate the French articles to English and then translate the English texts back to French. As for the cross-lingual pairs with German and English, we only back-translate the German part and then combine it with the corresponding English part to form a new sample.

3.1.2 Translate Train

Another weakness of the original training set is the severe lack of some monolingual language pairs which exist in the test set but not in the training set like Chinese and quite a few cross-lingual language pairs like German to French. To deal with this problem, we planned to generate translate-train data to fill the gap.

In such semantic comprehension tasks, it is undoubted that the richer semantic information is, the better the model performance will be. Therefore, for maintaining the semantic richness to the largest extent, we made an arrangement for the construction of the translate-train set (details are provided in Table 3).

As the average quantity of non-English monolingual samples in the training set is 430, for the sake

Table 2: Data distribution in each set. Columns with one language (e.g. "zh") mean the two articles in a pair are in the same language. Columns with two languages (e.g. "zh-en") indicate the corresponding cross-lingual pairs.

Origin	Quantity	Target
en-en	401	ru-ru
	800	zh-zh / zh-en
	586	it-it / es-en / es-it
pl-pl	349	pl-en
de-en	317	de-fr / fr-fr

Table 3: Arrangement for the construction of translate-train set.

of balancing the whole dataset, we decided to round it down to 400 and let it be the number of translated samples for Russian (due to some precision issues, it became 401 accidentally). As we may know, Russian and English both belong to Indo-European Family (Fortson IV, 2011) while Chinese is a member of the Sino-Tibetan Family (Thurgood and LaPolla, 2016), which indicates that there are quite a lot of common characteristics between the two languages like syntactic structures and lexical analysis methods. So, the most English samples in the original training set would help more in understanding Russian instead of Chinese. Therefore, we decided to generate more Chinese pairs and here we just doubled the number for Russian. Furthermore, the English samples left were all used for generating samples in Italian and Spanish.

In order to improve the reusability of those samples newly translated already, some work on recombination among different languages pairs was done in this phase. For instance, translating German to English samples to French would let us get German to French samples in the meantime.

3.2 Head-tail Combination

There is no doubt that different types of texts have different features. As for news, the title tends to be the most informative place in each article since the authors need to use as few concise words as possible to let the readers know what happened in the story. Besides, we believe the head and tail parts of a news article provide much information as well as similar to the introduction and conclusion parts in a research paper. As the XLM-R is capable of processing 512 tokens in each sequence (a pair of articles) at most and the large majority of articles in the training set are much longer than 256 tokens (see Figure 2), we tried different truncation strategies to further boost the model performance.

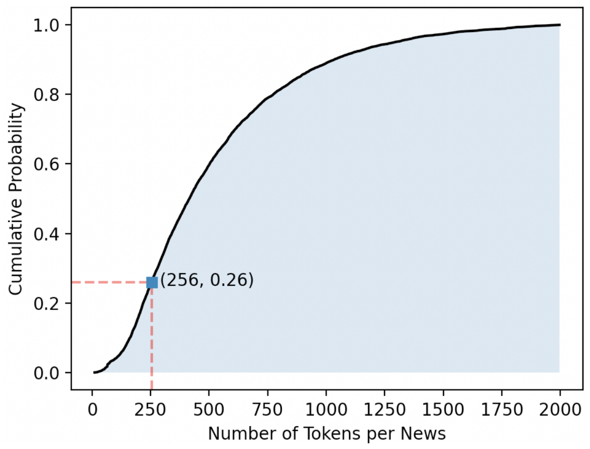

Figure 2: Cumulative probability distribution of article lengths in the training set.

3.3 Multi-label Loss

As introduced in Background, only the predictions for *Overall* will be used to evaluate, but the other 6 sub-dimensions are also probably helpful for assisting in building a better model. Consequently, we tried to assign various weights for *Overall* when calculating the loss while treating other sub-dimensions equally. For example, if the loss for *Overall* accounts for 40%, the percentages of the other six sub-dimensions are all 10% individually.

3.4 Adapted R-Drop

R-Drop is proved to be an effective regularization method based on dropout, by minimizing the KL-divergence of the output distributions of every two sub-models generated via dropout in model training (Liang et al., 2021). To better fit with this regression task, we replaced the KL-divergence loss with MSE loss (adapted R-Drop). Similarly, at each training step, we feed the samples through the forward pass of the network twice. Then, our adapted R-Drop method tries to regularize the model by minimizing the two predicted scores for the same sample, which is:

$$L_R^i = \text{MSE}(y_1^i, y_2^i)$$

where the y_1^i means the model output in the first forward pass for the i_{th} sample. With the basic MSE loss L_B of the two forward passes:

$$L_B^i = \frac{1}{2} \cdot (\text{MSE}(y_1^i, \hat{y}^i) + \text{MSE}(y_2^i, \hat{y}^i))$$

where the $\hat{y}^i$ is the label of the i_{th} sample, the final training target is minimizing L^i for i_{th} sample:

$$L^i = \alpha \cdot L_R^i + (1 - \alpha) \cdot L_B^i$$

where the α is the weight for the adapted R-Drop loss. Based on this introduction, it is easy to extend the formulas to those of forwarding three times.

3.5 Extra Linear Layers

In our baseline system, the prediction score is generated by passing the output of [CLS] token from XLM-R through a single linear layer with the size of (1024, 1). In other words, there are only 1024 parameters that are responsible for the regression from the sentence representation vector to the prediction score, which is probably beyond their power. Hence, we attempted to add a few more layers on top of the XLM-R.

3.6 Post-processing

Once getting the prediction scores, we further corrected some wrong numbers which were outside the expected range. As introduced in Section 2.1, the annotators annotated the similarity in the range (1, 4); consequently, we clipped the outliers.

4 Experimental setup

4.1 Dataset Split

Both the original training set and the training set with DA set were split into 10 subsets with no intersection by random sampling. All the experiments discussed in this paper were conducted with 10-fold cross-validation, and the results displayed are the averages. By using the cross-validation method (Browne, 2000), we could ensure the strategies applied will take a good effect on the final test set to the largest extent.

Baseline	84.94
+ Head-tail Combination	85.38
+ Multi-label Loss	85.33
+ Adapted R-Drop	**86.14**
+ Extra Linear Layers	85.50

Table 4: Best results with training methods we used.

4.2 Pre-processing

The news articles in all the data sets are released as URLs and the task organizers offer us a python script[3] which helps to download the pages. After downloading the original files in JSON format, we then extracted and combined "title" and "text" parts of each article and abandoned all other information like "description". Before starting training our model, apart from conducting data augmentation to the training set, we also cleaned the data and joined the head and tail parts of each article. During the process of cleaning, we mainly removed some dirty formatted data like URLs and file paths.

4.3 Evaluation Metrics

The evaluation metric for task 8 is the Pearson's Correlation Coefficient (Pearson's CC) which is a measure of linear correlation between two series of data with a range from -1 to 1 (from least to most correlated) (Stigler, 1989).

4.4 Others

Although hyper-parameters tuning is not a crucial point in our work, we tested a few values for several of them within a small range as they did have an influence on our decisions about how well a strategy worked (see Appendix). Additionally, to help readers replicate our experiments, the details of tools and libraries are provided (see Appendix).

5 Results

5.1 Overall Performance

Finally, our system got 0.818 on the evaluation set according to the official scoring system and

128	128	85.21
56	200	84.53
0	256	78.85

Table 5: Results on different head-tail combinations.

ranked 1st. As results are shown in Table 4, all the strategies introduced in Section 3 turned out to have positive effects, and we will discuss the effect of the strategies mentioned individually in the following subsections. For convenience, all the results from our experiments are multiplied by 100.

5.2 Data Augmentation

To find out whether the augmented data was helpful or not, we trained our system on the original training set and the training set with DA respectively (samples used for testing were removed in both of them), then tested it on each fold of the DA set. In experiments on other strategies, we trained and tested our system on the original training set. And this is the difference between the two baselines in Table 4.

Without any surprise, an evident increase is observed from the results displayed in the top part of Table 4, based on which we could make a conclusion that a more abundant training set is definitely beneficial for building a strong system.

5.3 Head-tail Combination

As introduced in Section 3.2, we realized the importance of the head and tail parts of the news articles. However, we cannot determine which part should be paid more attention to heuristically. So, we tried on different ratios of head-tail combination and the results are enumerated in Table 5. Clearly, the head part plays a much more important role by comparing the first and last rows where only either of them are used. However, from the middle three rows where the head and tail parts are combined, it is indicated that the tail part also benefits the whole model performance.

5.4 Multi-label Loss

As discussed in Section 3.3, we used other 6 dimensions and assigned a few different values for the weight of *Overall* from 0% to 100%. It is explicitly

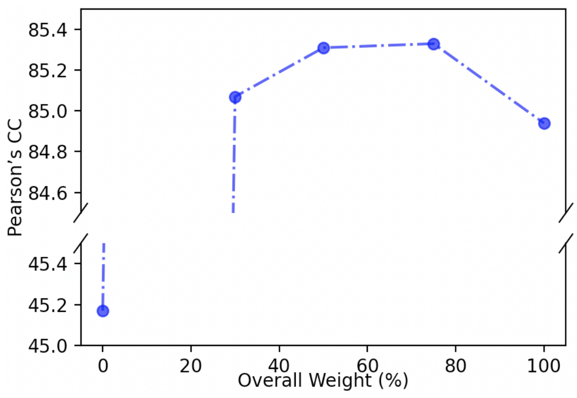

Figure 3: Results on training with multi-label loss.

observed from Figure 3 that there is an overwhelming increase followed by a slight drop while the weight of *Overall* rises gradually. Based on the experiment results, we believe that *Overall* is of the greatest importance to this task, yet the other 6 subdimensions also have a positive effect on achieving a better similarity assessment system.

5.5 Adapted R-drop

As described in Section 3.4, the training loss in our system is composed of both the loss between predictions and labels and the loss between the predictions from different forwarding processes. Here, we explored forwarding once to three times while changing the weight of adapted R-Drop loss.

Apparently, there is a phenomenon from Figure 4 that no matter how large the weight of R-Drop loss is, the more forwarding times are, the better results we will achieve. However, by comparing the results between forwarding once and twice and the results between forwarding twice and three times, we speculate that there is a marginal utility (Kauder, 2015) on this trick, which means the additional benefit from this method will decrease while simply continuing increasing the number of forwarding.

5.6 Extra Linear Layers

During the process of exploration in this direction, we attempted to add 2 or 3 extra linear layers to test if it worked. In the 2-layer setting, the sizes of the layers are (1024, 512) and (512, 1) while sizes composed of (1024, 768), (768, 256) and (256, 1) are prepared for the 3-layer setting. Two sets of experiments were conducted in both settings about whether to put an activation layer (we used GELU (Hendrycks and Gimpel, 2016) here) between adjacent linear layers or not.

It can be observed from Table 6 that there is only

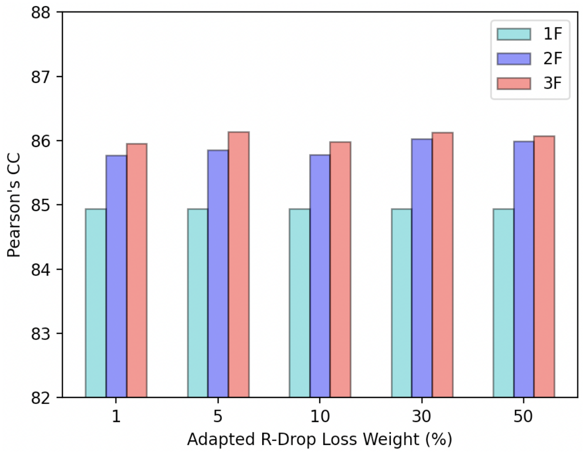

Figure 4: Results about adapted R-Drop (RD) in different settings. "2F" means forwarding twice.

System	Pearson's CC
1-layer	84.94
2-layer	85.46
+ activation	**85.50**
3-layer	85.32
+ activation	85.23

Table 6: Results on different extra layers.

a quite small difference that caused by activation layers in each setting and the effect of that is not always positive. In addition, by comparing the results from different settings, we could draw a conclusion that more parameters did help to boost the system performance even if the benefit does not show linear growth.

5.7 Negative Results

Aside from the strategies discussed above, several tricks that were attempted to deploy in our system as well turned out to be meaningless or had a bad effect on the model performance. For example, we tried to use a pooling vector (max or mean) or the fusion of [CLS] vectors from different layers in XLM-R as the article representation. We also tried to expand the length of sentences that XLM-R could process to 1024 tokens by modifying its position embedding matrix by means of adding a random shift vector after each vector or just randomly initializing the latter part of the learnable expanded matrix. Each negative strategy mentioned above brought approximately at least 2 points drop on the Pearson's CC. Furthermore, unsurprisingly, a two-tower architecture where each shared-parameter model processed each article in a pair led to scores of points decrease, which reflected the importance of semantic interaction via the attention mechanism inside the model.

81.97	68.89	64.31	82.68	

Table 7: Individual results of all language pairs in our best submission.

5.8 Error Analysis

After the evaluation phase ended, the evaluation data with labels were provided and we also checked the system performance on different language pairs individually. The details of our best submission are presented in Table 7. It is obvious that the model tends to perform worse on the language pairs which are rare or absent from the training set like German to Polish (only 64.31). Interestingly, although having seen monolingual samples in Polish and related cross-lingual data, the system still behaves badly on Polish monolingual data (just slightly over 75), which is probably due to its complicated lexical variation and grammar rules (Smoczynska, 2017).

6 Conclusion

By deploying various optimization methods, including data augmentation, head-tail combination, multi-label loss, adapted R-Drop and adding extra linear layers, we built a relatively strong system for assessing the similarity between a pair of news articles in multilingual and cross-lingual settings and ranked 1st in the competition with a Pearson's CC of 0.818 on the official evaluation set.

In the future, apart from enriching the training data, we are also supposed to analyze the languages individually and try to leverage the exclusive rules or features of each language rather than relying too heavily on general pre-trained models to further boost the model performance, especially on those minority languages.

GateNLP-UShef at SemEval-2022 Task 8: Entity-Enriched Siamese Transformer for Multilingual News Article Similarity

Iknoor Singh, Yue Li, Melissa Thong and **Carolina Scarton**
Department of Computer Science, University of Sheffield (UK)
{i.singh, yli381, mlthong1, c.scarton}@sheffield.ac.uk

Abstract

This paper describes the second-placed system on the leaderboard of SemEval-2022 Task 8: Multilingual News Article Similarity. We propose an entity-enriched Siamese Transformer which computes news article similarity based on different sub-dimensions, such as the shared narrative, entities, location and time of the event discussed in the news article. Our system exploits a Siamese network architecture using a Transformer encoder to learn document-level representations for the purpose of capturing the narrative together with the auxiliary entity-based features extracted from the news articles. The intuition behind using all these features together is to capture the similarity between news articles at different granularity levels and to assess the extent to which different news outlets write about "the same events". Our experimental results and detailed ablation study demonstrate the effectiveness and the validity of our proposed method.

1 Introduction

News article similarity measures could facilitate various important tasks such as the clustering of news (Montalvo et al., 2007; Azzopardi and Staff, 2012), duplicate news detection (Alonso et al., 2013; Gibson et al., 2008; Singh et al., 2021a; Theobald et al., 2008), fact-checking (Hassan et al., 2017; Jiang et al., 2021) and tracking of the spread of news (Zhai and Shah, 2005). SemEval-2022 task 8 (Chen et al., 2022) assesses the similarity between news articles in terms of the real world happenings. Therefore, it mainly considers the location, time, entities and narratives, instead of writing style, political spin, or tone of the article. The training set comprises of monolingual and cross-lingual news articles pairs in 10 different languages.

The main contributions in this paper are: 1) We propose an entity-enriched Siamese Transformer whose general idea is to enable the model to explicitly learn from entity features (geolocation, organization, date and quantity) that are crucial to determine the similarity between news events but difficult to extract directly from the language models during fine-tuning. 2) We explore different data augmentation approaches through semi-supervised learning in order to tackle the imbalanced data problem. 3) We compare our proposed model with strong baselines and conduct an ablation study to analyse the contribution of each component in our model. We also present an error analysis at the end of this paper. Our best system which exploits Language Agnostic BERT Sentence Representations (Feng et al., 2020) ranks 2nd in the competition.

2 Background

The goal of the task is to predict similarity scores ranging from 1 (most similar) to 4 (least similar) for a give news article pair. The training data consists of 4,964 article pairs in seven distinct languages (English, German, Spanish, Turkish, Polish, Arabic and French), with seven groups of monolingual pairs and only one group of cross-lingual pair (German and English). The 4,902 pairs in test data feature three more languages (Chinese, Russian and Italian) and seven groups of new cross-lingual pairs. Appendix A.1 (Figure 3) shows the distribution of the train and test data. Most of the news pairs exhibit low level of similarity. However, the test set contains more pairs with the same news stories. The similarity based on location, time, entities, narratives, style and tone is also annotated respectively and given for the training data.

Previous studies on textual similarity have investigated different approaches based on corpus, knowledge or deep neural network (Chandrasekaran and Mago, 2021; Gomaa et al., 2013; Devlin et al., 2019; Reimers and Gurevych, 2019; Thakur et al., 2021a; Singh et al., 2021b), but they mainly experiment with short text pairs (e.g., the Semantic Textual Similarity (STS) benchmark (Cer et al., 2017), which is a sentence-level task). Measurement of the document similarity is arguably more challenging than that of short text since the information in the document is sparse and the model is easier to be misled by non-essential content. This paper tries to tackle the above mentioned challenges to build robust models for document similarity (Section 3).

3 System Overview

We propose an entity-enriched Siamese Transformer model which exploits multiple multilingual pre-trained Transformers (MPT) for multilingual news document similarity. The main subdimensions of similarity as annotated by the annotators are geolocation, time, shared entities and the shared narratives between the news articles (Chen et al., 2022)[1]. All this information is encoded in our model to capture different dimensions of news articles. Figure 1 shows the architecture of our proposed model and section 3.1 discusses its details.

3.1 Model Details

Reimers and Gurevych (2019) propose a Siamese and triplet network training methodology for the BERT-based (Devlin et al., 2019) models to derive semantically meaningful sentence embeddings. Instead of just learning the sentence representations, we use the Siamese (or bi-encoder) network architecture to learn document-level representations for the purpose of capturing the narrative of the article.

In this work, we test multiple MPT models as the backbone Transformer (Vaswani et al., 2017) encoder for our Siamese network and train the model using a regression objective function (Reimers and Gurevych, 2019). In this, the model is trained such that it forces contextual representations from similar documents close to each other in contrast to dissimilar documents by reducing the mean squared error loss between the overall similarity score and the cosine similarity between document representations. First, we concatenate title and news article text together to generate a single document. For the documents that lie beyond the maximum input sequence length for the model, we truncate their length and use the initial part of the document as a proxy for its fundamental narrative that is usually stated in the title and the lead paragraphs of news articles.

In an effort to explicitly capture other dimensions of the news article such as mentions of geolocation, event date, organisations and other named entities, we use SpaCy NER[2] to extract entities from the documents. For the non-English documents, we use their machine translated English versions to extract the entities (Fan et al., 2021).[3] All the extracted entities are aggregated into four different types of entities. The entity types along with their SpaCy labels (in brackets) are:

- **Geolocation (GEO)**: Location (LOC) and geopolitical entities (GPE) which includes mentions of countries, cities, states etc.
- **Organization (ORG)**: Name of organization (ORG), person (PERSON) and mentions of other important named entities (FAC, EVENT, NORP, PRODUCT, WORK_OF_ART) which can include names of airports, highways, sports events, religious or political groups etc.
- **Date (DATE)**: Date of publish from training set and date (DATE) and time (TIME) extracted from the news articles.
- **Quantity (QTY)**: Mentions of numerical quantity (QUANTITY) which can include both ordinal and cardinal measurements (ORDINAL, CARDINAL).

After extracting the list of all the above mentioned entities for both the documents, we lowercase all the entities and compute the cosine similarity to get a single similarity score which we use as feature for further training. The complete algorithm to compute similarity between entities is presented at Algorithm 1. We use the cosine scores of these four additional entity features along with the shared narrative score from Siamese Transformer to train a multilayer perceptron (MLP) with sigmoid activation to get the final news article similarity score. Overall, only the Siamese Transformer model is differentiable and all other are non-differentiable static features before the MLP layer. It is worth noting that both the Siamese Transformer and the MLP layer are trained separately and not jointly. The intuition behind using all these features together is to capture the similarity between news articles with different granularity and to assess the extent to which outlets write about same events.

    MagnitudeB ⟵ Sqrt(Sum(B.count(ent)$^2$ for ent in Entities))
    Score ⟵ Product / ( MagnitudeA * MagnitudeB )
    return Score
end function
```

3.2 Semi-Supervised Learning

One of the issues with the training dataset is its imbalanced nature, i.e. there are considerably more document pairs with low similarity scores as compared to pairs with high similarity scores (Figure 3). In order to upsample the instances with high similarity, we first augment the training set and then adopt a semi-supervised training methodology to train the model. For this, we first explore randomly sampling document pairs and label them using our previous best model trained on the training set. However, we found that random sampling does not generate good quality augmented training data as most of the generated pairs still lie in the similarity range of [0.0,0.2]. Therefore, we employ the augmentation strategy similar to one proposed by Thakur et al. (2021b), i.e. BM25 sampling, for which we use the Elasticsearch[4] implementation of BM25 to generate augmented article pairs. However, our method is slightly different where we use the title of a news article as a query for retrieving other news article to get the document pairs. This helped the generation of documents pairs with similarity score that are more evenly distributed. A total of 59,943 additional document pairs were generated using the BM25 sampling and 2,845 document pairs were generated using machine translation. The complete details of the generation of augmented data is mentioned in Appendix A.2.

Semi-supervised learning (Zhu and Goldberg, 2009) is a widely known training paradigm where a model is first trained on a human labelled dataset and the model is further used to extend the training set by automatically annotating the unlabelled dataset. Following previous studies (Thakur et al., 2021b; Jurkiewicz et al., 2020), we initially start with training on the original training set and then for all the generated unlabelled document pairs, we use the previously trained model for inference to get the similarity scores for the new synthetic document pairs. Finally, we train our entity-enriched Siamese Transformer in a semi-supervised fashion on both the complete augmented training set.

4 Experimental Setup

The training set contain 4,964 article pairs, however, after removing pairs with empty documents or if one of the document has less than ten tokens, we get a total of 4,544 article pairs for training. For the experiments, the training set is split into train and development sets using a 80:20 split ratio. The data is split in a stratified fashion to keep equal proportion of all languages, except Arabic document pairs that only appear in the development set, keeping it as a unseen language for the training set We get a total of 3,635 document pairs for the training

[4]https://www.elastic.co/elasticsearch/

set and 909 document pairs for the development set. In the end, we train models on the complete train and development set for final evaluation on the test set consisting of 4,953 document pairs.

The training set has different types of labels which take into account different aspects of similarity among news articles (e.g., geolocation, narrative) (Chen et al., 2022). For our experiments, we use the "Overall" similarity as the true labels. However, the overall similarity label is in a range [1,4] where 1 signifies highest similarity and 4 means lowest similarity. In order to normalise these overall similarity label, we subtract all values from 4 to bring values in range [0,3], followed by min-max normalisation. The formula for this is as follows,

$$x_{norm} = \frac{x - x_{min}}{x_{max} - x_{min}} = \frac{4 - x}{3} \quad (1)$$

where x denotes the overall similarity value and x_{norm} is the normalised value in range [0,1] from least similar to most similar. We use these as labels for training our models.

Since there are no baselines provided by task organisers, we use strong baseline methods for comparison. First, we use separate entity-based cosine similarity scores (Section 3.1) to find the Pearson correlation with the official test set labels. Second, we use Siamese multilingual BERT (Devlin et al., 2019), XLM-RoBERTa base variant (Conneau et al., 2020), Universal Sentence Encoder (USE)[5] (Yang et al., 2020) and LaBSE (Feng et al., 2020). Third, we also use the pre-trained MPNet[6] (Song et al., 2020) and fine-tuned it on the machine translated English training set. Please refer to Appendix A.3 for training details and the hyper-parameters used in our experiments.

5 Results and Discussion

Table 1 shows the Pearson correlation coefficient scores on the official test data. The first part of the Table 1 presents the results of the baseline methods and the second part presents the results of our proposed model. For baselines, we find that if we just consider the entity-based features without training, organisation (ORG) achieves the highest Pearson correlation with the official test set. Furthermore, for the trained Siamese Transformer models, the LaBSE works best and the XLM-RoBERTa achieves the lowest score of around 0.70.

The second part of Table 1 shows the results of our entity-enriched Siamese Transformer trained on the augmented data using the semi-supervised learning paradigm. Training the Siamese Transformer on the augmented data brings significant improvements for all the models except USE when compared with the ones trained on the training set without augmentation. A potential explanation for LaBSE's impressive performance is the MLM and TLM pre-training objective on a dataset of 109 different languages, followed by training on a translation ranking task (Feng et al., 2020). We also test the Siamese Transformer both with and without the entity-enrichment in order to study how significant the improvements are statistically with entity features. Furthermore, we use Williams test (Graham and Baldwin, 2014) to test the statistical significance of increased correlation with the added auxiliary entity features. As shown in the Table 1, for all Siamese Transformers trained on the augmented data, entity-enrichment brings improvements in results to a statistically significant degree (p-value$<$0.01). We also find that the results of entity-enriched Siamese Transformers are statistically significant (p-value$<$0.01) when compared with the baseline Siamese Transformers for all the models. Overall, our entity-enriched Siamese LaBSE model trained on augmented data achieves the highest Pearson correlation of 0.80164.

Figure 2 presents the detailed analysis of the results for the entity-enriched Siamese LaBSE trained on augmented data model (best model). We observe that model performance varies in different language settings. The model performs the worst over German-French pairs (0.619), while it achieves the highest score on French-Polish articles (0.866). Overall, the model performs better on mono-lingual pairs than on cross-lingual pairs.

We further analyse the "serious mistakes" that our best model tends to make: giving high/low similarity scores for dissimilar/similar article pairs. We identify these instances based on the difference between the true similarity score and the predicted similarity score from the model. We examine the cases when the absolute values of the differences are larger than 2.0 (total 46 samples found), and observe that: 1) News pairs that cover different

Table 1: Pearson correlation coefficient score on the official test data. The best performance is in bold.

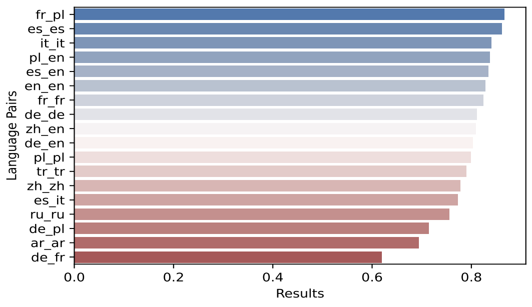

Figure 2: Performance over different language pairs in official test data. Average score of mono-lingual and cross-lingual pairs is 0.79833 and 0.78205 respectively.

stories around the same entities or topics are more challenging for the model. For example, the model outputs a similarity score of 1.77 for the following dissimilar news pair: an article about COVID-19 quarantine policy in Azerbaijan and another one regarding sanitary rules for preventing COVID-19 in Azerbaijan. 2) Web scraping could introduce noises in the model evaluation and obscure the true performance. We find that the scraping tool provided by the organizer fails to extract the real news content for all the Arabic news from Ahewar news website. The banner of the news website is returned instead. If we ignore the 25 pairs involving news from this website in the official test set, the Pearson correlation coefficient score over the Arabic data increases significantly from 0.69425 (2nd worst in Figure 2) to 0.84067 (4th best). 3) The model tends to overestimate the degree of similarity. Among the 46 "serious mistakes", only 15 of them are similar news pairs with predictions indicating dissimilarity. And these wrong predictions are all caused by scraping-related issues (the real content of news is not returned). However, we argue that our entity features may potentially increase the robustness and decrease the level of overestimation. We compare the performance between models with and without entity features. The results show that the differences between true label and prediction decrease for 22 of the 31 dissimilar news pairs.

6 Conclusion

We introduce an entity-enriched Siamese Transformer for SemEval-2022 Task 8: Multilingual News Article Similarity. The error analysis shows that the entity-enrichment leads to statistically significant improvement and make models more robust for computing similarity between news articles in both monolingual and cross-lingual setting. Our entity-enriched LaBSE model achieves a Pearson Correlation of 0.802, ranking 2nd in the competition. The code is available at `https://github.com/iknoorjobs/semeval-code`.

A Appendix

A.1 Data Distribution

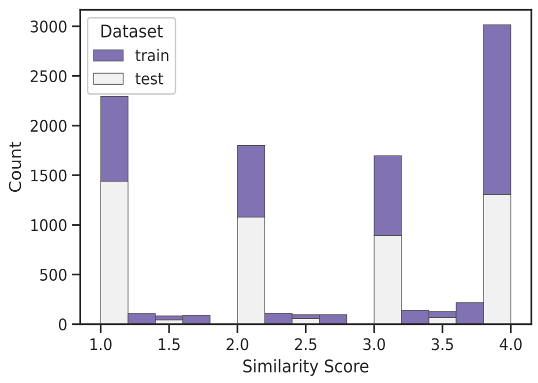

Figure 3: Distribution of training and test data

A.2 Augmented Data Generation

The details of augmented data used in our experiments is as follows,

Augment Data 1. In this, we used the training set provided by organisers where the title of the article is used as a query to all the other articles in the training set that are indexed in Elasticsearch. If title or article are not in English, then the English machine translated version is used to perform the retrieval. Also, we exclude the cases of document pairs that are already present in the training set. We generated 25,125 by using the top 5 retrieved documents for each case.

Augment Data 2. We machine translated the English document pairs with overall similarity score in range of [0.5-1] to other languages. We only choose to translate document pairs that are English to get a good quality machine translated augmented training data. For this we randomly sampled five different language pairs from the list of language pairs that follow the same distribution as that of language pairs found in the test set and machine translated the documents[7] (Fan et al., 2021). We generated 2845 additional document pairs using this augmentation strategy.

[7]Pre-trained model m2m_100_418M is used for our experiments. Ref. `https://github.com/pytorch/fairseq`

Augment Data 3. Here, we utilised "All the news" dataset available on Kaggle[8] which contains 143,000 articles from 15 American publications. Here, title from the SemEval training set is used as query to all the articles in Kaggle new datasets. We generated 34,818 document pairs using the top 5 retrieved documents.

In our experiments, we use augment data 1, 2 and 3 which constitute a total of 62,788 additional document pairs and use them all together along with the training set to train the models.

A.3 Hyperparameters

The Transformer encoder of our Siamese Transformer (shared parameters) model is trained for 4 epochs with a batch size of 8, learning rate of 2e-5 and maximal input sequence length of 512. The output of model along with entity features is passed to the MLP layer which is composed of 32 hidden units trained with learning rate of 1e-3. The output of this MLP layer is used to get the final similarity score for the news articles. Adam (Kingma and Ba, 2015) is used to optimize the model parameters. For all the experiments, the model which works the best on the dev set is submitted and evaluated on the test set provided by the task organisers. All experiments are conducted on a machine with NVIDIA GeForce RTX 3090.

Abstract

This work is about finding the similarity between a pair of news articles. There are seven different objective similarity metrics provided in the dataset for each pair and the news articles are in multiple different languages. On top of the pre-trained embedding model, we calculated cosine similarity for baseline results and feed-forward neural network was then trained on top of it to improve the results. We also built separate pipelines for each similarity metric for feature extraction. We could see significant improvement from baseline results using feature extraction and feed-forward neural network.

1 Introduction

For finding similarity between two documents, the general approach is to get the embeddings for the documents and use some similarity metric like cosine similarity to get similarity measures. Such work has been done in multiple domains like research papers, semantic similarity (Olizarenko and Radchenko, 2021) (Boom et al., 2015) document similarity (Ostendorff et al., 2020) (Rushkin, 2020) and for news articles (Watters and Wang, 2000) (Singh and Singh, 2020) (Blokh and Alexandrov, 2017). There have been other works to find similarity between documents of multiple languages (Potthast et al., 2008) as well. The most significant difference here is that authors have used subjective similarity measures like writing style and authorship for these works.

We do feature extraction corresponding to each similarity metric via a unique feature extraction pipeline. For example, for geolocation, we extract the locations from the text. To make it a domain-specific task, we train a network on top of the generic similarity pre-trained embedding model.

To test our approach, we use a pre-trained model for sentence similarity based on S-BERT (Reimers and Gurevych, 2019a) (Devlin et al., 2019). We calculate cosine similarity (Rahutomo et al., 2012) as our baseline on the embedding of the documents. We train a feed-forward network on top of the pre-trained embedding to learn about our domain-specific task. We also use a large pre-trained model, which can take more words as input and compare the results. Our approaches result in an almost 60% MSE improvement over the baseline model.

Our contributions are mentioned below:

- We implement a strong paraphrase-multilingual-MiniLM baseline and show significant gains in MSE by adding a feed-forward neural network on top to learn domain specific knowledge.
- We do domain-specific feature extraction for each similarity metric to prevent model from learning incorrect information. This feature extraction helps improve the final metrics for the task.
- We do qualitative result analysis and show that the baseline model does not learn relevant information for location/time/entity for the corresponding metrics. We observe that after adding feature extraction, the model learns metric specific information.

2 System Description

2.1 Feature Extraction

We extract the entities from the text using Stanza (Qi et al., 2020). Stanza is a python natural language analysis library that contains tools for parsing sentences, recognize named entities etc. Through our experiments we observe that for similarity measures like geography, entities and time, we just need to extract those relevant named entities from the text. To do this, we build seven stanza pipelines for the seven similarity measures. Feature extraction for each of the metric is described below.

1. **Geography:** We extract the location from the article for each pair. If Stanza cannot extract the location, we use the entire text as the embedding. We linearize the location and feed them to the pre-trained model if there are multiple locations. For example, if there are four locations in the article, the output of the pre-trained model is [4, embedding size]. To further linearize the input, we take the mean of all the rows, so the linearized input dims is [1, embedding size]. We repeat this process for the other news articles and calculate the cosine similarity between the two articles.
2. **Entities:** We extract all the named entities from the article for each pair. We linearize the input in the same way as geography, calculating the cosine similarity. There were no cases in this dataset where stanza was unable to extract entities, but in case there are, they will be handled similarly to location.
3. **Time:** We extracted time and date entities from the articles for each pair. If Stanza cannot extract the time entity, we create an embedding for the entire text instead of the time. The rest of the processing is similar to Geography and entities.
4. For **Narrative**, **Style**, **Tone** and **Overall**, we give the entire text as input to the pre-trained embedding and calculate the similarity based on that. In general, for this slightly subjective measure, the neural network learns the representations on its own.

Using the feature extraction defined above, we build our baseline model. Initially, we were giving entire text as input for location class but were getting similar results (less overfitted but worse on test data). We hypothesized that it might be because the model is not learning about specific location class entities but looking at the overall text. To confirm this hypothesis, we took two news articles that were outputting highly similar scores for location and manually changed the location of one article to some random place. The result was that the model was still outputting the two articles as quite similar, which showed that the model was not learning correctly. We extracted just the entities for an objective metric like location, time, and entities and gave that as input to the model. We are making sure that the model is not learning the wrong information to get correct results.

In the future, we can to try to extract the dependency parse of the sentence and give it as an input to the pre-trained embedding as another step in the feature extraction task. We hypothesize that for the style and tone metric giving the dependency parse of sentence as input to the neural network will improve the results. This is because style and tone of writing is author specific and depends on the writing style of the author which a dependency parse of the sentence can capture, but we have not used that approach for this paper.

2.2 Baseline Model

For the baseline model, we used the en-en articles as our dataset. We then do feature extraction to extract relevant features from the article corresponding to the similarity metric. After that, we got the embeddings for these pairs from the pre-trained model for sentence similarity (miniLM-v6) (Reimers and Gurevych, 2019a) and calculated the cosine similarity to find similarity between the articles and calculated the loss for each similarity metric separately.

Limitation The issue with the approaches done historically is that the similarity metrics were subjective, like comparing two documents to see if the same author has written them or not. For such tasks, semantic and syntactic features of the document play a vital role. For our task, we need to focus more on the article's content. For the baseline model that we create, there are two significant issues. First, we use en-en articles to train the model. To test, we translate other language articles to English using Google translate. This approach is error-prone as it compounds the error. Second, if we directly use the cosine similarity of two embedding from a generic document similarity model, we do not take advantage of the domain-specific task. For example, the document similarity in the case of medical documents will be much different in the case of research documents.

3 Proposed approaches

3.1 Feed-forward network

The first idea is to take advantage of the domain-specific task in this work. To do this, we train a feedforward model on top of the baseline to learn document similarity for the news articles domain. To implement this idea, we concatenated the embedding that we got using the pipeline in Figure 1. This input is fed through a three-layer neural network with a ReLU activation function after each

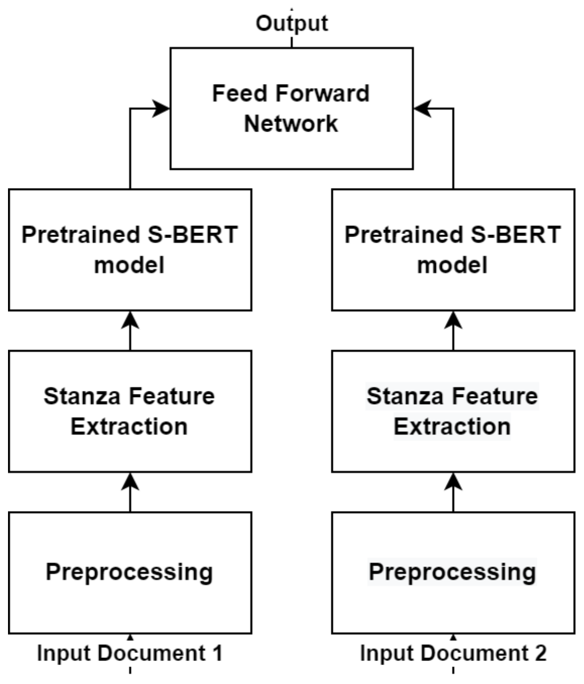

Figure 1: Pipeline for the task. The figure depicts the pipeline for similarity generation containing pre-processing, stanza feature extraction, and pre-trained S-BERT model steps. If we remove the feed-forward and directly calculate the similarity score, that is our baseline model.

layer. The final layer is passed through a softmax layer to get the similarity score between 0 to 1. This model uses MSE loss between the output and predicted value as the loss function, and the optimizer used to train this network is SGD.

3.2 Doc S-BERT

Doc S-BERT is a BERT-base document similarity model that is also called bert-base-nli-mean-tokens. The amount of resources needed to use a base pre-trained model for BERT is much more, but the idea behind using the large doc similarity model is due to a shortcoming in the miniLM model. The miniLM model takes a maximum of 256 words of a document, after which it truncates the rest of the document. The input text length went up to 1000 words, so we believe there is a loss of important information if we use the miniLM model. Both Doc S-BERT and MiniLM models belong to the family of Siamese BERT (Figure 2) (Reimers and Gurevych, 2019b) models.

3.3 Multilingual S-BERT

The idea is to use a multilingual pre-trained model to generate embedding instead of converting other

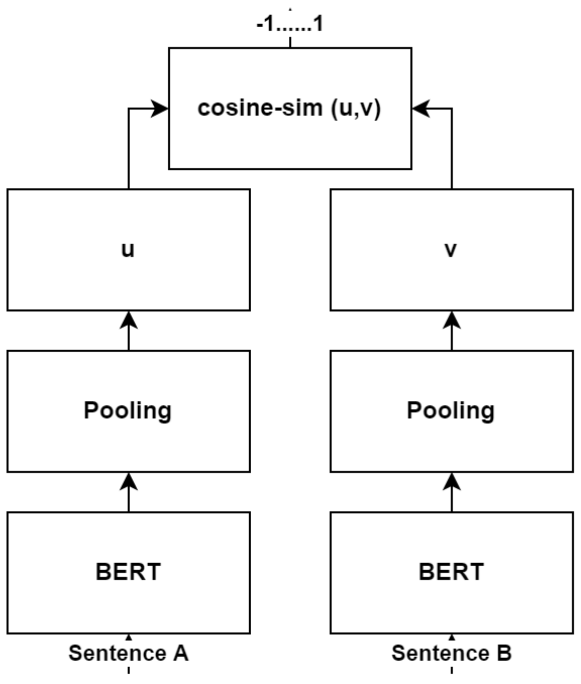

Figure 2: Architecture of S-BERT (Reimers and Gurevych, 2019b)

languages to English to prevent the compounding of errors. We use a multilingual pre-trained similarity embedding generating model. Multilingual miniLM is a single model that is pre-trained for multiple languages. The model is called 'paraphrase-multilingual-MiniLM-L12-v2'. The output embedding dimension from this is similar to our previous model, and the constraints are also similar. We hypothesize that if we can remove the compounding of errors, the multilingual model should give better results than the baseline.

4 Experimental Setup

4.1 Evaluation Measures

The dataset rates similarity metric between 1 to 4, where 1 means most similar, and 4 means most dissimilar. To convert this score to a more usable metric, we subtracted it from the max (4) and divided it by max-min (4-1). The score gets normalized between 0 to 1, with 1 being most similar and 0 being most dissimilar. This score is treated as a regression problem as the scores are rated continuously between 1 to 4 with small buckets.

To evaluate our model, we use MSE loss as the metric. Since we treat this as a regression problem, MSE loss is a good way to judge how the model performance.

$$\text{Mean squared error MSE} = \frac{1}{n}\sum_{t=1}^{n} e_t^2$$

where e_t is the difference between predicted and actual value.

We have also set a tolerance value to get the accuracy. We have tried different values of tolerance to see how our results vary.

If the predicted and actual value difference is less than tolerance, we predict it as a true label; otherwise, we predict it as a false label. We take the mean over the dataset to get the accuracy.

4.2 Preprocessing

We download news articles as HTML files from the URLs given in the dataset. We use beautiful soup to extract the headings and body of the text in the news article and store the metadata in JSON files for each article id. There was some junk data appended at the end of the news article that we manually removed in many articles. We removed the stop words from these articles because our pre-trained model has a word limit in the input document.

4.3 Experimental design

We used the dataset provided by the task organizers [1]. The train dataset has 4964 pairs of news articles with different language articles. En-en:1800, de-de:857, de-en:577, es-es: 570, tr-tr: 465, pl-pl: 349, ar-ar: 274, fr-fr: 72. We split the dataset into train and test sets with the division as 67:33. We did not use a validation set since the dataset was tiny.

We used a variation of S-BERT for all four approaches as the embeddings generation pre-trained model. For baseline and first approach, we use a miniLM model. We use a large miniLM model for the second approach. For the third approach, we used a small multilingual miniLM model. The input truncates after 256 words in the first approach (miniLM FFN) and the third approach(multilingual miniLM). For the second approach (Doc-S-BERT), the input truncates after 256 words.

The output of the embedding size from the small pre-trained model is (384,1). The input to the neural network will be two * embedding size since we concatenate the two article embeddings in our approach, it will be (768,1). We use a three layer feedforward network with layer sizes as (120, 84, 1). After each layer, we feed the input through a ReLU activation function. The final layer is passed through a softmax layer to get the similarity score between 0 to 1. There are seven models for each similarity metric as the input is different for each.

We train the model using SGD with the learning rate at 0.01 and momentum at 0.9. The loss function we chose to train this model is MSE. We trained the model for eight epochs (Early stopping) as the input size was small, and the model started overfitting on the data.

5 Result and analysis

5.1 Baseline

For **location**, the MSE loss that we got is around 0.15 (Table 1). The result is as expected as we hypothesized that just extracting the location entities should give us a good match for similarity. If we allow the threshold to be high (0.5), the accuracy, in this case, is around 0.82. Since its regression, we need to decide the threshold to calculate a metric like an accuracy. With a threshold of 0.33, accuracy was around 0.67. A low threshold like 0.2 gives an accuracy of 0.47.

Similarly, for **time** similarity, we got the MSE as 0.132 (Table 1) and the accuracy with 0.5 tolerance as 0.834. Comparatively, for time, the performance of cosine similarity is good, which is the expected behavior from our initial thoughts since it is a simple task of extracting time from an article and checking its similarity.

For **entities** similarity, we got the MSE as 0.288 (Table 1) and the accuracy with 0.5 tolerance as 0.507. The results are much worse for entities as compared to other results. Our initial thought was that cosine similarity should work with simple tasks like entity similarity. We observed that each article has more than 20 entities at the least, so doing mean of all entities makes it lose all necessary information. We might need to think of a more innovative way of using cosine similarity in this case or use the neural model.

As can be seen from the table, **Overall** class and **Narrative** class show promising results, which is intuitive as the text-similarity of the entire article captures the narrative class and the overall class similarity. As expected, **Style** class and **Tone** class do not show that great accuracy as both style and tone require hidden features like semantic and syn-

Metric	baseline (cosine-sim) MSE	miniLM (approach1) MSE	doc-SBERT MSE	M-miniLM-cosine-sim MSE	M-miniLM-MSE
Geography	0.15	**0.135**	0.164	0.175	0.134
Time	0.132	**0.074**	0.079	0.171	0.109
Entity	0.288	0.106	**0.098**	0.327	0.133
Narrative	0.129	**0.119**	0.131	0.258	0.127
Style	0.192	**0.075**	0.085	0.136	0.081
Tone	0.187	0.077	0.077	0.131	**0.075**
Overall	0.131	**0.122**	0.132	0.248	0.128

Table 1: Results of different approaches

tactic parse of the sentence, which text embedding similarity cannot capture. These results show the need for neural models to find these hidden features with little help from feature extraction if required.

5.2 miniLM

As we can see clearly from the table (Table 1), using a feed-forward network on top of the pre-trained embedding to make it a domain-specific task decreases the loss and improves the results for almost all similarity metrics. These results confirm our hypothesis for domain-specific knowledge.

Our hypothesis for location class not performing well is that the pre-trained embedding is for sentence similarity, all location entities should be nearby in the embedding space for such models, and overall it will be hard for such models to learn the differences between location classes. If we use a location-specific pre-trained model, we should get good results.

Also, we can see that the improvement is the most for entities, which is intuitive. The baseline model was poorly performing because embedding all entities averaged did not give any helpful information. Training a model on top of it allows the neural model to learn the differences in entities and output much better results. The logic is similar for the time similarity metric as well.

We see significant improvement for style and tone classes as the similarity score loss decreased from 0.192 and 0.187 to 0.075 and 0.077 (Table 1), respectively. As mentioned previously, these require semantic and syntactic information of the text, which a cosine similarity cannot find. The neural model can learn these differences better and show significant improvement.

Narrative class and Overall class gave good results with baseline as they depend on the embedding of the entire text, but the neural model can improve on those results slightly. These results are intuitive as the model does not learn meaningful additional information to improve those metrics.

5.3 Doc S-BERT

Using a large BERT model for sentence similarity did not lead to many significant improvements in test data (Table 1). The shortcoming of the initial model was that it truncates the text after 256 words. The reason for these poor results is that most of the information is present in the headlines and the first paragraph of news articles, and the rest of the article is a detailed explanation of these texts. This logic makes sense as to why the larger model is not showing significant improvement. The objective similarity metric can be calculated using these words, generally less than 256 words, and gain insightful results.

5.4 Multilingual miniLM

For the multilingual model, we first look at the baseline results, which are the cosine similarity between the embedding.

In Table 1, the most significant difference we see is between the narrative class and the overall class. For both these measures, our single language model performed much better than the multilingual model. We hypothesize that because of multiple languages, the embedding of this model learns less about the text itself as much as it learns the semantic and syntactic knowledge of the words.

This hypothesis can be confirmed by looking at the cosine similarity of style class and tone class, which depends more on these hidden features. As we can see, the multilingual model is performing better for these metrics because of the hypothesis stated above. We were unable to test this hypothesis in great detail but looking through online resources; intuitively, it makes sense.

Even the narrative and overall classes, which gave terrible results (Table 1) for cosine similarity, have almost the same accuracy as our English model, which contained only the English data. Using this model for different language types and still getting the same results strengthens our idea of using a multilingual model instead of compounding the errors.

The test loss for geography in multilingual miniLM and miniLM is precisely the same, which shows that the models have been trained similarly for this metric (Table 1). Our hypothesis in miniLM for location should also hold for this model.

The multilingual model is giving poor results for time and entity compared to our previous model (Table 1), which might be because of the feature extraction problem for other languages. We used Stanza to extract the features, but the overall accuracy is much lower for other languages than English. To confirm this hypothesis, we looked at the extracted entities from Other languages, and the number of entities was much lower than they were in English.

5.5 Best model final results

We experiment with multiple approaches using different parameters. Overall, the multilingual model gave us the most consistent results across all languages. We choose this to be our best model. Both models performed well in a few languages but poorly in others. Hence, we chose the most consistent model across all languages as there can be unseen instances of language in the test dataset.

We calculated the Pearson correlation coefficient on the test data to further test this model, which is the official task metric. On the test data [2] that the task organizers have provided, the coefficient was 0.288 for the multilingual model. The eval data has 4902 pairs of news articles and ten languages.

[2]URL of the dataset `https://competitions.codalab.org/competitions/33835#learn_the_details-timetable`.

One of the biggest reasons for the low coefficient was that both the stanza and multilingual model did not support pl and tr languages from the dataset. Further, the multilingual model did not support a few other languages from the eval dataset, which were absent in the training dataset. Due to these two significant shortcomings, our model performed poorly on a few dataset instances while performing well on other languages. In the future, we can try to find other parsers for Named Entity Recognition and different multilingual models which supports all languages.

5.6 Code

The google drive link for the code for this project is given here: link for google drive The link contains all the generated files, readme for instructions, and code.

6 Conclusions

We created an end-to-end pipeline to find similarities between two news articles in this work and used multiple approaches to find the most optimal way to calculate similarity. We were able to deal with the problem of multilingualism best using a multilingual S-BERT model. We were able to identify the shortcomings of the pre-trained model for similarity in the location metric. We also explored using a large model, which did not significantly improve the results. On the eval data, the multilingual model showed decent results even on unseen languages, which shows that we can extend the model to other languages with minor changes.

7 Acknowledgments

We did this work as part of the NLP course's final project, and we would like to thank prof. Niranjan and the TAs for guiding us in this work.

Abstract

This paper describes our contribution to SemEval 2022 Task 8 on Multilingual News Article Similarity. The aim was to test completely different approaches and distinguish the best performing. That is why we've considered systems based on Transformer-based encoders, NER-based, and NLI-based methods (and their combination with SVO dependency triplets representation). The results prove that Transformer models produce the best scores. However, there is space for research and approaches that give not yet comparable but more interpretable results.

1 Introduction

The SemEval 2022 Task 8 competition (Chen et al., 2022) aims to develop systems that identify multilingual news articles that provide similar information. This is a document-level similarity task in the applied domain of news articles, rating them pairwise on a 4-point scale from most to least similar. The alikeness of news is measured in such a sense: how similar are them in geography, time, shared entities, and shared narratives. The developed approaches for solving the task can be applied to several different real-world tasks. The first one is the clustering of news.

A lot of news-providing companies want thousands of articles from different publishers on one topic to be combined in a single page showing the news.

Another task is Fake News Detection. This task has become extremely important to solve lately. Different articles on the same news story can be compared to find contradictions in facts and details. This can be an indicator that the story is fake like it is shown in (Dementieva and Panchenko, 2021).

2 Related Work

In (Montalvo et al., 2007), authors extract `PERSON`, `ORGANIZATION` and `LOCATION` named entities (NE) and compose a vector for each of the category with the help of Levenshtein distance function and TF-IDF weighting function, which combines Term Frequency (TF) and Inverse Document Frequency (IDF). These 3 vectors are compared to 3 corresponding vectors of the second news with cosine distance. Obtained scores are combined with the set of IF-THEN rules. In (Rahimi et al., 2019) the approach for cross-lingual transfer is proposed which is evaluated on the Named Entity Recognition task. Dialogue competition (Gusev and Smurov, 2021) on Russian news clustering has produced many promising methods which could be adopted to the multilingual case. Most of them, like (Sergei et al., 2021; Glazkova, 2021), are the variations of fine-tuning the transformer models and making ensembles.

In (Martín et al., 2021), the authors developed the pipeline for checking the news on veracity. They compare embeddings of the news under consideration with ones from the database, using cosine distance. Then they take the most similar news found and apply Natural Language Inference (NLI) model to obtain the probability that two texts contradict each other. This probability is used to decide whether the input news is fake. However, NLI scores can be used to find the similarity between articles.

3 Methodology

To solve the task we have tried several approaches. In the subsection 3.1 we will give an overview on methods exploiting pre-trained transformer models as the foundation. In the next subsection we will explain how the Natural Language Inference (NLI) problem can be reduced to the task of News Article Similarity. Block 3.3 is dedicated to approaches based on the Named Entities extracted from the news texts. In the last section, the approaches which were tested to improve the quality of prediction during the post-evaluation period will be described.

3.1 Transformer-based Pre-trained Encoders

Pre-trained neural masked language models like BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have shown superior performance on a wide range of NLP tasks both in monolingual and multilingual settings. During the work on the task of the competition, the approach for fine-tuning Transformers was developed. The following multilingual models were tested: DistilBERT[1], BERT[2] RoBERTa[3], XLM[4]. All these models support all the languages included in the competition dataset. Two different architectures were chosen for fine-tuning the language models. The first one is based on the approach for the BERT Next Sentence Prediction problem described in the original article (Devlin et al., 2019). We will call it **TransformerEncoder-CLS**. The second approach is inspired by the articles (Reimers and Gurevych, 2019; Sergei et al., 2021). It will be labeled as **TransformerEncoder-CosSim** from now on.

3.1.1 TransformerEncoderCLS

The general scheme of the approach is shown in Fig. 1. The Transformer model takes as input 2 tokenized news texts separated by [SEP] token, which is needed for the model to distinguish words from different texts. Also, this sequence of tokens has a special [CLS] token in the beginning. Passing through the layers of the model, each token results in the embedding vector. All the information from the sequence is aggregated in the [CLS] token embedding. That is why we use it as the input to the regression head, which is the combination of fully-connected layer and Sigmoid nonlinearity. The linear layer dimensions are $emb\_len \times 2$, where emb_len is the dimension of the hidden layer. We use the output probability of the first class as the similarity score. Togeth er with mapped to $[0, 1]$ range ground true similarity scores, the predicted scores are passed to the MSE loss function. Transformers weights are not frozen while training and initialized from the aforementioned pre-trained multilingual models. The models were trained on GPU NVIDIA GeForce RTX 3090 for 10 epochs with a learning rate of 10^{-5} and batch size equal to 8.

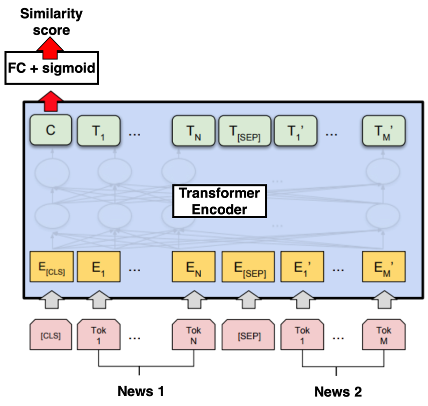

Figure 1: TransformersEncoderCLS architecture, depicted from the original paper (Devlin et al., 2019).

3.1.2 TransformerEncoderCosSim

The general scheme of the approach is shown in Fig. 2. The pre-trained Transformer model takes as input the tokenized news text. Then, Transformer output embeddings are passed through the average pooling followed by a fully-connected layer[5] and L2 normalization layer. This procedure is applied for both compared news. Then, the resulting text embeddings are passed in the cosine distance function which is computed with equation bellow to produce a distance score:

$$cosine\_dist = 1 - |cosine\_sim|.$$

We use absolute value of cosine similarity function because it takes values from -1 to 1. Together with mapped to $[0, 1]$ range ground true scores, the predicted scores are passed to MSE loss function. Transformers weights are not frozen while training and initialized from the aforementioned pre-trained multilingual models. The models were trained on GPU NVIDIA GeForce RTX 3090 for 10 epochs with a learning rate of 10^{-6} and batch size equal to 4.

3.2 Natural Language Inference

The task of estimation similarity between news contents can be reformulated as Natural Language Inference task, which is the main hypothesis tested in

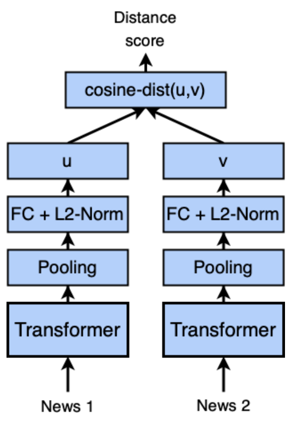

Figure 2: TransformerEncoderCosSim architecture.

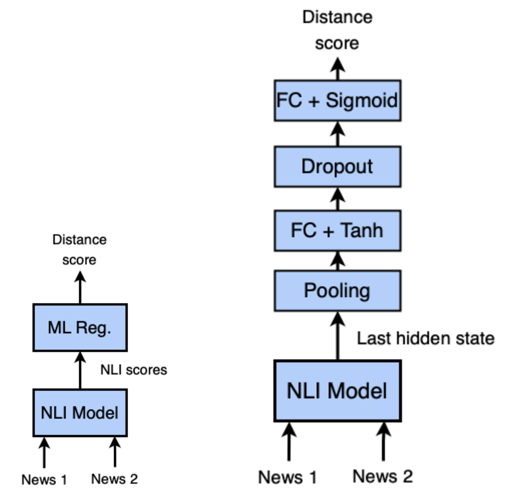
this work. *Natural Language Inference* (NLI) is the problem of determining whether a natural language hypothesis h can reasonably be inferred from a natural language premise p (MacCartney and Manning, 2008). The relations between hypothesis and premise can be *entailment*, *contradiction*, and *neutral*. The release of the large NLI dataset (Bowman et al., 2015) and later multilingual XNLI dataset (Conneau et al., 2018) made possible the development of different deep learning systems to solve this task. That is why the pre-trained NLI models like XLM-RoBERTa-large appeared. We use this model pre-trained on multilingual XNLI dataset[6] to obtain NLI scores for pairs "the first news as premise $p \leftrightarrow$ the second one as hypothesis h". The size N of the used content is a hyperparameter of this NLI based approach for the news content similarity computation. NLI model outputs the probabilities of news pair to be classified as entailment, contradiction, or neutral. Hence, it's 3 real numbers from the $[0, 1]$ range. These extracted NLI features are passed as input to the Machine Learning model, which predicts the similarity score for the pair of news under consideration. In our work, we've compared the performance of several regression models: Linear Regression, Support Vector Machine for regression, Decision Trees, Random Forest, Gradient Boosting. The last one gave the best results. The general scheme of the approach is shown in Fig. 3. Also, several improvements to this pipeline were tested:

1. **Both pairs**. Each piece of news is used as a premise and hypothesis. As a result, we get twice more features for training.



(a) Basic architecture. (b) Fine-tuning architecture.

Figure 3: NLI approach

2. **Subject-Verb-Object triplets**. We extract syntactic dependencies from the sentences of a text to make triplets consisting of subjects, verbs, and objects. These triplets are passed to the model. Such an approach shortens the input data, which makes the process of extracting NLI features faster and doesn't have the significant influence in quality of the method. We extracted syntactic dependencies with Spacy library (Honnibal et al., 2020).

3. **Fine-tune**. We fine-tune the NLI model on the data of the competition. The approach is based on the one proposed by (Martín et al., 2021). We add the regression head to the NLI model, which has global average pooling of the last hidden state of the transformer model, linear layer with 768 neurons and $\tanh$ activation, a 10% dropout for training, and a classifier linear layer with sigmoid. The output probability is treated as a similarity score, and MSE loss is used. This regression head is trained, freezing the XLM-RoBERTa-large weights to preserve the previous pre-training. This is optimized using Adam optimizer (Kingma and Ba, 2015) with 10^{-3} learning rate. The general scheme of the approach is shown in Fig. 3.

3.3 Named Entity Recognition

Transformers have great performance but almost no interpretability. In search of interpretability,

[6] https://huggingface.co/joeddav/xlm-roberta-large-xnli

the Named Entity Recognition-based approach has been developed. The general scheme of the approach is shown in Fig. 4. News texts are preprocessed and forwarded to the NER extractor to extract locations (LOC), organizations (ORG), and person entities (PER). For this task we've tested and compared several tools:

1. **Transformer for named entities tagging.** We used BERT[7] pre-trained model from the Hugging Face repository. It is a Named Entity Recognition model for 10 high-resource languages (Arabic, German, English, Spanish, French, Italian, Latvian, Dutch, Portuguese, and Chinese) based on a fine-tuned mBERT base model.

2. **Polyglot for Named Entity Extraction.** The models from this package (Al-Rfou et al., 2015) were trained on datasets extracted automatically from Wikipedia. Polyglot currently supports 40 major languages, including all presented in the dataset of the competition.

3. **Spacy.** Spacy library (Honnibal et al., 2020) provides huge variety of NLP tools, including NER extractor. We used multi-language model,[8] trained on Wikipedia.

In the next step, we vectorize extracted entities with Bag of Words, Tf-Idf, Fasttext (Bojanowski et al., 2017), Bert embeddings[9] for comparison. Then we average all the word vectors. As a result, we obtain 3 vectors (one for each of LOC, PER, ORG entities) for each text. Corresponding vectors for LOC, ORG, PER for two texts are compared with cosine distance to get 3 distance scores for every pair of news under consideration. Then, these scores are passed in the Machine Learning model to get the final distance score. We test several regression models: Linear Regression, Support Vector Machine for regression, Decision Trees, Random Forest, Gradient Boosting.

3.4 Additional study

To improve the quality of the prediction the following two techniques were tested:

1. **Augmentation.** Testing part of the dataset has a lot of language pairs[10] which are not presented in the training part of the dataset. To test the influence of unseen language pairs on the results, we added pairs of news for the missing language pairs. Such augmentation was performed with the help of the Google Translator, which was accessed with the help of Deep Translator python library. The pairs of news were selected randomly from the pairs written in English and then translated to the target languages. Samples were added to the training part of dataset in the same proportion they are presented in the testing part of the dataset. As a result, training dataset was extended to 7505 samples.

2. **Stacking.** Ensembling different models is a common way to improve the scores. To aggregate the dependencies caught by several models, we exploited the technique called stacking. To form the ensemble, we used TransformerEncoderCosSim, TransformerEncoderCLS, fine-tuned NLI model and NER model[11] which has shown the best results in the experiments described bellow. All the models were trained on three quarters of the training dataset. And one quarter of the dataset was used to train the aggregation model. We used Linear Regression model with L_2 regularization as aggregation model.

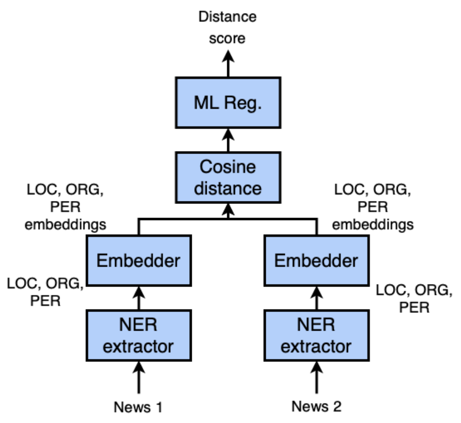


Figure 4: NER approach architecture.

4 Results

Our team has taken the 14th place among 32 participants. The best result for separate model, 0, 734 correlation, was reached by the TransformerEn-

[7] https://huggingface.co/Davlan/bert-base-multilingual-cased-ner-hrl

[8] xx_ent_wiki_sm

[9] bert-base-multilingual-uncased pre-trained model was used

[10] A pair of languages, in which a pair of news is written.

[11] We used the following combination: Huggingface NER tagger, Huggingface embeddings, Gradient Boosting ML model.

coderCosSim model. Final results for all separate methods, as well as the best competition score, are provided in Table 1. Also, we provide the results for ensembles of models in the Table 3. The application of ensembling and augmentation techniques improved the best result to $0,763$ correlation. In addition to the test set, which was provided by organisers during the evaluation period, the performance of the developed systems was evaluated on the validation set. Validation set was randomly sampled from the training data[12] in case of TransformerEncoder methods, including fine-tuned NLI model. For other methods the results on validation are the results obtained with 5-fold cross-validation.

	Validation	Evaluation
TransformerEncoderCLS	**0.813**	0.706
TransformerEncoderCosSim	0.793	**0.734**
NLI	0.478	0.477
NLI fine-tuned	0.670	0.632
NER	0.496	0.395
NLI + NER	0.615	0.546
Best SemEval result	—	0.818

Table 1: Overall results. Pearson correlation.

Transformer models. As it has already been said TransformerEncoderCosSim model has shown the best result. It was the one with XLM[13] pre-trained model. The worst score was given by the DistilBert model. We provide the comparison of different encoders from Transformers for 2 proposed models in the Table 6 in the appendix. As for the TransformerEncoderCLS model, its performance has dropped by 12% on the evaluation part of the dataset in comparison to validation part. And it's become worse than the TransformerEncoderCosSim model, although it showed better results on the cross-validation.[14] In general, the transformer-based models have a lower correlation on the evaluation data. You can see a similar behavior for the NLI fine-tuning approach.

NLI. The comparison of the results for NLI-based models is provided in Table 2. The best score for the NLI approach was given by the Gradient Boosting model. (We provide the comparison of results for different Machine Learning models for «NLI pairs - titles» in the Table 7 in appendix.) The fine-tuning approach has given the best correlation here. Also, there is a tendency for smaller input text to have better scores. The highest correlation was achieved when only titles were given as input. The reason for that could be that the NLI model was trained on the XNLI dataset, composed of short phrases. That is why it was decided to try to shorten the news with the extraction of SVO triplets from them. The extracted triplets were joined to form a text which was forwarded to the input of the NLI model. As you can see from Table 2 the quality of both methods (with fine-tuning and without) has dropped significantly. Hence, the conclusion is that despite SVO triplets give a good summary of the given text, they are not applicable, at least without any complex processing, for the task of comparing the news. Also, it could mean that the source of similarity of articles is not contained in Subjects, Verbs, and Objects. Last, it is worth mentioning that the resulting summary for big texts still has quite a large size in comparison to titles.
The idea to extract NLI scores from both pairs, as it was described in devoted subsection, gave an improvement. Also, it can be noticed that the NLI approach without fine-tuning is quite robust to adding new languages. The score for "NLI pairs - titles" has only a slight decrease on the evaluation dataset. Although the correlation for single NLI features is low, it becomes significantly better in combination with features with the NER-based method. This approach is described in more details in the devoted paragraph bellow.

	Validation	Evaluation
NLI tiltes	0.453	0.438
NLI pairs - titles	0.478	0.477
NLI pairs - titles + text	0.354	0.310
NLI pairs - SVO	0.154	0.107
NLI fine-tuned - titles	**0.670**	**0.632**
NLI fine-tuned - titles + text	0.627	0.589
NLI fine-tuned - SVO	0.495	0.422

Table 2: Comparison of NLI approaches. Pearson correlation.

NER. One can find the comprehensive comparison of different NER taggers, various vectorizing techniques and different Machine Learning models for prediction of distance score in the Table 5 in the appendix. You can see that the best correlation was shown by combination: Huggingface NER tagger, Huggingface embeddings, Gradient

[12] The size of validation set was 0.25 from the size of the training dataset.
[13] https://huggingface.co/xlm-mlm-17-1280
[14] Model which has shown the best result: https://huggingface.co/xlm-roberta-large

Boosting ML model. In general, Gradient Boosting has shown superior scores for all combinations of NER taggers and vectorizers. Also, Huggingface embeddings in combination with this model have shown the highest results for all vectorizing methods listed in the Methodology section. However, in comparison to NLI and Transformers approaches, the results for NER models are significantly lower. Looking at the outputs of the model (You can find the examples in Table 4 in appendix), the following behaviors can be noticed. In our method in cases when no named entities were found for the `PER`, `ORG` or `LOC` classes, the distance score was set to 0.5, because it is not clear whether the absence of named entities is an indicator of similarity or not. These 0.5 scores confuse the model, increasing its generalization error. The second problem is that when there is no overlap of named entities in one of the classes, it could lead to two bad outcomes. When the other two distance scores correctly reflect the ground true similarity, like in the second example in Table 4, the one with no overlap could be large, which spoils the overall prediction. The second behavior happens when the extracted entities have no straight overlap but happen to be similar in vector space. For example, two different news about the close locations. In this case, the model can output a small distance, which is not correct. Also, the errors of the NER tagger makes the model performance worse. As a result, the model tends to predict values from the middle of the $[1, 4]$ range, avoiding its edges. In addition, the problems described make the results even worse on unseen evaluation data. We provide the comparison of the best results for different NER extractors for validation and evaluation in the Table 8.

NER + NLI. As you can conclude from Table 1, NER features, having poor single performance, add significant improvement in correlation being combined with NLI features. To obtain this result we have taken the features used in best-scored NLI and NER models. For classification Gradient Boosting ML model was used as it had given the highest results for both approaches.

Additional study. The application of augmentation to the training part of the dataset improved the result of the best performing model from 0.734 to 0.746, which is a slight improvement. It can be concluded that the performance of this model is not highly effected by unseen language pairs. The increase in score may be caused just by the increase of the number of training samples.

	Correlation
TrEncCLS, TrEncCosSim	0.752
TrEncCLS, TrEncCosSim, NLI	**0.763**
TrEncCLS, TrEncCosSim, NLI, NER	**0.763**

Table 3: Comparison of the results for different ensembles on the evaluation dataset. Pearson correlation. The names of TransformerEncoders models were shortened.

The results for stacking of the models can be found in the Table 3. In this experiment stacking technique was combined with augmentation, which showed a slight improvement in score. You can see that the addition of the predictions obtained with the NER model gives no increase in score. Overall, the augmentation together with stacking gave the 4% improvement to the result of TransformerEncoderCosSim model.

5 Conclusion

We have tested several approaches, including two systems based on Transformer-based encoders, two NLI approaches (with fine-tuning and without), NER-based pipeline and the ensemble of these models. The best result was achieved by the ensemble of TransformerEncoderCosSim, TransformerEncoderCLS and fine-tuned NLI models. To improve the scores the following things can be done. For models based on Transformer-based encoders, sentence Transformers can be tested. To improve the NER-based method additional features can be added (addition of NLI features improved the correlation), and also we can apply the binary mask for the feature matrix not to take into account 0.5 values while calculating the loss during the training process can be applied.

Source code of our solutions is available online[15]. Also, the hyper-parameters of the models can be found there.

Table 4: Example of performance of the best NER model. (Huggingface NER extractor, Huggingface vectorizer, Gradient Boosting model).

In this section, we provide some further comments on Table 4. In the Table example output of the best-performing NER approach can be found. You can notice several patterns, which could be the reason for the low quality of prediction of NER approaches. First of all, the errors of the NER tagger makes the model performance worse. You can see several wrong detections. For example, «BarackO» definitely should be tagged as person, not location, in the second example.

Also, in our method, in cases when no named entities were found for the `PER`, `ORG` or `LOC` classes, the distance score was set to 0.5, because it is not clear whether the absence of named entities is an indicator of similarity or not. These 0.5 scores confuse the model, increasing its generalization error. The second problem is that when there is no overlap of named entities in one of the classes, it could lead to two bad outcomes. When the other two distance scores correctly reflect the ground true similarity, like in the second example in Table 4, the one with no overlap could be large, which spoils the overall prediction.

The second behavior happens when the extracted entities have no straight overlap but happen to be similar in vector space. For example, two different news about the close locations. In this case, the model can output a small distance, which is not correct. As a result, the model tends to predict values from the middle of the $[1, 4]$ range, avoiding its edges. However, there are examples which show good performance. In the third example, there is an overlap in one word for `LOC`, which gives the distance from the middle of the range. There is no overlap in organizations. As a result, we get a score quite similar to ground true, taking into account the peculiarities discussed above.

Abstract

The task of multilingual news article similarity entails determining the degree of similarity of a given pair of news articles in a language-agnostic setting. This task aims to determine the extent to which the articles deal with the entities and events in question without much consideration of the subjective aspects of the discourse. Considering the superior representations being given by these models as validated on other tasks in NLP across an array of high and low-resource languages and this task not having any restricted set of languages to focus on, we adopted using the encoder representations from these models as our choice throughout our experiments. For modeling the similarity task by using the representations given by these models, a Siamese architecture was used as the underlying architecture. In experimentation, we investigated on several fronts including features passed to the encoder model, data augmentation and ensembling among our major experiments. We found data augmentation to be the most effective working strategy among our experiments.

1 Introduction

News articles from the web covering the same event tend to differ on regional and political biases, style of writing, conciseness and preciseness of coverage and the intended audience of the news outlet. Misleading and confusing articles might lead to unnecessary confusion, chaos and tensions potentially exacerbating or even creating non-existent issues. Often, news articles covering the same event in different languages from varied regional sources are readily available. This can apply for happenings of local, regional as well as international significance. In such a scenario, it is pertinent to able to identify or cluster together news articles covering the same story in different languages and different view points while also being able to distinguish between articles similar in style but covering different happenings.

The significance of the problem of multilingual news article similarity (Chen et al., 2022) lies towards the applicability in this area by scoring a pair of news articles based on their similarity in coverage of the event without focusing on the subjectivity of the content.

In our approach, we model the task as a regression problem by making use of a Siamese neural network (Bromley et al., 1993) as the base architecture. We perform experiments in feature engineering by making use of metadata such as title, description, keywords and tags in addition to the news text. We also experimented with artificially augmenting the data by document permutation. Also, we tried with ensembling of two models - one trained using only textual features, the other using metadata information.

While data augmentation strategy did give a decent improvement in performance, considering the length of the news articles and the coverage of a variety of entities or events throughout the article, globally modeling the text representation might not be the best way to model for this task. In the subsequent sections, we elaborate on our experiments performed and the results obtained and analyze the same. We have open-sourced our code[1] for ease of replicability and improvement over our techniques.

2 Task Definition

The task of multilingual news similarity consists of predicting the similarity score between two news articles on a scale of 1 to 4, with a higher score indicating a higher degree of similarity. The news articles may belong to either the same or different

languages, with there being no specified set of languages in which the articles might be written in. Most of the pair of news articles were annotated by 1-3 annotators, with the maximum no. of annotations per data sample being 8. In case of multiple annotations per sample, the scores were averaged.

Statistics of the data created for the task are shown in table 1 and 2. The training and evaluation (test) splits were prepared such that the languages appearing in either of the sets might not occur in the other, which shows the necessity of a good multilingual representation for modeling a solution. The news articles were downloaded from the provided URLs following which the dataset was prepared for the task. There were 18 and 22 articles not accessible by the provided URLs in the train and test sets respectively, which were replaced by a placeholder dummy text. 10 % of the training data was used as the validation set. The model with the best performance on the validation split was evaluated on the test data.

3 System Description

Figure 1 shows the architecture we adopted for modeling the task. In the Siamese architecture (Bromley et al., 1993), an encoder representation is taken for each of the news articles following which a linear layer is used for reducing the dimensionality of the representation. An aggregation of these representations is then performed for having a unified representation of the two articles before passing them through fully connected layers that finally output the similarity score from 1 to 4. The entire architecture was trained end-to-end by minimizing the mean squared error (MSE) loss between the actual scores and model predictions. We experimented with various strategies in this generalized architecture which we elaborate in the remainder of this section.

Table 2: Stats of different languages available in test set

1. **Features passed to the encoder.**
   (a) **News text.** The plain text content of the news article is used as the input. The distribution of the news content lengths is shown in Figure 2. The articles have a mean length of 589 tokens and a standard deviation of 954, with about 60.5% of the documents having length greater than 512 tokens, which is the maximum tokenization output size for the encoders used. Considering, however, that most of the salient information of a news article is contained in its initial section, the token lengths were capped to 512 for all news texts before feeding to the encoder.
   (b) **Metadata.** Information such as title, description, keywords and tags was present for the many of the news articles, the statistics of which are shown in table 3. We ran experiments using only these features as well as concatenating them before the news text, capping the overall length to 512 tokens.
   (c) **NER-extracted features.** Since the task entails determining the similarity based on objective features such as entities, date/time

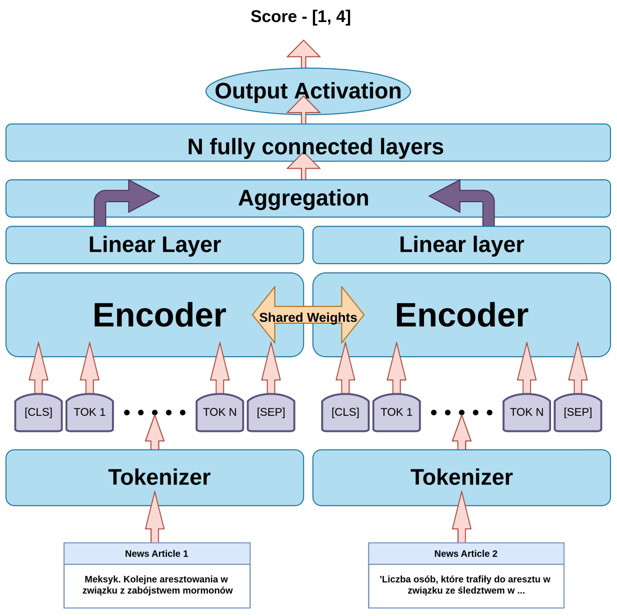

Figure 1: Underlying architecture used across the experiments performed

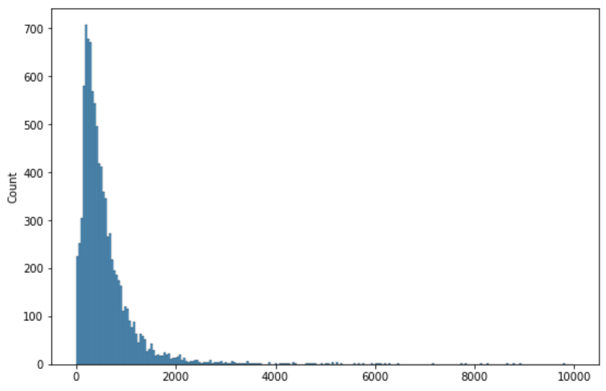

Figure 2: Distribution of number of tokens per news article

values, places, NER features for all the available tags were extracted from text using the Multilingual BERT model from DeepPavlov (Burtsev et al., 2018).

2. **Base encoder model.**
   (a) **XLM-RoBERTa.** (Conneau et al., 2020) This transformer-encoder (Vaswani et al., 2017) based model used was pretrained on 100 languages using masked language modeling objective, achieving remarkable improvements on various cross-lingual understanding tasks.
   (b) **Multilingual DistilBERT.** (Sanh et al., 2019) A distilled version of the multilingual cased BERT-base (Devlin et al., 2018) model trained on Wikipedia data from 104 languages was also used as the base encoder. While the performance of the distilled version was slightly lesser as compared to the original model, this version was chosen on account of it having relatively less no. of paramaters which usually suits well for low-data settings.

Attribute	Count
meta_keywords	4430
tags	4430
title	4421
meta_description	4121

Table 3: Count of the non-null metadata attributes present in the data for the ones used as additional features.

3. **Concatenating encoder representations.** The following concatenation strategies were tried out for building an aggregated representation of the two news articles:
   (a) $[\,|\,x_1 - x_2\,|\,;\,(x_1 + x_2)/2\,]$
   (b) $[\,x_1\,;\,x_2\,;\,|\,x_1 - x_2\,|\,]$

   Here, $x1$ and $x2$ are the encoder representations of the two news articles after passing through the linear layer for reduced dimensionality.

4. **Data augmentation.** Synthetic data samples were created by randomly permuting the sentence order in the news articles to create an augmented data of size 3, 4 and 5 times the original size.

5. **Output activation.** We tried using Sigmoid and ReLU activation functions at the output along with also trying out simple linear output without any activation to determine the best one.

6. **Ensembling.** An ensemble of two models was created by combining the prediction scores of the models by simple average as well as weighted average, in the latter case of which the scores were determined by first training a linear regression model based on the prediction scores on the train data.

4 Experimentation & Results

4.1 Experiments

In this section, we describe the set of experiments performed based on the strategies described in section 3. Unless otherwise specified, sigmoid activation was used at the output and the final score was scaled in the range of 1 to 4 as $3*sigmoid(.) + 1$.

1. **XLM-TXT**: News text feature passed as input to XLM-RoBERTa (XLMR).
2. **DB-TXT**: News text feature passed as input to the DistilBERT model.
3. **XLM-MTD**: Concatenated metadata features passed as input to XLMR.
4. **XLM-MTD-TXT**: Concatenation of metadata features with text passed to XLMR.
5. **XLM-NER-MTD**: Concatenation of extracted NER features and metadata passed as input to XLMR.
6. **DB-NER-MTD**: Concatenation of extracted NER features and metadata passed as input to DistilBERT.
7. **DB-CAT3**: The second concatenation strategy for feature aggregation as described in section 3 used in the same setting as DB-TXT.
8. **XLM-REL**: ReLU activation used at the output in the same setting as XLM-TXT.
9. **DB-CAT3-LIN**: A simple linear output without any activation kept in the same setting as DB-CAT3.
10. **DB-DA3**: Data augmented to thrice the original size, fed to setting same as DB-TXT.
11. **DB-DA4**: Data augmented to four times the original size, fed to setting same as DB-TXT.
12. **XLM-DA5**: Data augmented to five times the original size, fed to setting same as XLM-TXT.
13. **SA**: Simple averaging of the predictions of XLM-MTD-TXT and XLM-DA5.
14. **WA**: Weighted average of the predictions of XLM-MTD-TXT and XLM-DA5.

4.2 Training Setup

The training was done with the number of epochs ranging from 5 to 10. The batch size for train set was kept to be 4 and gradients were accumulated over 8 steps giving an effective batch size of 32. Adam (Kingma and Ba, 2014) optimizer with a weight decay (Loshchilov and Hutter, 2019) of 0.01 was used and the learning rate was kept to a constant value of 5e-6. Validation was performed four times per epoch and the model performance was evaluated using Pearson's Correlation Coefficient (PCC) and Mean Absolute Percentage Error (MAPE) along with the MSE loss value. The best checkpoint was saved based on the PCC score on validation set, following which the predictions on test set were sent for evaluation.

4.3 Results

Results for all the experiments performed on the validation set are shown in table 4 and the PCC reported on some of the experiments on test set are in table 5.

Experiment	Validation set		
	PCC	MAPE	MSE
XLM-TXT	0.53	0.39	0.98
DB-TXT	0.55	0.41	0.93
XLM-MTD	0.46	0.47	1.03
XLM-MTD-TXT	0.52	0.41	0.94
XLM-NER-MTD	0.45	0.43	1.05
DB-NER-MTD	0.47	0.43	1.04

Experiment	Test PCC
DB-DA3	0.436
DB-DA4	**0.441**
SA	0.43

Table 5: PCC for three of the experiments performed on test set.

4.4 Analysis

The major insights that can be derived out of the results on the validation set are:

- **Metadata as features.** Using plain text (XLM-TXT, DB-TXT) turned out to be the best way to capture the representation among the experiments we tried. The metadata information in itself (XLM-MTD) was insufficient to provide the representation. Even concatenating the metadata information with text (XLM-MTD-TXT) resulted in a suboptimal solution.

- **NER output as features.** The NER output concatenated with metadata features (XLM-NER-MTD, DB-NER-MTD) did not result in a great feature modeling, with the metadata in combination with text and only text input performing better.

- **Encoder model.** DistilBERT-based multilingual model performed consistently better than its XLMR counterpart across similar experiments (DB-TXT v/s XLM-TXT, DB-NER-MTD v/s XLM-NER-MTD). This might be due to DistilBERT having lesser no. of parameters, thus suiting better against overfitting.

- **Concatenation strategy.** The aggregation strategy of concatenating the absolute difference and average of the two news article representations (DB-TXT) worked better than the other strategy (DB-CAT3) tried out.

- **Output activation.** Sigmoid activation[2] achieved the best training trajectory and results as compared to ReLU (XLM-REL) and linear (DB-CAT3-LIN). During training, the loss from ReLU and linear activations started off with very high values before achieving convergence at values subpotimal as compared to that on sigmoid output.

- **Ensembling.** Simple (SA) and weighted averaging (WA) for ensembling performed competitively, with the validation PCC on simple averaging having an edge over the weighted averaging one.

- **Effectiveness of data augmentation.** Data augmentation turned out to be the best strategy so far, as obvious from the results on validation and test sets. Augmenting the data to 4 times the original size turned out to the best among the tried values $\epsilon \{3, 4, 5\}$ (DB-DA3, DB-DA4, XLM-DA5).

As an overall insight, it seems the method of globally representing the news article by a single representation after capping the length to a smaller, fixed size is not the best way in modeling a solution for this problem. A solution exploiting the information present in the articles at a more granular level - either by explicit feature extraction or implicit detection of these features through techniques suitable across multiple languages can be experimented with in pursuit of better results.

Another possible conjecture we speculate based on the poorer performance on the test dataset is that finetuning the underlying multilingual transformer encoder models might have hampered the effectiveness of the multilingual representation for languages that were not present in the training or validation sets, but were present at the time of evaluation. It is to be noted that since the validation dataset was a split taken from the original training data itself, there was not much of a difference between these two distributions. Hence, if this conjecture holds, a solution that trains the model parameters for the task without deranging their multilinguality aspect should provide a scalable solution across multiple languages.

5 Conclusion

We presented our base architecture adopted for the task of multilingual news article similarity and explained the various experiments performed on the same. An analysis of the results gave insights on what strategies worked best on our underlying Siamese architecture, of which we determined data augmentation to be the most effective one. Finally, we provided some insights on the modeling efficiency of the architecture adopted along with directions for possible improvement. This problem being very relevant in the face of diverse, multilingual news content being continually generated from diverse sources, improvements achieved in this task would be of value in industry and social benefit.

HuaAMS at SemEval-2022 Task 8: Combining Translation and Domain Pre-training for Cross-lingual News Article Similarity

Sai Sandeep Sharma Chittilla and **Talaat Khalil**
Huawei Technologies R&D
Amsterdam, Netherlands
{sandeep.chittilla, talaat.khalil}@huawei.com

Abstract

This paper describes our submission to SemEval-2022 Multilingual News Article Similarity task. We experiment with different approaches that utilize a pre-trained language model fitted with a regression head to predict similarity scores for a given pair of news articles. Our best performing systems include 2 key steps: 1) pre-training with in-domain data 2) training data enrichment through machine translation. Our final submission is an ensemble of predictions from our top systems. While we show the significance of pre-training and augmentation, we believe the issue of language coverage calls for more attention.

1 Introduction

In the recent few years, there has been a growing interest towards automating news understanding tasks thanks to the continuous demand by downstream applications. One of the most important aspects of news understanding is identifying news articles that cover the same stories. Grouping such similar articles can be useful in multiple application scenarios including news recommendation, news stories analysis, news retrieval and ranking amongst others.

Task 8 in SemEval 2022 (Chen et al., 2022) provides an experimental setup to address and identify the challenges of assessing the similarity between two news articles. Unlike standard document similarity tasks (Agirre et al., 2015), this task is focused on a more challenging multilingual setting where the systems are not only expected to evaluate pairs of long text articles in the same language but in different languages as well. Moreover, the task assumes that accurately identifying articles that share the same story cannot be solely captured by textual similarity since the underlying similarity function is hypothetically a combination of a set of other features like time, geo-location, mentions of named entities and narratives.

Participating teams are required to provide a similarity score for each pair of news articles. The scores should range between 1 and 4 where 1 indicates that two stories are almost identical and 4 indicates no similarity at all. The systems are evaluated based on the Pearson's correlation with ground truth scores which are provided in a test set annotated by human evaluators.

In our submission, we hypothesize that the sub-dimensions (that are assumed to be story similarity predictors by the task organizers) do not have to be independently modeled and present an approach that assumes that such sub-dimensions can be represented in the model's latent space while directly optimizing to learn article similarity scores. Formally speaking, we model the similarity task as a supervised regression problem to optimize the similarity score between two news articles. To test our hypothesis, we experiment with different pre-trained language models and evaluate multiple methods of boosting the model's performance via domain pre-training and data augmentation. Our final submission ranked 8 out of a total of 32 teams in the official rankings with a Pearson correlation of 0.771 - a score difference of 0.047 compared to the top ranked submission.

This paper is organized as follows: In section 2 we describe the official datasets as well as the external datastes that were used. In section 3 we present our baselines and systems' setups. Section 4 presents our data splits and model training specifics. We show and analyse our results in section 5, then we conclude and discuss future work in section 6.

2 Datasets

The used datasets are categorized into two categories: 1) Task Datasets which are provided by the task organizers and 2) External datasets that are used as additional assets for model training.

Pair	Training	Evaluation
ar-ar	263	298

zh-zh	-	769
Total	4643	4953

Table 1: Count of training and evaluation samples by language-pair. "-" means not present in training data.

2.1 Task Dataset

The task organizers provided a number of 4,964[1] news article pairs along with their "Overall Similarity" scores to be used for training purposes. Multiple trained human evaluators were asked to evaluate pairs of news articles and provide similarity scores for different sub-dimensions as well as an overall score; all in 1-4 range. The final scores are calculated by averaging the individual scores across all the evaluators. The training set contains same language pairs as well as cross-lingual pairs. The evaluation dataset was created in the same way as the training data however it contains new languages that are not present in the training set and the language pair distribution does not match the training set distribution as shown in Table 1.

2.2 External Datasets

We made use of monolingual datasets from multiple news sources to fine-tune the pre-training phase of the language models that we experimented with (see section 3 for the details). NADiA dataset (Al-Debsi et al., 2019) is used for Arabic, CCNEWS dataset (Hamborg et al., 2017) is used for English, Global Voices news data (Tiedemann, 2012) is used for Polish and MLSM (Scialom et al., 2020) dataset's input text is used for German, Spanish, French and Turkish.

[1]Task organizers published article URLs but only 4643 pairs were retrievable by the time we scrapped them

3 System Overview

All of our systems are solely trained on the text descriptions of input articles as features and their similarity score as the target variable. All the presented systems except for the baseline system 3.1, are based on XLM-RoBERTa (XLM-R). This choice is made based on the fact that it's a multilingual model that is pre-trained on large amounts of data spanning 100 languages and performs competitively on several cross-lingual transfer tasks (Conneau et al., 2019). The general architecture of our systems itself is kept relatively simple i.e. a Language Model with a regression head on top.

3.1 Baseline

Our baseline system is a multi-variate linear regression model that uses 2 independent variables: a) count of the named entities[2] that are shared between the two news articles and b) cosine similarity between the sentence embeddings of the news article pair. Formally speaking; We model this as $Y = A + B_1X_1 + B_2X_2$ where X_1 and X_2 are the aforementioned variables and Y is the similarity score. The model is trained to minimize the Mean Square Error (MSE). We also experimented with a Gamma Function for regression on the non-negative similarity values, however no difference was perceived in Pearson's scores. We evaluated sentence embeddings generated using LaBSE (Feng et al., 2020), MPNET (Song et al., 2020) and SBERT (Reimers and Gurevych, 2019) and reported baseline results using LaBSE embeddings since it resulted in the least MSE.

3.2 XLMR

Our first system dubbed *XLMR* is an XLM-R model with a regression head on top which is trained to minimize the MSE on the task dataset 2.1. The input is formed by concatenating the text of the two input articles and placing a special token in between.

3.3 XLMR-Pre

Our second system dubbed *XLMR-Pre* follows the same architecture as *XLMR* however, we continue model pre-training using the Masked Language

Modelling (MLM) objective (Devlin et al., Liu et al.) for languages in the training set using the collected external datasets 2.2.

3.4 XLMR-Aug

Our third system dubbed *XLMR-Aug* follows the same setup of *XLMR* however the training data is supplemented with data augmentation. Synthetic data is created in two different ways namely: pair switching and Machine Translation (MT). Pair switching is achieved by switching the text concatenation order of the input pairs to act against pair order bias. Machine Translation is leveraged to address the fact that the majority of the training set pairs are in the same language (4500 pairs) however the systems are evaluated on their ability to score cross-lingual pairs as well. A number of 1344 English pairs are sampled and translated to different languages. Additionally a number of 667 German language examples are translated into English to encourage improvements in the English language pairs. Translated pairs' statistics are reported in Table 2. The used MT system is an in-house general purpose Transformer Big model (Vaswani et al., 2017) that is not adapted to any specific domain.

3.5 Ensemble Systems

Ensemble systems are developed by averaging the individual scores of different combinations of our three systems: *XLMR*, *XLMR-Pre* and *XLMR-Aug*.

4 Experimental Setup

4.1 Data Setup

To be able to run our model selection experiments and validate our hyper-parameter settings, a standard split of 80:10:10 is applied to the task dataset 2.1 to split it into train, validation and held-out sets. This setting resulted in a training set size of 3719 samples, validation set size of 464 and a held-out set size of 460 samples. The validation set was used for hyper-parameter tuning and the held-out set was used for system comparisons since there were no datasets provided for such purposes by the task organizers. Our experiments that leveraged data augmentation techniques made use of a total of 12707 training samples. To avoid any data leakage, we only used samples from the train set to augment the data.

4.2 Hyper-parameters

Model hyper-parameters were initially setup with the recommended values for XLM-R model fine-tuning (Conneau et al., 2019) and were manually fine-tuned based on the correlation scores and the loss on the validation set. *XLMR* and *XLMR-Pre* systems were trained for 4 $epochs$ and *XLMR-Aug* system was trained for 10 $epochs$. In all the experiments, an $AdamW$ optimizer (Kingma and Ba, Loshchilov and Hutter) was used with a linear schedule, a $learning\_rate = 2e - 5$, $epsilon = 1e - 8$ and training and validation $batch\_size = 8$.

4.3 Training

The Huggingface transformers library[3] was used to conduct all our model training experiments and all our models were initialized using xlm-roberta-large[4] weights. All models were trained using 8 Nvidia Tesla-V100 GPUs.

4.4 Evaluation

We evaluated our models using Pearson's correlations score on the overall test set. Additionally, we conducted a per-language correlation scoring for better reasoning and model development.

System	Score
Baseline	0.677
XLMR	0.808
XLMR-Pre	0.804
XLMR-Aug	0.790

Table 3: Pearson's scores for different systems during model development on the held-out set

5 Results and Analysis

During the development phase, we used the fixed held-out set to compare the performance of different systems. When the evaluation phase ended, the gold labels were made available for the evaluation set and thus we re-evaluated all our systems using that set as well. The results on the held-out set are shown in Table 3 and the results on the evaluation set are shown in Table 4. A per language breakdown scoring is also provided on both the held-out and the evaluation sets in Table 5 and Table 6 respectively.

Our submitted system is ES_2S_3 (table 4) which is an ensemble of *XLMR-Pre* and *XLMR-Aug*, however our post-evaluation analysis showed that $ES_1S_2S_3$ which an ensemble of our three systems performs slightly better than our official submission with a marginal increase of 0.004 in the correlation score. We attribute this increase to the power of ensembling given that the three systems were competitive to each other in terms of the aggregate performance scores however each system has it's own strengths when it comes to language specific performances as shown in Table 6. A little inconsistency between the scores of the different systems on the held-out and evaluation sets is attributed to the fact that the evaluation set has unseen language pairs and a radically different language distribution compared to the training and held-out distributions.

Our per language evaluation (Table 6) reveals explainable patterns. *XLMR-Pre* performs the best on fr_pl and fr_fr language pairs due to abundance of French pre-training data in this model. *XLMR-Aug* performs the best in 12 out of 18 language pairs due to it's MT augmentation that boosts it's performance on unseen pairs. An ensemble of *XLMR* and *XLMR-Pre* performs the best for en_en pairs due to the bias of the original XLM-R model towards English, the news domain fine-tuning and the lack of translation noise or parameter sharing competition with other languages.

6 Discussion

In this paper we described our submissions to the news similarity task in SemEval 2022. Our models showed competitive performance by leveraging pretrained language models and showed that further improvements can be gained by the use of domain pre-training and data augmentation using machine translation. Due to the competition time limits such domain pre-training and translation experiments were conducted on relatively small datasets and we did not manage to experiment with a model that combines both additions. We believe that scaling these approaches by using huge amounts of monolingual data across different languages is potentially a direction that is worth exploring.

We see improvement posibilities when it comes to modeling as well. In the early stages of our experimentation we tried a contrastive learning based approach similar to the works done by (Chopra et al., 2005) though, initial results were not promising and we decided to discard this direction, we believe that further efforts can be fruitful. We've also experimented with explicit modeling of Named Entities within our models without a positive outcome

Table 6: Language pair wise Pearson's scores for different systems on the evaluation set. ES_iS_j is an ensemble of S_i and S_j

however this could be due to the fact that we used a very simple string matching approach for named entities identification. Another modeling aspect is the train/evaluation language distribution modeling. Given that the distribution of evaluation language pairs are available, one could leverage this to improve the model optimization process.

Finally, in this exploratory work we haven't made use of any available article related meta-data which can have strong predictive power of article similarity. Examples include URL normalization to identify parallel articles in different languages, domain and country information among other features. We leave out these territories to be explored in future works.

Abstract

This paper presents our approach for tackling SemEval-2022 Task 8: Multilingual News Article Similarity. Our experiments show that even by using multi-lingual pre-trained language models (LMs), translating the text into the same language yields the best evaluation performance. We also find that stylometric features of the text and meta-information of the news articles can be predicted based on the text with low error rates, and these predictions could be used to improve the predictions of the overall similarity scores. These findings suggest substantial correlations between authorship information and topical similarity estimation, which sheds light on future stylometric and topic modeling research.

1 Introduction

Given a pair of news articles in arbitrary languages, the objective of SemEval-2022 Task 8 is to predict whether the two articles cover the same story (Chen et al., 2022). While the task falls in the category of topical similarity estimation, traditional statistical topic models may not be appropriate due to the large vocabulary size and the difficulty of matching representative "topic words" across languages. For example, determining whether two articles are about the same news story requires answering questions such as what the article is talking about, who is involved, and where did it occur. We demonstrate this by applying an LDA model (Blei et al., 2003) on the original dataset, and using the LDA representations of news articles in a logistic regression (LR) model yields a Pearson correlation of 0.193 on the evaluation dataset.

Due to the difficulty of obtaining gold standard topical similarity annotations, prior research on this topic is mostly conducted under an unsupervised setting. For example, Bisandu et al. (2018) model text using n-gram features and cluster articles using an improved square root cosine similarity measure. Singh and Singh (2021) use the similarity of news headlines to approximate similarities of news articles. However, their approaches rely primarily on simple statistical features on the word level, which is not proper for our task. Rupnik et al. (2016) use an external event list as an alias of "topic words" with greater granularity to solve the topical similarity estimation task. While this idea could be well adapted to our task, engineering the list of events is effort-consuming and lacks generalizability to unseen data, since the news articles may not always talk about a singular, distinguishable event.

Our models are based on the pre-trained multilingual BERT (mBERT) model (Devlin et al., 2018), one of the most competitive models on multi-lingual natural language processing (NLP) tasks. Though mBERT could handle all the languages in the challenge dataset, we find that translating both news articles in each instance into the same language improves the performance of the model by 0.024 in Pearson correlation coefficients. This is counter-intuitive, since translating the text into another language unavoidably harms its syntactic quality. We hypothesize that the improvements result from the match of named entities across documents when they are translated into the same language.

In addition to text translation, we find that the intermediate scores of each instance that are related to stylometric features of the text and meta-information of the news articles could be predicted by the an mBERT model with high Pearson correlation scores (0.71 to 0.88). With a simple LR model, the six predicted intermediate scores (i.e., geography, entities, time, narrative, styles, and tone) can be aggregated to make more accurate predictions of the overall similarity scores. We speculate from this result that stylometric features are important for aligning the events and named entities across news articles, while the meta-information of these articles provides hints about whether the two articles are talking about completely irrelevant events. We additionally try injecting the predicted intermediate scores into the text encodings produced by mBERT. However, the performance of the ensemble model drops below the pure mBERT-based approach. This is expected since the predicted scores are not dimensionally compatible with text encodings. We leave for future research the problem of efficiently boosting the text encodings with stylometric features and meta information predicted from the text.

Our approach ranked the 10th in the all-language data challenge and the 6th most successful results in the English-only challenge. The main areas which impacted our model's performance were the languages and the lengths of the articles. Shorter articles and certain languages proved to confuse the model.

2 Dataset

Each sample in the training data for the task included a url and language code for each article and a score for the pair's overall similarity, along with a score for each of six stylistic features and news meta-information (i.e., geography, time, shared entities, shared narratives, style, and tone). The feature scores and overall similarity were calculated by averaging several annotators' scores and were rated on a scale of 1 to 4, where 1 indicated low similarity and 4 implied high similarity. Each pair of news articles is annotated by 1 to 8 annotators, with the majority of instances annotated by 1 to 3 annotators. In carrying out experiments, we split the released training data into two sets, 80% for training and the remaining 20% for validation. The evaluation dataset is left out for testing purposes only.

2.1 Scraping Article Contents

Since the dataset provides links to news articles, we scrape the text using the newspaper3k library [1]. Two links were provided for each article, one pointing to the article's most up to date link and another pointing to an Internet Archive site containing the earliest available version of the article. The analysis was meant to be carried out on the content of the earliest version of the article, however if that link was unable to be scraped, then the most up to date version of the article was used as the article's content. It is noteworthy that in 854 training instances, at least one news article cannot be retrieved from either link. Removing these data which were not usable resulted in a training dataset containing 7049 instances. Similarly, in the evaluation data, there were 31 instances where at least one news article could not be retrieved from either link.

[1]https://github.com/codelucas/newspaper

2.2 Training Data and Evaluation Data

Training data were released in two batches, where the first batch contained 2,939 pairs of news articles and the second batch contained 4,964 pairs of news articles.

A key difference between the first and second training datasets was that the second dataset included 577 pairs with articles in different languages (we refer to these as bilingual pairs in the rest of the paper) whereas in the first dataset, articles were paired with other articles in the same language. Additionally, the evaluation data had 1440 bilingual pairs, and the bilingual pairs in question had more variety in the languages appearing in the pairs.

The languages used in the training data were, in order of most to least prevalent: English, German, Spanish, Polish, Turkish, French, and Arabic. The only bilingual pairs in the training data were a set of article pairs where one article was in German and the other was in English. The evaluation data had the same languages as the training data, along with Russian, Italian, and Chinese (zh: ISO 639-1).

3 Experimental Setup

All our models are implemented based on the Multi-Task Deep Neural Networks for Natural Language Understanding (MT-DNN) (Liu et al., 2019) model. Specifically, we use the pre-trained mBERT model with 12 layers and 12 attention heads on each layer. For data pre-processing, we separately truncate or pad the two news articles in each instance to 512 words, join them with a "[SEP]" token, and tokenize the text with the mBERT tokenizer. The regression head of MT-DNN is applied on top of the last-layer output of mBERT to generate predictions.

For each approach we present, we fine-tune the mBERT model for 5 epochs with early stopping. A batch size of 8 and a learning rate of 5×10^{-5} are used for all the settings. These are default hyperparameters from the MT-DNN library. Additionally, we implement a bidirectional LSTM (BiLSTM)

(Hochreiter and Schmidhuber, 1997) model as our baseline, using exclusively the text of the articles as input. We set the dimension of hidden states to 100 for this model, and we train the model for 20 epochs with a learning rate of 0.001 and a batch size of 512 in all the experiments. Our BiLSTM model achieves a Pearson Correlation of 0.277 on the validation set.

We repeat all the evaluations three times with different random seeds (i.e., 0, 1, and 2), and we report the mean Pearson correlation coefficient and the standard deviation of scores. All the experiments are run on a single RTX-6000 graphics card.

3.1 Translating Articles

As mentioned in Section 2, there were a substantial number of bilingual article pairs in the training and particularly in the evaluation data. Since some of our approaches require translating both articles in each instance into the same language, we adopt googletrans[2] to carry out the translations. We experimented with settings where the articles are translated (1) into English, (2) into the language of the first article, or (3) into the language of the second article, and in the evaluations we used the setting under which each model performs the best on the validation set.

3.2 Approaches

Figure 1 visualizes the three approaches we tried in the challenge.

3.2.1 LR-Based Feature Ensemble Model

In our best-performing model, the mBERT model is used to encode the text and predict six intermediate scores provided in the training dataset. An LR model with the intermediate scores as input is then used to predict the overall similarity scores. The scikit-learn (Pedregosa et al., 2011) implementation of the LR model is used in our model.

3.2.2 Text-Based Regression Model

For this approach, we rely purely on the text encoding ability of mBERT to make topical similarity predictions. Under this setting, we remove all the meta-information or stylistic clues of the documents from the input and directly fine-tune the vanilla mBERT model to predict the overall similarity scores.

[2]https://github.com/ssut/py-googletrans

3.2.3 Feature-Injected mBERT Model

Since the meta-information and stylistic features of the news articles have proven to be useful in Section 3.2.1, we attempt to combine these intermediate predictions with text encodings produced by mBERT. Specifically, in each instance, we predict the six intermediate scores and concatenate these to the last-layer hidden state of mBERT to make predictions on feature-enhanced text representations. Other parts of the mBERT model remain unchanged. Different from the ensemble model, the feature-injected model is end-to-end.

4 Results and Analysis

The efficacy of each approach was judged on the Pearson Correlation between the predicted similarity and the ground truths (Freedman et al., 2007). With this metric, scores closer to 1 and -1 imply the strongest positive and negative correlations possible, and scores close to 0 imply poor to no correlation.

A summary of the scores can be found in Figure 2. The three approaches worked most successfully when used in tandem with translations. Here we focus on the best performing translation setting for each of the three approaches described in Section 3.2 and compare it to the same approach applied to non-translated data.

4.1 Impact of Language Unification

For our LR-based model, the best performing setting was translating the bilingual pairs in the training data and the evaluation data to the first language of the pair. As discussed in Section 3, we ran this setting with three different seeds, and the approach yielded a mean of 0.746 with a standard deviation of 0.00210. This represented an increase in the correlation by 0.024 when compared to the same setting with no translation.

The next best performing approach was our text-based regression model, with translations to the first language in the bilingual pair. The vanilla mBERT model yielded a mean correlation of 0.737 and a standard deviation of 0.00398. Translation in this setting proved to increase the correlation of the scores by 0.020.

Lastly, the injected features approach performed best when the bilingual pairs were translated to English, and yielded a mean score of 0.737 with a standard deviation of 0.00642. Although this approach scored the lowest among the three, trans-

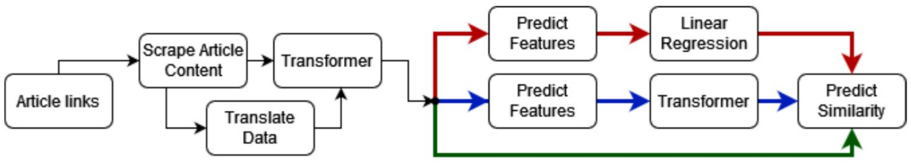

Figure 1: A visualization of three different models we explore in the challenge. The red line shows the approach outlined in Section 3.2.1, the green line shows the approach outlined in Section 3.2.2 and the blue line shows the approach outlined in Section 3.2.3

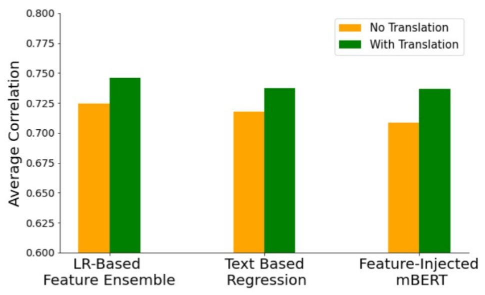

Figure 2: Pearson correlation coefficients achieved by our models on the evaluation dataset. For each model, the green bar represents the score achieved when both documents in each instance are translated to the same language.

lation proved to be the most useful when applied in this setting, with an increase of 0.29 when compared to injecting the features without translation.

Due to the nature of the task, i.e., determining whether articles speak about the same event, it is reasonable to infer that translating articles into the same language boosted performance because of the alignment of named entities in the same language. Although mBERT can manage all of the languages used in the dataset, named entities may be harder to represent between languages, and given their significance in determining article similarity, it is likely that their translation into the same language was the operative factor in enhancing performance.

4.2 Error Analysis for the LR-Based Feature Ensemble Model

When examining the samples where our LR-based model's predictions were furthest from the ground truth annotations, the length in the pair of articles proved a significant factor. The shorter the length of the articles, the more difficult it was for the model to produce accurate predictions, and conversely, samples with longer article lengths tended to yield higher correlation. The shorter articles on which the model was failing tended to be articles where

Langs	Overall (%)	Outliers (%)	Short (%)
ar - ar	6.08	15.85	18.07
zh - zh	15.69	22.95	48.27
ru - ru	5.85	11.47	4.70
pl - pl	4.57	7.10	1.65

Table 1: Percentage of same-language instances in the entire evaluation data (Overall), in the subset of evaluation data where our best model performs at least 1.5 points off the gold standard labels (Outliers), and in the subset of evaluation data where at least one article in a pair is at most 80 characters in length (Short).

we had only been able to scrape the headline of the article.

For example, our model incorrectly predicted that the following two articles were dissimilar: (1) “释放激发制造业活力稳定经济增长-商会频道-长城网” and (2) “稳外贸工作座谈会释放利好一揽子新举措待发–财经–人民网” (translated: “Release to stimulate the vitality of the manufacturing industry to stabilize economic growth - Chamber of Commerce Channel - Great Wall Network”, “Symposium on Stabilizing Foreign Trade Unleashes Favorable Package of New Measures to Be Launched”). In this case, the articles are lacking in substance to investigate their similarity. Instead, the model has to rely on the articles' headlines which contain far less information.

Another likely influence on the model's prediction was the language on which it was predicting. Although our approach leveraged multilingual models, there were certain languages which tended to yield poor outcomes. The most notable were Chinese-Chinese, Arabic-Arabic, Polish-Polish, and Russian-Russian pairs. Some of these could be explained by the prevalence of certain language pairs in the subset of evaluation data where article lengths were particularly short. This is detailed in Table 1. Thus, it is difficult to determine whether the length of the article or the language is the operative factor in the poor predictions. It

Instances	LEN-A1	LEN-A2
Good preds	1427	1354
Poor preds	394	507

Table 2: The median number of characters in Article 1 (LEN-A1) and Article 2 (LEN-A2) for each instance of the evaluation datasets where the error margin achieved by our best model is small (Good preds) or large (Poor preds). We regard the instances where the predictions are within an error margin of 0.2 points as good predictions and those whose error margins are above 1.5 points as poor predictions.

is important to note, however, that in the case of articles written in Chinese, each character encodes substantially more information than a character in the Latin, Arabic, or Cyrillic alphabets. Nevertheless, it is noteworthy that two of the four languages which confused the model were those which it had not seen in the training data.

4.3 Inter-Approach Error Analysis

Our LR-Based model tended to outperform the text-based regression and feature-injected mBERT models when the article pairs spoke about the same news story but with different entities as subjects. For example, in one pair of articles, both articles referred to tableau proposals for India's Republic Day celebration being rejected, however one speaks about the proposal from the Maharashtra and the other about the West Bengal government proposal. Due to the articles being about a similar event, they contain similar phrases, such as "Twenty-two proposals, 16 from states and union territories and six from central ministries — out of a total 56 have been short-listed for this Republic Day parade" and "the Ministry of Defence has selected 22 tableaux out of 56 proposals for the Republic Day parade." This pairing was given a similarity score of 1.5; our LR-based model predicted 1.48, our text-based regression model 2.42, and our feature-injected mBERT 2.67. Because the latter two models rely more heavily on textual data than the former, the articles' similar phrases likely inflated their scores while the LR-based model was more greatly influenced by the pair's features. In this case, both articles were written in English.

Conversely, our LR-based model underperformed when the textual similarity correlated more with the score than the features did. In one case, one article refers to Austrian MPs who are sick with COVID-19 and the other compares Austria and the EU's approach to dealing with MPs who are sick with COVID-19. Similar phrases and words appear in both articles, such as the pair "That will depend above all on whether the government submits corresponding requests to Parliament", "Now the President wants to discuss Parliament's timetable", and the pair "how MPs who have tested positive could also take part in votes", "Ten MPs of the ÖVP ... are in self-quarantine." This pairing was scored 3.0 for overall similarity, however the feature scores for this pair are 1.0, 2.0, 1.0, 4.0, 1.0, 1.0 for geography, entities, time, narrative, style, and tone, respectively. Our LR-based model predicted 1.95, our text-based regression 2.63, and our feature-injected mBERT 2.87. It is reasonable to conclude that the overwhelmingly low features scores contributed to the large difference in our LR-based model's prediction and the annotated score, while the textual similarity of the pair improved the scores for the latter two models.

5 Conclusion and Future Work

This paper describes the model we use for tackling SemEval-2022 Task 8: Multilingual News Article Similarity. Our work shows that while the vanilla mBERT model could greatly outperform shallower baseline models (e.g., BiLSTM and LDA) on this task, introducing intermediate prediction objectives (e.g., stylometric features and meta-information of news articles) helps improve the performance of mBERT noticeably. Additionally, we find that unifying the languages of news articles in each training and evaluation instances has a positive effect on the ensemble model's performance. We speculate that translating both articles in an instance into the same language helps the model align similar named entities across articles, which is important for assessing whether a pair of articles focus on the same set of events or entities.

Since it is shown by our experiments that stylometric features are contributive for topical similarity estimations, future work can extend our ensemble model by involving a richer list of writing-style-related linguistic features.

Abstract

This work represents the system proposed by team Innovators for SemEval 2022 Task 8: Multilingual News Article Similarity (Chen et al., 2022). Similar multilingual news articles should match irrespective of the style of writing, the language of conveyance, and subjective decisions and biases induced by medium/outlet. The proposed architecture includes a machine translation system that translates multilingual news articles into English and presents a multitask learning model trained simultaneously on three distinct datasets. The system leverages the PageRank algorithm for Long-form text alignment. Multitask learning approach allows simultaneous training of multiple tasks while sharing the same encoder during training, facilitating knowledge transfer between tasks. Our best model is ranked 16 with a Pearson score of 0.733. We make our code accessible here[1]

1 Introduction

Over the last decade, English has been one of the most dominant languages on the internet. However, the number of non-English websites is rapidly increasing. From 2001-to 11, online use of English increased at a slower rate than that of Spanish, Chinese, etc. Approximately 4 billion people connect to the internet every day, but only half of them access web pages written in English (Pimienta, 2009). This creates a severe problem regarding verifying the integrity of the documentation because most systems in use are enhanced with English as the medium of information delivery.

SemEval has conducted similar tasks on sentence-level semantic textual similarity in the past. The SemEval 2017 Task 1 (Cer et al., 2017) dealt with finding the similarity between sentence pairs of both monolingual and cross-lingual nature. ECNU (Tian et al., 2017) was the best model that used feature engineering and deep averaging network (DAN) (Iyyer et al., 2015).

Furthermore, language-agnostic representation for sentence similarity described in Tiyajamorn et al. (2021) uses meaning embedding to estimate the cross-lingual sentence similarity without using human annotations. It improves the performance of any pre-trained multilingual sentence encoder, even in low-resource languages, with a few thousand parallel sentence pairs.

Inspired by Ham and Kim (2021), we explored the concept of semantically aligned multilingual sentence embedding. It covers the biases induced by monolingual similarity evaluation and multilingual sentence retrieval to generate language-aware embeddings. This method aligns semantic structures across different languages and uses a teacher network to distill the knowledge of pivot languages, thus achieving state-of-the-art STS 2017 multilingual corpora.

Our model is inspired by a multitask training approach using a BERT-based encoder. We use multiple subtasks to improve the overall accuracy score. Our model uses a machine translation model to cope with the articles' linguistic diversity. Additionally, since the average size of each article in the training data is close to 512 tokens, we use a text ranking algorithm that can capture the long-range sentence-level similarity between two documents. The next sections provide a more in-depth exposition.

* First three authors have equal contribution

2 Task Description

The shared task emphasizes finding the similarity of multi-lingual news articles irrespective of the style of writing, political spin, tone, or any other more subjective "design decision" imposed by a medium/outlet. It gives participants access to a cross/multi-lingual dataset that spans over ten languages, including English, German, French, Italian, Polish, Russian, Chinese, Turkish, Arabic, and Spanish. The dataset includes an overall matching score between two different news articles. Additionally, the dataset consists of other dimensionality scores, such as Geo-location, Time, Shared Entities, and Shared Narratives (see table 1). These scores are based on a four-point scale ranging from the most to the least similar.

Table 1 indicates two examples: the first pair of articles shows extreme similarity with a Pearson score of 1.25, and the second pair shows non-similar articles with a Pearson score of 4. The second pair of articles is a cross-lingual pair where one article is in English and another in German. The next section outlines the overview of the model proposed by our team.

3 System Overview

Our system pipeline can be decomposed into four modules i.e., extraction, translation, text ranking, and multitask training.

3.1 Extraction

We extract title, descriptions, meta-description, and text from the JSON files obtained by scraping the news articles from the URLs given in the dataset. In most instances, the description and meta-description are the same, so we merge them by creating an additional field in the dataset called "extra text." The intuition behind this is to provide more context, as the title and descriptions tend to convey the overall message of the news article. This led to an increase in Pearson score by 0.07.

3.2 Machine Translation

Our translation module is based on the OPUS-MT (Tiedemann and Thottingal, 2020), a transformer-based neural machine translation model. This model uses Marian-NMT (Junczys-Dowmunt et al., 2018), a stable production-ready neural machine translation toolbox with efficient training and decoding capabilities. It is pre-trained on freely available parallel corpora collected in the large bitext repository OPUS (Tiedemann, 2012). The pre-trained version of the OPUS-MT model has six self-attentive layers in both the encoder and decoder networks and eight attention heads in each layer. Also, to handle the long-form nature of text articles, we use the chunking technique to segment texts into various chunks and then concatenate these derived chunks with other characteristics.

3.3 Text Ranking

There are many instances where the combined token length for a pair of articles exceeded the length of 512 tokens. Often, there are many irrelevant sentences with no semantic significance. So, these sentences are eliminated since they contribute much less to the overall context of the article. To achieve this, we adopt sentence-level noise filtering approach similar to Pang et al. (2021) & Mihalcea and Tarau (2004). In this, we first concatenate the pair of texts d_a and d_b obtained in the previous sections and split them into their component sentences s_i as shown in equations 1 & 2.

$$d_a = \{s_1^1, s_2^1, s_3^1, ..., s_n^1\} \tag{1}$$

$$d_b = \{s_1^2, s_2^2, s_3^2, ..., s_m^2\} \tag{2}$$

Then we concatenate d_a and d_b into S as shown in equation 3 later we derive representation matrix by taking the mean of the component word embeddings.

$$S = (s_1^1, ..., s_n^1, s_1^2, ..., s_m^2) \tag{3}$$

We use fastText embeddings (Bojanowski et al., 2017) which construct a better node similarity matrix than traditional methods and generate the embeddings by capturing transitive relationships and utilizing very sparse random projections. To generate the sentence similarity graph, we calculate the pairwise similarity of the sentence embeddings. The sentence similarity is defined as the same as TextRank (Page et al., 1999) to measure the overlapping word ratio between two sentences:

$$Sim\left(s_i, s_j\right) = \frac{\left|\{w_k \mid w_k \in s_i, w_k \in s_j\}\right|}{\log\left(|s_i|\right) + \log\left(|s_j|\right)}, \quad s_i, s_j \in \mathcal{S} \tag{4}$$

Then, we apply the Page rank algorithm (Page et al., 1998) to calculate the sentence importance score of each s_i in S and sort in decreasing order of importance. Finally, we extract the top λ sentences from d_a and d_b separately such that it is less than 512 tokens when combined. If the two articles

are similar, the sentences on the top of the ranked corpora reflect the same. As hypothesized, the title and *extra text* often appear on the top since they are rich in information.

3.4 Multi-task Training

Our multitask approach is based on the architecture proposed by Pruksachatkun et al. (2020). As shown in 2, the model consists of separate task-specific heads with their preprocessing methods but a shared encoder where the weights of all the tasks are updated simultaneously. This approach of introducing multiple subtasks supplements the main task. As evident from table 3, when more relevant tasks are added as task heads, the performance improves. In our best-performing model, the task head consists of an auxiliary semantic similarity task, a hyperpartisan identification task, and the main task. If required, the provided dataset and the hyperpartisan dataset are preprocessed by translation and text ranking modules. The sentences in the two ranked documents are combined, and a separator token separates the documents. This output is then fed into our multitasking model based on DeBERTa. The Loss during training was calculated using Mean Square Error (MSE) Loss function.

4 Experimental Setup

This section describes various hyper-parameters we use in data preprocessing and training. After scraping all the valid URLs, we could access 3651 pairs of articles for training, 408 for validation, and 4902 for a test. For training, we implement simple transformer models. We use DeBERTa (He et al., 2020) as the pre-trained language model with a batch size of 4. We found that the model performs better when the initial learning rate is 10^{-6} to 10^{-5}. We use the AdamW optimizer. We use Google Colab with a Tesla V100 GPU for various experiments. We apply various Python libraries like Pytorch, Transformers, Numpy, and Pandas to implement our multitask learning model.

4.1 Selecting Loss Function

We tried various approaches for selecting the loss function for our model. Initially, we experimented with many different loss functions such as Mean Square Error (MSE), weighted MSE, and dice loss. Furthermore, we experimented with a multi-objective weighted loss function as the data had multiple features. This loss is calculated as the weighted loss of L_E, L_N, and L_O, which are the

$$L = \alpha L_O + \beta L_E + \gamma L_N \tag{5}$$

5 Performance Analysis

In this section, we analyze the performance of several components of our system and compare different schemes for representing the document and the techniques used. Since the commencement of this task, Our team leaned toward using a multi-task learning strategy because it seemed to be the ideal fit for this problem. To do so, we ideated with several subtasks and experimented with our base encoder architecture. Table 3 shows all the different combinations of subtasks and base encoders used. Since the task prompts the participants to use multilingualism as a feature, our initial models utilized multilingual transformers such as XLM-Roberta (Conneau et al., 2019), and RemBERT (Chung et al., 2020), both of which are efficient with multiple languages. However, the primary issue we faced was the cross-linguality of the data; since the delivery style of information varies within every language, it becomes challenging to surface common information among pairs of text articles.

Thus, we emphasize more on translating the articles into English. We utilize a state-of-the-art publicly available model OPUS-MT. This translation module helped all articles to be represented in the same language. Doing so opens up the opportunity for us to choose from multiple encoders instead of our previous approach, where the number of encoders is limited.

After experimentation with various combinations of subtasks, as mentioned in table 3, we see that each of the subtasks has a unique attribute that can contribute to the overall performance of our model. After extensive experimentation, we chose two subtasks along with one main task.

5.1 Maintask - SemEval2022

As described earlier, our approach for generating the overall similarity is quite simple yet effective. The model uses an aggregate of title, text, and descriptions, which is then ranked based on the importance of each sentence in the article. The SemEval 2022 task-8 has various features to consider alongside the overall similarity score, rated between 1- and 4. During the task, the system pipeline supplies a pair of translated and ranked articles to the model, using the Deberta encoder to generate optimally aware document embedding. These embeddings are then supplemented with a set of linear layers to generate a final similarity score.

5.2 Subtask 1 - Hyperpartisan News Detection

As shown in Table 2 we used the Hyperpartisan News Detection dataset for detecting extreme sentences that may be biased towards a political group or a cause. The intuition behind this subtask was distinguishing news articles supporting extreme causes from more general articles. In sporadic cases, these two types of articles show similarities. This task also neglects political biases induced by media outlets and encourages us to treat each pair of articles impartially.

5.3 Subtask 2 - Semantic Textual Similarity

The semantic textual similarity closely relates to our main task since this involves finding the semantic proximity between pairs of texts. Because the STS-b dataset uses small sentence pairs with a max word limit of 40, it improved sentence-level similarity for the main task. The STS-b dataset covers a broad spectrum of sentences from news articles, image captions, and forums, which helps the model diversify across varied sentence-type situations.

5.4 Additional Models

We experimented with different combinations of Transformer based models and datasets. Table 4

Subtask	***Description***	***Dataset***
Semantic Textual Similarity	Determine how semantically similar two pieces of text are.	STS benchmark
Hyperpartisan detection	Given a news article, decide whether it follows a hyperpartisan argumentation, i.e., whether it exhibits blind, prejudiced, or unreasoning allegiance to one party, faction, cause, or person.	Hyperpartisan News Detection (Kiesel et al., 2019)
Stance detection	It involves estimating the relative perspective (or stance) of two pieces of text respective to a topic, claim or issue.	Fake News Challenge - 1 (Hanselowski et al., 2018)
Fake news inference detection	Fake news Detection using the Natural Language Inference. This entails categorizing a piece of text into categories such as "pants-on-fire", "false", "barely true", "half-true", "mostly true", and "true."	Fake news inference dataset
Language Inference	Determine whether a "hypothesis" is true (entailment), false (contradiction), or undetermined (neutral) given a "premise"	DocNLI Dataset (Yin et al., 2021)
Emotion Detection	Our Intuition behind this subtask was that if two articles are similar, they will exhibit same type of emotion. However, after experimentation we found this false as this subtask did not contribute towards the main task.	Go-Emotions Dataset (Demszky et al., 2020)
Paraphrase detection	Determine whether a particular sentence is a paraphrase of the original text.	Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005)

Table 2: Brief description of all different subtasks used for experimentation

Model subtasks	Model Type	Pearson Score (on validation set)
Stance detection	Translated text with RoBERTa	0.800
Stance detection	Untranslated text with XLM-RoBERTa	0.737
No Subtask (Multi-Objective Loss)	Weighted loss on Entity (0.15), Narrative (0.15) and Overall (0.7) Similarity (Sener and Koltun, 2018)	0.815
No Subtask (Multi-Objective Loss)	Weighted loss on Entity (0.2) and Overall (0.8) Similarity	0.811
Stance detection + Hyperpartisan detection	Translated text with RoBERTa	0.809
Hyperpartisan detection + Semantic Textual Similarity	**DeBERTa**	**0.835**

Table 3: Combination of all the subtasks and model types we used in experimentation. The results here are calculated on the validation set.

represents the score we achieved while developing the model. These scores are on the validation dataset that comprises 408 article pairs. Our model performed well during the developing stage. For instance, our best-performing model achieved a Pearson score of 0.835, and subsequently, we achieved a Pearson score greater than 0.8 in two other approaches. Table 3, however, shows the Pearson scores evaluated on the test dataset. We believe that the decline in performance was caused by the new languages (Chinese, Italian, Russian) introduced in the test dataset. These languages were not present in the training or validation set. This could be linked to the shift in writing style imposed on new languages, regardless of translation. According to our validation results, the model could not interpret the new languages and the unique cross-lingual pairs in the dataset.

6 Results

We use the Pearson score to evaluate SemEval 2022 task 8, which measures the linear relationship between the predicted and ground truth values. Like other correlation coefficients, the Pearson score varies between -1 and +1, with 0 implying no correlation. Correlations of -1 or +1 imply an exact linear relationship. The dataset available in the evaluation phase of the task lacked features like Geography, Entity, etc., which were present in the training phase. Furthermore, the test dataset has an additional set of languages not present in the training dataset. This test dataset ensured that the model trained by the participants was an accurate multilingual model. Table 4 shows the models submitted by our team for the SemEval 2022 task-8; our best model achieves a Pearson score of 0.733, placing us amongst the top 15 of all participating teams.

As stated in the second row of table 3 we also experiment with a singleton multitask learning model separate from a machine translation system. The model, however, was unable to generalize adequately for each language in the dataset, and there appeared to be considerable sparsity between the predicted scores, particularly for low-resource languages like Turkish and Polish. Also, the lack of invariant multilingual data, specifically for each of the languages listed previously, was crucial in our decision to switch to a translation-based approach.

Next, table 5 showcases two instances where our model is successful and two instances where it fails to predict the correct value. We believe that this behavior is due to the machine translation module in our pipeline. Our model performs poorly for the following language pairs: de-en, ar-en, pl-en, and zh-en. This can be closely connected to the OPUS-MT model's BLEU score values, which are much lower for the language mentioned above pairs. This

Model Type	Model Subtasks	Pearson Score (on test set)
RoBERTa	Semantic Textual Similarity + Stance Detection	0.724
	Phrase Detection + Stance Detection	0.730
DeBERTa	**Semantic Textual Similarity + Hyperpartisan Detection**	**0.733**

Table 4: Models submitted by our team for the SemEval 2022 Task-8

Article 1	Article 2	Predicted Similarity Score	Actual Similarity Score	Language Pairs
Paraguay: Presidente promulga ley contra el "dinero sucio" en campañas (link)	Paraguay: Deputies approve the law on "dirty money" in political campaigns (link)	1.045	1	de-de
Conductores chocan por detenerse a ver accidente (link)	Paraguay: Deputies approve law on "dirty money" in political campaigns (link)	3.8	4	de-de
Schlag gegen den rechtsnationalen Flügel (link)	AfD-Rechtsaußen unter Druck (link)	1.02	3	es-es

Table 5: First two rows of this table represents the instances where our model performed up to the mark and the last two rows represent the cases where our model failed to predict the right values

	Pearson Score
Ours	**0.733**
Average	0.624
Best in all teams	0.818

Table 6: Comparison of ours result with the best and the average pearson score

indicates that the model cannot comprehend these languages adequately, resulting in unclear results. Additionally, our system performs exceptionally well for data in French and Spanish, where the BLEU score values were 59.66 and 57.5, respectively. Furthermore, the results on en-en pairs are very accurate since they are not translated, thus retaining the writing style of the editor/outlet. Also, We encountered numerous challenges while scraping the data; not all websites were fully accessible, others only included photos or titles, and a handful swapped the URL with that of the main website's landing page. Next, the scrapper made numerous mistakes in discovering and assigning relevant tags to the articles' various subsections. A common erratum was combining description and title and attributing the title of the continuing piece to some random advertisement or supporting material.

7 Conclusion & Future Work

Our model performs well on English, Spanish, and French data while falling short on German. Even though the German data is the second largest, the biggest problem is that there is a lot of data to consider. The model could not correctly address each attribute of the article, resulting in underperformance. Some of the future work we anticipate to do which can increase the performance of our model are stated below:

1. Better Neural Machine Translation system which can effectively produce English sentences. We do suggest using AWS Translate since it makes more accurate predictions.

2. Using a finely trained multilingual model, enhanced explicitly for dealing with documents. DocMT5 (Lee et al., 2021) is one considered model; however, due to its public unavailability at the time of writing this paper, made us unable to use it in our approach.

Abstract

We investigate the capabilities of pre-trained models without any fine-tuning, for a document-level multilingual news similarity task of SemEval-2022. We utilize title and news content with appropriate pre-processing techniques. Our system derives 14 different similarity features using a combination of pre-trained `MPNet` with well-known statistical methods (i.e. TF-IDF, Word Mover's distance). We formulate the multilingual news similarity task as a regression task and approximate the overall similarity between two news articles using these features. Our best performing system achieved a correlation score of 70.1% and was ranked 20^{th} among the 34 participating teams. In this paper, in addition to a system description, we also provide further analysis of our results and an ablation study highlighting the strengths and limitations of our features. We make our code publicly available at https://github.com/cicl-iscl/multinewssimilarity.

1 Introduction

Assessing semantic similarity between two given content pieces has become one of the important natural language processing (NLP) tasks. This task can help researchers estimate the quality of their models for many other tasks such as: machine translation (MT), summarization, question answering (QA), semantic search, dialog, and conversational systems. Extending semantic similarity task to a cross-lingual setup can extend the evaluation benefits to cross-lingual tasks as well. Previous works (Agirre et al., 2016; Cer et al., 2017) focus on sentence level cross-lingual semantic similarity. The presented shared task, Chen et al., 2022, proposes a novel problem that focuses on document-level semantic similarity based on news articles.

The multilingual news similarity task contains monolingual as well as cross-lingual pairs of news reports. This setup enables researchers to test their multilingual models on a document-level semantic similarity task. There can be multiple extensions to this, including the clustering of news articles and tracking similarity of news coverage between different outlets or regions.

In this work, we investigate the capabilities of pre-trained multilingual language models (LMs) as well as word-embedding models in this task, without fine-tuning them on the task data. Our solution pipeline combines pre-trained `MPNet` (Song et al., 2020) with well-known statistical methods with well-known statistical methods (i.e. TF-IDF, Word Mover's distance) to derive the semantic similarity features between articles using their *title* and *textual content*. We use these similarity features to approximate overall similarity between article pairs.

Our system performance is encouraging for this task, albeit with room for improvement. In the following sections, we describe our approach and provide a detailed study of the errors made by the system. We also report the results of an ablation study highlighting strengths and limitations of our derived features.

2 Task Setup

2.1 Dataset

The shared task introduced a new dataset consisting of 4964 article pairs in the training set and 4953 article pairs in the hidden test set. The participants were provided with these news articles' URLs and a Python script to scrape the texts. The training data contained an annotated overall similarity score for each pair and other similarity scores corresponding to features such as geography, entities, time, narrative, style, and tone.

The released training data consisted of monolingual pairs in English, German, Spanish, Turkish, Polish, Arabic, and French, and one cross-lingual

[*] Both authors contributed equally.

pair: German-English. The evaluation data contained 4,953 news article pairs. To the languages included in the training data, there were added monolingual pairs in Italian, Russian, and Chinese, and the cross-lingual pairs: German-French, German-Polish, Spanish-English, Spanish-Italian, French-Polish, Polish-English, and Chinese-English. For more details, please refer to table 5 and 6 in the Appendix. These monolingual and cross-lingual news article pairs are annotated on a 4-point scale from most to least similar.

2.2 Evaluation

The overall similarity between the two news stories is the only score used to evaluate system performance. The online scoring system calculates Pearson's correlation between system-generated overall similarity ratings and the gold standard ratings.

3 System Overview

In our approach, we formulate the multilingual news article similarity as a regression task, relying on different similarity features to approximate the overall similarity between two news reports. We choose this approach as the language pair distribution differs significantly between training set and the test set. This setup enables us to investigate the capabilities of pre-trained multilingual language models (LMs) as well as word-embedding models on document-level similarity task without fine-tuning.

We divide the news similarity task into a pipeline of five subtasks: Article Scraping, Preprocessing, Embedding Creation, Feature Calculation, and Inference. Figure 1 illustrates the architecture of our system.

3.1 Article Scraping

We used the script[1] provided by the organizers to download the article content from the web. After multiple tries, we were able to retrieve news content for 4940 out of 4964 training article pairs (see Table 5 in the Appendix). Similarly for evaluation data, we were able to retrieve news content for 4903 out of 4953 article pairs (see Table 6 in the Appendix).

3.2 Preprocessing

Our preprocessing step takes an article as an input and generates a json object containing only the information which is relevant for our approach. As we do not fine-tune any model based on the textual content, data cleaning is an important step for our system. We remove irrelevant content from the data in the following manner:

Copyright text: The article texts sometimes contains information regarding the copyright policy of the news websites. We observed a few cases where the scraper only downloaded the copyright notice instead of the news content. In such cases, copyright content increased or decreased the similarity significantly. To avoid errors in similarity feature calculation, we remove such copyright lines.

URLs: Generally, news reports also link other relevant references in their articles but parsing them to make them useful can be tricky. Moreover, sometimes these can contain unrelated advertisement links. Hence, we remove all kinds of links from the text for our purposes.

Cookies text: Similar to the copyright content, the scraper also ends up downloading text with information regarding the usage of cookies from the website. As this text is irrelevant for measuring content similarity, we remove this information from the article text.

Image captions: News stories can also contain images referring to some event or place that is covered in the news article. Such images are generally captioned with the details of the photographer credits. We find such credits irrelevant for our task and clean them from the article text.

3.3 Embedding Creation:

We use vector representation of article title and text to compute similarity features. We obtain these representations using `MPNet` and `FastText`. We calculate these vector representations once and store it on the disk. This way, we do not have to calculate these representations every time we need them. We utilize a multilingual version (Reimers and Gurevych, 2020) of `MPNet` (Song et al., 2020), fine-tuned on a paraphrasing task using parallel data for 50+ languages for calculating vector representations. We also experimented with language-agnostic BERT (Feng et al., 2020), but we dropped it after initial results.

For the longer text, multilingual `MPNet` model simply truncates the text and returns the representation of the first 512 tokens. We need a way

[1]https://github.com/euagendas/semeval_8_2022_ia_downloader

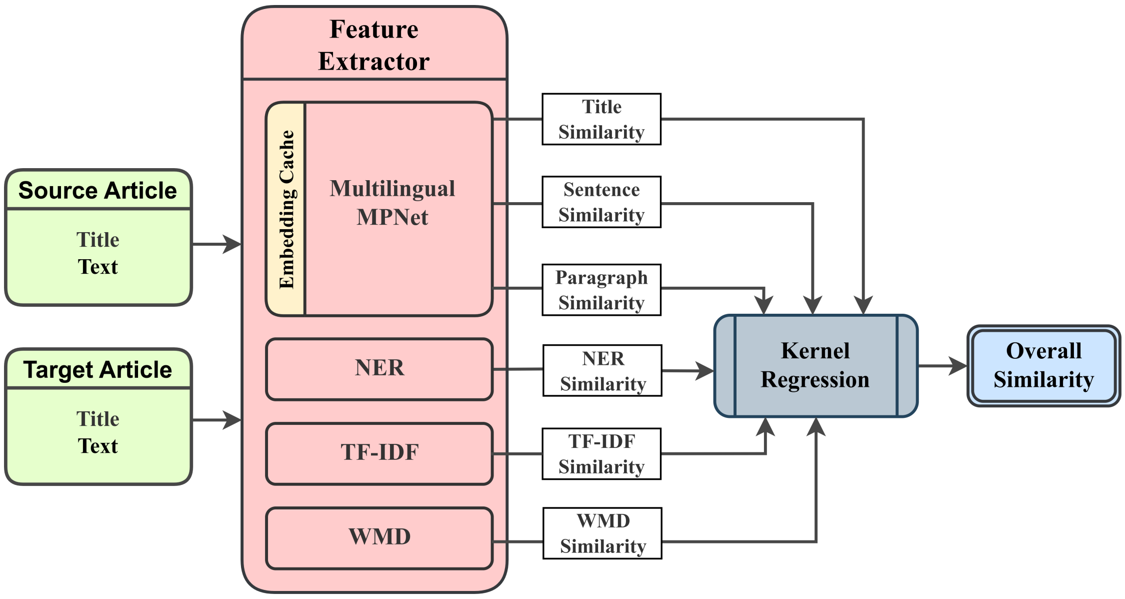

Figure 1: A schematic of our approach. We utilize Zero-shot feature extractors to derive similarity features from the articles. We use these features to train our regression model and obtain overall similarity score.

to be able to compute accurate vector representation of news articles irrespective of their length. Hence, we compute representations for article text at two different granularity levels: sentence-level and paragraph-level.

We obtain separate sentences using a multilingual sentence tokenizer from `SpaCy`.[2] For paragraph-level representation, we tokenize the text using a pre-trained tokenizer, provided along with `MPNet` model, and take the first and the last 512 tokens of the article. We obtain the vector representations of these sentences, the first 512 tokens, and the last 512 tokens using the `SentenceTransformers` (Reimers and Gurevych, 2019) library. Similarly, we compute the vector representations of the news title. From now on, we will refer to the first 512 tokens as the `first paragraph` and the last 512 tokens as the `last paragraph`. Note that for articles shorter than 512 tokens, the first and the last paragraph will be the same.

3.4 Feature Calculation

To estimate overall news article similarity, we derive 14 unique similarity features from the news title and text pairs. In this subsection, we describe all the features in detail.

[2]https://spacy.io/models/xx

3.4.1 Sentence similarity

We derive four similarity features from the article text to capture the sentence-level similarity between articles. These features are obtained as follows:

Sentence mean similarity: The average cosine similarity scores of the top matching sentence vectors between the source and target articles.

Sentence maximum similarity: The maximum cosine score of the top matching sentence vectors between the source and target articles.

Sentence minimum similarity: The minimum cosine score of the top matching sentence vectors between the source and target articles.

Sentence median similarity: The median of the cosine similarity scores of the top matching sentence vectors between the source and target articles.

3.4.2 Paragraph similarity

Additionally, we derive two similarity features from the article text to capture the paragraph-level similarity between articles. These features are obtained as follows:

First paragraph similarity: The cosine similarity value between the `first paragraph` vector representations of the news articles.

Last paragraph similarity: The cosine similarity between the `last paragraph` vector representations of the news articles.

3.4.3 Title similarity

The title should summarize the article text in a meaningful manner. We calculate five similarity features from the article title, capturing title similarity as well as inter and intra title-text similarity between articles. These features are obtained as follows:

Title similarity: The cosine similarity between the title vector representations of the news article pair.

Inter title-text similarity: We calculate inter title-text similarity to see how the source title is similar to the text of the target and vice versa. We utilize stored vector representations of the corresponding news entities and calculate cosine similarity between these entities. Note that we produce two separate features for inter title-text similarity (i.e. $sim(\text{title}_s, \text{text}_t), sim(\text{title}_t, \text{text}_s)$).

Intra title-text similarity: Similarly, to measure title-text coherence, we calculate intra title-text similarity between the title and the text of same news article using the stored vector representations. Note that we produce two separate features for intra title-text similarity (i.e. $sim(\text{title}_s, \text{text}_s), sim(\text{title}_t, \text{text}_t)$).

3.4.4 NER similarity

We calculate named entity similarity NE_{sim} using the below equation.

$$\text{NE}_{sim} = \frac{|\text{NE}_s \cap \text{NE}_t|}{max(|\text{NE}_s|, |\text{NE}_t|)}$$

where NE_s represents set of named entities in the source article, NE_t represents set of named entities in the target article.

3.4.5 TF-IDF Similarity

We first remove stop words using `NLTK`'s language-specific stop words corpus. We then estimate the cosine similarity between TF-IDF representations of the article pair.

3.4.6 WMD Similarity

Similar to TF-IDF similarity, we calculate the Word Mover's distance of two texts without stop words using multilingual `FastText`(Bojanowski et al., 2017) model from `Gensim`.[3]

[3]https://fasttext.cc/docs/en/crawl-vectors.html

3.5 Inference

The last part of our system is estimating the overall similarity using the features obtained. We experimented with three different setups: regression over all the features, multitask regression using additional available scores, and regression over reduced feature space (i.e. principle components, autoencoder representations). In this subsection, we mention all the setups briefly and provide details of our best performing system.

Multitask Regression: The training data contains similarity scores for geography, entities, time, narrative, style, and tone along with Overall article similarity. We trained a Multi-task Lasso model and Multi-task autoencoder on the training set but after initial experiments, we decided not to pursue these setups further.

Regression over reduced feature space: We apply principal component analysis on our feature space for dimensionality reduction.

Regression over entire feature space: We experimented with Linear regression, Decision Tree regression, Random Forest regression, Kernel ridge regression, Multilayer perceptron regression, and TabNet regression (Arık and Pfister, 2021).

Our two best performing systems used Kernel ridge regression. In the highest ranked system, we train a Kernel ridge regressor using a polynomial kernel of degree 3 and a regularization co-efficient of 1.0. This way we allow our model to learn from non-linear features. Our second best performing system uses Kernel ridge regression (KRR) with RBF kernel over top-4 principal components and achieves 70% Pearson correlation. TabNet regression ranked third during the evaluation phase, with a correlation score of 69.1%. We describe the implementation details of our best performing setup below.

Implementation details: We split the data into 95:05 training and evaluation datasets and utilize the entire feature space. Going from 80:20 split to 95:05 split boosted our model accuracy by half point. As a final step, we also clip the model predictions between 1-4 to make sure that our model predictions remain inside the range. We use `scikit-learn` (Pedregosa et al., 2011) for training the kernel regression model and `wandb` (Biewald, 2020) for hyperparameter tuning.

4 Results

All the submissions for this shared task were evaluated with regard to Pearson's correlation coefficient. Our best performing system achieved a score of 70.1% in the evaluation phase. We were officially ranked 20th out of 34 teams on the main task leaderboard. On the English-only subtask, we were ranked 15th out of 34. We report scores for our top three submissions during evaluation phase in Table 1. All three systems use all the features to predict the overall similarity.

Model	Data Split	Score
KRR-poly	95:05	70.1
KRR-rbf	80:20	70.0
TabNet	95:05	69.1

Table 1: Correlation scores of our top performing systems on the hidden test set

We report our results for each monolingual language pairs in Table 2 and cross-lingual pairs in Table 3. The general system performance was similar for monolingual and cross-lingual pairs, with an average accuracy of 0.71 for monolingual pairs and 0.72 for cross-lingual ones.

Language	Score	Language	Score
fr-fr	84.34	tr-tr	70.36
es-es	81.24	zh-zh	64.42
en-en	79.55	ar-ar	62.23
it-it	79.42	pl-pl	61.49
ru-ru	73.50	de-de	59.43

Table 2: Correlation scores for monolingual pairs

Language	Score	Language	Score
pl-en	82.84	fr-pl	74.76
es-en	80.13	es-it	70.95
zh-en	76.91	de-pl	60.11
de-en	76.54	de-fr	55.47

Table 3: Correlation scores for multilingual pairs

The highest accuracy was achieved in the French monolingual pair, with 0.84, but the lowest accuracy score was found in the German-French cross-lingual subsection with 0.55. This can be explained by the general low results that the system achieved in the pairs with news written in German, be it in the monoligual subset (0.59), or cross-lingual pairs German-French and German-Polish (0.60). Only one pair with German language had an above average accuracy, the German-English cross-lingual pair (0.76).

5 Performance Analysis

In this section, we analyze the performance of feature sets used by our system and compare different subsets against each other. We also discuss some errors made by our system and possible improvements.

5.1 Ablation study

We conducted ablation experiments to evaluate the importance of different feature sets on the results. We use released test set labels and our best performing model, Kernel Regression to conduct this study. We report the results of this study in Table 4. Note that these results were obtained after extensive hyperparameter tuning, which was not feasible during the shared task evaluation phase.

Features	Correlation
MPNet features	71.83
Non-MPNet features	47.15
MPNet features + WMD distance	71.35
TF-IDF + WMD distance	47.89
MPNet Sentence features	63.21
MPNet Title features	64.11
MPNet Paragraph feature	63.73

Table 4: Results of feature ablation study

We observe that features derived from `MPNet` perform better than our reported system and slightly improve the correlation score. We also observe that adding other features with `MPNet`-derived features rather degrades the system performance (i.e. `MPNet` features + WMD distance). Other features perform very poorly compared to `MPNet` features through our setup. While `MPNet` feature sets perform substantially better individually compared to other features, combining all `MPNet` gives the best performance on the task.

5.2 Error analysis

In order to closely examine the performance of our system, we analysed a subset of the news pairs which were classified in the wrong category. This subset only included news pairs written in English, German, Spanish, Italian or French and its cross-lingual combinations. Most differences between our systems' result and the annotation guidelines differed in less than one point. Since the different categories of similarity proposed in the dataset also differed in one point, we considered this as our threshold for error analysis.

The following patterns were found when our system overestimated the similarity between two news pairs:

Articles with parallel structures: Some news genres present a more fixed structure than others. Such is the case for police reports, which include similar key phrases but narrate different events.

Same location: Two different events which happened in the same location.

The following patterns were found for when our system underestimated the similarity between two news pairs:

Scraping errors: At least one of the articles did not contain any textual content relevant for the news article.

Lack of information: At least one of the news articles was extremely brief (less than one paragraph), and lacked information about the event.

Different titles: The titles focused on different aspects of the news report.

6 Conclusion

In this paper, we have described our participation in the Task 8 of SemEval-2022, "Multilingual news article similarity". We developed a system to investigate the capabilities of pre-trained language models (LMs) as well as word-embedding models. Our results suggest that the system performs similarly for monolingual and cross-lingual pairs, but its performance varies based on the specific language pairs. The ablation study showcases the strength of the pre-trained multilingual language models for this task. Given the performance of our system, despite the noticeable variation in language-pair distributions, we speculate that our approach can be used to deliver similar results for additional languages as well.

For the future, we would like to explore the system's performance with the same features but also fine-tuning our `MPNet` model on the training dataset. This would allow us to compare the effectiveness of pre-trained models against the fine-tuned model. Additionally, we would like to experiment with new features such as article summary similarity and article topic similarities.

Acknowledgements

We would like to thank Prof. Çağrı Çöltekin for the his inputs and helpful discussions.

Team TMA at SemEval-2022 Task 8: Lightweight and Language-Agnostic News Similarity Classifier

Nicolas Stefanovitch
European Commission - Joint Research Centre
nicolas.stefanovitch@ec.europa.eu

Abstract

We present our contribution to the SemEval 22 Shared Task 8: *Multilingual news article similarity*. The approach is lightweight and language-agnostic, it is based on the computation of several lexicographic and embedding-based features, and the use of a simple ML approach: random forests. In a notable departure from the task formulation, which is a ranking task, we tackled this task as a classification one. We present a detailed analysis of the behaviour of our system under different settings.

1 Introduction

Detecting similar news is a key component of media monitoring, such as the one done by the Europe Media Monitor[1], which collects daily about half a million articles in more than 80 languages. This shared task (Chen et al., 2022) allows to study two important challenges that arise in practice: articles can be similar to several extent and in different ways; massive multilingualism requires language agnostic approaches. We report in this paper the result of an experimental approach to tackle this task.

We considered computing simple lexicographic and embedding-based features and using simple ML approach for complexity reasons, having in mind that pair-wise comparison of half a million articles each day is not possible with heavier solution without massive resource cost. There are two important tasks when building such large scale news clustering: determining which pair of articles are worth comparing, and computing the actual similarity between pairs of articles. While this shared task deals only with the second approach, the presented system has been designed to tackle also the first one.

[1]https://emm.newsbrief.eu/

2 System Description

Our system computes several lexicographic- and embedding-based similarity features, which are fed to a standard random forest. We used the following hyperparameters: 100 trees and a leaf split parameter of 3 data points. On the train set, these parameters avoided extreme overfitting to the data, while not degrading significantly the performances. We used 5-folds cross validation in order to choose the hyper parameters.

For each article we consider separately the similarities related to 4 fields of the news item: the title, the description, the first sentence and the snippet. The snippet is constituted of the first 4 sentences comprised within the first 512 characters of the text - everything after was ignored, sentences were not truncated. We present here the set of features that have been computed for each of these fields, and for some cross field (title-description, title-first sentence, description-first sentences), all features are normalized.

Lexicographic measures: we consider two sets of representation: the set of words, and the set of multi-word expressions (MWE). The MWE were computed by splitting the text around stopwords and punctuation marks, essentially similar to RAKE keyword extraction (Piskorski et al., 2021). The features include the proportion of matching words and proportion of matching MWE between both articles. In the case of MWE, a margin of error was allowed in that two non strictly equal MWE were considered equal if the longest common subsequence between them was of 75% the length of the longest one. For both words and MWE we compute the raw count of elements in common and the length of the corresponding span of text.

Embedding-based measures: all embedding-based measures are based on LASER embeddings (Artetxe and Schwenk, 2019) which are aligned multilingual embeddings covering over 100 languages and that perform well for multilingual semantic comparison. They are BiLSTM based, and as such are much faster than transformer-based solutions, it also has to be noted that out of the box BERT solutions do not perform well on the task of semantic similarity, and LASER embeddings have a better performance (Reimers and Gurevych, 2020). On top of the pairwise comparison between the aforementioned fields, we also compute the equivalent of Word Mover Distance (Zhao et al., 2019) between the first 4 sentences of the articles, by binning sentences in pairs of decreasing similarity.

Non linguistic features: the only non linguistic feature considered is the difference in publication date of the two articles.

When developing the system, the results were checked for near misses, by considering all the clusters produced, and checking for missing links between elements of the clusters. This approach was able to catch such misses, including in the training data itself, but it was not used in the final system due to lack of time.

3 Data

The training data provided by the organizers is a list of 4964 article pairs covering 9431 articles in 16 languages, while the 7 main languages represent 99% of the dataset. The pairs are associated with several similarity scores; one of them giving the overall similarity is ranked between 1.0 (maximum) and 4.0 (minimum) and is the only one considered in our approach. Test data contains 4890 pairs over 9715 articles in 10 languages. There is a notable difference between both datasets, in that train data contained almost no pairs of article in different language, while such pairs represented 15% of the evaluation dataset. A major difference was also the introduction of Chinese in the test set.

3.1 Acquisition

The data was given as a list of urls to download, and this proved to be a daunting exercise fraught with difficulties and eventually taking more time and dedication than the development of the system itself. The scrapper provided by the organizer was not used, we relied on the *trafillatura* (Barbaresi, 2020) library, which was desirable thanks to its good metadata extraction capacities and overall performances. A total of 3 different scrapping approaches were used: first trying to scrap directly from the original url, then trying to scrap from the internet archive, finally, in case the url was reachable but the data was not correctly extracted, we wrote an ad-hoc scrapper whose extraction rules were manually written for each problematic news source. Despite these efforts, about 7% of the test data was impossible to download. We report these numbers in Table 1. Most of the articles that had to go through the ad-hoc scrapper were from Chinese sources, for several of these it was possible to extract only the title, this created a difference in the features available with several missing values.

set	direct	arch.	ad-hoc	total	absent
train	8108	951	159	9431	274
test	7348	847	838	9715	682

Table 1: Number of additional downloaded pairs of urls by scrapping method, total and missing pairs

3.2 Preprocessing

The data underwent significant prepossessing. The title was cleaned of mentions to the news source. In order to do that, if the source name was extracted from the metadata and was present in the title it was removed, if a token was ending with an internet top level domain, the token was removed, if a pipe bar was present, the leftmost part of the bar was kept. If it was detected that a source always had the same title, indicating that the scrapper was not correctly extracting it, then the title was replaced by the first sentence of the description if available. If the description was not available, the first sentence of the article was used instead, in case the article had no text but had a description, the description was used for the text, and in case there was not description but a title, the title was used for the description. This procedure aimed at minimising the impact of missing values.

The text was preprocessed by removing likely source name, author name and date mention at the beginning of the text, using an heuristic rule-based procedure focusing on the presence of numbers, uppercase letter, short sentences and typical start of text markers, such a double dashes. Out of the remaining text, a snippet was extracted, taking the sentences spanned by the first 512 characters, with a maximum of 4 sentences. Unicode letters were normalized to canonical forms. The language annotation provided in the dataset was not trusted, and we instead relied on the one provided by the lan-

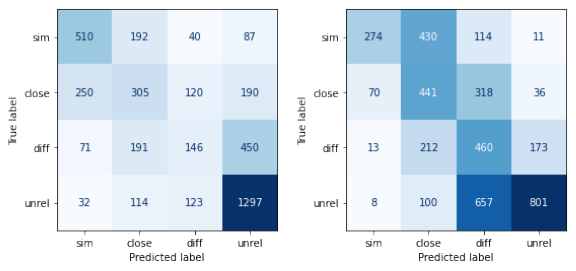

Figure 1: Confusion matrix for random forest classification (left) and rounded random forest regression (right)

guage detector of `fasttext` (Grave et al., 2018). Chinese texts were segmented using the `jieba` library in order to insert spaces between words so as to further deal with them in a language agnostic way.

4 Experimental Results

4.1 Experiments on train dataset

We settled on using random forests on the classification task as our contribution model after preliminary trial showed that random forests had better performances than neural networks and that the label distribution produced by random forests on the classification task was much more coherent with the ground truth than the one produced by random forests applied to the regression task. Given that we will tackle the problem as a classification problem, we will consider 4 classes labelled from 1 to 4, denoting the following relations in article pairs: similarity (sim), close similarity (close), different (diff) and unrelated (unrel). Unless specified otherwise, all the values computed over the train set are an average over 5-fold cross validation.

In Figure 1 we report the confusion matrix over the 4 classes using all the features with a random forest classifier (RF-C) and regressor whose output have been rounded to the closest integer (RF-R). RF-R has more errors than RF-C, but these are less significant as classes are mistaken mostly between related classes: for instance the classes sim and close are more often confused than with RF-C, but the classes sim and unrel are significantly less confused.

In Figure 3 we report the label distribution of the classifier and the regressor when trained and tested over the full training set and compare it with the ground truth. In this same setting, in Table 2 we report the Jensen-Shannon divergence of these label distributions, measuring the distance with the train data label distribution (Fuglede and Topsoe, 2004), we also report the micro F_1 and macro F_1 performance of RF-C and RF-R. Despite a seeming overfitting of RF-C, the distribution of labels produced by RF-C is clearly closer to the one of the ground truth than the one of RC-R. For all these different reasons we decided to tackle this task as a classification problem instead of a regression one.

Figure 2: Caption

macro F1	93.7	78.9
JS div.	0.0016	0.0098

Table 2: Performances on the train data, and distance of the label distribution with respect to the train dataset distribution

In Table 3 we report the performance of our classifier (RF-C) over different subsets of the training data, in function of the language pairs considered: all (MULTI), only same languages (SAME), only English (EN) and only different languages (CROSS). Both micro an macro F_1 are the highest for EN, nevertheless MULTI is the second best performing subset in terms of macro, with only one point less, while the micro difference of 6 points is important. The performance of SAME an MULTI are similar, this seems to indicate that specifically for English the performances are better. This could be due to the fact that English is the less flexional language of all the languages in the training set, as such, string matching is more likely to report the correct answer, both for exact and approximate matching. CROSS has the second highest micro score, but has the lowest macro score. This approach tends to rely more heavily on the embed-

subset	micro F_1	macro F_1
MULTI	55.2	47.5
SAME	54.1	47.2
EN	61.1	48.3
CROSS	58.0	40.1

Table 3: multilabel evaluation of RF-C: micro F_1 and macro F_1 performance of different subsets of language pairs of the train dataset

subset	F_1 (1 vs rest)	F_1 (1+2 vs rest)
MULTI	60.1	78.0
SAME	59.1	74.1
EN	64.5	75.1
CROSS	56.3	76.1

Table 4: binary evaluation of RF-C: the F_1 measure is reported for two binary classifier: class 1 (similar articles) vs rest and class 1+2 (similar and close articles) vs rest.

ding feature as lexical matches are unlikely except for named entities.

In Table 4 we report the measures for the same subsets, but applied when considering binary classifications problems. We consider two such classifiers: when considering class 1 (similar articles) versus the rest of the classes and when considering class 1 and 2 (similar and close articles) versus the rest of the classes. The performance of the binary classifiers are clearly superior to the performance of the multilabel classifier: on MULTI the former has a micro F_1 performance about 5 points better, and the later has a better performance by 22 points.

Study of the correlation matrix of the features with the ground truth, not reported in this paper for readability reasons, shows that all lexicographic-based features are the highest correlated features, with a correlation percent of about 50%. Among the several embedding-based features, only the distance between titles correlated highly with ground truth with 46%, second to it only similarity between title and description has a significant correlation of around 32%.

In Table 5 we report the performance of our classifier on the train dataset for different subsets of the features: all the features (ALL), only lexicographic-based ones (LEX), only embedding-based one (EMB), a combination of both (LEX+EMB) and date (DATE). ALL has clearly the best performance both in terms of macro and micro F_1, despite integrating the date feature, which on itself performs

features	micro F_1	macro F_1
ALL	55.2	47.5
LEX+EMB	53.3	44.8
LEX	49.6	40.4
EMB	51.3	42.6
DATE	37.5	22.6

Table 5: evaluation of different subsets measured as the micro and macro F_1 of RF-C in a multilabel setting

subset	support	micro F_1	macro F_1
all eval dataset	4902	44.1	40.5
all downloaded	4455	46.5	41.5
all with text	3946	47.6	42.4

Table 6: micro and macro F_1 performance of our approach on the evaluation dataset, for different subsets of articles pairs

quite poorly. However, we believe that the impact of this feature is heavily biased by the way both the train and test datasets have been constructed, as the organizer of the shared task have fetched news over a time period of several years, while about half the items are related, and about a quarter are similar. As a consequence, it happens that close dates are related to similar news more than it would appear in an uniform sample over the same time period. For that reason, we don't expect that this feature would generalise well, but we left it nevertheless as we expect the train and test distributions to be similar.

4.2 Experiments on test dataset

When evaluating on the test dataset, we use a classifier (RF-C) trained on the full training dataset. Because of the difficulties in downloading the test data, we report the performance of the classifier on different subsets of the downloaded data.

In Table 6 we report the micro and macro F_1 performances of our classifier, as well as the support, counted in number or article pairs. We consider three subsets: all evaluation data (including also article pairs whose articles were not downloaded, and for which a default score of 2.69 was used - which was the average predicted value of our classifier for the other articles), all pairs whose corresponding articles have been successfully downloaded, all pairs for which the text of the corresponding articles have been successfully downloaded. The best performance on the test data is on average 5 points lower both in term of micro an macro than on the

subset	micro F_1	macro F_1	F_1
MULTI	46.5	41.5	74.0
SAME	43.7	42.0	78.6
EN	58.4	42.7	79.0
CROSS	43.8	38.3	71.7

Table 7: performance on the evaluation dataset of the classifier, using micro and macro F_1 as well as F_1 for the corresponding binary classification problem

train dataset. Expectedly, the model evaluated on the full dataset performs the worst, but reasonably so with only 2 points down the performance on the subset of successfully downloaded articles while 9% of the data rely on the default value. Further restricting the evaluation on the articles that had a successfully downloaded text content only provides one additional point of performance.

In Table 7 we report the performance of the classifier on the test dataset for different subsets of language pairs, as already previously described. The measures are micro and macro F_1, as well as the F_1 of the class 1+2 when considering tackling the problem as binary classification. Interestingly, while the mutlilabel performances are lower than on the training set by about 9 points, the binary classification performance is only lower by 5 points in a cross language setting and actually higher by 4 points in a same language setting.

In Figure 5 we report the true positive rate by language pairs for pairs of languages having more than 10 data points, evaluated on the subset of the dataset for which articles were successfully downloaded. We consider a true positive in case the predicted and ground truth had exactly the same label, as such it is not possible to assess how close to the actual label the predicted values are. Therefore, this figure only allows to give an overall picture of the respective performances for pairs of languages. When considering pairs of articles in the same languages, French, Spanish and English performs the best. Among these, Chinese has the worst score, this could be related to the fact that a few Chinese sources representing a significant share of articles were impossible to be correctly downloaded (text and other metadata are absent). Surprisingly some pairs of different languages perform better than for these languages considered individually, this is the case for German and Chinese. Nevertheless, articles pairs in different languages tend to perform worse than pairs in the same language.

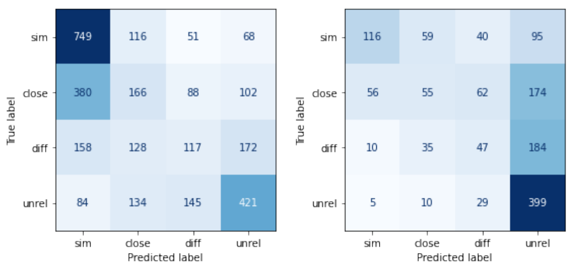

Figure 4: Confusion matrix of RF-C on the test set, for same-language pairs (left) and cross-language pairs (right)

In Figure 4 we report the confusion matrix of our classifier, by considering separately two cases: the confusion matrix for same-language pairs and for cross-language pairs. From this figure it is clear that our classifier tends to over-estimate the similarity of articles written in the same language, while underestimating the similarity of articles written in different languages.

5 Discussion

Despite the problem of the shared task being posed as a regression one, we have chosen to address it as a classification problem. This has two direct negative consequences on the performance of the model: firstly due the mandatory discretization step of the real-valued evaluation score provided in the training data and expected by the evaluation system; secondly due to the fact that the notion of related classes, such as "similar" and "close", are lost and penalized as much as if "similar" had been predicted as "unrelated". This is clearly shown by the fact that the multilabel classifier trained on 4 labels performs significantly worse than a binary classifier trained on two classes, which has actually acceptable performances. Despite being language agnostic our approach performs better in a same language setting than in a cross language one. This indicates either the high importance of the lexicographic as being a good predictor, or that multilingual embeddings perform significantly differently on different language pairs.

The lexicographic-based features perform surprisingly well, only two points under the performance of the embeddings-based features when evaluated on the full training dataset contain. A potential reason for that could be that named entities can differ only slightly between languages and that the soft lexicographic measure used is good at capturing these variations. The performance of our

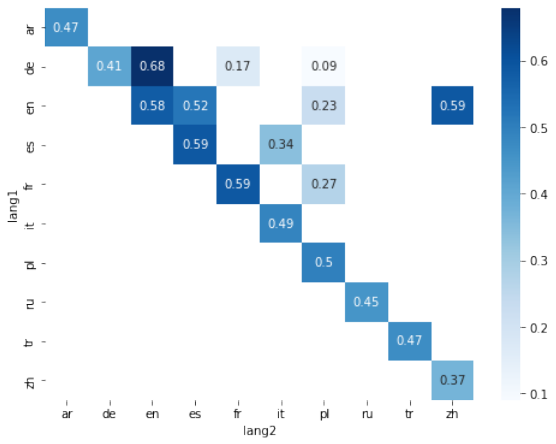

Figure 5: True Positive Rate by language pair of the multilabel classifier on the test dataset

approach is lower on the test dataset, such a drop in performance could be due to different reasons among others: the fuzzy lexicographic matching having lower performance in a cross language setting (much more prevalent in the test dataset than in the training); the difficulty to download data and correctly extract it, making the data incomplete; the heuristic reconstitution of missing description and text content could have introduced noise in some cases; maybe the fact that only tiny snippets of the full article were considered; or potentially a more fundamental limitation of the approach. Our approach could be improved by considering the actual language pairs as features, using more advanced features based on named entity extraction, and using exclusively data without missing values. However, we lacked time to investigates all of these configurations. Interestingly, of the embedding-based features, the title and the description are the most important features, and work better than more advanced ones, such as word mover distance applied to the sentences of the snippets.

Given these results, we can argue that the language agnostic approach we developed is an interesting solution for a coarse grain similarity evaluation, but not for a fine grained one. Given the fast computation time, a few minutes to compute all the features on a CPU machine without using multi-threading, our approach could be used as a preprocessing step before using more precise but also more time consuming approaches. Particularly, this approach is interesting when a news processing system has to process hundreds of thousands articles a day, preventing the use of costly solutions.

6 Conclusion

In this paper we presented the system we used to tackle the multilingual news clustering shared task at SemEval-22. Our approach is language-agnostic and inherently multilingual. It relies on a set of relatively simple lexicographic- and embedding-based features, and as such is able to process documents efficiently. We tackle the task as a classification problem rather than a regression problem. Our approach performs satisfyingly when evaluated over a simpler binary classification problem.

Abstract

This article introduces a system to solve the SemEval 2022 Task 8: Multilingual News Article Similarity. The task focuses on the consistency of events reported in two news articles. The system consists of a pre-trained model(e.g., INFOXLM and XLM-RoBERTa) to extract multilingual news features, following fully-connected networks to measure the similarity. In addition, data augmentation and Ten Folds Voting are used to enhance the model. Our final submitted model is an ensemble of three base models, with a Pearson value of 0.784 on the test dataset.

1 Introduction

The task (Chen et al., 2022) aims to design a system that can find the similarities of multi-language news articles. The task focuses on the consistency of actual events reported in two news articles, but not the subjective factors such as writing style or political factors. Geographical location, time, common entity, and common narrative were used to judge similarity. Consistency is measured by a float value between [1,4]. The lower the value is, the more likely the two news are reporting the same thing. The metric is the Pearson Coefficient of the predicted and ground truth values.

Challenge of this task: 1. Need to understand every aspect of a news event: what happened, where and when, who was involved, and why and how it happened 2. Make the writing style and common phrases clear because some unnecessary content can be misleading. 3. Some information about the event is hard to get, such as the time, location, and description of the event.

We use the pre-trained language model XLM-Roberta and INFOXLM to fine-tune. Specifically, we splice the available information of two news articles (exact method will be described in Chapter 3), input it into the pre-trained model, and then transmit the output vector to the fully connected layer of downstream tasks. For the original fine-tuning task, we try to use various techniques to make the program run faster and work better. The techniques include 1. Freezing the lower layers of the pre-trained model, means not updating their parameters during training. 2. Data Augmentation. Use translation software to translate the original news text to expand the data. 3. Divide the training set into 10 parts. the ten folds voting was adopted to make full use of the data set.

Our code is available on github[1].

2 Related Work

2.1 Background

The input of the task is the content of two news, and the output is the Overall label of them. Overall label is a float value between 1 and 4, which is used to measure whether two news report a same thing.The lower the Overall score, the more likely the content of the two news to be the same. The datasets including nearly 5,000 pairs of news with Overall label given. In addition to the Overall label, Geography, Entities, Time, Narrative, Style, and Tone label are also noted in the datasets. The news is given in the form of links and contains seven languages(en, de, ar, es, fr, pl, tr), while the test set contains the other three languages(it, ru, zh). It should be noted that the dataset contains news pairs in different languages.

2.2 Pre-trained language model

Pre-trained language models such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) start to make a difference in the way of word representations rather than static word embedding methods, and Word2Vec (Mikolov et al., 2013) and FastText

[1]*These authors contributed equally.

[1]https://github.com/SemevalITNLP/Semeval8NewsCorrelation

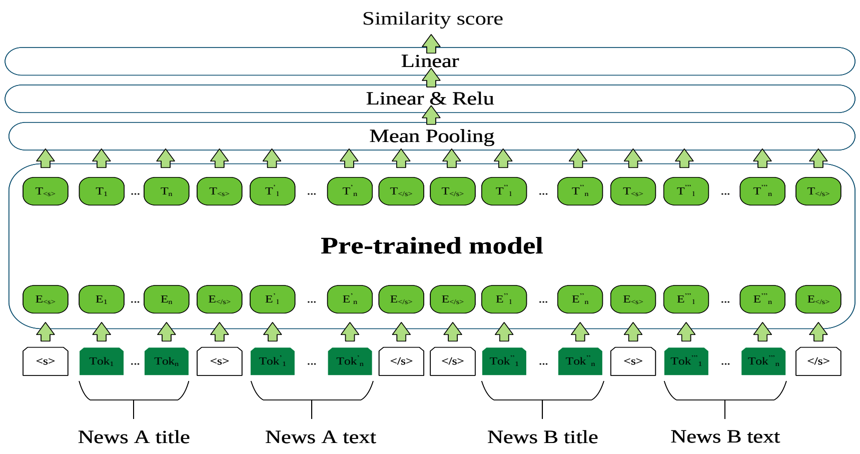

Figure 1: The architecture of the system.

(Joulin et al., 2016) are two examples. In particular, the XLM-RoBERTa (Conneau et al., 2019) model is a newly released large-scale cross-lingual language model based on RoBERTa and trained on 2.5TB filtered CommonCrawl data in 100 languages. Unlike other XLM models (Lample and Conneau, 2019), XLM-RoBERTa does not require language tokens to understand which language is used and can recognize the correct language from the input id.

INFOXLM (Chi et al., 2020) is a cross-lingual pre-trained model based on the XLM-RoBERTa structure, using monolingual and parallel corpora to train the model. Specifically, in addition to the masked language modeling(MLM) and the translating language modeling tasks(TLM), INFOXLM is jointly pre-trained with a newly introduced cross-lingual contrastive learning task. Through comparison, the cross-lingual uses bilingual pairs as the two views of the same meaning, making their encoded representations more similar than the negative examples. It uses the [CLS] tokens from the BERT encoder as sentence representations with linear projection heads. The momentum encoder is used to encode the query, while the online encoder is updated with InfoNCE (Van den Oord et al., 2018) loss.

2.3 Sentence similarity

There are usually two methods for comparing the similarity between two sentences. Cross-encoders perform full-attention over the input pair, and Bi-encoders map each input independently to a dense vector space.(Thakur et al., 2020)

3 System Description

3.1 Data processing

We use crawlers and the newspaper3 [1] library to download and parse news web pages to obtain various information about news, including title, text, pictures, keywords and abstracts. For the news data in the training and test set, some missing titles and body texts. At the same time, some web pages have errors during the crawling process, or the crawler crawls wrong news information. We revisit the news link and the alternate link to modify the news data. In addition, there are still problems such as advertising webpages and link failures, which are omitted in the training process.

3.2 Model

We designed cross-encoder model to solve the task. The structure of the cross-encoder model shows as Fig 1. It contains the pre-trained language model, pooling layer, and downstream layers, consisting of two fully connected layers and a relu activation function, to learn the Overall value of each news pair.

The inputs of cross-encoder model are composed of contents of two news which are named news A and news B. For each news, we use title, text and keywords. We use the symbol <s> to separate different parts of the news, the symbol </s> as the separator for two news articles, and add <s> and </s> at the beginning of each news pair. The input form finally can be illustrated as: <s> news A </s></s> news B </s>.

[1] https://github.com/codelucas/newspaper

For the pooling methods, we compared two methods of learning the representation of the whole news pair: 1. use the output of the model Pooler, which is similar to the token's representation of the [CLS] of BERT; 2.mean pooling: use the average vector of the whole hidden state. Experiments have shown that the latter works better.

The model eventually outputs a value between 1 and 4, which calculate MSE loss (Mean Squared Error Loss) with the standard Overall label of the data.

3.3 Methods

- **Ten-Fold Voting** Ten-Fold Voting method shuffles and divides the training set into ten parts equally, and separately chooses one of them as a validation set, while the remaining nine part are used as the training set. As a result, we end up with 10 models. These ten models use averaging method to vote, which increases model generalization. For example, we use 10 models to obtain 10 Overall predictions for a given news pair, and the average of these 10 results is taken as the final prediction for that news pair.

- **Data Augmentation** Due to the addition of three new languages (zh, ru, it) in the test set, we added translation corpus to the training data so that the model can better deal with the new languages. Specifically, we use Baidu translation API [1] to obtain the translated text, and the news in each language is translated into the other 9 languages. Different epochs are trained alternately with the original and translated data. Each news is translated into one of the nine other languages with the same probability at the epoch using translated data.

- **Frozen Layers** Generally, lower layers of a language model encode more local syntax while higher layers capture more complex semantics (Tenney et al., 2019). Therefore, during training, we freeze the parameters of the embedding layer and some lower layers of the pre-trained model. The parameters of frozen layers cannot participate in back propagation thus keeping the original parameters. Therefore, we aim to choose the most memory-efficient hyperparameters.

- **Multi-task Learning** We noticed that the training data not only has the Overall label but also has other labels. Considering that Narrative and Entity are consistent with the target task, we let the model fit the Overall label and the Narrative label and Entity label. Specifically, after the pre-trained model, we separately use a dense layer to obtain different predicted values for Entity, Narrative, and Overall and calculate the MSE loss of the three labels: $loss_{entity}$, $loss_{narrative}$ and $loss_{Overall}$. Then the multi-task loss of the model, $loss_{multi-task}$, take the weighted sum of the three.

- **Auxiliary Loss** We add a loss function to help the model distinguish those news pairs. In addition to calculating the similarity of each news pair, we also calculate the MSE loss between the predicted Overall labels of the two news pairs and their true Overall labels, which is as following.

$$loss_{AL} = mse(\hat{y_1} - \hat{y_2}, y_1 - y_2) \qquad (1)$$

  where y_1 is the standard Overall value of news pair 1 and $\hat{y_1}$ is the predicted Overall value of news pair 1, so as y_2 and $\hat{y_2}$. Two news pairs are randomly selected. In practice, we randomly draw several news pairs from a batch and combine them. The training data was shuffled before the start of each training epoch so that the data within the batch are not precisely the same in different epochs.

4 Experiment

All experiments were run on two GPUs: NVIDIA GeForce RTX 3080 Ti and NVIDIA GeForce RTX 3090. For optimizer selection, we use Adamw optimizer with weight decay taken as 0.01 and set 1e-5 as learning rate for the pre-trained layer and 1e-4 for downstream layers with the batchsize 8.If not specified, we use **INFOXLM-large** as the pre-trained model from Hugging Face[2].The weight of the $loss_{entity}$, $loss_{narrative}$ and $loss_{Overall}$ in the $loss_{multitask}$ are set to 0.3, 0.7 and 1.0 respectively.The weight of the $loss_{AL}$ is set to 0.1.

4.1 Information Selection

This section presents experiments to explore which news information should be used. From Table 1

[1] http://api.fanyi.baidu.com/

[2] https://huggingface.co/models

,it can be seen that the result of using only title and only text is not as good as using title and text at the same time. The model shows better performance when facing more text types, which may be because different texts contain different information. The title focuses on summarizing the news and represents the article's central idea; The text focuses on describing the event and conveying more detailed information. The performance of using title, keywords and text is not improved. Most of the keywords information is likely contained in the first two.

Model	$\mathcal{D}_{val}$	$\mathcal{D}_{test}$
Title60	0.798	0.684
Text100	0.813	0.702
Title60+Text100	0.852	0.759
Title60+Text100+Keywords50	0.855	0.760
Title60+Text150	0.859	**0.772**
Title60+Text200	**0.859**	0.769

Table 1: The impact of using different information and different content lengths on the model. Pearson coefficients in the table are the maximum values for the validation set, notated $\mathcal{D}_{val}$ in 15 epochs, while $\mathcal{D}_{test}$ is the corresponding pearson coefficients in test set at this time.The number after the title and text in the table indicates how many text words are used. For example, Title60 indicates using the first 60 words of the title; The ratio of validation set to training set is 1:9.

The text length of each news article is related to the final prediction of the system. The table shows the Overall scores of different text lengths. Due to the input length limitations, our max length of the title is 60, while the max length of the text is between 100 and 200. The model works better with longer text lengths in the validation set, probably because longer texts contain richer information, while it achieves the best result in the test set when text length is 150. The reason may be that the behavior of the test set is inconsistent with the validation set.

4.2 Frozen layers

We tested the performance of unfrozen, frozen embedding layers and partial transformer layers respectively. The results are shown in Table 2. As we can see, when freezing embedding layers and the layers from 0 to 11, the result is similar to not freezing all layers, but it saves memory and reduces training time. So we take these kinds of parameters in the following experiments.

Frozen layers	$\mathcal{D}_{test}$
no freezing	0.760
freeze embedding + layers 0$\sim$5	0.759
freeze embedding + layers 0$\sim$11	0.759
freeze embedding + layers 0$\sim$14	0.750

Table 2: Results of freezing different pre-trained model layers on the test set.

4.3 Strategies

We also conducted additional experiments, including data augmentation through translation, a multi-task learning approach, and Auxiliary Loss mentioned before. These methods are effective in the validation set, but some did not improve much in the final test set.

Table 3 shows the comparison of different methods used in the model. The parameters used by the base model are INFOXLM$_{\text{large}}$, Title60 and Text100. The split ratio between the training set and the validation set is 9:1. According to the table, we have the following conclusions:

In the validation set, when the model cumulatively uses Multi-task Learning, Auxiliary Loss and Data Augmentation, the performance is continuously improved. When the three methods are used together, the model performance is best to reach 0.8627 in the validation set. Multi-task Learning and Auxiliary Loss increase the learning and representation ability of the model by modifying the task and loss. Data Augmentation improves the generalization of the model by introducing the translation corpus.

In the test set, when the model uses Multi-task Learning and Auxiliary Loss, the performance is not much different from that of the base model. This may be that Multi-task Learning and Auxiliary Loss can improve the representation ability of the model in the validation set, but they are lack of generalization and generally perform in the face of a large amount of data and new data. However, when the model uses Data Augmentation, the performance reaches 0.7667 in the test set, which is greatly improved compared with the base model and the model using Multi-task Learning and Auxiliary Loss. This may be because the translation corpus introduces languages (Chinese, Russian and Italian) that the model has not encountered before. The newly introduced language enhances the model's generalization ability in the test set and enables the model to understand the news in the test set better.

Model	$\mathcal{D}_{val}$	$\mathcal{D}_{test}$
Base	0.852	0.759
Base + MT	0.854	0.758
Base + MT + AL	0.859	0.759
Base + MT + AL + DA	**0.862**	0.766
Base + MT + AL + DA + TFV	/	**0.781**

Table 3: Results of system under different methods. Base: $\text{INFOXLM}_{\text{large}}$ +Title60+Text100; MT:Multi-task Learning; AL:Auxiliary Loss; DA:Data Augmentation; TFV:Ten-fold voting

Finally, we can see that when the model uses Ten-Fold voting, the performance is improved from 0.7667 to 0.7810. There may be two reasons for this. On the one hand, the Ten-Fold voting essentially uses all the training data, and the expansion of the amount of data may increase the performance of the model. On the other hand, the Ten-Fold voting integrates the model results under ten different training data sets, which greatly improves the robustness of the results and strengthens its generalization ability.

4.4 Ensemble

The ensemble technique is a widely used strategy. Ensemble methods work by aggregating the predictions of multiple single models. The strategy we use in the competition is simple averaging. The final prediction value is obtained by averaging the prediction results of different models, which will improve the robustness of the prediction results. The results are shown in Table 4.

Model	$\mathcal{D}_{test}$
INFOXLM	0.776
INFOXLM + DA	0.781
XLM-RoBERTa + DA	0.779
Ensemble	**0.784**

Table 4: Results of base models and ensemble model.

All three base models use Title60, Text100, Multi-Task Learning and Auxiliary Loss. The latter two models additionally use the Data Augmentation strategy. The result of the ensemble model achieves the best performance in our competition.

5 Conclusion

In this paper, we summarize our work in Multilingual News Article Similarity. We utilize INFOXLM and XLM-RoBERTa pre-trained models to handle multilingual news. In addition, many methods are used such as Data Augmentation and Ten-Fold Voting. Our final submitted model is an ensemble of three base models, and we achieve Pearson value of 0.784 on the test dataset.

Acknowledgements

Thank the organizer for holding a great competition and providing the large multilingual news article similarity dataset. This research was supported in part by the National Natural Science Foundation of China under contract 62176074.

Abstract

This paper introduces our submission for the SemEval 2022 Task 8: Multilingual News Article Similarity. The task of the competition consisted of the development of a model, capable of determining the similarity between pairs of multilingual news articles. To address this challenge, we evaluated the *Word Mover's Distance* in conjunction with word embeddings from *ConceptNet Numberbatch* and term frequencies of *WorldLex*, as well the *Sentence Mover's Distance* based on sentence embeddings generated by pretrained transformer models of *Sentence-BERT*. To facilitate the comparison of multilingual articles with *Sentence-BERT* models, we deployed a Neural Machine Translation system. All our models achieve stable results in multilingual similarity estimation without learning parameters.

1 Introduction

The assessment of similarity between documents is a central challenge in the context of information retrieval. Especially the evaluation of similarities between news articles across different languages opens up opportunities for numerous downstream tasks, such as the analysis of regional differences in news coverage of topics or sentiments towards events and news.

Task 8 of the *SemEval* challenge 2022 (Chen et al., 2022) posed the problem of the assessment of similarity of news articles across a variety of languages and provided a dataset of news article pairs in seven languages, as well as a number of bilingual pairs. Apart from an overall similarity score to be estimated in the challenge, a number of scores for similarity in different categories, such as *narrative* or *entities* were provided.

For our submission for this task, we evaluated the performance of the *Word Mover's Distance* (WMD) and *Sentence Mover's Distance* (SMD) in the context of similarity assessment of multilingual news articles. We participated in all given languages, comparing both document pairs in the same language, as well as pairs in different languages. Our code is available at `https://github.com/StefanJMU/SemEval2022_Task_8`.

We considered WMD and SMD due to their conceptual simplicity and capability to integrate well with resources such as pretrained word embeddings or sentence embeddings, produced by state-of-the-art language models. Additionally, they offer the appeal of being themselves parameter-free, and hence independent of labelled training data.

The rest of the paper is organized as follows: We introduce the approaches deployed in the challenge submission, as well as the used resources, supplementing the *WMD* and *SMD*. Subsequently, we present the results achieved and conclude with a discussion of the results.

2 System Overview

Figure 1 shows a schematic overview of the methods we investigated for our submission. We evaluated two different methods for this task, namely the *Word Mover's Distance* (WMD) (Kusner et al., 2015) and the *Sentence Mover's distance* (SMD) (Clark et al., 2019). Both approaches take two news articles and calculate a similarity score from the representation of both texts as either *Bag of Words* or *Bag of Sentences*, respectively. Both approaches have been found to constitute a metric exhibiting a pronounced correlation with the human-assessed similarity scores of the text pairs (Kusner et al., 2015). We create the required word and sentence representations using *word embeddings* and *sentence embeddings* generated from state-of-the-art language models.

For the *WMD* approach, we deployed a preprocessing pipeline, involving the tokenization of both news articles, as well as the removal of stopwords and punctuations. Subsequently, the preprocessed texts were transformed into a *Bag of Words* using

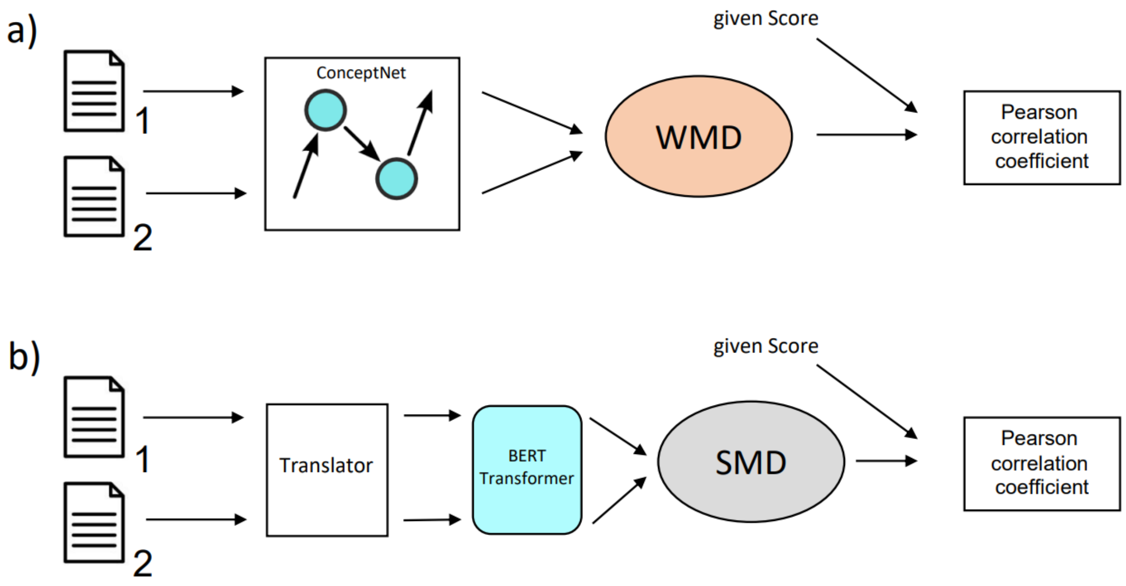

Figure 1: Schematic overview of our experiments in order to determine the best model for submission. Given two news articles, we **a)** use pretrained multilingual ConceptNet Numberbatch word embeddings for both articles and compute the *Word Mover's Distance* (Kusner et al., 2015) between both non-translated texts; also **b)**, we obtain sentence embeddings from a Sentence-BERT model (Reimers and Gurevych, 2019) by first translating both articles to English and then computing the *Sentence Mover's Distance* (Clark et al., 2019) on the translated documents.

the vector representations provided by *ConceptNet Numberbatch*. These vector representations, together with the dot-product similarity, constituted the metric at the core of the linear optimization problem forming the *Word Mover's Distance* between two texts. The *WMD* also allows for a different weighting of the words of texts in the evaluation of similarity. These weights were chosen according to the respective *TF-IDF*, calculated with the help of *WorldLex* (Gimenes and New, 2015).

The *SMD* approach required the decomposition of texts into sentences, which were subsequently encoded with a transformer language model, resulting in a *Bag of Sentences* representation of texts. By interpreting these sentence embeddings as words, a similarity score is readily computable using the *WMD* again.

The following subsections introduce both metrics in more detail, as well as the word embeddings and models involved, which were deployed to extend the application of the metrics to similarity assessment of texts across of different languages.

2.1 ConceptNet Numberbatch

For the calculation of *WMD* for multilingual articles, we deployed ConceptNet Numberbatch word embeddings (Speer and Lowry-Duda, 2017). ConceptNet Numberbatch are embeddings based on the knowledge graph ConceptNet (Speer et al., 2017). Due to its multilinguality (and support of all languages used in the challenge), we selected these embeddings to facilitate the calculation of the *WMD*.

2.2 WorldLex

Evaluating semantic similarity by matching words across texts can be obstructed by the presence of stop words or words, which can occur in many semantic contexts and are therefore no compelling indicators for semantic similarity. Apart from the removal of stopwords, we deployed a weighting of words according to the occurrence frequency in Twitter, blogs and newspapers gathered by Gimenes and New (2015), which are curated in the WorldLex database and were available for all languages used in the SemEval task. To create the WorldLex database, the authors converted all collected documents to lowercase. After that, the frequencies of all of the different words were calculated and lists of words were extracted utilizing spellcheckers to remove words with orthographic and typographic errors, as well as foreign words.

2.3 Word Mover's Distance

In 2015, the *Word Mover's Distance* has been proposed by Kusner et al. (2015) and constitutes a conceptually simple mean of quantifying the distance (and inversely correlated, the similarity) between texts, by optimizing a linear program for a cost minimal mapping between words of two texts with respect to a similarity measure between words. A text with n distinct words is considered as a vector $t \in \mathbb{R}^n$, with $||t||_1 = 1$ and t_i indicating the weight (from the WorldLex Database described in Section 2.2) of the ith distinct word of the text. The rationale of the *WMD* is, that for each word in a text, the weight has to be accounted for by words in the other text, while no word can account for more than its own weight. Considering two vector representations t^1 and t^2 of texts T_1 and T_2 of length n_1 and n_2 respectively, the distance between both texts Ω can be mathematically formulated as

$$\Omega = \min_M \sum_{i,j} M_{ij} c(i,j) \tag{1}$$

$$s.t. \sum_{j=1}^{n_2} M_{ij} = t_i^1 \, , 1 \leq i \leq n_1 \tag{2}$$

$$\sum_{j=1}^{n_1} M_{ji} = t_i^2 \, , 1 \leq i \leq n_2 \, , \tag{3}$$

where $c(i,j)$ is the distance between the ith distinct word of T_1 and the jth distinct word of T_2, and M is the accounting matrix, where M_{ij} indicates the amount of weight the ith word of T_1 provides for the accounting of the weight of the jth word of T_2. The resulting Ω can subsequently be used as measure correlated with smililarty or distance of text pairs.

Many options for choosing the weights of words, such as the document frequency of the word, are possible. We deployed a TF-IDF weighting of the words, where the inverse document frequency was derived from the *WorldLex* database introduced in the previous section. The rationale for introducing also the inverse document frequency, instead of only a term frequency weighting as suggested by Kusner et al. (2015), was to have a stronger emphasis of words, which are potentially more semantically meaningful and are therefore more suited for comparing themes and content of two texts.

For the quantification of distances between words, Kusner et al. (2015) propose distance measures such as cosine similarity on dense word embeddings, and use themselves word embeddings generated by *Word2Vec* (Mikolov et al., 2013). To facilitate the comparison of multilingual text pairs, we used multilingual *ConceptNet Numberbatch* embeddings (Speer and Lowry-Duda, 2017).

2.4 Sentence Mover's Distance

For our second line of experiments, we used the *Sentence Mover's Distance*, which was introduced by Clark et al. (2019), who adapted the concept of the *Word Mover's Distance* to calculate the distance of texts based on sentences instead of words, in order to address the typical shortcomings of approaches considering only Bag of Words without the incorporation of any compositional information contained in the word order. For the required representations of sentences, Clark et al. (2019) suggest averaging the word embeddings of the words in a sentence and a subsequent weighting of the sentences within the *Bag of Sentences* according to the number of constituent words.

Apart from the operating mode of the *SMD* proposed by Clark et al. (2019), the Sentence Mover's Distance allows also the incorporation of more rich representations of sentences, such as sentence embeddings produced by complex transformer-based models. Trained implementations of such models are readily available, such as the *Sentence-BERT* proposed by Reimers and Gurevych (2019). For the evaluation of the *Sentence Mover's Distance*, we deployed the pretrained *all-MiniLM-L12-v2* provided on `sbert.net`, which embeds an English sentence into a 384-dimensional embedding vector and supports the dot-product as similarity measure.

2.5 Neural Machine Translation

Since the used pretrained transformer can only embed English sentences, we propose to use English as an intermediary language, into which the multilingual news articles were automatically translated using a Neural Machine Translation system.

For the translation of the articles, we used a model submitted to WMT's 2021 News translation task (Chau et al., 2021). This translator has ranked first in the most language directions the team participated in, introducing the first multilingual model with stronger translation performance than bilingual ones. Using the *any-to-English* model and *DeepL*[1] (for the languages not supported by the first translation model), we translated all news articles

and used them to calculate BERT transformer embeddings. These in turn were used for the *SMD* calculation. We also evaluated possible performance differences for the *WMD*, if texts are translated beforehand, instead of relying on the power of the multilingual word embeddings of *ConceptNet Numberbatch*.

3 Experimental Setup

For preprocessing routines, the Python *nltk*-package was utilized (version 3.6.5). The embeddings have been conducted using *ConceptNet Numberbatch* version 19.08. The *TF-IDF* weighting used *WorldLex*. *WorldLex* is no longer under active development.[2] The transformer model was *all-MiniLM-L12-v2* provided on `sbert.net`.

We employed three experiments to find the best model used for submitting to the task's evaluation:

1. Word Mover's Distance with multilingual ConceptNet Numberbatch embeddings

2. Word Mover's Distance with translated news articles before embedding them using ConceptNet Numberbatch embeddings

3. Sentence Mover's Distance using translated news articles embedded with an English Sentence-BERT model

For the evaluation, the Pearson Correlation Coefficient (Pearson, 1895) was used. The target similarity scores range from one (very similar) to four (not similar), so these scores really correspond numerically to distances. We can thus use the computed distances directly as predictions. Since the calculation of the Pearson Correlation Coefficient normalizes all predicted and actual similarity scores using the mean and standard deviation, we do not need to scale the predicted scores to the range of the labels.

Due to the fact that our employed methods do not need any training labels, we can directly evaluate the results on the training data provided by the task organizers. The model found to perform best was then used for the task submission. The number of articles used for each language is listed in Table 1.

[2]The deployed data can be retrieved from `http://www.lexique.org/?page_id=250`.

4 Results

Table 2 shows the Pearson Correlation Coefficient of the articles for the provided training data consisting of eight language pairs. Comparing the results of *WMD* applied to original and translated documents shows, that the estimation of text similarity with the proposed model benefits from a translation in a common language, instead of solely relying on a multilingual word embedding (all documents were translated into English). It can also be seen from the table, that for all language pairs except for *ar-ar* and *de-de*, *SMD* shows the best performance. As in the analysis of Kusner et al. (2015), we also find, that using the richer representations of complete sentences, instead of words, is generally beneficial. For the two remaining language pairs, *WMD*, applied on translated articles, achieves higher scores than the other metrics.

Given these results, we used the *Sentence Mover's Distance* with translated input texts and the pretrained language model for sentence embeddings as the model for our task submission. We achieved the 23nd place with an overall Pearson Correlation Coefficient of 0.57. Table 2 also shows the final scores for all 18 language pairs present in the test set. For the most language pairs, the results on the test data are very similar or even slightly better compared to the scores on the training set. We expected this behavior, since the used approach does not use any training labels for optimization and is hence not prone to overfitting. The rigidness of the optimization and straightforwardness of the similarity notion however, allows also for higher performance fluctuations observed for instance in the two language pairs (**en-en** and **de-de**), which perform noticeably worse for the test set than for the training data, while **pl-pl** shows much better performance on the test data.

Also, language pairs including German news articles are typically performing worse than average

	Training Language Pairs								Test
Model	**en-en**	**de-en**	**es-es**	**fr-fr**	**tr-tr**	**ar-ar**	**pl-pl**	**de-de**	**ru-ru**

Table 2: Pearson Correlation Score for all language pairs in the provided training and test data of the task evaluation. Since the *SMD* worked best on the training data overall, we used this method for the final submission.

and thus decrease the overall test score in the challenge. While looking for possible reasons for such poor results, we found some articles in training and test data, which could not be extracted correctly. For instance, some German articles from the test data are identical and contain only information about the issue of opening the web pages due to privacy regulations[3]. Another reason for bad performance in similarity estimation of pairs containing German article (or comparison of two German articles) could be the incompletely loaded content of some German pages, since some articles only contain the beginning of the actual text[4], which is indicated by the spontaneous termination of the article content with the following sentence "read the full article..."[5].
In order to eliminate such externally imposed assessment impediments, the data scraping system[6] would need to be overhauled.

5 Discussion and Conclusion

For our submission, we evaluated multiple approaches, that operate on the word or sentence level and calculate a distance between two texts using a linear program optimized on pretrained word or sentence embeddings. To be able to apply English-only models for the representation of sentences, we used a Neural Machine Translation system that, in our experiments, improved the performance of multilingual word embeddings. The proposed model shows stable performance in similarity estimation between mono- and multilingual document pairs. The usage of state-of-the art pretrained word and sentence embeddings led to a fast system with low computational cost, allowing implementation without use of graphics processing units. The use of an extensively pretrained *Sentence-BERT* transformer for sentence embeddings of documents, that were translated into English, confirmed, that the proposed model is well suited for the similarity comparison of multilingual articles without optimizing any parameters in the model.

dinabpr@gmail.com, a.zubiaga@qmul.ac.uk

Abstract

This paper describes the participation of the team “dina” in the Multilingual News Similarity task at SemEval 2022. To build our system for the task, we experimented with several multilingual language models which were originally pre-trained for semantic similarity but were not further fine-tuned. We use these models in combination with state-of-the-art packages for machine translation and named entity recognition with the expectation of providing valuable input to the model. Our work assesses the applicability of such “pure” models to solve the multilingual semantic similarity task in the case of news articles. Our best model achieved a score of 0.511, but shows that there is room for improvement.

1 Introduction

The Multilingual News Article Similarity Task[1] (SemEval 2022 Task 8) is designed as a shared task to encourage participants to build systems that check if a monolingual or cross-lingual pair of news articles belong to the same story (Chen et al., 2022). The task consists in providing a similarity score from 1 to 4 for a pair of news articles.

In this paper, we describe the participation of the “dina” team in the shared task. In our participation, we took an exploratory approach focusing on language features, while trying several multilingual language models as baselines. These language models had been pre-trained for semantic similarity and are “pure” (without any fine-tuning conducted for the task), which we enhance to use jointly with state-of-the-art packages for machine translation and named entity recognition.

Our best-performing submission to the task is based on a “pure” paraphrase-xlm-r-multilingual-v1 model combined with the presence of overlapping named entities and overlapping dates, which achieved a Pearson’s correlation score of 0.511 in the final evaluation.

2 Related Work

Multiple prior SemEval semantic similarity tasks (2012-2017) focused on estimating the degree of semantic equivalence between two text fragments. In 2014 and 2015, two subtasks were proposed for semantic textual similarity in English and Spanish (Agirre et al., 2015). It was found that aligning words between sentences worked best for English, using features such as WordNet, word embeddings, or paraphrase databases. In 2016, a new cross-lingual subtask was added for English and Spanish. In 2017, participants were instructed to predict the degree of semantic similarity (namely, a continuous valued similarity score on a scale from 0 to 5) between monolingual and cross-lingual sentences in Arabic, English and Spanish (Cer et al., 2017). State-of-the-art deep learning models and feature engineered systems were implemented (Tian et al., 2017), and machine translation was widely used for cross-lingual and non-English setups, in order to convert two sentences into the same language. Based on the corpus of English tasks data (2012-2017), the STS benchmark was presented for training and evaluation[2]. Its extended version is often used to evaluate the performance of multilingual pre-trained models[3].

Currently, state-of-the-art methods are based on pre-train transformer language models, which are fine-tuned for downstream tasks. Multilingual pre-trained language models for 50+ languages are freely available[4], such as distiluse-base-multilingual-cased models,

[2]http://ixa2.si.ehu.eus/stswiki/index.php/STSbenchmark

[3]https://www.sbert.net/examples/training/multilingual/README.html

[4]https://www.sbert.net/docs/pretrained_models.html#multi-lingual-models

paraphrase-multilingual-MiniLM-L12-v2, paraphrase-multilingual-mpnet-base-v2, LaBSE (Feng et al., 2020), and other various models, such as paraphrase-xlm-r-multilingual-v1[5] (Reimers and Gurevych, 2019). All these models are applicable to the sentence similarity task.

Event clustering can be considered as a task that is close to the task of semantic similarity between news articles. Miranda et al. (2018) used similarity metrics and ranking for clustering documents into monolingual and cross-lingual story clusters. Linger and Hajaiej (2020) used multilingual DistilBERT and Sentence-BERT for multilingual document representation. In general, BERT-like models with different averaging and pooling are widely used for document representation in the clustering task too.

In the system proposed in our paper, we build on this line of research of leveraging large multilingual language models, which we further experiment with by incorporating machine translation and named entity recognition components.

3 Task and Data

The aim of the task was to check, at the document level, if a pair of news articles, which can be written in the same or different languages, provide similar information. The training set provided by the organisers includes 4,964 monolingual and cross-lingual pairs of news articles: 1800 English-English pairs, 857 German-German pairs, 577 German-English pairs, 570 Spanish-Spanish pairs, 465 Turkish-Turkish pairs, 349 Polish-Polish pairs, 274 Arabic-Arabic pairs, and 72 French-French pairs. For test data, the organisers added three new languages: Italian, Russian, Chinese.

For each entry in the dataset, different similarity scores are given for "Geography", "Entities", "Time", "Narrative", "Style" and "Tone", in addition to the main "Overall" similarity score. These scores are based on a 4-point scale, from most (1) to least (4) similar. The aim of the task is to predict the "Overall" score, but the participants can make use of the other auxiliary scores. For the final evaluation, the organisers proposed to use Pearson's correlation between the predicted similarity score and the gold "Overall" similarity score. Correlation scores for different article pairs are then averaged to compute the final score.

A script[6] provided by the task organisers enabled downloading news article pairs pertaining to train and test subsets. This script retrieves the URLs of news articles, using the Internet Archive[7] to support this retrieval.

4 Data Preprocessing

Upon downloading the news articles with the script provided by the organisers, we noticed that some texts were not correctly parsed: they contained only non-relevant texts (e.g. error messages), without the main content. Therefore, we removed such problematic text pairs from the training set, based on the manually collected list of strings and heuristic rules for them, mostly for English (e.g. texts that started with "Get full access to" or "TAKE A FREE TRIAL"); pairs with short texts (< 400 characters) that contained mostly metadata were also removed from the training set. Finally, our training set consists of 4,228 text pairs. From texts both in the training and test sets, we also applied heuristic rules based on the manually collected list of strings (mostly for English) to remove non-relevant text fragments (e.g. "Your browser does not support the audio element" or "Share this item on Twitter") from texts.

All texts (in the training and test sets) were split into sentences using the stanza[8] python package, which supports all the languages under consideration. We relied on the assumption that news texts usually contain the most important information at the beginning, while the remainder of the story contains other less important details, according to the 'inverted pyramid' principle (Pöttker, 2003). According to this principle, the first paragraph or sentences of a news article are generally expected to cover the main information addressing the who, what, when, where, and why of a story. Therefore, aiming to improve both the efficiency and effectiveness of our system, we only take the first 10 sentences of all non-English texts and we translate them into English using m2m100 models (Fan et al., 2021): 1.2B model[9] for the training set and 418M[10] model for the test set (the latter model was

chosen, as it is faster). Given that similar events are expected to mention the same or related named entities, we used the spacy[11] python package on English texts (original and translated) for named entity recognition.

All the preprocessing, fine-tuning and evaluation tasks were performed using Google Colab and two NVIDIA GeForce GTX 1080 Ti Graphics Cards (22 GB RAM).

5 Description of Models and Experimental Setup

In order to detect similarity at the document level, we focused on sentence-transformer models. All similarity scores were calculated based on cosine similarity. During the development stage, we conducted all our experiments on the training set, with a held-out subset reserved for evaluation.

We tested different transformer models, including LaBSE (Feng et al., 2020) and paraphrase-xlm-r-multilingual-v1[12]. Based on the assumption that the main information about a story is expected to appear in the beginning of news articles, different setups for both models were taken: mean semantic similarity (cosine similarity) for all pairwise sentence-to-sentence similarities for the first 4 sentences in both articles (`4 sent`) and the first 5 sentences in both articles (`5 sent`); and the semantic similarity between the merged set of first 3 sentences from each article (`3 sent merged`). To come up with the best approach to submit to the shared task, we conducted three sets of experiments.

Experiment set 1. Table 1 provides performance scores for the different "pure" pre-trained language models, measured based on Pearson's correlation values between predicted and gold similarity scores. Among the sentence selection approaches, the best-performing setup is the one based on the merged combination of the first 3 sentences (`3 sent merged`). Among the pre-trained language models, the paraphrase-xlm-r-multilingual-v1 model performs better than the other one. This finding confirms the notion that LaBSE works less well in detecting similarity of sentence pairs that are not translations of each other other[13] (Reimers and Gurevych, 2020). Multilingual distiluse-base-multilingual-cased-v1[14] model, one of the models recommended[15] for semantic similarity tasks, was also included in experiments, namely, for the best setup (first 3 sentences merged), but performed worse than paraphrase-xlm-r-multilingual-v1 model.

Experiment set 2. In addition, we also conducted some baseline fine-tuning experiments. We took XLSum dataset as the biggest dataset with available news texts that contains most of the languages present in our train and test sets (Arabic, Chinese, English, Spanish, Russian, and Turkish are included; it does not include German, Italian, and Polish). XLSum consists of 1.35 million article-summary pairs from the BBC in 44 languages (Hasan et al., 2021). We selected a smaller sample of 98,697 news texts with as balanced representation of 6 languages as possible (15,000 or fewer random examples for each language). Unsupervised domain-specific fine-tuning of the paraphrase-xlm-r-multilingual-v1 model on the news dataset (1 epoch with MultipleNegativesRankingLoss) did not improve the results: Pearson's correlation score was 0.63 for all text pairs from the preprocessed

training set, and 0.71 for only English-English pairs. Masked Language Model approach (1 epoch, batch size 16) also yielded worse scores (0.41 and 0.51 respectively).

Experiment set 3. We also conducted more model fine-tuning experiments. For internal evaluation, 10% of the training set was selected as an internal test set (with a balanced representation of English, Spanish, German, and Polish languages), and training was made on the remaining 90% (internal train set). The models distiluse-base-multilingual-cased-v1 and paraphrase-xlm-r-multilingual-v1 were fine-tuned on the internal train set (with MultipleNegativesRankingLoss, 3, 5, 8 epochs with 5 epochs as the best option, the latter one better). The model distiluse-base-multilingual-cased-v1 was also fine-tuned on the aforementioned XlSum dataset part (3 epochs with MultipleNegativesRankingLoss). On the internal test set, the models ensemble of distiluse-base-multilingual-cased-v1 fine-tuned on train set and distiluse-base-multilingual-cased-v1 fine-tuned on news dataset, with addition of named entities intersection ratio, achieved the best score, but still lower than the baseline "pure" models.

Other models considered. Apart from the three main sets of experiments above, we also considered other options. Our experiments with baseline experiments with generative pre-trained models did not lead to competitive results. Experimental results with GPT-Neo 2.7B[16] on English texts yielded only 0.13 correlation score between the perplexity scores for the first sentences and the gold scores. Basic fine-tuning for the mt5-base model[17] (setups up to 5 epochs, the task was handled as a multi-class classification task with 7 labels) did not give relevant results (all texts were misclassified for the highest scores).

Other features considered. Another possibility we considered was to include the dates mentioned in the news articles into our model. This was based on the assumption that news articles that are related to each other are supposed to be published in similar dates. However, our attempts at parsing dates from the articles (using the dateparser and num2words python packages) led to noisy outcomes, so we ended up using a rule-based approach to extract months and days from texts in English (original or translated). We check if both texts contain the same months and days (handled as intersections with two different sets).

[17]https://huggingface.co/google/mt5-base

6 Results

6.1 Analysis of Results

On the test set, among our submitted results, the setup leading to the best performance score was a "pure" paraphrase-xlm-r-multilingual-v1 model combined with named entities intersections and dates intersections (0.511 Pearson's correlation). This setup performed better than a "pure" paraphrase-xlm-r-multilingual-v1 model (0.502 Pearson's correlation) or a "pure" paraphrase-xlm-r-multilingual-v1 model combined with named entities intersections (0.508 Pearson's correlation), so the features helped improve the model's scores. Named entity and date intersection scores were added to the model's scores using rule-based coefficients selected manually.

The best model also performed slightly better than the ensemble of a "pure" paraphrase-xlm-r-multilingual-v1 model and a distiluse-base-multilingual-cased-v1 model fine-tuned on news (0.502 Pearson's correlation). It shows that more domain-specified models and more complicated fine-tuning techniques should be used for the task. Among the setups we considered, we observe that "pure" models can be deemed stronger baselines.

6.2 Error Analysis

We performed an error analysis to understand why our proposed models yielded moderate performance scores. We identified two main reasons that can inform future directions of our research in improving these models:

1. Text parsing errors in the test set: some texts include, or sometimes solely consist of, meta-information that was not excluded by rules. Our rules did not cover all cases for all languages, as they required language knowledge, and should ideally be further pre-processed to reduce the noise and improve model performance. Examples of these cases include:

- German: *"OK Wir setzen auf unserer Website Cookies und andere Technologien ein, um Ihnen den vollen Funktionsumfang unseres Angebotes anzubieten"*

- German: *"Um die Funktion unserer Website zu verbessern und die relevantesten Nachrichten und zielgrichtete Werbung anzuzeigen, sammeln wir technische anonymisierte Informationen über Sie, unter anderem mit Instrumenten unserer Partner. Ausführliche Informationen zur Datenverarbeitung finden Sie in den Datenschutzrichtlinien. Ausführliche Informationen zu den von uns genutzten Technologien finden Sie in den Regeln der Cookies-Nutzung und des automatischen Einloggens. Indem Sie „Akzeptieren und schließen" anklicken, stimmen Sie ausdrücklich der Verarbeitung Ihrer persönlichen Daten zu, damit das beschriebene Ziel erreicht wird. Ihre Zustimmung können Sie auf die Weise widerrufen, wie in den Datenschutzrichtlinien beschrieben."*

- Italian: *"Informativa Privacy Questo sito utilizza cookies per migliorare servizi ed esperienza dei lettori. Le informazioni raccolte dai cookies sono conservate nel tuo browser e hanno la funzione di riconoscere l'utente quando ritorna sul nostro sito web e aiutare il nostro team a capire quali sono le sezioni del sito ritenute più interessanti ed utili."*

2. Translation errors. It produced model "hallucinations" and repetitions, such as "Chief Executive Officer of the Ministry of Foreign Affairs and Foreign Affairs of the Ministry of Foreign Affairs" or "WASHINGTON-SANA WASHINGTON-SANA WASHINGTON-SANA" instead of the correct English translations. We noticed this to be the case particularly for articles originally written in Chinese and Arabic (translations of more than 30% of test samples in these languages contained such translation errors). Therefore, other translation approaches, i.e. using Google Translate API, might be used to obtain better English translations to detect named entities intersections.

Table 2 provides the best model setup scores, broken down by language. For this analysis, we selected only monolingual language pairs. The best results are for Spanish, French and English, while Arabic, German and Chinese yield the lowest scores. It can be caused by parsing errors, as well as by translation errors. Separate monolingual language models for these languages can be applied in further research, as well as models with better transfer learning techniques for these languages. In the future, further experiments could be conducted for the multilingual XLSum dataset, using different sampling techniques and sample size.

Language	Score	No. of pairs
`French`	0.692	111
`Spanish`	0.678	243
`English`	0.625	236
`Turkish`	0.610	275
`Italian`	0.573	411
`Russian`	0.530	287
`Polish`	0.512	224
`Chinese`	0.426	769
`German`	0.250	608
`Arabic`	0.154	298

Table 2: Pearson's correlation scores for paraphrase-xlm-r-multilingual-v1 model combined with named entities intersections and dates intersections, for different languages from the test set (monolingual text pairs).

7 Conclusion

This paper presents the participation results of our team "dina" in the Multilingual News Similarity shared task held as part of SemEval 2022. We tested a range of state-of-the-art pre-trained multilingual transformer models, which were further tested by incorporating features based on dates, machine translation and named entity recognition. Our best model achieved a Pearson's correlation score of 0.511. It can be considered as a moderate performance score with substantial room for improvement, based on performance scores from other participants in the task, where the best system achieved a score of 0.818. In future experiments on cross-lingual semantic similarity of news texts, we aim to focus on more sophisticated fine-tuning techniques for domain adaptation on a further preprocessed and cleaned dataset.

Abstract

Previous studies focus on measuring the degree of similarity of texts by using traditional machine learning methods, such as Support Vector Regression (SVR). Based on Transformers, this paper describes our contribution to SemEval-2022 Task 8 Multilingual News Article Similarity. The similarity of multilingual news articles requires a regression prediction on the similarity of multilingual articles, rather than a classification for judging text similarity. This paper mainly describes the architecture of the model and how to adjust the parameters in the experiment and strengthen the generalization ability. In this paper, we implement and construct different models through transformer-based models. We applied different transformer-based models, as well as ensemble them together by using ensemble learning. To avoid the overfit, we focus on the adjustment of parameters and the increase of generalization ability in our experiments. In the last submitted contest, we achieve a score of 0.715 and rank the 21st place.

1 Introduction

Providing computer the ability to understand the abstract meaning of real world is a fundamental tasks. Given a pair of news articles, this task seek to evaluate the semantic similarity between them, which focuses on the real world-happenings covered in the news articles. It's a regression problem for measuring similarity of multilingual texts.

Previous studies measured the similarity between texts by using traditional machine learning methods, such as using Support Vector Regression (SVR) (Šarić et al., 2012). Recently many deep learning methods came out, such as pre-trained model. It had attracted the interest of researchers and had shown good result. For example, Exploring Bidirectional Encoder Representations from Transformers (BERT), XLNet and Robustly optimized BERT approach (RoBERTa) and finally got a good ranking (Yang et al., 2020). And a new hybridized approach using Weighted Fine-Tuned BERT Feature extraction with Siamese Bi-LSTM model has been implemented. It is employed for determining question pair sets using Semantic-text-similarity from Quora dataset (Viji and Revathy, 2022). These novel deep learning methods have performed well.

In this study, we explored some transformer-based models. We had employed BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), A Lite BERT for Self-supervised Learning of Language Representations (ALBERT) (Lan et al., 2020), DistilBERT (Sanh et al., 2020; Gou et al., 2021), besides this, we used them as base models, merged them together with ensemble learning, and the prediction result is used as a new training set, and then SVR is used as the meta model. The training set generated by the base model is put into the meta-model. Afterwards, the final result is predicted by the meta-model. The advantage of the pre-trained model is that the upstream corpus has already trained the parameters of the model well. We only need to fine-tune it, and we don't need a huge training set for training (Kong et al., 2022).

The rest of this paper is organized as follows. Section 2 describes all the models which are used for measuring similarity between sentence pairs. Experimental results are summarized in Section 3. Conclusion is drawn in Section 4.

2 Model Description

This section will describe what models we have used, and how they organized. Because of the attention mechanism, pre-trained model had been made a huge success in Nature Language Processing (NLP). We use transformer-based models such as BERT, RoBERTa, ALBERT, DistilBERT to produce hidden representations. Then, a stacking ensemble strategy was used to ensemble the results. The details are presented as follow.

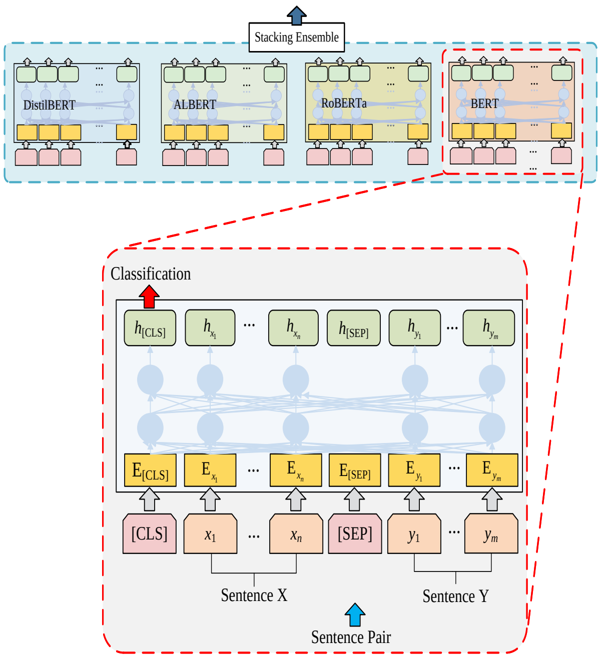

Figure 1: The overall architecture of the proposed method.

2.1 Base Models

Based on the self-attention mechanism, transformer-based model become a popular method in NLP. The models, such as BERT, ALBERT, RoBERTa, DistilBERT are variants on the improvement of the transformer architecture (Huang et al., 2021).

For four Transformer encoders, we applied a similar architecture as sentence pair classification to learn representation for the final regression. Given two sentences and $\mathbf{X} = [x_1, x_2, ..., x_n]$ and $\mathbf{Y} = [y_1, y_2, ..., y_m]$. The model used WordPiece tokenizer to obtain subwords sequences. Two special tokens, i.e., [CLS] and [SEP], were added to the beginning of the whole sequence and between two sentences.The model architecture we use is shown in Fig. 1 The details of each Transformer encoder are presented as follows.

BERT. BERT stands for Bidirectional Encoder Representations from Transformers. BERT is designed to pretrain deep bidirectional representations from unlabeled text by jointly conditioning on both left and right context in all layers. The checkpoint we use is “bert-base-multilingual-cased”, which uses 12-layer, 768-hidden, 12-heads, 110M parameters. Trained on cased text in the top 104 languages with the largest Wikipedias. The outputs tensor contains the batch_size, sequence_length, hidden_state and we use the first token to regress (Zhang et al., 2021). Moreover, BERT uses character-level BPE encoding.

RoBERTa. RoBERTa is a robustly optimized BERT pretraining approach, it’s an improved recipe for training BERT models, that can match or exceed the performance of all of the post-BERT methods. Our modifications are simple, they include: (1) training the model longer, with bigger batches, over more data; (2) removing the next sentence prediction objective; (3) training on longer sequences; and (4) dynamically changing the masking pattern applied to the training data. The checkpoint we use is “roberta-base”, which uses 12-layer, 768-hidden, 12-heads, 125M parameters. RoBERTa using the BERT-base architecture. So the output of RoBERTa is similar to BERT. The token of RoBERTa is called ‘sos’. After that, RoBERTa uses byte-level BPE encoding.

ALBERT. ALBERT is a lite BERT for self-supervised learning of language representations which lead to models that scale much better compared to the original BERT and it uses a self-supervised loss that focuses on modeling inter-sentence coherence, and show it consistently helps downstream tasks with multi-sentence inputs. The checkpoint we use is “albert-base-v2”, which uses 12 repeating layers, 128 embedding, 768-hidden,

MODEL	PEARSON	MSE
DistilBERT+ALBERT+BERT+RoBERTa	**0.880**	**0.298**
DistilBERT+BERT+ALBERT	0.879	0.301
DistilBERT+ALBERT+RoBERTa	0.815	0.450
DistilBERT+BERT+RoBERTa	0.879	0.301
ALBERT+RoBERTa	0.815	0.452
ALBERT+RoBERTa+BERT	0.880	0.298
BERT+ALBERT	0.877	0.306
BERT+RoBERTa	0.878	0.303
BERT+DistilBERT	0.879	0.301
ALBERT+DistilBERT	0.805	0.472
RoBERTa+DistilBERT	0.799	0.483
DistilBERT	0.749	0.587
BERT	0.874	0.310
ALBERT	0.792	0.504
RoBERTa	0.790	0.509

Table 1: The Pearson Score and MSE of Each Model in Test Data.

12-heads, 11M parameters. ALBERT base model with no dropout, additional training data and longer training. And ALBERT is also using the first position of token to regress which is similar to the token of BERT.

DistilBERT. DistilBERT is a distilled version of BERT,which pre-train a smaller general-purpose language representation model and can then be finetuned with good performances on a wide range of tasks like its larger counterparts. The checkpoint we use is "distilbert-base-cased", which use 6-layer, 768-hidden, 12-heads, 65M parameters. The DistilBERT model distilled from the BERT model bert-base-cased checkpoint. And the tokenization of DistilBERT is also similar to BERT.

2.2 Ensemble Learning

In ensemble learning, we train multiple models to solve the same problem and combine them to get better results. The most important assumption is that when weak models are combined correctly, we can get more accurate or robust models. We decide to use stacking as our ensemble learning model. Stacking usually considers heterogeneous weak learners and stacking learning to combine base models with meta-models.

We concatenate the output of the base regressor. Then we put the output into the meta-model which we use SVR as. After that, we use grid sweep to get the optimizer parameters, using SVR to output the prediction results.

We divide the base models into RoBERTa, BERT, DistilBERT and ALBERT, we first train each base model and save the best performing model, and then we combine them separately. We use SVR as our meta-model, take the output of the base model as the input of the meta-model, and then train the input data through the meta-model.The data we use is the test set divided from the training set, and the pearson score and MSE are used to judge the quality of the entire model. For different base models, we will adjust the parameters on the meta-model, so that each set of base models perform as best as possible. The final result is shown in Table 1.

3 Experimental Results

In this section, we will describe how the whole experimental part is done, and the main focus will be on the part that implements the model. The experimental part will be divided in to 5 parts as follows.

3.1 Datasets

In raw dataset, there are many descriptions about the news from different part such as Geography, Entities, Time, Narrative, Overall, Style, Tone. However, as the issue overview said, the annotation task consists of carefully reading each of the two news articles in a pair and selecting the Overall similarity score. As written in the description, systems will be evaluated on their ability to estimate the Overall similarity between two pairs of news stories, not any of the other scores. So we focus on the relationship between the Overall and the sentences, we use sentences separately.

3.2 Evaluation Metrics

In the evaluation dataset, we find that the evaluation dataset is mixed with many languages that does not appear in the training set, such as Chinese, so we try to add some languages that appear in the evaluation dataset in the text back translation. We use Google's translation API, we translate non-Chinese source language into Chinese, and increase the amount of train data through this form The submissions were scored using Pearson's correlation with the 'Overall' column. We use Pearson's correlation as our evaluation metrics. The definition of Pearson's correlation is as follows:

$$\rho_{x,y} = \frac{E(XY) - E(X)E(Y)}{\sqrt{E(X^2) - E^2(X)}\sqrt{E(Y^2) - E^2(Y)}} \quad (1)$$

where the X is the predicted value, and Y is the ground-truth value. Further, mean squared error is calculated as follows:

$$MSE = \frac{1}{N}\sum_{i=1}^{N}\left(y_i - \overset{\wedge}{y_i}\right)^2 \quad (2)$$

where y_i is the predicted value, and $\overset{\wedge}{y_i}$ is the ground-truth value.

3.3 Implementation Details

The train data is split into 3 parts, the base data which is for the part of base regressor, the ensemble data which is for the part of ensemble learning and the test data for the final test, and the test data is used in Table 1. According to the paper (Sun et al., 2020), we truncate the middle part of the text of tokens larger than 512.

In the part of base regressor. At first, we clean the data, fill and delete the missing values in the dataset. The cleaned data is split to train data, validation data and test data. The raw sentences are put into the tokenizer that the tokenizer is corresponding to each model such as BertTokenizer and the tokenizer uses the upstream model to complete the tokenization. After that, we use tf.data.dataset to wrap the tokenizer so that the it can be used by regressor. Then The transformer-based model is used as our regressor such as BertForSequenceClassification, when the parameter num_labels=1, it can be used as a regressor. Adam (Kingma and Ba, 2017) is chosen as our optimizer and MSE is used as the loss function and Pearson as evaluation metrics to train the model. The validation data is used in each epoch to judge the performance of model. After training, we use the trained model to make predictions. The test data is used to detect which model perform better. We choose the best model and save it. In addition, we start to tune the parameters such as learning rate, weight decay and epochs. Because of the limit of the memory, we set batch size to 8 so that the model can run smoothly. We use grid search so that we can find the optimal parameters accurately and quickly.

3.4 Parameters Fine-tuning

WeightsBiases is a visualization tool to supervise the model training process. When tuning the parameters, we use it so that we can record the change curve of the parameters and easy to find optimal parameters (Wang et al., 2022). After tuning the parameters, we use test data to test. Finally, we set learning rate to 1e-5, set weight decay to 1e-6, set epochs to 50. And the C parameter of the SVR is set to 10, and the C parameter is essentially a regularisation parameter, which controls the trade-off between achieving a low error on the training data and minimising the norm of the weights.The kernel parameter is set to "linear". We show the adjustment process of our parameters through two line graphs fig 2 and fig 3.

3.5 Comparative Results

We use the test data which is split from train data. We use this test data to calculate the Pearson score and MSE for each model's predictions, and the result is shown in Table 1.

We submit these models to the organizer. But the method of stacking doesn't achieve a good result. The model of BERT gets the best score in this competition which the score is 0.715. After submitting our final prediction, the best score is obtained by BERT instead of stacking. We submit these models to the final evaluation, but the only scores returned to us are BERT and stacking. The model of BERT got 0.715, the model of stacking only got 0.464. The reason why we set the topic as stacking ensemble learning is because we spend most of our time on it during the entire competition, and we think it does achieve better results on the training set, so we set the topic to stacking ensemble learning. And we reflect that it may be caused by insufficient generalization ability of our base model or meta-model. It may also be caused by insufficient differences in the base model during

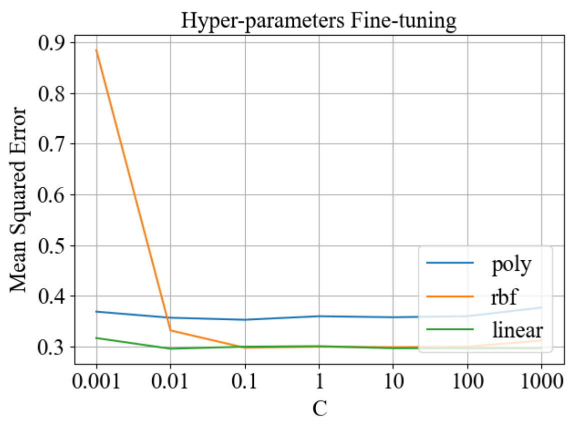

Figure 2: The performance of different parameters on MSE.

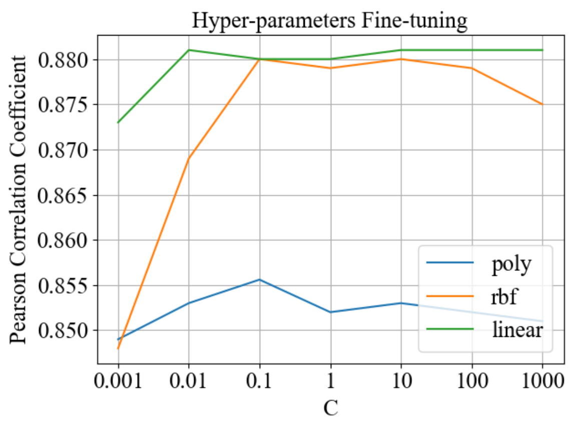

Figure 3: The performance of different parameters on PEARSON.

stacking, or it may be that the selected parameter adjustment method does not make the parameters optimal. This is what we reflect on after getting the feedback.

4 Conclusions

In this paper, we are participating in SemEval-2022 Task 8 (Chen et al., 2022). In this task, we perform regression prediction on the similarity of multilingual news articles, and we use various methods such as BERT, ALBERT, RoBERTa, DistilBERT, and the stacking method built with them as the base model. The model we proposed can effectively predict this task. Among the multiple models we submitted, the BERT model we finally submitted achieved the best score with a score of 0.715, ranking 21st in the leaderboard. At present, in terms of deep learning, the processing methods of multilingual texts have not been widely popularized. So in the future, we hope to go further in the processing of multilingual texts.

Nikkei at SemEval-2022 Task 8: Exploring BERT-based Bi-Encoder Approach for Pairwise Multilingual News Article Similarity

Shotaro Ishihara **Hono Shirai**
Nikkei, Inc. Chiyoda, Tokyo, Japan
{shotaro.ishihara,hono.shirai}@nex.nikkei.com

Abstract

This paper describes our system in SemEval-2022 Task 8, where participants were required to predict the similarity of two multilingual news articles. In the task of pairwise sentence and document scoring, there are two main approaches: Cross-Encoder, which inputs pairs of texts into a single encoder, and Bi-Encoder, which encodes each input independently. The former method often achieves higher performance, but the latter gave us a better result in SemEval-2022 Task 8. This paper presents our exploration of BERT-based Bi-Encoder approach for this task, and there are several findings such as pretrained models, pooling methods, translation, data separation, and the number of tokens. The weighted average ensemble of the four models achieved the competitive result and ranked in the top 12.

1 Introduction

Measuring sentence and document similarity is a task that has been studied for many years in the field of natural language processing. One of the applications is to identify whether news articles address the same subject. If news articles can be properly clustered, they can be used for a wide range of purposes, such as recommendation and displaying related articles. SemEval-2022 Task 8 attempts to tackle this task with multilingual news articles (Chen et al., 2022).

Nowadays, it is common for this kind of tasks to use transformer-based models like BERT (Devlin et al., 2019). There are several research directions, including post-processing (Li et al., 2020; Wang and Kuo, 2020), unsupervised learning (Zhang et al., 2020; Tiyajamorn et al., 2021), and supervised learning (Reimers and Gurevych, 2019; Thakur et al., 2021; Feng et al., 2020; Jiang et al., 2022). Here, since a labeled dataset was provided, we decided to use a supervised learning approach.

It is standard practice to combine two sentences as input when dealing with pairwise similarity of

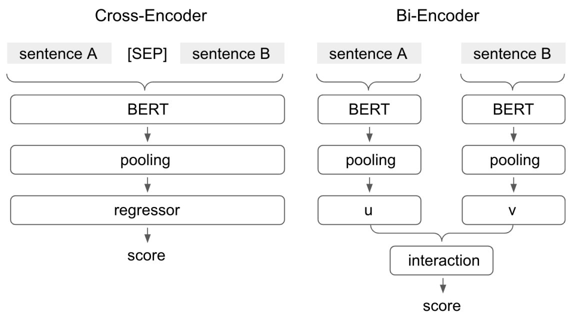

Figure 1: The architectures of Cross-Encoder and Bi-Encoder. The input of the Cross-Encoder architecture is two sentences joined by `SEP`, and through BERT and a pooling layer, the regressor outputs a score. In the Bi-Encoder architecture, each sentence is transformed by BERT and pooling layers, and the score is calculated through interaction of the two vectors.

sentences in a supervised learning approach with BERT (Lin et al., 2021; Reimers and Gurevych, 2019). In contrast, we chose an approach that embeds each sentence separately. Figure 1 shows these two approaches, named Cross-Encoder and Bi-Encoder to follow the previous research (Thakur et al., 2021).

This paper describes our system in SemEval-2022 Task 8. First, we explain the experimental results by adopting the Bi-Encoder architecture rather than Cross-Encoder. We also present the following research questions: 1) which pretrained model works well when dealing with multilingual news articles, 2) what kind of pooling method is proper for this task, 3) is it useful for translating the other language into English, and 4) is there some effect of data splitting and max length? Our code is available at https://github.com/upura/semeval2022-task8-multilingual-news-article-similarity.

2 Task Description

SemEval-2022 Task 8 provides a dataset that contains pairs of news articles. The dataset contains the information like the language and URL of each arti-

Table 1: Language pairs in the training and evaluation dataset. There are eight language pairs in the training dataset, and an additional ten language pairs appear in the evaluation dataset.

cle and the target score named `Overall`. Training dataset consists of 4,964 pairs of articles. Table 1 shows the number of each language pair. It is interesting that a large number of new language pairs appear in the evaluation dataset. It is inferred that building machine learning models using only the language pairs in the training dataset results in poor performance for these unknown language pairs. Therefore, it is essential to address multilingual datasets in some way. Information such as the title and body text of the article is available by scraping the data from the URL[1]. Figure 2 shows the histogram of the number of tokens[2]. Most titles are around 20-30 tokens, and the body text often has a maximum token length of 512. Each `Overall` score is calculated by averaging the annotators' scores.

The evaluation dataset, in which the labels are

hidden from the participants, consists of 4,902 pairs. The ranking of the task is determined by Pearson's correlation between the labels in the evaluation dataset and the submitted predictions. Participants are allowed to submit their predictions five times per day, but none of the scores could be observed until the deadline. The leaderboard is also kept private until the end, so it is impossible to know the scores of the other teams.

3 System Overview

The developed system is outlined in Figure 3. The final prediction is calculated by a weighted average of the output of the four neural networks. Figure 4 illustrates the base architecture of each neural network. We use a Bi-Encoder approach where the two texts are entered into separate BERT. Each input is the combined title and body text of the article. As a pooling method, the representations of the last four `CLS` tokens are concatenated. `CLS` is the token to be attached to the beginning of an input of BERT. At the end, the score is given based on the interaction of the two sentence vectors.

The rest of this section describes the key points of the system. First, we consider whether Cross-Encoder or Bi-Encoder should be used. Next, we address the perspectives of the research questions listed in Section 1: pretrained models, pooling methods, translation, data splitting, and maximum length. Finally, we explain the ensemble of models.

3.1 Cross-Encoder vs Bi-Encoder

In the Bi-Encoder architecture, each sentence is transformed into an embedding by BERT, and the sentence vectors are obtained by a pooling layer. Denote two vectors A and B, then their interactions are designed as `distance` and `angle` with reference to (Tai et al., 2015) in the following formula. Here, `distance` is calculated as an element-wise absolute error, and `angle` is calculated as an element-wise multiplication.

$$\texttt{distance} = |A - B|, \quad \texttt{angle} = A \otimes B$$

In addition to `distance` and `angle`, traditional features are also created and combined. We use Jaccard Index (Jaccard, 1912), Dice Index (Dice, 1945), and cosine similarity. These features may not work when dealing with pairs with different languages. However, when building a prediction model with LightGBM (Ke et al., 2017) using only these features, Pearson's correlation achieved 0.2989 in the evaluation data set. We believe that these features can contribute to some extent and combine them into the layer.

A comparison between Cross-Encoder and Bi-Encoder is reported in Section 4.1. The Cross-Encoder architecture for the comparison is shown in Figure 5. We use two BERT models, one with concatenated article headlines and one with concatenated body text. The pooling method and features are fixed to the same settings. The regressor is a simple fully connected layer.

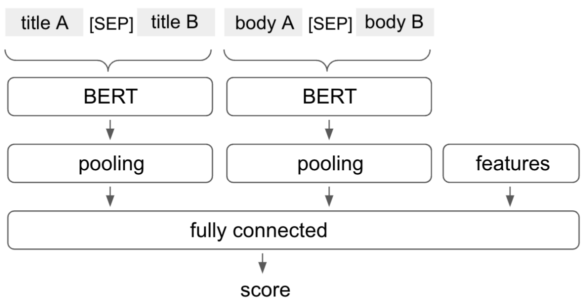

Figure 5: Cross-Encoder architecture for the comparison with Bi-Encoder architecture shown in Figure 4.

3.2 Pretrained Models

We considered various pretrained BERT models of Hugging Face Transformers (Wolf et al., 2020). There are some multi-lingual pretrained models such as mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) available[3] and the following models are selected as candidates.

- `bert-base-multilingual-uncased`
- `bert-base-multilingual-cased`
- `xlm-roberta-base`

Since none of the models performed badly, we used all of them for the final submission as shown in Figure 3. A comparison among models is reported in Section 4.2.

3.3 Pooling Methods

There are several ways to extract the sentence vector from the output through BERT. One of the simplest ways is to use the embedding of the `CLS` token in the final layer, but some methods are proposed to use information from other layers as well. A number of experimental results have been reported (Reimers and Gurevych, 2019; Gao et al., 2021; Jiang et al., 2022; Conneau and Kiela, 2018), but we believe that the results depend largely on the individual task. Therefore, we consider the following four methods.

- `CLS`: Concatenate the last four representations of `CLS` token.
- `CNN`: Use the convolutional neural network (CNN) to extract sentence vectors.
- `LSTM`: Use the long short-term memory (LSTM) for extracting sentence vectors.
- `MAX`: Use max-pooling to extract sentence vectors.

On the basis of the results of our experiments, we adopted the first method. A comparison among the pooling methods is reported in Section 4.3.

3.4 Translation

One of the ways of dealing with multilingual datasets is the translation. Here we examine a method of translating all datasets into English and using pretrained models in English.

[3] `https://huggingface.co/docs/transformers/multilingual`

Table 2: Experimental results of Pearson's correlation for the validation and evaluation dataset. The columns named "pool" and "length" represent pooling methods and max length respectively.

id	architecture	model	pool	folds	length	validation	evaluation
0	Cross-Encoder	`bert-base-multilingual-cased`	`CLS`	5	512	0.7045	0.6188
1	Bi-Encoder	`bert-base-multilingual-cased`	`CLS`	5	512	0.7688	0.6922
2	Bi-Encoder	`bert-base-multilingual-uncased`	`CLS`	5	512	0.7627	0.6940
3	Bi-Encoder	`xlm-roberta-base`	`CLS`	5	512	0.7118	0.6153
4	Bi-Encoder	`bert-base-multilingual-cased`	`CNN`	5	512	0.4892	0.3269
5	Bi-Encoder	`bert-base-multilingual-cased`	`LSTM`	5	512	0.4979	0.3271
6	Bi-Encoder	`bert-base-multilingual-cased`	`MAX`	5	512	0.7221	0.6313
7	Bi-Encoder	translation with `bert-base-uncased`	`CLS`	5	512	0.7505	0.6748
8	Bi-Encoder	`bert-base-multilingual-cased`	`CLS`	20	512	0.7853	0.7107
9	Bi-Encoder	`bert-base-multilingual-cased`	`CLS`	5	256	0.7427	0.6616
10	Bi-Encoder	`bert-base-multilingual-cased`	`CLS`	5	128	0.7137	0.6355
11	Bi-Encoder	`bert-base-multilingual-cased`	`CLS`	5	64	0.6744	0.5782
12		weighted average ensemble				**0.7902**	**0.7425**

We use Googletrans[4] for the translation, and `bert-base-cased` as a pretrained model. In conclusion, the translation approach did not improve the performance of the multilingual models. A comparison result is shown in Section 4.4.

3.5 Data Splitting and Max Length

We also investigate the effect of data splitting and max length. The number of data partitions in cross validation (Blum et al., 1999) affects the number of available training samples. When the size of the training dataset is not very large, as in this task, it may affect the performance. The setting of the max length based on the distribution of the token size introduced in Section 2 is also an adjustable element. In general, news articles contain important information early in the article, so there is a possibility that a smaller max length works well.

For data splitting, it was suggested through the experiment that the larger the number of splits, that is, the larger the training dataset, the higher the performance. We set the max length to 512, because, in contrast to the hypothesis, the smaller max length led to the poor performance. Both comparison results are shown in Section 4.5.

3.6 Weighted Average Ensemble

In the weighted average of the models, the performance on the validation dataset was taken into account to determine the models to be used and their weights. In the final submission, we used the average of all models obtained in the cross validation process. In case of folds set 5, five models were generated. This means that $(5+5+5+20)$ models were used in Figure 3. The improvement through the ensemble is reported in Section 4.6.

[4]`https://github.com/ssut/py-googletrans`

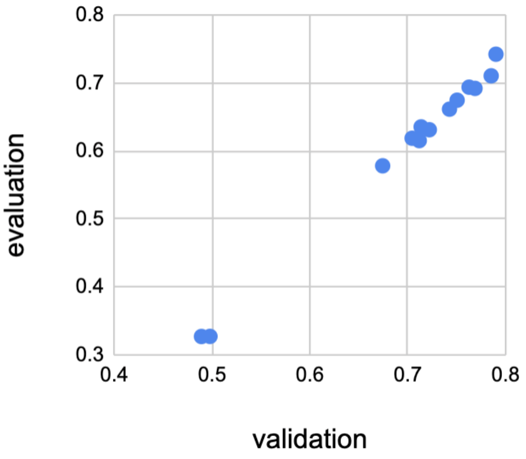

Figure 6: Scatter plot of Pearson's correlation for the validation and evaluation dataset. It can be observed that the scores are correlated.

4 Results

This section reports the experimental results that facilitated the design of the system described in the previous section. Table 2 lists the scores of Pearson's correlation for the validation and evaluation dataset.

The validation dataset is extracted from the training dataset. The column named "folds" shows the number of folds in cross validation. That is, in case of folds set 5, 20 % of the training dataset is removed for the validation. Each model is trained for seven epochs, and the scores with the best performance on the validation dataset are reported. In our experimental setting, the performance for the validation dataset converged after about five training epochs.

The scatter plots of the performance for the validation and evaluation datasets are shown in Figure 6, and it can be observed that they are correlated. It is suggested that the improved performance on the validation dataset is also useful on the evaluation dataset, and that the validation framework works well.

The rest of this section describes the result in detail from the same perspective as in the previous section. The models in Table 2 are referred to as experiments 0-12 respectively, and their performances are compared for the discussions.

4.1 Cross-Encoder vs Bi-Encoder

Comparing the results of experiments 0 and 1, we see that the architecture of Bi-Encoder worked well rather than Cross-Encoder. There is a large difference of more than 0.06 in Pearson's correlation. The results are only for this task and our experimental setup and should not be overly generalized. However, it is an interesting case study, as the results contrast with the use of Cross-Encoder in some of the previous studies presented in Section 1. The results suggest that it is important to try both Cross-Encoder and Bi-Encoder in the search for high performance.

4.2 Pretrained Models

The results of experiments 1-3 show the performance of each pretrained model. The model with `bert-base-multilingual-uncased` and `bert-base-multilingual-cased` performed better than `xlm-roberta-base`.

4.3 Pooling Methods

Seeing the results of experiments 1 and 4-6, we can say that the best pooling method in this task is `CLS`. It outperformed the other three methods.

4.4 Translation

The results of experiment 7 show that the translation approach did not improve the performance from experiment 1.

4.5 Data Splitting and Max Length

In experiment 8, the number of folds was changed from 5 to 20. This was not an exact comparison since the validation dataset was changed, but there was 0.03 improvement in Pearson's correlation from experiment 1. For max length, we examined values from 64 to 256 in experiments 9-11. It was observed that the performance was getting worse as the max length was decreased.

Table 3: Correlation between the experiments used in the final submission (1, 2, 7, and 8).

id	2	7	8
1	0.9156	0.8812	0.9348
2	-	0.8752	0.9105
7	-	-	0.8730

Table 4: Median of absolute error and the number of samples for the evaluation dataset for each language pair. The symbol ✓ means the language pair is included in the training dataset.

language-langage	median	samples	training
German-English	**0.2971**	185	✓
Chinese-English	0.4092	213	
French-French	0.4213	111	✓
Spanish-Italian	0.4251	320	
Polish-English	0.4286	64	
English-English	0.4662	236	✓
Spanish-Spanish	0.5223	243	✓
Spanish-English	0.5239	496	
Polish-Polish	0.5256	224	✓
Italian-Italian	0.5444	411	
Chinese-Chinese	0.5450	769	
Russian-Russian	0.5722	287	
Turkish-Turkish	0.5789	275	✓
French-Polish	0.5855	11	
German-German	0.6030	608	✓
Arabic-Arabic	0.6765	298	✓
German-French	0.6905	116	
German-Polish	**0.7751**	35	

4.6 Weighted Average Ensemble

The results of experiment 12 show that the weighted average of the models boosted the performance. It is important to highlight that when comparing experiment 8 and 12, the performance improved by only 0.005 on the validation dataset, but by more than 0.03 on the evaluation dataset. Table 3 describes the correlation between the experiments used in the final submission (1, 2, 7, and 8). We can see that there is a high similarity between experiments 1 and 8, where the only difference is the number of folds. It is also observed that the translation approach contributes to the diversity, because its correlation is low. This was our submission for SemEval-2022 task 8. The score 0.7425 for the evaluation dataset ranked 12th out of 32 teams.

4.7 Error Analysis

Here we describe the analysis results using labels of the evaluation dataset. First, a comparison of each pair of languages shows the performance differences observed in Table 4. The median absolute error for German-English is 0.2971, whereas German-Polish is 0.7751. German-German performs relatively poorly, and their proportion in the evaluation dataset is high as shown in Table 1. Focusing on these language pairs may improve the overall performance of the system. It is noteworthy that even language pairs that are not part of the training dataset, such as Chinese-English, show excellent performance. It can be suggested that models pretrained in multilingual languages worked well.

Next, we identified the problem in obtaining the article body text by checking extremely incorrectly predicted samples. For example, consider the sample with `pair_id` equals `1512411298_1512618793` where the system predicted 3.555 and the correct answer was 1.000. We checked the body text of the article `1512618793` and found that the extracted text by the script was different from the actual body text for some reasons such as the page layout like advertisements or related articles.

5 Conclusion

This paper presented our exploration of BERT-based Bi-Encoder approach for SemEval-2022 task 8. The experiment showed that Bi-Encoder architecture worked better than Cross-Encoder. There are several findings, such as pretrained models, pooling methods, translation, data separation, and the number of tokens. The exploration of these different variants led to the creation of several diverse models. Finally, a weighted average ensemble of the four models achieved the competitive result.

YNU-HPCC at SemEval-2022 Task 8: Transformer-based Ensemble Model for Multilingual News Article Similarity

Zihan Nai, Jin Wang and **Xuejie Zhang**
School of Information Science and Engineering
Yunnan University
Kunming, China
{wangjin,xjzhang}@ynu.edu.cn

Abstract

This paper describes the system submitted by our team (YNU-HPCC) to SemEval-2022 Task 8: Multilingual news article similarity. This task requires participants to develop a system which could evaluate the similarity between multilingual news article pairs. We propose an approach that relies on Transformers to compute the similarity between pairs of news. We tried different models namely BERT, ALBERT, ELECTRA, RoBERTa, M-BERT and Compared their results. At last, we chose M-BERT as our System, which has achieved the best Pearson Correlation Coefficient score of 0.738.

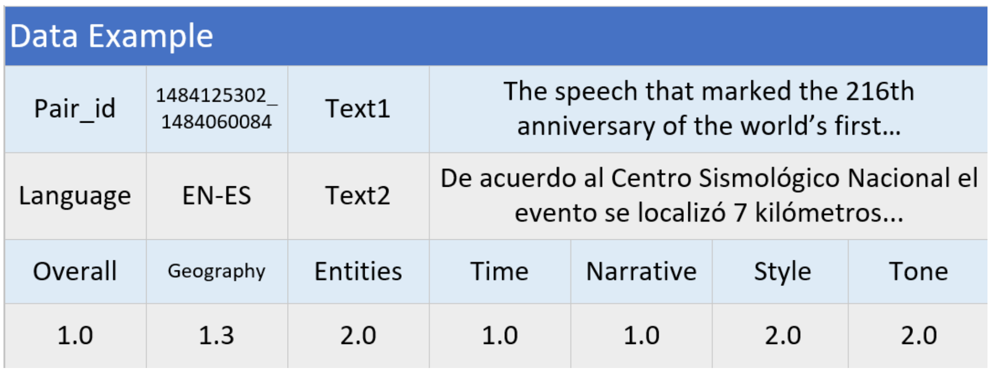
1 Introduction

In the field of Natural Language Processing (NLP), how to measure the similarity of two texts has been a topic of interest among researchers for decades. Text similarity measures play an increasingly important role in text related research and applications in tasks such as information retrieval, text classification, document clustering, topic detection, topic tracking, questions generation, question answering, essay scoring, short answer scoring, machine translation, text summarization and others(Gomaa, Fahmy, et al. 2013). It is widely known that text is a high-dimensional semantic space, hence how to abstractly decompose it so that we can quantify its similarity from a mathematical point of view has become the focus for many researchers. There are three methods to measure text similarity: one is the traditional method based on keyword matching, such as N-gram similarity; the second is to map the text to the vector space, and then use the cosine similarity and other methods; the third is the method of deep learning, such as the deep learning semantic matching model DSSM based on user click data, ConvNet based on convolutional neural network, and the current state-of-art Siamese LSTM and other methods. However, since the introduction of bidirectional encoder representations from transformers (BERT)(Devlin, Chang, Lee, and Toutanova 2018), the accuracy and training efficiency in both text classification and sequence labeling have reached new heights.

SemEval 2022 Task 8 is a multilingual news article similarity task(X. Chen, Zeynali, Camargo, Flöck, Gaffney, Grabowicz, Hale, Jurgens, and Samory 2022). There are mainly 3 difficulties in the task compared with regular text similarity task: (1) the task is interested in the real world-happenings covered in the news articles, not their style of writing, political spin, tone, or any other more subjective design. Therefore, the system built by participant should neglect the subjective part of the text and focus on objective part only;(2) there were over six different languages in both training and test dataset, and some of test data set were composed of multilingual text pair to test the multilingual ability of participating system; (3) the test dataset contains new languages which have never appeared in training data. This situation disguisedly reduces the training data required to train the model.

In this paper, we primarily present a deep learning system for the SemEval-2021 Task 8: Multilingual News Article Similarity. Since there are not any subtasks in the SemEval 2022 Task 8, our system will focus on calculating the overall similarity only. Our approach is based on Transformers, which is a classic NLP model proposed by Google's team in 2017(Vaswani, Shazeer, Parmar, Uszkoreit, Jones, Gomez, Kaiser, and Polosukhin 2017). We fine-tuned pre-trained masked language models namely BERT, ALBERT, ELECTRA, RoBERTa and M-BERT, which are all based on Transformers. We compared their performance at the task, then picked best of them as our system.

Experimental results show that most of the Transformers based model are valid in the field of text similarity(Mittal and Modi 2021). However, when it comes to multilingual text, there is a clear drop



Data Example						
Pair_id	1484125302_ 1484060084	Text1	The speech that marked the 216th anniversary of the world's first...			
Language	EN-ES	Text2	De acuerdo al Centro Sismológico Nacional el evento se localizó 7 kilómetros...			
Overall	Geography	Entities	Time	Narrative	Style	Tone
1.0	1.3	2.0	1.0	1.0	2.0	2.0

Figure 1: the example of the given training data

in results for all models. Among these models, M-BERT has achieved the best score with the Pearson Correlation Coefficient of 0.738. That is why we chose M-BERT as our system at last. The implementation for our system is made available via Github [1].

The rest of the paper is organized as follow. Section 2 describes the specific requirements of the task and dataset. Section 3 describes the details of the Transformers model used in our system. Section 4 presents the experimental results. Finally, the results and conclusions are presented in Section 4 and 5.

2 Task Overview

The task organizers have provided training and test dataset for the task. The details of this task are given below, and some examples are shown in the Figure 1.

2.1 Problem Description

Given a pair of news articles, are they covering the same news story? Based on the same event, different journalist could write completely different news article, because of their political stance. The kernel of this task is to ignore the subjective part of news article, and calculate the similarity score according to objective facts such as time, geography, entities, etc. A pair of news article will be rate pairwise on a 4-point scale from most to least similar. Systems will be evaluated on their ability to estimate the Overall Similarity between two pairs of news stories, not any of the other scores. The similarity ratings will be compared with the gold standard ratings using Pearson's correlation.

[1]https://github.com/151140043/Sem2022task8.git

2.2 Data Description

The task organizers have provided training and test dataset. The training data consists of 4,964 pairs of news articles, and every pair of news articles have their unique pair_id, the counts of language-pairs is following: en-en: 1800, de-de: 857, de-en: 577, es-es: 570, tr-tr: 465, pl-pl: 349, ar-ar: 274, fr-fr: 72. Apart from the overall score, the score of "Geography", "Entities", "Time", "Narrative", "Style", and "Tone" are also given to contestants. However, they are all for reference only and will not be evaluated as final score. The test data consists of 4954 pairs of news articles. It is worth mentioning that the test dataset is contained more forms of pairs of multilingual news article which are not existed in training data.

3 System Description

We use the transformer based pre-trained model as solution to accomplish the task. As shown in Figure 2, the system we built contains a tokenizer, a model layer, fully connected layer and mean squared error function. The mean squared error is loss function of our system. The model layer represent a Transfomers based pre-trained model, it will be replaced by BERT or any model mentioned above to compare their effect on task 8. The rest of the section will describe the details of every part of the system and their mechanics.

3.1 Tokenizer

Tokenization is essentially splitting a phrase, sentence, paragraph, or an entire text document into smaller units, such as individual words or terms. Each of these smaller units are called tokens. Since the requirement of the task is to evaluate the similarity between two news articles, both the articles will be entered into the tokenizer at the same time. To

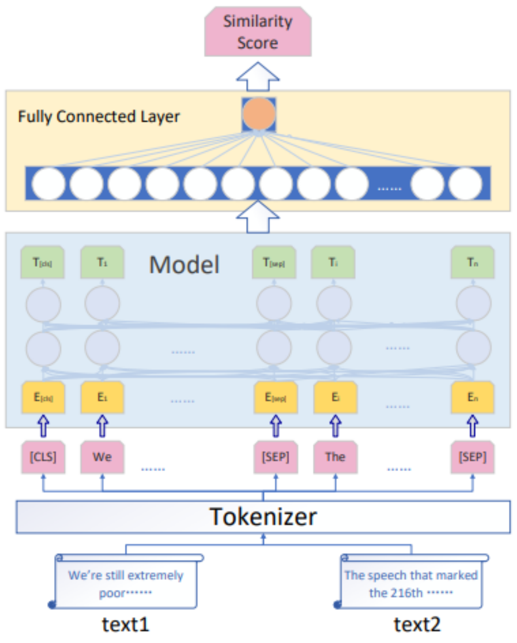


Figure 2: The structure of system

distinguish them, the tokenizer will add a special token named "[SEP]" between them and the last of second article. in addition to "[SEP]", the tokenizer will also add a special token named "[CLS]" at the begin of the first article which is necessary for subsequent step.

3.2 Model

Model layer is an abstraction of a pre-trained Transformer model, it can be a BERT model or any models mentioned below in practical application. In this step, the tokens we got from tokenizer will be passed to the layer, and layer will generate 768-dimensional word embeddings for each word in the news article(Xinge Ma and Zhang 2021) (Most of the models we used generate 768-dimensional word embeddings, a few models generate other parameters, which we will mention later). Then, the model will take the word embeddings of the first token of each article (i.e., '[CLS]') to evaluate the similarity between two news articles, because it integrated the semantic information of the whole sentence. Below we will introduce the specific model we used in the task.

BERT. BERT is a pretrained language representation model, which stands for Bidirectional Encoder Representations from Transformers (Devlin, Chang, Lee, and Toutanova 2018). BERT builds two pre-training tasks, Masked Language Model (MLM) and Next Sentence Prediction (NSP). Unlike traditional left-to-right language model pre-training, BERT is using a MLM pre-training objective, which make BERT to generate deep Bidirectional Linguistic Representation (Devlin J, Chang M W, Lee K, et al. 2018). We used the "bert-base-uncased" in our task. The size of BERT model we use in the task: Layers=12, Hidden Dimension=768, self-attention head =12, Word Piece embedding size =768, Total Parameters=110M.

ALBERT. ALBERT,which stands for A Lite Bert, is proposed to solve the problem that the parameters of the current pre-training model are too large (Lan, M. Chen, Goodman, Gimpel, Sharma, and Soricut 2019). In the classic BERT model, the size of Word Piece embedding (E) is always the same as the hidden layer size(H), i.e., E=H. ALBERT break the binding relationship between E and H, thereby reducing the number of parameters of the model and improving the performance of the model. Another method for ALBERT to reduce the amount of parameters is parameter sharing between layers, which mean, multiple layers could use the same parameters. There are three ways to share parameters: (1) Only share the parameters of the feed-forward network. (2) Only share the parameters of the attention. (3) Share all the parameters. Through these methods, ALBERT could greatly reduce the total parameters. We chose "albert-base-v2" as the model, and the size of model we use in the task: L=12, H=768, A=12, E=128, Total Parameters=12M.

ELECTRA. ELECTRA is a model that share some ideas with BERT, but the main structure is still different. It also can be named as "Efficiently Learning an Encoder that Classifies Token Replacements Accurately" (Clark, Luong, Le, and Manning 2020). The pre-training of ELECTRA can be divided into two parts, which are generator and discriminator. The generator is still MLM, the structure is similar to BERT, but the model will be much smaller than BERT. The output of generator is the input of discriminator. The role of discriminator is to distinguish whether each token input is original or replaced. For each token, the discriminator will perform a binary classification on it, and get the loss. The approach above is called replaced token detection. We chose the "google/electra-base-discriminator" as our model, whose size is: L=12, H=768, A=12, E=768, Total Parameters=110M.

RoBERTa. The full name of RoBERTa is "Ro-

model name	L	H	E	A	P
BERT	12	768	768	12	110M
ALBERT	12	768	128	12	12M
ELECTRA	12	768	768	12	110M
RoBERTa	24	1024	1024	16	355M
M-BERT	12	768	768	12	110M

Table 1: Model structure
L represents L Layers,H represents Hidden Dimension H, E represents WordPiece embedding size E, A represents A self-attention head, P represents Total Parameters

bustly optimized BERT approach" (Liu, Ott, Goyal, Du, Joshi, D. Chen, Levy, Lewis, Zettlemoyer, and Stoyanov 2019). From the perspective of the model, there are not novel innovation in RoBERTa. There are only some adjustment made on the basis of BERT: 1) The training time is longer, the batch size is larger, and the training data is more; 2) The next predict loss is removed; 3) The training sequence is longer; 4) The Masking mechanism is dynamically adjusted. The model we used in the task is "roberta-base", and the architecture of it is: L = 24, H = 1024, E=1024, A = 16, Total Parameters =355M.

M-BERT. The structure of Multilingual-BERT(M-BERT) is exactly the same with the common BERT model. The biggest difference between M-BERT and BERT is that M-BERT is pre-trained on the top 104 languages with the largest Wikipedia using a masked language modeling (MLM) objective. While the common BERT is pre-trained on English Corpus.

3.3 Transformers

Transformers is the base of all the model we mentioned above. Like many neural sequence transduction models, Transformers also have an encoder-decoder structure.

Encoder. The encoder is composed of a stack of N = 6 identical layers. Each layer has two sub-layers. The first is a multi-head self-attention mechanism, and the second is a fully connected feed-forward network (Vaswani, Shazeer, Parmar, Uszkoreit, Jones, Gomez, Kaiser, and Polosukhin 2017). The output of the sub-layer can be expressed as:

$$sub\_layer\_output = LayerNorm(x + Sublayer(x))$$

Decoder. The decoder is also composed of a stack of N = 6 identical layers. In addition to the two sub-layers in each encoder layer, the decoder inserts a third sub-layer, which performs multi-head attention over the output of the encoder stack.

Multi-Head Attention

Given a set of vector set values, and a vector query, the attention mechanism is a mechanism that computes a weighted sum of values based on the query. In Transformers, they compute attention as:

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V$$

The multi-head attention allows the model to concatenate different attention results, and it can be represent as:

$$MultiHead(Q, K, V) = Concat(head_1, ..., head_h)W^O$$

$$where \quad head_i = Attention(QW_i^Q, KW_i^K, VW_i^V)$$

3.4 Fully Connected Layer

In the fully connected layer, word embeddings acquired from the previous step will be converted into 1-dimensional numerical values. then, the fully connected layer will output the similarity score depend on the 1-dimensional numerical values.

4 Experiments

4.1 Data Preprocessing

As shown in Figure 2, tokenizer is the data processing structure of our system. After feeding data into tokenizer, it will return a dictionary of 3 lists of ints, which are input_ids, attention_mask and token_type_ids. The input ids are token indices, numerical representations of tokens building the sequences that will be used as input by the model. The attention mask is an optional argument used when batching sequences together. This argument indicates to the model which tokens should be attended to, and which should not. The token_type_ids allow some models to understand where one sequence ends and where another begins. But RoBERTa is an exception, RoBERTa removes NSP, so RoBERTa do not need the token_type_ids as input. We will split ten percent of the training data as validation data to prevent overfitting.

4.2 Evaluation Metrics

Systems will be evaluated on their ability to estimate the Overall Similarity between two pairs of news stories, not any of the other scores. The similarity ratings will be compared with the gold standard ratings using Pearson's correlation.

Epoch	1	2	3	4	5
score	0.681	0.712	0.738	0.721	0.694

Table 2: The relationship between epoch and Pearson coefficient

4.3 Implementation Details

The 5 models that mentioned above are all applicated in the task to evaluate the overall similarity between the given pairs of news articles. The datasets we used were all provided by the competition, with no other external corpus. For all the models, we set learning rate = $5e^{-6}$, epsilon=$1e^{-8}$, loss function as mean squared error, and a batch size of 8 for three epochs.

4.4 Hyper-parameters Fine-tuning

In the experiment, we have tried to change specific parameters while controlling other parameters unchanged, to see if we can get better results. The following will introduce our attempts on fine-tuning parameters.

Loss function. At the beginning of the experiment, we had to choose loss function from mean squared error and cosine similarity. Therefore, we trained an ALBERT model with the loss function of mean squared error based on the news article provided by official, and get the Pearson's correlation of 0.543. Then, we trained another ALBERT model with the loss function of cosine similarity, but only got Pearson's correlation score of 0.055. As a result, we chose mean squared error as loss function.

Batch size. Appropriate batch size is important for the optimization of model. If batch size is too small, the result may be poor. If the batch is too large, it will cause memory overflow. So we chose a batch size of 8.

Epoch. Take M-BERT as an example, the test data provided by task organizers are feed into the model to exam the effect of different epochs. The relationship between epoch and Pearson coefficient score is shown in table 2. It is obvious that the Pearson coefficient score come to the highest when epoch=3. So, we set the epoch equals to 3 in the experiment.

4.5 Comparative Results and Discussion

The results are evaluated by Pearson Correlation Coefficient with the test data provided by official, which is shown in table 3. BERT reach an accuracy of 0.464, ALBERT of 0.543, ELECTRA of 0.474, RoBERTa of 0.475, and M-BERT of 0.738. Our best individual score is 0.738 for M-BERT. As can be seen from the results, BERT, ALBERT, ELECTRA and RoBERTa have similar scores which greater than 0.45 and less than 0.5. M-BERT is the highest among them, whose score is over 0.7. Our results show that M-BERT is able to perform cross-lingual generalization surprisingly well. We believe that the reason why M-BERT outperforms other models is that M-BERT is pre-trained on the Corpus contained 104 languages while other models are pre-trained on a Corpus contained English only. Our conjectures are not groundless. A research (Papadimitriou, Chi, Futrell, and Mahowald 2021) demonstrate that mBERT representations are influenced by high-level grammatical features that are not manifested in any one input sentence, and that this is robust across languages. And mBERT does not encode subjecthood purely syntactically, but that subjecthood embedding is continuous and dependent on semantic and discourse factors, as is proposed in much of the functional linguistics literature. But there is a defect in M-BERT which is while M-BERT's multilingual representation is able to map learned structures onto new vocabularies, it does not seem to learn systematic transformations of those structures to accommodate a target language with different word order (Pires, Schlinger, and Garrette 2019). For example, cross-script transfer is less accurate for pairs like English and Japanese, which have a different order of subject. Therefore, our experiments still have many areas for improvement.

model	Pearson Correlation Coefficient
BERT	0.464
ALBERT	0.543
ELECTRA	0.474
RoBERTa	0.475
M-BERT	0.738

Table 3: Comparable results of experiments

5 Conclusion

In this paper, we described our deep learning models for the multilingual text similarity task SemEval-2022 shared Task 8. The best Pearson's correlation score we got was 0.738. We showed that the Transformer based approaches is valid in the field of multilingual text similarity. However, our system is far from perfect, lots of possible improvement can be implemented in the current model. We would like to further explore how to improve it, and employ more interesting methods in the task.

Abstract

This paper presents our system for document-level semantic textual similarity (STS) evaluation at SemEval-2022 Task 8: “Multilingual News Article Similarity”. The semantic information used is obtained by using different semantic models ranging from the extraction of key terms and named entities to the document classification and obtaining similarity from automatic summarization of documents. All these semantic information’s are then used as features to feed a supervised system in order to evaluate the degree of similarity of a pair of documents. We obtained a Pearson correlation score of 0.706 compared to the best score of 0.818 from teams that participated in this task. Our source code can be found at GitHub[1].

1 Introduction

Measuring semantic textual similarity has been a research subject in natural language processing, information retrieval and artificial intelligence for many years. Accurate modelling of textual similarity is fundamental for many applications. Previous efforts have focused on comparing a short text with a long text (e.g., Web search), two sentences or other short text sequences (e.g., paraphrase recognition, image retrieval by captions and Twitter tweets search). There are many other tasks requiring computing the semantic similarity between two long texts (e.g., document classification, document clustering and tracking the similarity of news coverage between different regions).

Semantic textual similarity (STS) measures the level of semantic equivalence between two textual contents. In this paper, we are interested to develop a system that identifies news articles that provide similar semantic information. More specifically, given two news articles, we aim to compute their similarity based on four characteristics: geolocation, time, shared entities, and shared narratives. To achieve this goal, we must identify important elements of the news articles content, such as the discussed event, location, time, and people involved. More precisely, the task 8 of SemEval-2022 edition focuses on the analysis of documents (long texts) that can share different semantic information and can be from different natural languages in both monolingual and cross-lingual settings.

The STS task has been held in SemEval since 2012. More precisely, the semantic similarity systems between sentences using paraphrase datasets have been proposed (Agirre *et al.*, 2012). In the 2013 edition of Joint Conference on Lexical and Computational Semantics – *SEM (Agirre *et al.*, 2013), STS task was focused in using cultural heritage items which are described with metadata such as title, author, or description. Thereafter, systems that compare snippets of text are proposed in the 2016 edition of SemEval (Agirre *et al.*, 2016). Afterwards, the 2017 edition of SemEval proposed to compare sentences in a dimension of monolingual and cross-lingual contents (Cer et al., 2017). In the last few years, many semantic

[1] https://github.com/jln-brtn/BL.Research-at-SemEval-2022-Task-8

similarity datasets and systems have been explored. Among the elements that characterize this new edition of SemEval-2022 compared to 2017 is the fact that we are interested in measuring the similarity between long news contents and not sentences, snippets of texts or short texts.

We encountered many challenges: First, the content scraping of the provided URL (in the first attempt, we had empty or incomplete content in many examples). Then, we have many languages (new languages in the test set are not present in the train set). Finally, it was challenging to choose the type of the predicted score: decimal or integer, which is different according to the number of human annotators per document.

In this paper, we present our approach for SemEval-2022 Task 8. The system that we propose is based on the computation of different scores by document pairs. These scores are used as features to train a supervised system. Regarding the multiple languages, we have developed a dedicated model for some of them, and translations in a pivot language for others.

The paper is organized as follows: we describe the problem and the data in section 2. Then, we give an overview of the related work in section 3. Next, we present the proposed system in section 4. We detail the performed experiments and the results in sections 5 and 6. Finally, we conclude the paper in section 7.

2 Background

2.1 Problem Description

The objective of this task at SemEval-2022 is to compare the similarity between two news articles and to be as consistent as possible with manual annotations provided by native annotators. We identified several challenges and issues in this task:

- **Scraping of the data**: probably not foreseen, because the final access to a clean and complete text was not always possible. For example, scraping sometimes empty, incomplete, or not correct (name of the newspaper, badly identified characters, and others).
- **Multilingual aspect of this task**: several languages used, some of which difficult or poorly modeled like Russian, Chinese, Turkish, and also text pair analysis where text content are provided by different languages.
- **Similarity evaluation of texts**: on a precise topic basis, on concordant geographical or temporal elements, on a similarity of tone and common style.

2.2 Data Description

Data used to train consisted of a total of 4,964 pairs of news articles written in seven different languages, namely: English (EN), French (FR), Spanish (SP), German (DE), Polish (PL), Arabic (AR) and Turkish (TR). The pairs were formed either with the same language or with different languages. In the training corpus, seven couple types are monolingual and only one is cross-lingual (DE_EN). For the test corpus, we have a total of 4,953 pairs of news articles and ten different languages with three new languages, namely: Russian (RU), Chinese (ZH) and Italian (IT). In this corpus, we have eight cross-lingual couple types with seven couple types that never seen in train corpus. Table 1 describes the number of document pairs for each corpus and each language pair.

Couple Type	Monolingual			Couple Type	Cross-lingual	
	Train	Test			Train	Test
EN_EN	**1,800**	236		DE_EN	577	190
FR_FR	72	111		SP_EN	—	498
SP_SP	570	243		PL_EN	—	64
DE_DE	857	611		ZH_EN	—	223
PL_PL	349	224		SP_IT	—	320
AR_AR	274	298		DE_FR	—	116
TR_TR	465	275		DE_PL	—	35
RU_RU	—	287		FR_PL	—	11
ZH_ZH	—	**769**				
IT_IT	—	442				

Table 1: statistics on the number of examples of train and test corpus.

Each pair of documents was annotated by one to eight annotators based on seven score categories that are “Geography”, “Entities”, “Time”, “Narrative”, “Overall”, “Style”, and “Tone”. For each category of each pair, a score on a 4-point scale was given by the available annotators then the average resulted in floats or integers. The score ranges from 1 as most similar to 4 as least similar. In addition to the mentioned scoring categories, the article pair identifiers, languages, and URLs were given for each pair. Using the URLs, we were able to retrieve data from the articles such as: titles, texts, keywords, tags, authors, publication date, abstracts, and meta-descriptions along with other irrelevant information. Finally, evaluation data were released later by organizers in the same format as train data except for the previous cited scoring categories as our system were judged based on one of those scores that is the “Overall score”.

3 Related Work

Semantic textual similarity deals with determining how similar two pieces of texts are. This can be done by assigning a rating from 1 to 4 (or 1 to 5) for more similar to less similar content pairs. Related tasks are paraphrasing or duplication identification. There are many interesting works for STS, an Evaluation Toolkit for Universal Sentence Representations, named SentEval has been proposed (Conneau and Kiela, 2018). It includes 17 downstream tasks[2], including common STS tasks from 2012-2016. We describe in this section some existing systems from the previous editions of SemEval.

Tian *et al.* (2017) proposed three feature-engineered models using Random Forest, Gradient Boosting, and XGBoost regression methods. Their features are based on n-gram overlap; edit distance, longest common prefix/suffix/substring, tree kernels, word alignments, to cite a few. They also propose four deep learning methods. The difference between the methods is the approach to sentence embeddings using either: averaged word embeddings, projected word embeddings, a deep averaging network, or LSTM (Long-Short Term Memory) (Hochreiter and Schmidhuber, 1997). To build the global model, they average scores of the deep learning and the feature-engineered models.

Wu *et al.* (2017) use sentence information content with WordNet (Wallace, 2007) and BNC word frequencies (Leech, Rayson and Wilson, 2001). One variant uses sentence information content exclusively. Another variant uses ensembles information content with Sultan, Bethard and Sumner (2015)’s alignment method. The third variant uses ensembles information content with a cosine similarity of summed word embeddings with an IDF (Inverse Document Frequency) weighting scheme (Jones, 1972).

Shao (2017) proposed a convolutional Deep Structured Semantic Model for the generation of sentence embeddings. The embeddings are compared using cosine similarity and element-wise difference with the resulting values fed to additional layers. This architecture is similar to Tian *et al.* (2017)’s deep learning models.

Henderson *et al.* (2017) proposed a feature engineering approach that they complete with deep learning. Ensembled components include alignment similarity; string similarity measures such as matching n-grams, summarization, Machine Translation (MT) metrics, an RNN (Recurrent Neural Networks), and RCNN (Recurrent Convolutional Neural Networks) over word alignments, and a BiLSTM (Bidirectional Long-Short Term Memory) networks.

4 System Overview

Some strategies can be considered to resolve the task 8 of SemEval-2022 :

- Building a model for each training dataset by language: English, French, Spanish, German, Polish, Arabic and Turkish.
- Building a unique model in English[3] and translating all texts into that language.
- Building a multilingual model that can handle two texts into different languages.

The advantage of the first and the third strategies is that they avoid translation to a pivot language. The second strategy has the advantage of enabling consistent training and being able to handle all languages using a single model. Our system is neither based on the translation of all texts in English, nor on the construction of a multilingual model. We have chosen to build learning models in some main languages, namely: English, French, Spanish, German, Arabic and Turkish. We abandoned Polish language because we did not find adequate pretrained models. When two texts to be compared are not in the same language, they are translated into the main language selected.

A fundamental point for the final score to be generated is the choice on the precision of the answer in terms of decimals. We have noticed that for some languages, the Overall score obtained is

[2]http://nlpprogress.com/english/semantic_textual_similarity.html

[3] The global reference language and therefore the one best managed by all techniques in natural language processing.

an integer. In English, for example, there is a decimal score and more annotators. The actual number of annotations cannot be determined in advance. We have therefore defined rules to complete our evaluation according to the score obtained and the language. We did not use the metadata of the news articles (authors, dates, newspaper, tags, etc.) because these data were incomplete. We simply retained both titles and text contents. We also noticed:

- Strong correlations between the Overall score and the scores of Entities, Narrative, and Geography. Table 2 describes the correlations between annotator scores.
- The training dataset is unbalanced, especially in English. We have more than four scores. The figure 1 describes more information about this dataset.

	Geography	Entities	Time	Narrative	Overall	Style	Tone
Geography	1	**0.63**	0.12	0.52	0.59	0.33	0.35
Entities		1	0.25	**0.74**	**0.80**	0.32	0.39
Time			1	0.4	0.43	0.10	0.18
Narrative				1	**0.88**	0.32	0.45
Overall					1	0.33	0.45
Style						1	0.57
Tone							1

Table 2: Correlations between annotator scores.

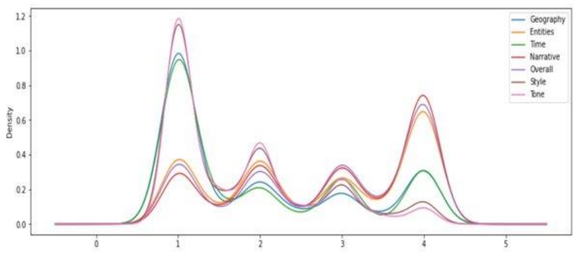

Figure 1 : Density of annotator scores.

Following the observations that are seen in table 2 and figure 1, we implemented a scoring system based on each language who will be features to feed a supervised system. We detail below our features:

1. A similarity score of titles based on sentence transformers with a pretrained encoder model (Reimers and Gurevych, 2019).
2. We used text summarization based on pretrained transformers in each language to measure a similarity score between these summaries. We tested several models on some examples and selected those which seemed to be the best. Based on the language, we were able to obtain one or two models of summaries and thus one or two scores. We have mainly turned to BART (Lewis *et al.*, 2019) or Sequence-to-Sequence models (Chen *et al.*, 2021; Zhang *et al.*, 2019; Shleifer and Rush, 2020; Eddine, Tixier and Vazirgiannis, 2021). The models are pretrained on different summarization corpus variants, for example MLSUM, the Multilingual Summarization Corpus (Scialom *et al.*, 2020).
3. We used identification and extraction of keywords/'key terms' in titles and content texts by using the PKE toolkit library (Boudin, 2016). The extracted tags are nouns, proper nouns, verbs, and adjectives only with stemming adding the ten semantically closest words by using Word2Vec (Mikolov *et al.*, 2013) with Gensim library (Řehůřek and Sojka, 2010), if a model exists in a specific language. We compute the number of common terms in both texts.
4. We used identification and extraction of common named entities between titles and content texts, namely: places, persons, organizations, and dates. We used two libraries: Spacy (Honnibal *et al.*, 2020) and Stanza (Qi *et al.*, 2020), and pretrained transformers models. As for keywords and key terms, we compute the number of identical entities in both texts.
5. For the various geographical detected entities (cities, regions, countries), we calculate a score for the proximity between places based on geocoding[4].
6. We used the zero-shot classification models (Yin, Hay and Roth, 2019) based on Press topics that we have defined manually: *politics*, *sport*, *health*, *economy* and *technology*. The similarity score obtained reflects the number of common topics between two texts.

[4] https://geopy.readthedocs.io/en/stable/#nominatim

7. Finally, sentiment analysis models are used to identify if the sentiment polarity is positive, negative, or neutral in both texts. The models used are proposed by Wolf *et al.* (2019), Guhr *et al.* (2020), Demange (2021) and Pérez, Giudici and Luque (2021). The similarity score obtained thus reflects the number of common points.

With all these features, it is possible to make a final rating based on the classification or regression techniques. For the classification, we have tested Random Forest classifier and Logistic Regression for the algorithms that achieve the best performance. For the regression, we have tested Linear Regression, Partial Least Squares (PLS) and Extra Trees Regressor. That said, we can obtain a final evaluation of the selected strategy. To optimize the Pearson correlation score (the measure chosen by the organizers for the evaluation), we use PyCaret library (Moez, 2020) to compare all possible models (by using cross-validation with 10 folds).

For our English model, the various elements found allowed to have a good performance quickly (approximately 0.85 of Pearson correlation). The only concern was the strong imbalance of the training dataset that we needed to rebalance. The French model had a poor training dataset (only 72 pair examples). Thus, we selected a more efficient NER (Named Entity Recognition) Transformer model [5] than Spacy; and supplemented and balanced it to 200 pair examples with Spanish train texts to obtain a correct performance. We also focused on optimising the Turkish model in the same way with an efficient NER transformer[6]. We have not worked to optimize the German model which ought to have been much better.

5 Experimental Setup

We applied our scoring models to every pair of titles and content texts. For Polish language and the new languages observed in the evaluation dataset like Chinese, Russian and Italian, all texts were translated into English with deep Translator library[7] (Google Translate model) and then applied the English model. When there are two different languages, they are translated into English (for DE_EN, SP_EN, PL_EN and ZH_EN pairs), French (for FR_PL pairs), Spanish (for SP_IT pairs) or German (for DE_PL and DE_FR pairs). Finally, a compromise strategy was used between the score obtained in classification (integers) and in regression (value between 1 and 4 with selected rounding). Table 3 describes the confusion matrix after a test on a subset of train corpus.

Annotation score	1	2	3	4
1	**136**	27	4	0
2	50	**84**	35	16
3	6	42	**53**	89
4	0	20	33	**363**

Table 3: Example of Confusion Matrix obtained in English (test on the training dataset) after a Classification Random Forest Model.

6 Results and Analysis

Our final Pearson correlation on the test corpus is 0.706. A closer look at the results shows inconsistent performance scores for different languages. Table 4 shows the obtained results on the test corpus for each language pair. There are very good results for English and French (0.82 as Pearson correlation), good for Spanish (0.75), rather interesting for Turkish (0.74), disappointing for German (0.60, poorly optimized and badly managed model), and weak for Arabic (0.64). The final result for a specific language is generally consistent with the evaluations made previously on the subset (cross-validation) of training dataset.

For the translation part, we observe a fast drift according to the languages: the ZH_EN examples translated into English remain very accurate (0.79) but the ZH_ZH examples only obtain an average score of 0.69. We thus have a significant performance reduction in IT_IT (0.74) and SP_IT (0.61) compared to cases when English is used.

We found that most of the large deviations in evaluation (45 greater than 2 and 98 greater than 1.5) were related to scraping errors (blank or inconsistent text) where 2 and 1.5 are "Overall scores". This derivation also resulted in an evaluation of 3 to 4 on our part for an actual close to 1. We did not find a reverse case where our score was close to 1 and the actual close to 4.

[5] https://huggingface.co/Jean-Baptiste/camembert-ner
[6] https://huggingface.co/savasy/bert-base-turkish-ner-cased
[7] https://deep-translator.readthedocs.io/en/latest/

We observe in conclusion that 71% scores of pairs were excellent (below 0.1), 84% were good (below 0.5) and 96% below 1. We believe that our English, French, Turkish and Spanish models are correct and could have been further optimized cleanly. We had technical difficulties in making a correct Arabic model. As for the German model, we did not work on it enough and it should have obtained a performance close to 0.80.

Language pair	Pearson correlation
EN_EN	**0.82**
DE_DE	0.60
SP_SP	0.75
PL_PL	0.55
TR_TR	0.74
AR_AR	0.64
RU_RU	0.67
ZH_ZH	0.69
FR_FR	**0.82**
DE_EN	0.74
SP_EN	0.79
IT_IT	0.74
PL_EN	0.73
ZH_EN	0.79
SP_IT	0.61
DE_FR	0.61
DE_PL	0.4
FR_PL	0.74
Global	**0.706**

Table 4: System results on the test corpus.

7 Conclusion

In this paper, we described our supervised semantic textual similarity system developed for the SemEval-2022 task 8 and the result of the corresponding run we submitted. Our system uses different features reflecting the similarity that can be obtained, for example, between shared key terms and named entities, or even topics by using zero-shot learning for text classification systems. In addition, we use geolocation for location entities and measure the semantic similarity through the use of lexical embeddings at the sentence level (text title) and paragraph level (text summarizer obtained automatically by using transformers).

Beyond the use of a supervised system to measure the degree of similarity between two given texts, we are in a context of documents that can come from different languages by processing both pairs of monolingual documents and pairs of cross-lingual documents. Since the test corpus may contain documents written in natural languages not processed during learning phase, our system is able to perform an automatic translation into a pivot language in order to project new documents into already known spaces.

Acknowledgments

We would like to thank Berger-Levrault for giving us the opportunity to participate in the 2022 edition of SemEval. Our thanks also go to the research and technological innovation department (DRIT) which is an important part of Berger-Levrault.

Abstract

In this paper, we describe the approach we designed to solve SemEval-2022 Task 8: Multilingual News Article Similarity. We collect and use exclusively textual features (title, description and body) of articles. Our best model is a stacking of 14 Transformer-based Language models fine-tuned on single or multiple fields, using data in the original language or translated to English. It placed fourth on the original leaderboard, sixth on the complete official one and fourth on the English-subset official one. We observe the data collection as our principal source of error due to a relevant fraction of missing or wrong fields.

1 Introduction

SemEval-2022 task 8 (Chen et al., 2022) (Multilingual News Article Similarity) is a document-level similarity task on news articles data. The goal is to predict whether two multilingual news articles cover the same real-world happening regardless of their writing style, political spin and tone. The task included resources written in 10 different languages: English, German, Spanish, Turkish, Polish, Arabic, French, Chinese, Italian and Russian (the training dataset included news written only in the first seven languages). This task is interesting as we can apply the obtained approaches to cluster news articles and track the similarity of news coverage between different outlets or regions as done in the Agenda Setting project[1].

Our best model is a simple but effective Stacking of a set of Language Models trained on different combinations of textual features. We fine-tune 14 Language Models, half of them with original multilingual texts and half with texts translated to English. We select three textual fields from the features extracted by our scraper (title, body and description of the news article), and we fine-tune a model for every combination.

Our model achieved a maximum Pearson correlation score of 0.790 and scored 4th on the leaderboard that considers the best test result for each team. However, the final ranking, based on a bootstrapping approach across teams' submissions to estimate the expected rank, penalizes us to 6th place since it assumes that submissions are an exploration of the hyperparameter/model configuration space of the system. The assumption, released after the end of the competition, does not hold for our team.

Our model mainly struggles with missing or wrong data since the training and evaluation datasets were released as links to scrape due to privacy policies. We noticed that we could not collect parts of the datasets, and some of the collected data were clearly wrong (e.g. "Get in touch with us. All rights reserved" as the body of an article).

The code will be available on GitHub[2].

2 Background

2.1 Task Setup

The organizers of the competitions provided two datasets: the training dataset and the test dataset. The training dataset is a collection of 4964 pairs of links to news articles with gold labels: real numbers ranging from 1 to 4, where 4 represents completely different articles. The test dataset is a collection of 4953 pairs of links to news articles without gold labels. Both datasets included the languages of the original articles so that we do not need to infer them from the data. Both datasets also included duplicated rows that we discarded. Due to copyright problems, the datasets did not directly contain the contents of the articles but only the links (original link and the Internet Archive version) to scrape them with a public script. Figure 1 shows the distribution of languages is in the two datasets. The test data contains news written in languages never

[1]`http://www.euagendas.org/`

[2]`https://github.com/DataSciencePolimi/MultilingualNewsArticleSimilarity`

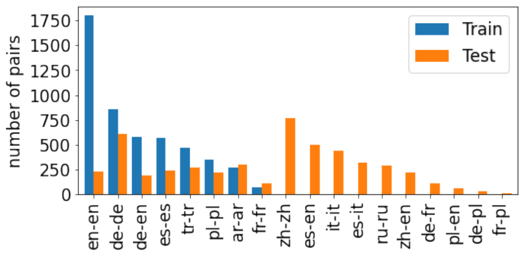

Figure 1: Distribution of language pairs in both datasets.

used in the training dataset (Chinese, Italian and Russian). Moreover, only 577 training pairs of news articles are in different languages (English and German). The performance of the models was computed using the Pearson Correlation Coefficient.

2.2 Related Work

We relied on transformers-based models and, in particular, we leverage the SentenceTransformers (Reimers and Gurevych, 2019) framework, which learns meaningful sentence Embeddings using Transformer-based Language Models (Vaswani et al., 2017). We build our solutions on top of the best pre-trained models provided and suggested by SentenceTransformers. Both models are based on Microsoft MPNet (Song et al., 2020), a pre-training approach that inherits the advantages of BERT's Masked Language Modeling (Devlin et al., 2019) and XLNet's Permuted Language Modeling (Yang et al., 2020) and avoids their limitations, providing better performances.

3 System overview

3.1 Data retrieval

To facilitate re-hydrating the textual content of the news articles, organizers provided a script[3] that downloads the earliest available version of each one of them from the Internet Archive and, only in case of problems, attempt to download them from the original site of publication using newspaper3k. For each article, we obtain the HTML content of the page and a JSON file containing additional information extracted from the page. We select the article's title, body and a brief description as features to feed our LMs.

In populating the dataset, we encountered two main challenges:

- We could not download the complete training dataset due to sites inaccessibility issues or anti-scraping systems. We did not encounter this issue on news articles from the Test dataset;

- The JSON files contains missing and noisy data. We believe that empty, unusable, or obviously incorrect fields are due to the low robustness of newspaper3k when applied to non-standard news websites.

While the first issue is hard to solve *a-posteriori* and could have been tackled by downloading the data as soon as the links were released, we improved the quality of the obtained dataset with Trafilatura[4] (Barbaresi, 2021), an alternative to newspaper3k. Trafilatura is an accurate web scraping tool for text discovery and retrieval that allows to prioritize the precision of the collection, i.e. yielding less but cleaner data.

3.2 Key algorithms

3.2.1 Single-field Language Models

As baseline models, we fine-tuned pre-trained Transformer-Encoder Language Model on a single field. We initialize the LMs with the pre-trained models suggested by SentenceTransformers (Reimers and Gurevych, 2019): a version of MPNet fine-tuned with self-supervised contrastive learning objective over a 1B sentences pairs obtained concatenating more than 20 datasets and trained using a self-supervised contrastive learning objective[5], and a similar multilingual alternative [6]. Every model was downloaded from Huggingface (Wolf et al., 2020).

The selected models are trained to generate, from variable-length input texts, fixed-size dense embeddings that encode semantic similarity: similar documents are mapped to vectors close to each other. We minimize the MSE loss between the cosine similarity of the embeddings obtained from the LMs and the rescaled labels (details about how and why we rescale the original labels in Section 5.1).

We trained the Single-field LMs on the three selected fields independently: Title (T), Description

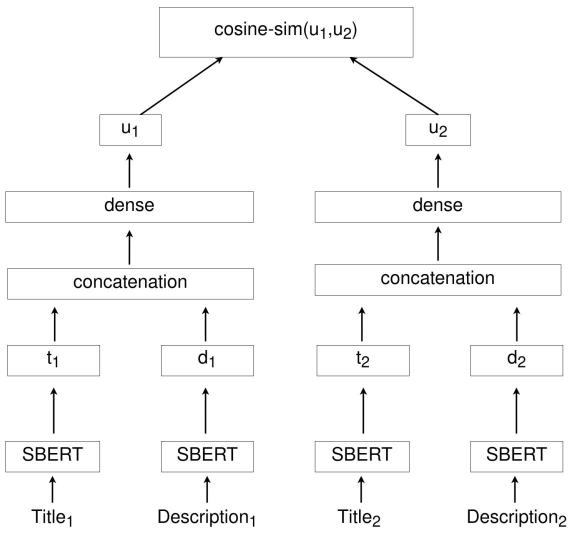

Figure 2: Schema of the two-fields (*title* and *description*) Language Model

(D) and Body (B). We obtain 6 different Single-field LMs, three of them fine-tuned on the original multilingual fields and three on the fields translated to English.

3.2.2 Multiple-fields Language Models

To improve the Single-Field LMs, we design an architecture that can handle multiple textual fields to generate semantically informative dense embeddings. Figure 2 shows the schema of such a model. Firstly, we select two fields (the alternative with the three fields is straightforward), and we feed them into a pre-trained Sentence-LM to generate two dense fixed-size embeddings for each news article (t_i and d_i). Then we concatenate the obtained embeddings, and we feed the result to a single learnable dense layer, initialized with Xavier (Glorot and Bengio, 2010), to generate a 768-dimensional global vector that includes information of both fields (u_i).

We train the model using every combination of two fields (TD, TB and DB) and also using all of them (TDB). We obtain 8 fine-tuned models, four of them fine-tuned on the original multilingual fields and four on the fields translated to English.

As for Single-field LMs, we minimize the MSE loss between the cosine similarity of the embeddings obtained from the LMs and the rescaled labels.

3.2.3 Stacking

Since ensemble learning has proven to be effective in competitions, we perform Stacking (Wolpert, 1992) on sets of the previously described models. We tested as final estimators simple regressors (implemented in scikit-learn (Pedregosa et al., 2011)) such as linear regressors regularized with Lasso (Tibshirani, 1996) or Ridge (Hoerl and Kennard, 2000), ElasticNet (Ela), Support Vector Machines (Cortes and Vapnik, 1995), KNN (Altman, 1992) and shallow Multi-layer Perceptrons (Hastie et al., 2001). Our best model is a MLP with 3 layers, 10 units per layer, trained with Adam (Kingma and Ba, 2015) and learning rate 3×10^{-2}, obtained using 5-fold cross-validation on the validation set.

4 Experimental setup

4.1 Data splitting, cleaning and preprocessing

We partitioned the available training data into two portions using an 80/20 training/test split stratified for language pairs and score (we approximate the labels to their integer part during this step).

We clean our dataset with the following preprocessing approaches:

- We remove duplicated rows. Some of the duplicates pairs obtained different similarity scores, so we replaced them with their mean;
- We detect the right character encoding with cChardet[7], a library to automatically detect the character encodings. Most of the files encoded with rare encodings were Turkish or Arabic news articles (encoded with legacy standards Windows-1254 and Windows-1256 respectively). When cChardet fails to detect the right encoding, we scrape the original website with Trafilatura;
- Some news articles had missing fields. We replace missing descriptions with bodies and missing titles with descriptions.

4.2 Translation

We fine-tuned our models on original data or translated data. Fine-tuning on original data requires a robust multi-lingual model that can compute semantic similarities regardless of the language of the documents. Fine-tuning on data translated to English requires an accurate Neural Machine Translation (NMT) model. We believe that Stacking both alternatives improves the overall performance since the final prediction relies on the strengths of both.

[7]https://github.com/PyYoshi/cChardet

We translated the whole dataset using EasyNMT[8] , a container of different NMT models. In particular, we used the Opus-MT (Tiedemann and Thottingal, 2020) model provided by the Helsinki NLP group.

4.3 Hyperparameters

Every LM was fine-tuned using the default optimizer (AdamW) with learning rate 2×10^{-5} and weight decay 0.01, using 10% of train iterations as warm-up. We trained the models for 3 epochs on our Training set, and we select the best model as the one that maximizes the Pearson Correlation Coefficient on the Validation set. Every experiment was performed using Colab (Bisong, 2019).

4.4 Evaluation measure

We evaluate our models using Pearson Correlation Coefficient of the cosine similarity between the embeddings generated by the models and the similarity manually scored by annotators. The scores ranges from 1 (perfect positive correlation) to -1 (perfect negative correlation), where 0 represents uncorrelated data.

5 Results and Ablation

Table 1 shows the results of our models. We obtain the best performing model on the Test set by Stacking 3 carefully selected Single-field Models fine-tuned respectively on translated titles, translated bodies and original bodies. The final estimator is a MLP with 3 layers and 10 units per layer as described above.

However, we obtained our best *submitted* prediction using our best performing model on the Validation set: a Stacking of all Single-field and Multiple-fields LMs, with the same final estimator as before. This model allowed us to score fourth in the original leaderboard that includes the best performing model for each team, and sixth on the official ranking[9].

Table 1: Pearson's $r \times 100$ on Validation and Test Datasets. We indicate with T the title, D the description and B the body of the articles. A stands for title, description and body, both original and translated, both obtained with Single-field and Multiple-fields approaches. The subscript t indicates translated texts. Values marked with † refer to the models evaluated with 5-fold crossvalidation on the validation dataset. All fields are truncated at 256 tokens except when specified with a subscript. The model marked with * was not submitted before the end of the competition.

The first part of Table 1 reports the results of the six Single-field LMs. As expected, the model fine-tuned on the body (B) of the news articles, the longest, thus most informative field, obtained the best results, both in the Validation and Test set. Models fine-tuned on the description (D) perform worse, probably due to the higher noise of the field (i.e., sometimes the content was missing or contained general information about the journal or the website). English models (reported as MPNet to highlight their initialization model) trained on translated data generally perform better than multilingual models (reported as M_MPNet) trained on original data.

The second part of the table reports the results of the six Double-fields LMs and the two Triple-

[8]https://github.com/UKPLab/EasyNMT

[9]The final ranking was computed using a bootstrapping approach across teams' submissions. This approach assumes that multiple submissions by the same team represent an exploration of the hyper-parameter/model configuration space. This approach allows the organizers to estimate the general performance of the proposed models. However, the organizers announced this evaluation procedure after the end of the competition. We remark that the assumption does not hold for our team, and penalizes us on the final leaderboard. To get an idea of the overall test performance, several submissions from our team, especially at the beginning of the challenge, were generated with simple (sometimes even not fine-tuned) models. Moreover, due to technical problems of the challenge, we submitted opposite predictions from the same model to be sure that at least one scored correctly.

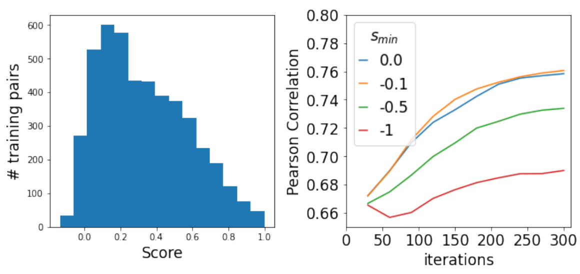

Figure 3: (*left*): Distribution of scores of pairs of titles from training set. (*right*): Pearson correlation during training for different values of s_{min}.

fields LMs. Combinations and interactions of fields give performances worse than our best performing Single-field LMs (MPNet on Body). We believe that this degradation of performance is due to two main factors. First, the noisiness of the title and description, as a higher percentage was missing or wrong. Second, due to memory issues, we had to perform Multiple-field LMs training reducing the maximum length of the body to 256 tokens instead of 512, as used when training Single-field LMs.

The third part of the table shows performances of our best four Stacking models. We evaluated many final estimators and combinations of first estimators and we submitted the scores from the models that performed better on our validation set. We computed the validation performance of stacking models using 5-fold cross-validation on the original validation dataset.

Finally we report the performance of the best team that participated to the competition. Up to now we do not know details about their approach.

5.1 Label rescaling

When we train our models we have to linearly scale the labels from the original range [1, 4]. While the straightforward choice of the final range could be [-1, 1] since our scores naturally fits that range due to the nature of the final cosine similarity computation, we observe that in practice, there are no pairs of titles from the training dataset that score less than -0.15 when we use a pre-trained model (see Figure 3 (left) for the complete distribution). Thus, we treat the lower bound of the transformed range s_{min} as an hyper-parameter to set. Figure 3 (right) shows values of Pearson Correlation on the validation dataset during the first training epoch for different choices of this parameter. We noticed that setting $s_{min} = -1$ as previously hypothesised leads to a slow training phase. We find $s_{min} = -0.1$ the best value among the tested ones. On the contrary, setting the higher bound $s_{max} = 1$ is optimal.

pl-en	87.1
fr-pl	88.3

Table 2: Pearson's $r \times 100$ of our best model on subsets of the Test dataset.

5.2 Error analysis

We report in Table 2 the performance of our best model for each language combination of the Test set. We believe that lower correlations are due to scraping issues, translation issues and to the different distribution of languages between the Training and Test sets.

6 Conclusion

To quantify the similarity between news articles, we propose an approach trained exclusively on the extracted textual data. We initialize our architecture with SOTA Semantic-Similarity Language Models, which we fine-tuned on titles, descriptions and texts of the articles. We also design a simple variant to process many textual fields at once. Finally, we perform stacking with a simple MLP, as it was proved to improve the overall performance of models trained on different features. Results show how the approach successfully estimated similarities since the main sources of error involved missing or wrong data.

Abstract

We present a system that creates pair-wise cosine and arccosine sentence similarity matrices using multilingual sentence embeddings obtained from pre-trained SBERT and Universal Sentence Encoder models respectively. For each news article sentence, it searches the most similar sentence from the other article and computes an average score. Further, a convolutional neural network calculates a total similarity score for the article pairs on these matrices. Finally, a random forest regressor merges the previous results to a final score that can optionally be extended with a publishing date score.

1 Introduction

The goal of the *Multilingual News Article Similarity* task (Chen et al., 2022) is to check pairs of multilingual news articles against each other in terms of similarity of their information content. The challenge focuses on *what* is talked about (time, geolocation, shared entities), not *how* the information is expressed (writing style, emotional tone, etc.), which is essential for applications such as analyzing the news coverage between different regions. The participants' objective is the creation of a model that rates the similarity of article pairs on a 4-point scale from most (1) to least (4) similar and achieves the highest possible Pearson correlation score compared to the gold standard. The languages covered by this competition are English (en), German (de), Spanish (es), Turkish (tr), Polish (pl), French (fr) and Arabic (ar) in the training, additionally Italian (it), Russian (ru) and Chinese (zh) in the evaluation.

Our system uses an ensemble approach to score pair-wise sentence similarity matrices of the article pairs, which are created with SBERT and Universal Sentence Encoder sentence embeddings. Scores are obtained through simple matrix operations and our convolutional neural network *SimCNN* based on the TextCNN by Kim (2014). Finally, a random forest regressor (Breiman, 2001) consolidates the individual scores into a final result, which we extend with a publishing date score.

The key challenge of this task is the usage of multilingual text pairs, which requires the application of less precise multilingual language models. Also the splitting of sentences and named entity recognition becomes hard to accomplish, since models for these tasks are still monolingual in most cases and we found the few multilingual ones to be unreliable. The article scraping tool provided by the authors also did not reveal meaningful features to work with besides the article title and text, since the scraped keywords, tags and publishing dates were not always available and in a utilizable format.

In the competition, we took 9th place with a Pearson correlation coefficient of 0.759 on the evaluation set, which differs from the observed performance on our own validation sets. This is due to a shift from Latin languages to more complex languages like Chinese in the evaluation data, where the performance of the multilingual models and sentence tokenizing algorithm decreases. Our code is publicly available[1].

2 Background

The starting point of the task is the training data — a CSV file — which contains a list of article pairs[2]. Each article pair consists of the languages, IDs and URLs for both articles and the gold standard similarity scores for multiple aspects of the articles (Geography, Entities, Time, Narrative, Style, Tone, Overall), of which only the overall score is relevant for our evaluation.

To get the content and metadata of the articles,

[1] https://github.com/simontrapp/semeval-22-task-8

[2] We used the most recent version 0.2 with 4,964 labeled article pairs.

the task authors provide a scraping tool[3] utilizing the *newspaper3k* python package that downloads the HTML page and creates a JSON file that contains the title, text, keywords, labels, date, and more properties of each news article. For the training of the prediction system on the JSON files, the results can be compared against the overall scores in the initial CSV file. The final evaluation data CSV, for which the results are submitted, does not provide scores to compare against.

3 Related Work

For the scoring of our similarity matrices in subsection 4.4, we use an idea from Ginzburg et al. (2021), who introduce Self-Supervised Document Similarity Ranking (SDR), an unsupervised approach built upon the RoBERTa language model to rank the semantic similarity of a collection of documents to a source (query) document. SDR captures the intuitive fact that for each sentence or paragraph in one document, there should be at least one similar one *anywhere* (obtained by a *max* operation on the rows and columns of the similarity matrix) in the other document if both deal with the same topic. Since SDR is monolingual and is only trained on English texts, we combine its scoring approach with multilingual embeddings obtained from SBERT (Reimers and Gurevych, 2019) and Universal Sentence Encoder (Cer et al., 2018) for this challenge.

4 System Overview

Our system (see Figure 1) first splits the article text into a list of sentences including the title. Then we compute embeddings with SBERT and Universal Sentence Encoder for all sentences and create the respective similarity matrices (similarity of all sentences of one article to all sentences of the other) of all article pairs. In the next step, we apply two different scoring approaches to these matrices: First, we apply simple maximum and average operations to the two matrices for four similarity scores, as proposed by Ginzburg et al. (2021). Second, we feed the matrices into our *SimCNN* to increase score accuracy (see Appendix C). Finally, we combine the five scores into a final score with a random forest regressor to get a stable prediction. Optionally, an additional score for the publishing date distance of both articles can be computed and merged with the random forest result to refine the prediction.

[3]`https://github.com/euagendas/semeval_8_2022_ia_downloader`

4.1 Preparation of Article Data

We decided that only the title and the text of the article should be relevant for our model, since other features such as keywords, tags or publishing date of the articles are not always available or feasibly retrievable. We use the `sent_tokenize` function of the `nltk` python package to split the text of both articles into a list of sentences and append their title strings to the respective list. This allows us to feed text of arbitrary length into the embedding models.

4.2 Creation of Embeddings and Similarity Matrices

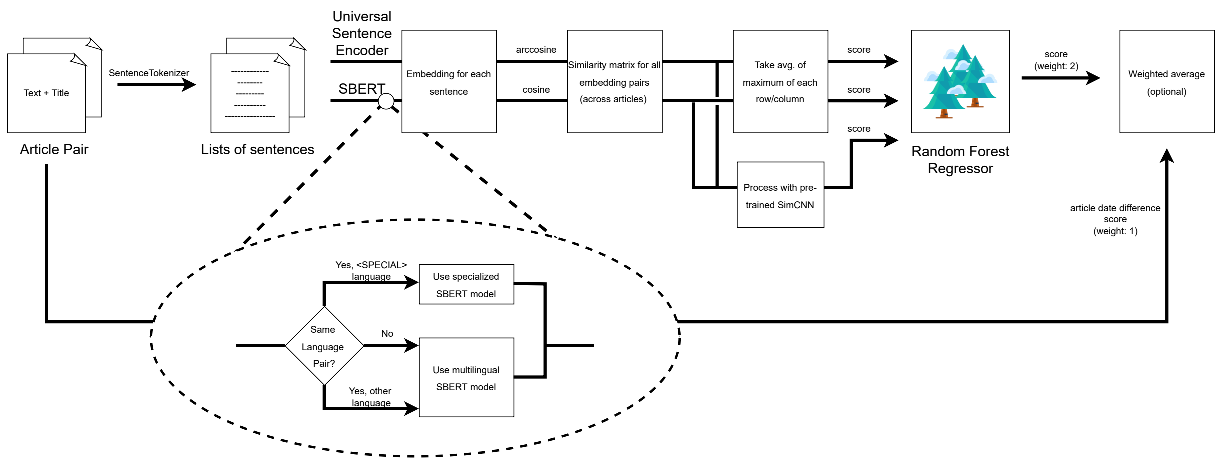
For all sentences in the lists, we create two separate sets of sentence embeddings:

The Universal Sentence Encoder (Yang et al., 2019) always uses the same pre-trained model (see subsection 5.2) to create the embeddings, for which we calculate the recommended *arccos*-based text similarity (Yang et al., 2018), that converts the cosine values into angular distances in $[0, \pi]$ pair-wise between all sentences of both articles.

For SBERT, the model that is selected to create the embeddings depends on the languages of both articles: If both are the same and a model with better performance than the multilingual one is known (see subsection 5.2), this model computes the embeddings for both articles, otherwise the default multilingual model is used. The pair-wise similarity matrix between article sentences is created analogously to the Universal Sentence Encoder, but with cosine similarity instead of *arccos*, because SBERT was optimized for it.

4.3 Architecture of SimCNN

The architecture of our CNN is based on the architecture by Yoon Kim for CNNs for text processing (Kim, 2014) (detailed layer information in Appendix A). As input, we use both precomputed sentence embeddings from the SBERT and the Universal Sentence Encoder model of two articles with lengths x and y. Further, we calculate one similarity matrix from both the SBERT and the Universal Sentence Encoder embeddings since tests have indicated an increased performance using this input. Finally, the input of the CNN is an $x \times y \times 2$ matrix, generated by concatenating the SBERT and the Universal Sentence Encoder similarity matrices. Due to this input, we named our network *SimCNN*. However, the CNN requires



Text + Title
Article Pair
SentenceTokenizer
Lists of sentences
Universal Sentence Encoder
SBERT
Embedding for each sentence
arccosine
cosine
Similarity matrix for all embedding pairs (across articles)
Take avg. of maximum of each row/column
Process with pre-trained SimCNN
score
score
score
Random Forest Regressor
score (weight: 2)
Weighted average (optional)
article date difference score (weight: 1)
Same Language Pair?
Yes, <SPECIAL> language
No
Yes, other language
Use specialized SBERT model
Use multilingual SBERT model

Figure 1: The data flow of the article pairs from raw text to the final score. If both articles are written in the same language, we use an SBERT model that is better than the default multilingual one, if one exists (see subsection 5.2).

a fixed input size within the y-dimension, so we set y to 100 (using zero-padding if $y < 100$ and cropping if $y > 100$). We chose $y = 100$ based on analysis that indicates only a few articles have longer sentence lists and do not set it to the maximum sentence list length since broken lists with up to 1500 sentences can occur.

Adapted from the TextCNN of Yoon Kim, the network consists of seven different convolutions with kernel size $w \times 100$ with $w \in \{2, 3, \ldots, 9\}$, and 128 filters, named sliding window. For extended feature extraction, we added two convolutional blocks before each sliding window SW_w, consisting of five convolutions. Thereby, each convolution of a block SW_k uses a kernel size of $w \times w$, the same padding, and 32 filters within the first block and 64 within the second. Furthermore, each convolution follows a ReLU6 activation and a batch normalization layer and, additionally, a dropout layer ($probability = 0.25$) after the 2nd and 4th convolution. After each sliding window convolution, a max over time pooling extracts the best feature of each filter, so we get a output vector of size 128. Afterwards, a separate linear layer is applied to each vector(mapping to 128 features), followed by another dropout ($probability = 0.5$) and a ReLU6 layer.

For the final prediction, we concatenate all vectors of the different sliding windows to one vector of size 1024 that is fed into five consecutive linear layers. Thereby, the output size for each linear layer is half the input size and every layer uses a ReLU6 activation function and, additionally, a dropout layer ($probability = 0.5$) every second time. Finally, a linear layer with an input size of 32 and output size of 1 predicts a score $s \in [0, 1]$ using a sigmoid activation function. This score is scaled to our target values $s \in [1, 4]$ subsequently.

4.4 Ensemble Scoring of Article Similarity

In addition to being fed into the SimCNN, the *arccos* and *cosine* similarity matrices of the article pairs are processed by taking the average over the maximum value of each row/column of the matrix, similar to the approach by Ginzburg et al. (2021) in section 3. The maximum values yield the most similar sentence in the other article for each sentence and the average operation acts as a proportion of how many sentences of one article share statements with the other article. By doing this for both rows and columns, we obtain two scores for both articles respectively. Figure 2 visualizes this process.

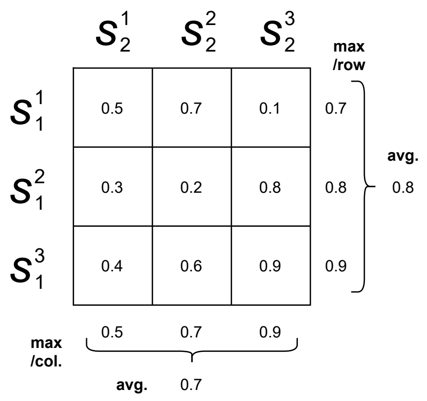


Figure 2: Example of the scoring operation on the *arccos* and *cosine* sentence similarity matrices. The superscript number denotes the number of the sentence in the document, the subscript number marks the document number of the sentence.

Finally, the four matrix scores (article similarity SBERT 1-to-2 and 2-to-1, Universal Sentence Encoder 1-to-2 and 2-to-1) and the SimCNN score are fed into a random forest (Breiman, 2001) regressor from the `scikit-learn` Python package[4]. The forest uses the results of 100 different trained decision trees and takes the average of their predictions, which is the final score reported back by the model.

4.5 Integration of a Publishing Date Score

We also compute scores based on the publishing date distances of each article pair (if available) for the reason that the further the publishing dates are apart, the more likely the articles are about different topics. In accordance with the 4-point score used for the text scoring, we use 10, 20, and 50 days as the boundaries, meaning the score would be ignored if the difference is less than 10 days, between 2 and 3 if the difference is between 10 and 20 days, between 3 and 4 if the difference is between 20 and 50 days, and a hard 4 for a difference of more than 50 days.

If a date score can be calculated and is not ignored, a weighted average of the random forest score (weight 2) and the date score (weight 1) is returned as a final result, otherwise the random forest score is returned. The 10, 20, and 50 day boundaries, as well as the weights, were determined based on experiments on the training data.

5 Experimental Setup

After outlining the model components and their interactions in the previous section, here we cover the data sets, experiments and training processes used to configure the separate parts of the system. The sole evaluation metric for this competition is the Pearson correlation coefficient r (Pearson, 1896; Lee Rodgers and Nicewander, 1988), which describes the linear association between two related variables X and Y. A score close to -1 or 1 implies that a linear equation can express the relationship between the two variables almost perfectly, while a score of 0 indicates no correlation.

5.1 Validation Data Sets

The only labeled data available for training are the 4,964 article pairs provided by the task authors. We reserve a static 10% subset of the training data consisting of 470 pairs of diverse language combinations for our model validation in Table 2, Appendix D and the following experiments. The other 90% of the data are used for the actual training.

5.2 Selection of Pre-Trained Models

The pre-trained multilingual SBERT model *paraphrase-multilingual-mpnet-base-v2* performed best overall on the validation set, so it is used as the default model. We could improve the accuracy for some same-language article pairs by using specialized pre-trained models (**en-en**: *all-mpnet-base-v2*, **es-es**: *distiluse-base-multilingual-cased-v1*, and **fr-fr**: *sentence-transformers/LaBSE*). For Universal Sentence Encoder we used version 3 of the model *multilingual-large*.

5.3 SimCNN Pre-Training

The presented model was implemented in python using `PyTorch` (Paszke et al., 2019) and trained on a consumer graphics card. For updating the parameters in the network, we employed the Stochastic Gradient Decent optimization algorithm using a learning rate of 0.05 with a batch size of 8. Mean squared error was used as the loss function, and additionally, we monitored the mean average error and the Pearson correlation coefficient for performance evaluation. We used early stopping with a patience of 20 epochs to prevent overfitting, so the network was saved when no longer improving in terms of the Person correlation coefficient. Eventually, our network was trained around 30 epochs before overfitting.

5.4 Random Forest Regressor Pre-Training

After the training of the SimCNN model, five similarity scores per article pair of the training data are available through our model pipeline: Two scores for both the SBERT and Universal Sentence Encoder matrices and the SimCNN score. These scores are fed into a random forest (Breiman, 2001) regressor[5] with the provided *Overall* scores of the training data as labels. The random forest is populated with 100 decision trees and uses the squared error as the optimization criterion. Appendix C shows how the performance of the model increases as we provide more data.

Model	Pearson r	
	Validation	Evaluation
SimCNN	0.800	0.699
RF	0.797	0.702
RF + Date	0.800	0.715

Table 2: Performance of our models on our validation set and the final evaluation data. The random forest (RF) is able to improve over just the SimCNN on the evaluation data when combined with the date score.

6 Results

Our system ranked 9th place in the competition with a Pearson score of 0.759.

To find the best models for submission, we tested the three last stages of our system on the aforementioned validation set separately: Just the SimCNN score, the prediction of the random forest regressor and the weighted average of the random forest score and the publishing date score.

The results in Table 2 indicate that the random forest regressor replicates the results of the SimCNN and barely considers the additional information provided. The combination of the random forest with the publishing date score on the other hand improves the results. Further, our models generally predict perceptibly worse scores on the evaluation data than on the training data split.

The language distribution in Appendix B shows a shift from Latin languages and article pairs to vastly different and more complex languages: Chinese-Chinese article pairs account for over 15% of article pairs in the evaluation data. Russian, Polish and Arabic articles also occur often, frequently in combination with other article languages such as English, French and German. This leads to problems in the preparation of the article texts for our system because our sentence tokenizer only supports English or similar texts and many of the new languages have a different structure and alphabet.

When taking a look at the performance per language pair of our model in Table 1, another reason for the score drop-off between training split and evaluation data becomes apparent: The commonly occurring Chinese-Chinese article pairs perform bad with a Pearson score of 0.64. Also, other combinations which previously did well on the split of the training data gave significantly worse results on the evaluation set, indicating that maybe the quality or structure of the new data differs from the earlier samples. Interestingly, our system improved on the English-English evaluation pairs.

All things considered, we achieved satisfying results with just slightly modified publicly available models to create sentence embeddings and a CNN to work with them. The system only depends on an article's text, title and sometimes the publishing date, if it is available, and is still able to achieve a Pearson correlation score of about 0.6 even for the most difficult examined language.

7 Conclusion

Pair-wise sentence comparison is a simple way to calculate the similarity of texts of arbitrary length if suitable multilingual models for sentence embeddings are available. With simple matrix operations like taking the maximum or average and a random forest regression algorithm, good results can be achieved. After introducing the more complex SimCNN and combining it with a score of the publishing dates of the article pairs, our model surpassed a Pearson correlation coefficient of 0.8 in some conditions.

Nevertheless, the current state of the system leaves many things to be improved: The sentence tokenizing currently only reliably works for English and similar languages. With a sentence splitting algorithm, that is capable of differently structured languages like Chinese or Japanese, results on such articles could be greatly improved. Further, our pair-wise sentence similarity matrix approach could be extended to named entities like locations and persons, which we think would also greatly improve accuracy, but for that, a more sophisticated multilingual algorithm for named entity recognition would be needed.

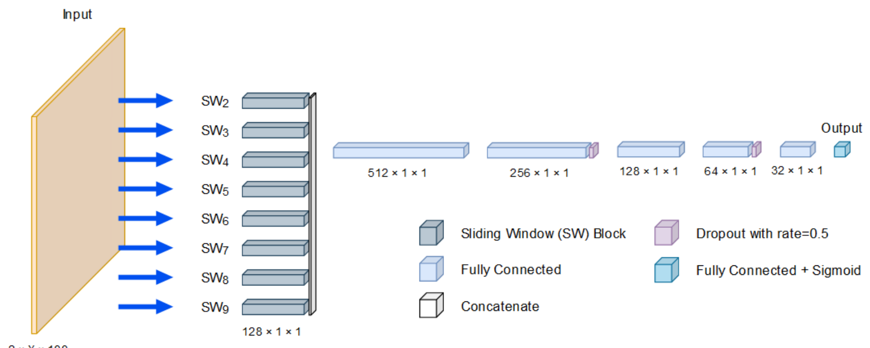
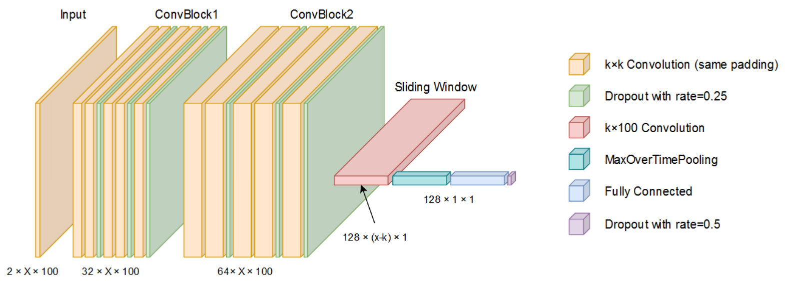
A Architecture of SimCNN



(a) SimCNN



(b) Sliding Window Block with size k

Figure 3: Architecture and methods of the SimCNN based on the TextCNN described by Kim (2014).

Figure 3a shows the architecture of the SimCNN. The SimCNN is based on the architecture by Yoon Kim for CNNs for text processing (TextCNN) (Kim, 2014). It consists of seven sliding window blocks SW_w with window size $w \in \{2, \dots, 9\}$. Each block SW_w receives the input of size $2 \times x \times 100$ and is structured as illustrated in graphic 3b. First, two convolution blocks, with five convolutions each, are applied to the input. Each convolution of SW_w has a kernel size of $w \times w$ and uses same padding. The convolutions of the first block have 32 filters and the ones of the second block 64. After a convolution, first, a ReLU6 activation layer is applied and, subsequently, a batch normalization layer. Furthermore, after the second, fourth and last convolution, a dropout is executed with a probability of 0.25. Afterwards, the sliding window convolution is applied, using a kernel size of $w \times 100$ and 128 filters, followed by a ReLU6 and a batch normalization layer. Next, a MaxOverTime pooling layer extracts the best feature of each filter. Last of the sliding window block, a fully connected layer using a Relu6 activation function, followed by a dropout with a probability of 0.5, maps to a feature vector of 128 features.

After all sliding window blocks $SW_2, \dots, SW_9$, the outputs are concatenated to a feature vector of 1024 features. Five fully connected layers with output sizes 512, 256, 128, 64 and 32 are applied to this vector. A Relu6 is used as activation function after these layers, and a dropout is performed after the second and fourth layer with a probability of 0.5. Finally, a fully connected layer maps the feature vector to one number, that is processed in a sigmoid function, to get the score $s \in [0, 1]$

B Language Distributions of Data Sets

	en-en	de-de	de-en	es-es	tr-tr	pl-pl	ar-ar	fr-fr
Absolute Count	1800	857	577	570	465	349	274	72

Table 5: Pearson correlation score of our model configurations on different language pairs. They often do perform significantly better on the validation data (V) than on the evaluation data (E) and seldom vice versa. The additional languages in the evaluation data do not perform noticeably worse than some of the languages already seen in the training set.

SemEval-2022 Task 9: R2VQ – Competence-based Multimodal Question Answering

Abstract

In this task, we identify a challenge that is reflective of linguistic and cognitive competencies that humans have when speaking and reasoning. Particularly, given the intuition that textual and visual information mutually inform each other for semantic reasoning, we formulate a Competence-based Question Answering challenge, designed to involve rich semantic annotation and aligned text-video objects. The task is to answer questions from a collection of English language cooking recipes and videos, where each question belongs to a "question family" reflecting a specific reasoning competence. The data and task result is publicly available. [1]

1 Introduction

One of the fundamental goals of Artificial Intelligence (AI) has been to create systems that interact with human users fluently and intelligently, by demonstrating inferencing and reasoning capabilities that would be expected of a human partner. This includes a growing interest in posing larger challenges to end-to-end systems employing architectures with deep neural networks (DNNs) (Ribeiro et al., 2020; Prabhumoye et al., 2020; Rogers et al., 2021; Minaee et al., 2021). Here we argue that we should start focusing on linguistic *competencies*, and not just on Question Answering (QA) skills or "challenge checklisting". There are some moves in this direction already (Johnson et al., 2017), but there is still no generally accepted distinction in current Natural Language Processing (NLP) between challenge-based tasks and competence-based performance (Bentivogli et al., 2017). Analogous to human cognitive competencies, there is both a methodological and modeling advantage to focusing a system's performance on competence-based learning rather than a narrowly defined task or challenge checklist.

First we define competence-based knowledge, and then the questions that can be generated from such knowledge. While Chomsky (1965)'s distinction between competence and performance has long been debated in linguistics, the term *competence-based* has been applied to a number of different concepts in both the science of learning and educational communities (Bechtel et al., 1999; Voorhees, 2001; Chyung et al., 2006; Platanios et al., 2019; Hsiao et al., 2020). The common core to both is a concept capturing a coherent set of abilities that an individual has in a specific domain (Doignon and Falmagne, 1985; Heller et al., 2013).

Here we focus on *lexical competence* as deployed in both single and multiple sentence composition (Pustejovsky, 1995; Marconi, 1997; Geeraerts, 2009; Asher, 2011). A competence-based question will query competence-based knowledge structures. For this task, lexical competence will involve the following:

- Understanding implicit arguments that are not present (due to syntactic ellipsis or semantic defaulting or shadowing), and being able to use this (missing) information to formulate knowledge about the event or situation (Malmaud et al., 2014; Kiddon et al., 2015);
- Understanding the dynamics of the text or narrative and how events can change an object or contribute to new properties (and subsequent descriptions) of objects in the text (Tandon et al., 2018; Das et al., 2018; Brown et al., 2018).

It is clearly the case that these two phenomena require non-extractive QA capabilities of some sort. We describe our dataset, Recipe-to-Video Questions (R2VQ), and summarize the procedures implemented by task participants for answering such

[1]https://competitions.codalab.org/competitions/34056

questions in the remainder of the paper.

2 Overview

2.1 Summary of the task

The task is structured as QA pairs, querying how well a system understands the semantics of English language recipes.

We hope that this task will help move NLP system design and evaluation towards the construction of meaning representations involving linguistic and multimodal situated grounding. In the present context, this involves identifying cooking entities and activities from recipe text, as well as linking them to videos of related recipes, entities, and activities.

Participants are provided with a multimodal training set, and are asked to provide answers to unseen queries. These questions can be answered using a unimodal dataset of text recipes and associated annotations. Participants are also encouraged to explore the full multimodal training set with additional cooking videos to potentially improve the results from the unimodal models. Following SemEval guidelines, the R2VQ dataset is publicly available[2] in CONLL-U format, with annotations encoded in plain text files.

2.2 Impact of the task

When we apply our existing knowledge to new situations, we demonstrate a kind of understanding of how the knowledge (through tasks) is applied. When viewed over a conceptual domain, this constitutes what we will refer to as a *competence*, and the corresponding challenge can be called a competence-based challenge. Competence-based evaluations can be seen as a new approach for designing NLP challenges, in order to better characterize the underlying operational knowledge that a system has for a conceptual domain, rather than focusing on individual tasks.

3 Related Work

NLP challenges have helped drive progress in the field recently. These challenges in part have been framed as specific tasks, and advances are largely driven by leaderboards on benchmark datasets or model comparison on individual datasets. Common benchmarks such as GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) have been used widely. They contain several language understanding tasks such as Winograd Natural Language Inference (WNLI) (Levesque et al., 2011) as an inference task, and Winograd Schema Challenge (WSC) (Levesque et al., 2011) as a coreference resolution task. A survey (Rogers et al., 2021) showed the recent trend to measure various machine reasoning capabilities using different designs of QA tasks.

While all the tasks aim to advance the research towards corresponding NLP challenges, whether these reflect human competencies remains a question, especially in recent years with the success of transformers (Devlin et al., 2019; Yang et al., 2019; Liu et al., 2019). Many top-ranked NLP models that have shown better performance than humans on benchmarks may have come from overfitting to the dataset rather than addressing the challenge (Rogers, 2019). Current pre-training paradigms may also tune models towards capturing merely statistical patterns, so datasets should be designed to align the model's ability with human expectations (Linzen, 2020). Sugawara et al. (2020) found that most of the questions from common QA and reading comprehension datasets can be correctly answered by models without complex reasoning.

Recent work has been trying to identify and evaluate the tasks that are reflective of human linguistic and reasoning competencies. For example, Kim and Linzen (2020) proposed a semantic parsing dataset that evaluates the human-like compositional generalization of models. Ribeiro et al. (2020) designed three test types that can be used to test various linguistic capabilities of NLP models. More closely related to our work, QA-SRL (He et al., 2015) use predicate-argument structure to represent QA pairs. SynQG (Dhole and Manning, 2021) and RoleQ (Pyatkin et al., 2021) try to incorporate existing semantic annotations to generate comprehension questions.

4 Task Description

We formulate the task as competence-based QA, designed to involve rich semantic annotation and aligned text-video objects. The goal of this task is to answer questions from a collection of cooking recipes and images. Each question belongs to a "question family" that characterizes a specific reasoning competence to be tested. These competencies include abilities such as spatial and temporal reasoning, semantic role assignment, and object

[2] https://competitions.codalab.org/competitions/34056#participate

Recipe Title: **Appelkoek** *Passage:* Peel and cut apples into eighths (wedges). Sift together flour, baking powder and salt with 4 tablespoons of the sugar. Cut in butter. Combine egg and milk and add to flour mixture. Turn batter into greased 8 inch square cake pan. Press apple wedges partly into batter. Combine remaining 2 tbsp sugar and cinnamon. Sprinkle over apple. Bake at 425 degF for 25 to 30 minutes.

IMPLICIT	How do you cut apples into wedges? - by using a knife
ELISION	What should be sprinkled over apple wedges? - cinnamon sugar
LOC. CHANGE	Where was the batter when you press apple wedges? - in the pan
OBJ. LIFESPAN	What's in the appelkoek? - apples
SRL-TIME	For how long should you bake appelkoek? - 20 to 35 minutes
SRL-VALUE	How do you bake appelkoek? - bake at 425 degF

Table 1: Example competence-based questions. Color-coded text spans represent how information has been collected and generated in the questions.

cardinality and counting.

We adopt the concept of "question families" as outlined in the CLEVR dataset (Johnson et al., 2017). While some question families (e.g., integer comparison, counting) naturally transfer over from the Visual Question Answering (VQA) domain (Antol et al., 2015; Zhu et al., 2016), other concepts such as ellipsis and object lifespan must be employed to cover the full extent of competency within procedural texts. On the basis of the aforementioned competencies, we categorize the questions into five question families. Table 1 shows the definition of each question family as well as sample questions.

The question families are defined as follows:

- *Cardinality*: covers concepts of integer comparison and counting.
- *Elision*: deals with identifying arguments (ingredients in most cases) that are omitted from a text, but can be understood from context.
- *Implicit*: covers both implicit tools and habitats introduced in the text. This is distinct from elision, as these are not solved merely through contextual clues. Instead, they require general competence; applying world knowledge of an action and its requirements to a novel situation.
- *Obj. Lifespan*: covers different states of an object in a cooking event.
- *Semantic Role Labeling (SRL)* covers semantic roles that are modifiers to a cooking event.

5 Data and Resources

The textual component of our dataset consists of a collection of English language recipes sourced from two open-source recipe wikis, Recipe Fandom[3] and Foodista[4], and is labeled according to three distinct annotation layers: (i) Cooking Role Labeling (CRL), (ii) Semantic Role Labeling (SRL), and (iii) aligned key frames image triples taken from creative commons cooking videos downloaded from YouTube.

Compared to text of news or narratives, procedural text such as recipes and user manuals tend to be task-oriented, and the main content is split into steps that describe small goals to accomplish the final task. We believe such texts are a good fit for our task, as it involves the understanding of how to reach the goal locally for each step, as well as how each step contributes to the final task globally. Further, the step-wise progression inherent in the goal-oriented narrative contributes both an interpretative dynamics as well as contextualized elision of arguments.

5.1 Train/Dev/Test Datasets

There are 1,000 recipes released as part of the task (800 for training and 100 each for validation and testing). Table 2 shows the basic statistics of the dataset. We exclude any "less informative" recipe that has less than 4 sentences from our dataset. For each recipe, there are an average of 35 questions (5 from each question family). Each recipe is also paired with an additional set of 10 "unanswerable" questions (answers that cannot be found in a given recipe) as negative samples.

5.2 Cooking Role Labeling

Cooking Role Labeling (CRL) is a domain-specific dependency relation annotation for the cooking domain. CRL is done via a two-phase annotation. First, to identify mentions of cooking events and

Figure 1: Docanno environment for event and entity annotation.

entities and put labels on them, and then to establish relations between those mentions.

Each step in a given recipe is annotated for cooking-related *events* and the associated *entities* (ingredients and props such as tools, containers, and habitats). The ingredients can be either labeled as explicit (those listed in the ingredients section of the recipe) or implicit (intermediate outputs of applying a cooking action to a set of explicit ingredients).

We post-process the data by running the Stanza pipeline (Qi et al., 2020) on the raw text of each recipe to get tokenization and other basic linguistic features including word lemmas, part-of-speech tags. We took a semi-automated approach to performing the span-level entity annotations. First, using a small labeled dataset as seed training data, we trained a character-level named entity recognition (NER) model using Flair embeddings (Akbik et al., 2019) to pre-annotate the recipe text. We then validated the model predictions using the Docanno annotation tool (Nakayama et al., 2018) to create our gold set of event and entity mentions. Figure 1 shows an example from the Docanno environment, with annotations for Event, Implicit Ingredient, and Habitat.

For the next phase of annotation, we developed Deep Event & Entity Palette or DEEP, a specialized annotation environment to manually annotate cooking role relations. Annotators start from documents that are already annotated with span-level entity tagging from Docanno. The primary job of annotators is to draw links between entities (coreference) or between an entity and an event (participant). DEEP provides an intuitive and easy interface for pairwise linking annotation, as well as a holistic view of the document-level context using color coding of tokens related to the selected events or entities, as shown in Figure 2. All annotation is done at document-level, namely, annotators can create long distance links. For example, a food entity from a previous step can be linked to an event in the next step even if the direct object of the event is omitted on surface (or "hidden"). And finally, DEEP also provides an interface to add such hidden entities with a free-text identifier and immediately link it to an event.

More specifically, event-entity links can be one of several possible link tags, which can be made between explicit spans of text or between an event and a hidden entity that does not explicitly appear in the recipe text. These relations are:

- **Ingredient**: identifies the food material that participates in cooking events.
- **Result**: identifies entities produced as the output of an event.
- **Tool**: relates objects with the events they are used in. Tools may appear in the text ("Cut the pear with a sharp knife"), or they may be hidden ("Cut an apple" requires an unmentioned knife).
- **Habitat**: links events with the objects in which they take place. Habitats may appear in the text ("Bake in a preheated oven"), or they may be hidden ("Saute the onion" requires an unmentioned pan).

Table 3 shows the statistics of cooking role annotation on the dataset. EVENT should always be explicit, while the other cooking roles can be either explicit text spans or hidden entities. We hired 8 student annotators for the CRL annotation work. All annotators were students at Brandeis University, ranging from undergraduate to master's level.

5.3 Semantic Role Labeling

Aside from the above-described annotation layer, which is tailored to highlight domain-specific events and entities, each step in the recipes featured in R2VQ is automatically tagged and manually validated according to the predicates and constituents identified at the Semantic Role Labeling (SRL) level, i.e., the task of identifying and labeling predicate-argument structures within a sentence (Gildea and Jurafsky, 2002). More specifically,

Table 3: Statistics of cooking role annotation on R2VQ.

each recipe step is semantically enriched by (i) identifying all its predicates, i.e., those words or multi-word expressions that denote an event or an action, (ii) assigning the most appropriate sense label to each identified predicate according to a predefined inventory, (iii) detecting all the arguments, i.e., the parts of the text that are semantically related to each predicate, and (iv) choosing the most fitting semantic role for each predicate-argument pair. Let's consider the example "John bakes potatoes". In this case, SRL consists of (i) identifying "bake" as a predicate, that is, something that denotes an action or an event; (ii) disambiguating the predicate, that is, assigning the most appropriate sense for "bakes" in this context; (iii) identifying the arguments of each predicate, that is, those parts of the text, "John" and "potatoes" that are semantically linked to "bakes"; and (iv) assigning a semantic role to each predicate-argument pair, e.g., "John" is the *Agent* of the predicate "bakes", whereas "potatoes" is the *Patient*.

In SRL, there are two main annotation formalisms for tagging arguments: span-based and dependency-based. We adopted the former; the core and only difference between the two lies in the fact that, in the span-based SRL, semantic role labels are applied to the whole span of a given argument, whereas, in dependency-based SRL, the label is only applied to the argument's head (e.g., we label "the broccoli" and not "the").

The SRL task is often tied to a linguistic resource, which defines the inventory of predicate senses and semantic roles. For this task, we chose VerbAtlas[5] (Di Fabio et al., 2019) as our inventory of predicate senses and semantic roles given its high coverage in terms of verbal lexicon[6], the informativeness of its human-readable roles (e.g., *Agent*, *Patient*, *Instrument*), and its mapping to the PropBank frame inventory (Palmer et al., 2005) and to the BabelNet multilingual knowledge base (Navigli and Ponzetto, 2012; Navigli et al., 2021).

The annotation process for the SRL layer featured three distinct stages. In detail, we first employed the Stanza toolkit (Qi et al., 2020) to perform PoS tagging over the R2VQ corpus so as to

[5]VerbAtlas is freely available for research purposes at http://verbatlas.org/.

[6]VerbAtlas covers all the verbal senses defined in WordNet, and clusters them into predicate frames.

identify verbal predicates, and proceeded to manually include predicates that were not discovered automatically (e.g., *season* was often incorrectly labeled as a noun), as well as fixing instances erroneously labeled as predicates (such as adjectival or prenominal predicates, as well as predicates appearing within ill-formed sentences).[7] Secondly, we employed a state-of-the-art system (Conia and Navigli, 2020) to automatically label recipes in a span-based fashion, concurrently assigning VerbAtlas frames and arguments to recipes, and manually validating the whole corpus once more in order to verify the automatically-generated outputs, fixing errors and inconsistencies.[8]

We used BabelNet 5.0 as the inventory to validate predicates, first picking the most suitable word sense to disambiguate a given verb, and then selecting the relative frame in VerbAtlas according to its original mapping. As our final step, we instructed annotators to manually tag as many arguments as possible for each predicate (adding arguments where needed and removing additional arguments such as *Negation* in the process), first, referring to the predicates' prototypical arguments according to VerbAtlas, and then, providing additional arguments. We used VerbNet (Schuler, 2006) argument descriptions and examples along with in-house argument descriptions for ambiguous argument assignments (e.g., "in the oven" in "Jennifer baked the potatoes IN THE OVEN" is not a *Agent*, but rather an *Instrument* with respect to to the predicate "bake").

With respect to the SRL layer annotators, in order to make use of the Mechanical Turk platform already employed in the context of the aligned image frame annotation, we initially devised HITs for both predicate sense disambiguation and argument labeling. Though, independently of the rates and templates employed, we kept collecting low-quality or suboptimal data, likely, due to the background knowledge needed to perform such tasks in an adequate fashion. In light of this, after several attempts, we eventually decided to have one in-house annotator with extensive experience in SRL validate the whole corpus at all stages required, and asked a second annotator to review the validation instances,

[7]We also labeled word forms with typos in the original recipes as predicates (e.g. *prehet* as *preheat*). Additionally, we labeled as multi-word predicates those predicates whose form was featured as a compound in BabelNet.

[8]See Appendix A for details about the SRL annotations' format.

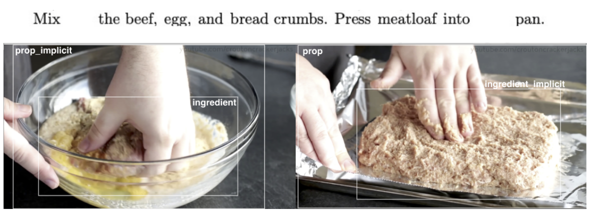

Figure 3: An aligned CRL-Image Frame annotation.

seeking agreement in case of discrepancies. As an additional step to ensure data quality, a third, external annotator was assigned with the task of reviewing recipes in order to look for potential formatting issues.[9]

5.4 Aligned Image Frame Annotation

Accompanying each recipe is a series of images extracted from YouTube videos that are associated with a particular event in the recipe. We pulled the images from a set of YouTube videos that were selected by querying YouTube for recipe titles. For each recipe title, we downloaded 5 Creative Commons licensed videos. These videos were indexed by generating an embedding using the Tensorflow implementation of the S3D Text-Video model trained on HowTo100M using MIL-NCE (Miech et al., 2020, 2019). For each cooking event in the recipes, the 5 closest clips as scored by L2 distance were selected from the YouTube videos we downloaded. We showed the annotators the first, middle and last frame from each 4 second clip alongside a list of the CRL representations of the events in the recipe. We asked the annotators to rank the match of the image and the cooking event as a good match, a partial match, or not a match. The Swipe Labeler (Peterson Jenessa, 2021) tool was used to conduct the annotation. The tool was modified to included the recipe event text, with the full recipe displayed and the current step in bold text. An example of the frame annotation is shown in Figure 4.

Due to complex combinations of ingredients in many of the recipes and the limitation of considering only Creative Commons videos, many events did not match with any of the detected segments. Partial matches were included in order to increase the total number of events represented. Importantly, the action represented in the image clips does nec-

[9]All annotators employed in the SRL layer have effective operational proficiency in English and received a wage in line with their country of residence. Annotation has been carried out by means of user-friendly shared worksheets.

Figure 4: Swipe Labeler Annotation Tool

essarily include the exact same ingredients of as those used in the recipe. The videos were chosen based on the similarity of the cooking event described in the sentence. In total, 1927 events were matched with images across 655 recipes.

5.5 Generating Competence-based Questions

We first design text templates for each type of question. Then we generate QA pairs by populating the templates in a cloze test style with the data annotated in CRL. Table 4 shows the text templates for two types of questions we want to use for the QA task. ELISION identifies arguments (ingredients in most cases) that are omitted from a text, but can be understood from context. IMPLICIT covers both implicit tools and habitats introduced in the text. This is distinct from ELISION, as these are not solved merely through contextual clues. Each text template has several slots that can be filled with corresponding entities from CRL.

To increase the variety of questions, we also include adjunct slots into the templates. As shown in Table 4, adjunct slots include tool or habitat phrases and SRL modifiers. SRL modifiers are any semantic roles that are not claimed by CRL entities such as `TIME` and `VALUE`. For example, one ELISION question can be as short as *What should be cut?* or *What should be cut on the board with a knife into eighths?* with all the adjunct slots. We argue that it is helpful to generate questions more challenging to the systems. Adding more adjunct slots completes the context for the question, but also introduces unseen context if the slots contain hidden entities.

These slotted templates are further processed to improve the readability of generated questions. We change word inflections and insert articles and agreements. For the templates with [habitat_phrase] and [tool_phrase] slots, we fill those with corresponding `LOCATION` or `INSTRUMENT` spans from SRL. If a slot is filled with a hidden entity that has no associated semantic roles, we run a BERT-based model (Devlin et al., 2019) to get the most likely preposition given the sentence as context through the masked language modeling task. SRL modifiers are populated in the same order as they were in the original sentence.

5.6 Details of copyright

All recipes are distributed under Creative Commons license. The YouTube videos queried were limited to Creative Commons videos only. No personally identifying information is included in either the text or visual components of the dataset.

6 Participation

We discuss the baseline system and the systems from participants in this section.

6.1 Evaluation Metrics

All systems are asked to provide answers to the open-ended questions based on the textual and visual information encoded in the dataset. The results are evaluated using exact match (EM) and token-level F1 score (F1) following Rajpurkar et al. (2018).

6.2 Baselines

To build a model that is reflective of the nature of the abstractive question answering task and benefits from the aligned key frames to the text, we adopt a vision-and-language text genertation model as the baseline for our task. We build the baseline with the model framework that is proposed by Cho et al. (2021). They propose the model VL-T5 based on T5 text generation model (Raffel et al., 2020) by extending the original T5 text encoder to a multimodal encoder that can take both textual and visual embeddings as the input.

Following closely the VL-T5 work (Cho et al., 2021), we prepare the key frames as model input by encoding them into visual embeddings using Faster-R-CNN. We prepare the text input by appending the task-specific prefix to the question and context text: `"question: {question_str} context: {recipe_str}"`. The `recipe_str` is the concatenation of the text of all cooking steps from the recipe the question is generated from. We fine-tune the VL-T5 model for our QA task on the

QUESTION TYPE	TEXT TEMPLATE	QUESTION-ANSWER PAIR
Elision	What should be verb [habitat_phrase] [tool_phrase] [modifiers]? — ingredient_obj	What should be cut on the board with a knife into eighths? — apples
Implicit	What do you use to verb obj [habitat_phrase] [modifiers]? — tool Where do you verb obj [tool_phrase] [modifiers]? — habitat_phrase	What do you use to sauté the onions [in the pan]? — spatula Where do you arrange the slices [into rounds]? — in the casserole

Table 4: Text templates and example of generated questions. The squared brackets ([...]) in the templates indicates adjunct slots.

training set, and run the fine-tuned model on the test set. As a comparison, we also fine-tuned the T5 model with text input only. Baseline results are shown in Table 5 along with other results from participants.

	EM	F1	Key Frames?
SRPOL	92.53	94.34	
ITNLP&QMUL	91.33	94.23	
PINGAN_AI	78.21	82.62	
Slug	69.49	77.37

BASELINE (T5)	65.34	75.22	
ych	10.23	10.23	
UoR	5.90	15.78	✔
CLT6	0.0	0.0	

Table 5: Task results from participant teams and the baseline. The ranking is based on EM score. The last column indicates whether the system uses key frames for training.

6.3 Description of team submissions

We collect successful submissions from 8 participating teams (including the baseline), as well as one participating team that did not submit predictions that passed our automated evaluation script. The results and final ranking are shown in Table 5. We summarize their work below:

- **SRPOL**: This system attains the highest scores in this task by adopting a hybrid approach. The system includes a rule-based system for intent identification and finding N/A questions. It also applies a transformer-based model ELECTRA for generating extractive answers.

- **ITNLP&QMUL**: This system attains the second highest scores in this task. The system adapts a T5 model to the task by altering the input to include semantic and cooking role labels that are provided in the data.

- **PINGAN_AI**: This system attains the third highest scores in this task. The system uses the BERT model as the backbone, and enhances the model by incorporating additional knowledge about cooking entities and part-of-speech tags in the format of plain text and embeddings.

- **Slug**: Semantic labels were preprocessed using BERT and handmade rules, with hidden roles infused into the recipe. A task-finetuned T5 model was then used for question answering.

- **UoR**: The only submission that exploited the visual information provided in the dataset, this system used an Inception V3 model (pre-trained on ImageNet), to extract image features that were used to train an image captioning model on the MS-COCO dataset. These captions were included alongside the recipe text in a Retrieval-Augmented Generation model for question answering.

7 Discussion

In this paper we have described the new task of Competence-based Multimodal Question Answering. In this task, we extended the traditional question answering by providing text-visual aligned data as the context, and asking questions that reflects reasoning competences over the question context. To create the dataset for our task, we proposed and applied a rich annotation of semantic role labels, cooking role labels and aligned video key frames to a set of cooking recipes.

A criticism of the approach we adopted to create annotated dataset is that the video key frames are not well aligned with the text, thus making it difficult to include those into the modeling training. Although with the full awareness of this, video annotation and alignment remains a very difficult task. Copyright issues also make it challenging for us to get enough video sources to work with. Future work to improve the key frame annotation may include utilizing entity recognition so that more accurate alignment to text can be made. We will also consider reusing the key frames and adding static images to represent similar events from different recipes to increase the coverage of annotation. Another criticism of the data is the semantic ambiguity and loose definition of certain questions. For example, the same How-to question can have multiple reasonable answers, but only one is considered as the gold answer. Although this is the semantic ambiguity as it is, we intend to improve it by replacing the question phrase "How to ..." to more specific phrase like "What tool ..." based on the answer it is inquiring about.

An analysis of the systems that participated in our task showed the major improvement over the evaluation scores is achieved by making the hidden information appear on the surface. In general, two approaches are proven to be useful for this purpose by the participating systems. One is to train an end-to-end system to generate text that contains CRL-SRL annotation, so that the hidden information is expressed explicitly in the generated text. Then an extractive QA system can be adopted to identify text spans as answers. The second approach involves rules and heuristics to identify question intents, and get auxiliary knowledge. Intent identification can help classify questions into different categories. Each question category is associated with a rather fixed set of answer templates and possible entity types to be filled in. Auxiliary knowledge is generated by associating specific entities with their co-referred mentions or result ingredients (e.g. "small balls" to "flour mixture").

The analysis of the results from participating systems also reveals some interesting characteristics about the dataset and is useful for future task design. Despite the error rate of the top-performing systems such as SRPOL and ITNLP&QMUL is only 8%, the cardinality questions and How-to questions solely contribute the majority of the errors. As it is mentioned above, the innate ambiguity of How-to questions makes it difficult for both humans and systems to get a single correct answer. The poor performance on cardinality questions shows that the "counting reasoning" remains a big challenge to current transformer-based systems. In the R2VQ dataset specifically, the mentions of the entity involved a cardinality question can scatter over the whole recipe, which requires a larger context to answer such questions. Due to nature of "constant ingredient transformation" in cooking recipes, the mentions of the same entity could vary in our definition. For example, in the appelkoek recipe (Table 1), *apples*, *peeled apples*, *apple wedges*, *apples with batter* all refer to the same entity *Apple*. This characteristic of cardinality questions also hinders the systems from counting the mentions of the entity properly.

The human benchmark created by the SRPOL team provides useful insights on our future QA task design. They asked six linguists to answer $2,000$ questions selected randomly from the validation set. By examining the manual annotation on the questions, they found that although 73% of the annotated QA pairs have the same meaning as the gold answers, the EM score is quite low. This reveals the fact that traditional QA metrics that focus on string match might be too strict in our task. For example, from the analysis of the human benchmark, for the question *What's in the mixture?*, both the gold answer *the egg and mixture* and the human answer *the butter, sugar, tangerine zest, vanilla, baking powder, salt and egg* can be considered correct. Other metrics like BERTScore (Zhang et al., 2019) might be a good compliment to account for the syntactic and semantic variance between the model inference and the gold answer.

8 Conclusion

In this paper we described *SemEval-2022 Task 9: R2VQ – Competence-based Multimodal Question Answering*. The task is to answer questions from a collection of cooking recipes and videos, where each question belongs to a "question family" reflecting a specific reasoning competence. We developed a new dataset of cooking recipes with rich annotation for cooking roles, semantic roles and aligned video key frames. We collected 8 result submissions and analyzed the participating systems by highlighting and summarizing their findings to help future research pertaining the topic of our task.

A Reading SRL Annotations in R2VQ

Predicate frames. Each predicate is labeled according to its VerbAtlas sense/frame. A value of "_" means that the corresponding word is not a predicate.

In the example below, there is only one predicate, "Cut" with the corresponding sense/frame "CUT" in position 1.

1	Cut	[...]	CUT	B-V
2	the	[...]	_	B-Patient
3	broccoli	[...]	_	I-Patient
4	into	[...]	_	B-Result
5	flowerets	[...]	_	I-Result
6	.	[...]	_	_

Semantic roles. For each predicate, we provide its semantic roles in BIO format (B - Beginning, I - Inside, O - Outside). Note that, for this dataset, we only use B and I to indicate the first token of a span and the rest of the tokens in the same span, respectively. In the example above, "the broccoli" is a *Patient* of the predicate CUT, with the token "the" as the Beginning of the span (B-Patient) and the token "broccoli" as the Inside of the span (I-Patient). Note that the predicate that refers to a specific column of semantic roles is always labeled with the notation B-V. Should the predicate consist of a multi-word expression, the other tokens apart from the first are labeled as I-V:

1	Deep	[...]	COOK	B-V
2	-	[...]	_	I-V
3	fry	[...]	_	I-V
4	till	[...]	_	B-Result
5	crispy	[...]	_	I-Result
6	&	[...]	_	I-Result
7	golden	[...]	_	I-Result
8	brown	[...]	_	I-Result

Should the multi-word expression be made of non-adjacent words, tokens apart from the first are instead labeled as D-V:

1	Bring	[...]	CHANGE_APP./STATE	B-V
2	the	[...]	_	B-Patient
3	water	[...]	_	I-Patient
4	to	[...]	_	D-V
5	boil	[...]	_	D-V
6	.	[...]	_	_

In the case of multiple predicates in the same sentence, there will be multiple semantic role columns, one for each predicate. For example, if there are two predicates in the sentence, one column will indicate the semantic roles for the first predicate, and the following will show the semantic roles for the second predicate.

1	Reduce	[...]	REDUCE_D.	B-V	_
2	heat	[...]	_	B-Attr.	_
3	,	[...]	_	_	_
4	and	[...]	_	_	_
5	simmer	[...]	COOK	_	B-V
6	for	[...]	_	_	B-Time
7	1	[...]	_	_	I-Time
8	hour	[...]	_	_	I-Time
9	.	[...]	_	_	_

HIT&QMUL at SemEval-2022 Task 9: Label-Enclosed Generative Question Answering (LEG-QA)

Abstract

This paper presents the second place system for the R2VQ: competence-based multimodal question answering shared task. The task consisted in building question answering systems that could process procedural recipes involving both text and image, and enriched with semantic and cooking roles. We tackled the task by using a text-to-text generative model based on the transformer architecture, with the aim of generalising across different question types. Our proposed architecture incorporates a novel approach for enriching input texts by incorporating semantic and cooking role labels through what we call Label-Enclosed Generative Question Answering (LEG-QA). Our model achieves a score of 91.3, with a significant improvement over the baseline (65.34) and close to the top-ranked system ((92.5). After describing the submitted system, we analyse the impact of the different components of LEG-QA as well as perform an error analysis.

1 Introduction

The objective of text-and-image multimodal question answering (QA) is to jointly leverage both textual and visual information to mutually inform each other for semantic reasoning (Ben-Younes et al., 2017). A SemEval 2022 shared task titled Competence-based Multimodal Question Answering (R2VQ) focuses on this task. In the R2VQ task, participants were invited to develop QA models to resolve questions associated with procedural recipe instructions. The corpus provided for the task is made of recipes, which include rich semantic annotations and where textual instructions are aligned with images illustrating them. The authors proposed to address a set of 18 question families, for which participants could develop and evaluate their own proposed solutions.

This paper describes the participation of the HIT&QMUL team in the R2VQ task, for which we proposed a methodology that we call label-enclosed generative question answering (**LEG-QA**). Through this methodology, we proposed enclosing labels providing semantic information embedded in the input texts. This methodology has proven competitive by achieving a score of 91.3% in exact match accuracy, ranking 2nd overall in the competition.

Our code is available at `https://github.com/weihezhai/HIT-QMUL-at-SemEval-2022-Task-9`.

2 Task and System Description

Building on the transformer architecture (Vaswani et al., 2017), we use T5 an encoder-decoder model (Raffel et al., 2020) implemented using Hugging Face[1]. We chose T5 given its reasonably good general language learning abilities, and provided that the downstream task of R2VQ covers a diverse set of task types that are also shared by T5. Intuitively, a task-agnostic model like T5 would be expected to perform well on R2VQ. We further adapt the T5 model to the task by altering the input to include semantic and cooking role labels enclosed in the textual recipe instructions.

2.1 Task and Data

The R2VQ (Tu et al., 2022) task proposed the use of multimodal models to leverage both text and image for QA in the context of recipes. The R2VQ task adopts the definition of 'Question Family' from the CLEVR dataset (Johnson et al., 2017), where each type of question-answer pair comes from a template identified by task organisers. Each of these question type is meant to evaluate a different ability for reasoning.

The R2VQ dataset consists of a collection of 1,000 recipes, of which 800 are used for training

*contribute equally
†corresponding author

[1]`https://huggingface.co/`

and two sets of 100 recipes are used for validation and testing. These recipes involve more than 30K question-answer pairs, where each recipe consists of texts with procedural instructions as well as associated images. Questions are intended to require both visual and textual information jointly to produce effective answers. However, based on our initial explorations of the dataset provided and after considering the use of multimodal models, we found that the majority of the questions could be answered through the sole use of text. Hence, we thought that the use of an image processing component could be avoided while producing an accurate answer generation model for the dataset at hand. Further improvement of the model through the use of an image processing component is therefore left for future work.

For in-depth analysis of the system results, we grouped the 11 question types[2] provided by the organisers into 4 categories, i.e. generative, number reasoning, classification and extractive (see Table 5 in the Appendix for category details). Note that each of these classes comprises questions intended to evaluate different abilities of models.

2.2 Soft Constrained Generative QA as Multitask Transfer Learning

Soft Constrained Text-to-Text Generation Mainstream text-to-text generation methods mostly aim to learn meaningful mappings between input and output sequences. This is particularly the case for the recent pre-trained language models (Lewis et al., 2020; Raffel et al., 2020), where the model is expected to identify what to attend to in the source input and what to include in the model output. Models like UniLM, T5 and GPT2 unify the generation and understanding tasks within a single model, but none of them investigates the model's ability of generating free-form answers which includes both generative and discriminative tasks.

In R2VQ, all questions are created through a semi-automated method. Generative questions such as implicit argument identification (e.g. how do you drain the pasta?) cannot be answered independently by an extractive question answering approach, hence some question types should be treated as a soft constrained generation (SCGen) problem (See et al., 2017; Dou et al., 2021). SCGen implicitly specifies token constraints that the model needs to focus on in the answer output. For instance, in the question example above, one of the following words must be present in the answer: "by", "using" (gerund of a verb), "in/on/at", "with". There are many variants of models considering soft constraints, but usually they are achieved by adding an attention mechanism to the source keywords (Yao et al., 2019).

[2]To be clear, 11 types of questions are defined on the R2VQ homepage but not the types of question-id in the dataset.

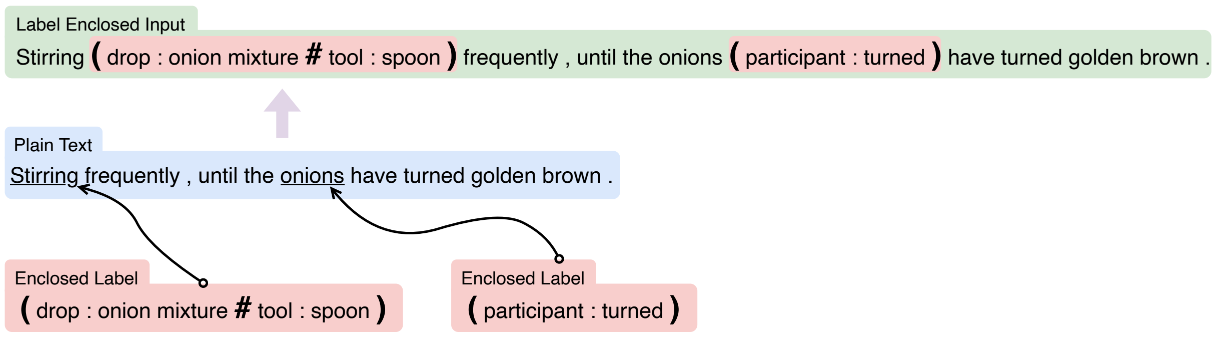
Multitask Transfer Learning Multitask learning consists in training the model on multiple tasks at a time. This means the model has an objective of simultaneously taking on more than one task. In LEG-QA, we leverage and transfer the prior knowledge from T5 and apply to our R2VQ tasks to solve the unseen SCGen problems. The reason why we do not train separate models for each of 4 categories in Table 5 is that we observe non-negligible accuracy drop when missing some of the question families.

2.3 Label-Enclosed Input

The key modification we made on the T5 model to prepare our submitted system is a rarely adopted heuristic method for embedding label information. Instead of appending supportive external features to the text sequence (He et al., 2017, 2018), we fuse the hidden cooking entities into the original text through our proposed approach called **label-enclosed input**. Typically, to grammatically and syntactically maintain the textual structure, the text should not be broken down into pieces by inserting annotations. However, we noticed that with the knowledge of labels appearing in the enclosed form, a pretrained text-to-text multitask model (in our case T5) can effectively process the enclosed noise from external information. In turn, the model using this enriched input behaves better than using a clean text input, when generatively answering questions with soft constraints.

2.4 Input Format

Figure 1 depicts the pipeline for the input data preprocessing through which the attributes of cooking roles are transformed and enclosed into the input sequences. We employed different processing approaches for each type of semantic and cooking roles. Through close observation, the most frequent attributes that take place in the answers are the 'Hidden' labels which consist of multiple values and keywords. As shown in the example, after text regularisation and reorganisation, attributes



Label Enclosed Input
Stirring (drop : onion mixture # tool : spoon) frequently , until the onions (participant : turned) have turned golden brown .
Plain Text
Stirring frequently , until the onions have turned golden brown .
Enclosed Label
(drop : onion mixture # tool : spoon)
Enclosed Label
(participant : turned)

Figure 1: Pipeline for creating label-enclosed inputs. In this case, labels are wrapped in braces, and labels for the same event but are of different categories are separated by hashtag.

(e.g. stirring) are enclosed in special tokens before embedding them into the input. While the example shows the use of brackets for enclosing labels, we tested different approaches, which we discuss in more detail in Section 3.

3 Experiments

Since different formats of enclosing special tokens can result in considerably different scores, we compare a range of experiment settings to evaluate their performance. For more detail on the different enclosing methods tested, see Table 4 in Appendix A.

We conduct a series of experiments to answer the following questions:

Q1: Which way of enclosing special tokens performs best? Is there any big difference between them, and any measurable explanation for the gap?

Q2: Which label combos achieve the best accuracy?

Q3: How significant is the difference between results generated by size-equivalent models?

3.1 Experimental Settings

For the purpose of, as much as possible, controlling variables unrelated to the pre-trained language model, we experiment with five input variants on T5-large (our suboptimal result model). For comparison, we also show results for models based on different architectures. In this case, we use BART(Lewis et al., 2020), a denoising text-to-text model.

All the performance scores we show indicate the exact match (EM) accuracy on the development data.

	Enclosing Method	GEN	CLS	NUM	EXT	Overall
T5-Large	brackets	87.3	97.0	**82.6**	93.4	89.9
	hash	86.9	**97.4**	80.6	93.6	89.5
	dollar sign	**88.2**	96.9	81.0	93.8	**90.2**
	[BOL] [EOL]	87.0	97.2	81.0	93.4	89.5
	parallel	81.2	97.0	79.7	**94.1**	86.5

Table 1: Detailed results for different enclosing methods. The default method is "( )" which is used for our final submission. The dollar sign enclosing method is evaluated after the final submission so is not reported as the best practice during the competition.

3.2 Comparative study

To answer Q1, we report EM score for every 2K steps up to a total 26K steps. This is equivalent to approximately 10 epochs. Table 1 summarises scores achieved by the T5-Large model with the 5 different label-enclosing methods. The *Hidden, Part and Event* labels are examined together, given for that our best-performing model so far follows this paradigm. The special token "$" dollar sign has a noticeable positive impact on the GEN task, leading to the overall best performance. The "Parallel" enclosing method refers to directly attaching all labels horizontally aligned with plain text. Additionally, the [BOL] and [EOL] are special symbols inherent to BERT-like models. Unsurprisingly, joining labels in parallel with text without breaking sentence syntax helps achieve better EXT score. The reason for ultimately choosing "( )" is that we believe that its directional attribute could help the model parsing the label structure to some extent. A further combination comparison is discussed when answering Q2.

To answer Q2, we carry out label combination experiments to compare the effectiveness of different roles when contributing to the 4 question categories. Table 2 analyses the benefit of gradually

	Labels Combo	GEN	CLS	NUM	EXT	Overall
T5-Large	HIDDEN	86.5	**97.2**	81.7	94.3	89.5
	HIDDEN + PART	87.2	**97.2**	80.4	**94.6**	89.8
	HIDDEN + PART + EVENT	**87.3**	97.0	**82.6**	93.4	**89.9**
	Text Only	46.8	93.8	66.4	93.9	66.7

Table 2: Scores achieved with ensembles of selected labels, each of which is picked out as a result of benefiting certain types of questions.

appending additional roles to each identified entity, i.e. adding more extrinsic information which frequently matches with answers. Note that the *Hidden* label is the dominant among participants, as it appears approximately in all generative questions, and compared with the text-only method, there is a noticeable improvement after adding *Hidden* to it. First, introducing more applicable labels has a positive impact on the overall accuracy. We observe the triplet leads to overall best performance. Second, plain text behaves consistently to what we find in answering Q1, which performs worse in tasks like generative questions, however achieving strong performance in the extractive questions.

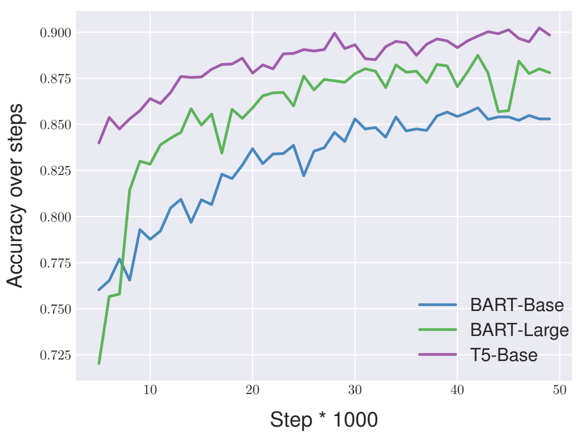


Figure 2: Models accuracy on validation dataset report every 1k step for three representative models.

To answer Q3, the tested models need to be comparable. We could say if two models (1) are roughly of the same amount of parameters (i.e. the same size). (2) share similar architectural design methodology (e.g. transformer-based), they would be considered comparable. We list the performance comparison of five models for 26k training steps in Table 3. We see that BART-Large is on a par with T5-Base from many aspects but performs poorly on a number of reasoning and generative questions. This is likely because T5 is fine-tuned on a more diverse mixture of tasks along with a very large pre-training dataset. Figure 2 demonstrates that BART-Large performs poorly at the beginning, taking off at around the 10k steps i.e. the second epoch. Moreover, later in the training stage, T5-Base has a slight advantage in achieving low variance. By contrast, the performance of BART-Large drops.

		Model	GEN	CLS	NUM	EXT	Overall
Enclosed by ( )	HD + PT + ET	BART-Base	82.9	94.2	74.7	92.7	86.0
		BART-Large (850 MB)	85.6	96.8	78.5	93.0	88.4
		T5-Base (950 MB)	87.0	96.4	81.7	**93.9**	89.6
		T5-Large	87.3	97.0	**82.6**	93.4	89.9
		T5-3B *	**88.6**	**97.4**	81.5	93.6	**90.5**

Table 3: Models comparison between T5 and BART of multiple sizes, result of T5-3B without error correction is used as our final prediction model. Note that T5-3B is 4 times the size of T5-Large. HD, PT and ET are short for HIDDEN, PART and ENTITY labels. Note that those labels are defined by the R2VQ dataset.

3.3 Error Analysis

Table 6 gives detailed examples including denoting mistakes of our suboptimal models i.e. T5-Large, which is slightly worse than our best T5-3B. As shown in questions 1 and 3, the model has a tendency to include more unrelated label information when answering generative questions. However, in question 4, it ignores some non-label important ingredients. That is in part because the transformer's attention mechanism sometimes fails at choosing whether to attend to labels or not when filling the answer template. Additionally, the worst performnace is for the 'number reasoning' question type, which is very challenging given that it needs to pay attention to multiple labels in combination. This could possibly be improved by further re-designing the transformer block or by including a memory block over the context.

3.4 Best-performing Submission

Even though we submitted multiple systems throughout the evaluation phase, our best-performing submission is the model that uses T5-3B and integrates the label-enclosing approach based on round brackets "( )". This system achieved an overall 91.3 in the test set, attaining the 2nd position in the competition.

4 Conclusion

In this paper, we describe the participation of the HIT&QMUL team in the R2VQ shared task, where we ranked second. Our model is based on a unified generative text-to-text approach, in which we propose a novel label-enclosed input technique to include annotation labels to include semantic and cooking role labels. Our model achieved an exact match accuracy of 91.3, well over the baseline model (65.3) and only slightly behind the top-ranked system (92.53). Table 7 lists the top five final results on the R2VQ test set from all user submissions ordered by Exact Match score.

Through our comparative study, "$" enclosed labels proved to be best, with the most effective generative answering ability. A combination of HIDDEN, PART and ENTITY provides the best set of labels. Our study of the label-enclosing approach has some limitations given our focus on a small number of experimental label combinations. In future work, more analysis can be conducted exploring other label combinations potentially leading to further improved performance. In addition, the error analysis reveals that the model sometimes lacks the ability to attend to related labels possibly due to attention decay. Deeper investigation of this is left for future work.

C Error Example

Context
1. Mash eggs & mix with salad cream or mayonnaise. If you prefer a sweeter taste, go with salad cream. I like mine with mayo. 2. Clean & devein prawns; separate the heads. Blanch prawns & heads. 3. Drain & transfer to ice water to prevent them from over-cooking. Dice prawns & set aside. 4. Remove apple & mango skin & dice fruits into small cubes. Soak apple in salt water, lemon juice or cider vinegar to prevent it from browning. I usually use the traditional method of soaking in salt water handed down by my mom. Add them into egg mixture, together with the diced prawns. 5. Remove excess sauce from beancurd skin & stuff mixture into the pockets. You may have to cut & adjust the pocket height. 6. Cut up watermelon & start plating your dish. Chill your appetiser & youre ready impress your guests with this Inari Age Laughing Prawns Salad.

Question	T5-Large	Gold Answer
1. How did you get the mixture?	by adding the diced prawns, apple, mango and prawns to the bowl	by adding the apple, mango and prawns to the bowl
2. How do you soak apple to prevent it from browning?	soak apple in salt water, lemon juice or cider vinegar	soak apple in salt water , lemon juice or cider vinegar
3. What's in the inari prawn salad?	the pocket height and pockets	the pockets
4. What should be diced?	the apple mango	the fruits, apple and mango
5. How many times is the pot used?	2	3

Abstract

In this work we present an overview of our winning system for the R2VQ — Competence-based Multimodal Question Answering task, with the final exact match score of 92.53%. The task is structured as question-answer pairs, querying how well a system is capable of competence-based comprehension of recipes. We propose a hybrid of a rule-based system, Question Answering Transformer, and a neural classifier for N/A answers recognition. The rule-based system focuses on intent identification, data extraction and response generation.

1 Introduction

The goal of the task[1] was to develop a system applying existing knowledge to new situations, demonstrating a kind of understanding of a real-world domain. The competition presents a QA[2] challenge requiring linguistic and cognitive competencies that humans have while speaking and reasoning (Tu et al., 2022).

The task dataset contains questions belonging to "question families" based on CLEVR (Johnson et al., 2016), reflecting specific reasoning competences. These families were explicitly marked as 19 categories, the last one having no answer (N/A), but direct reference to these categories was prohibited by the task requirements.

The cooking recipes included in the dataset were provided with exceptionally extensive annotations containing semantic information. The authors applied CRL and span-based SRL using VerbAtlas (Di Fabio et al., 2019) for the reference inventory of frames and semantic roles. Subsequently, human annotators were asked to validate and correct frames and argument labels.

The dataset was split into training (26,526), validation (3,829) and test set (3,442 questions). At the competition evaluation stage, the answers to the latter were not revealed, but the annotations were retained.

Our source code is available on GitHub[3].

2 Related Work

In the recent years, deep learning systems trained on large datasets began to outperform humans and other algorithms in the whole QA discipline. Challenges presented in works such as SQuAD (Rajpurkar et al., 2018), MS MARCO (Nguyen et al., 2016), CoQA (Reddy et al., 2019), multilingual MLQA (Lewis et al., 2020) and others popularized various machine learning models for extractive QA. Meanwhile, visual and multimodal QA contests started to appear, e.g. VQA (Antol et al., 2015) or Audio-Visual Scene-Aware Dialog (Alamri et al., 2019). They require understanding of images, natural language and their mutual relations to produce answers. One should not overlook QA systems applying SRL annotations used in advanced answer and question generation, such as Fitzgerald et al. (2018).

QA systems were proposed for open domains as well as specific ones, including medicine, education, tourism, weather forecasting, etc. One of the most popular yet challenging topics for QA is cooking. The system in Khilji et al. (2021) required preparing a cooking-related ontology, categorizing questions and extracting potential answers.

[2]Abbreviations used in the text: QA: Question Answering; SRL: Semantic Role Labeling (or Labels); CRL: Cooking Role Labeling; EM: Exact Match; RC: Reading Comprehension; DNN: Deep Neural Networks.

[3]https://github.com/samsungnlp/semeval2022-task9

Haussmann et al. (2019) focused on a knowledge graph used to answer a range of questions related to healthy diet.

Furthermore, food recognition could be perceived as a part or a preliminary step for cooking QA. Mohanty et al. (2021) and Akhi et al. (2018) seek for deep learning classifiers to properly identify food from real images.

3 System Overview

3.1 Questions Categorization

Because using original question categories was not allowed, we started with building a categorization solution. We based it on syntactic and lexical structure of the questions and used regular expressions as a way of distinguishing them; details can be found in Appendix C. Subsequently, to discover relationships between resulting question groups, as well as within them, we took SRLs and CRLs into account. They allowed us to determine a word or a phrase that should be included in the answer to a given question. Finally, we distinguished 17 question categories. To match the answers more effectively, some of them were later divided into subcategories:

1. COUNTING TIMES — counting how many times a given TOOL or HABITAT is used.
2. COUNTING USES — counting how many TOOLS or HABITATS are used.
3. COUNTING ACTIONS — counting how many actions it takes to do something.
4. ELLIPSIS — searching for direct object(s) which has undergone a certain process.
5. LOCATION (CRL) — searching for the place to which something is being transferred or in which it is located (a CRL is returned).
6. LOCATION (SRL) — similar to the above, but an SRL is returned.
7. METHOD — searching for a way of performing an action, with four subcategories according to which a CRL or an SRL is returned as an answer:
   - Question about a TOOL,
   - Question about an INSTRUMENT — objects or forces (such as heat, cold) that come in contact with an object and cause a change in it,
   - Question about an ATTRIBUTE — a property that a direct or indirect object possesses,
   - Question about a GOAL — the point to which something (e.g. temperature/heat/flame, consistency, thickness) needs to be brought.
8. LIFESPAN (HOW) — searching for a result of a process; a related action and its objects are returned as the answer.
9. LIFESPAN (WHAT) — similar to the above, but only related objects are inserted into the answer (without the action).
10. EVENT ORDERING — checking which action should be performed first.
11. RESULT — searching for expressions determining to what point a condition has changed.
12. TIME — searching for a specific expression relating to time.
13. EXTENT — searching for expressions specifying the range or degree of change.
14. PURPOSE — searching for expressions describing why an action needs to be performed.
15. CO-PATIENT — searching for indirect objects that undergo a process, are affected in a certain way, are situated in a particular location or are transferred to a different location.
16. SOURCE — searching for a starting point of a motion.
17. LOCATION CHANGE — searching for previous location of an object.

3.2 Approach Based on Semantic Roles

The system uses the following three-step path to find the answer: intent identification, data extraction and response generation.

Having the intent predicted, the question is dispatched to one of the per-category handlers. We designed the system to use a separate answerer for each category. LOCATION, RESULT, TIME, EXTENT, PURPOSE, CO-PATIENT and SOURCE share the same code after some parametrization, see Table 4. For the remaining categories (COUNTING, ELLIPSIS, LOCATION CHANGE, EVENT ORDERING, METHOD and both LIFESPANS) we use separate sub-engines, as we need to perform diverse tasks.

The implementations (except for METHOD) are pretty straightforward and obey the general rule:

- identify a reference verb and / or object in the question,
- search for a relevant sentence using the same verb / object in the given role (category-dependent) and extract relevant informa-

tion from the sentence using semantic roles (category-dependent again),
- if necessary, rephrase the information to form the answer.

Since METHOD contains four original categories (2, 6, 10 and 14) and direct use of the category ID was prohibited, the sub-engine for METHOD runs the above steps multiple times for: ATTRIBUTE, INSTRUMENT, GOAL and TOOL, returning the first found answer. The exact order of the labels was found empirically, by minimizing the number of category mismatches on the validation set.

In following sections we discuss the details.

Intent Identification

In almost every category the key to answering a question is identifying the verb and the object associated to it (jointly referred to as *intent*) and then finding the answer in the annotation.

First, a question classifier (see Section 3.1) is used to assign the question to the relevant category. Then, the analysis of the recipe is performed in an iterative way. We start with a small chunk (sentence or paragraph) to prevent mismatches resulting from looking too broadly. Verbs from the analyzed part are collected using either SRL (more specifically, tokens labeled as B-V), or a CRL and SRL combination, namely finding B-EVENT (CRL) with corresponding SRL (I-V or D-V). A detailed description of the annotation system is presented in Tu et al. (2022).

The next step of the intent identification requires iteration over the collected verbs to find a related object for each of them. The objects may be annotated in numerous ways:

- using SRL (e.g., PATIENT, THEME)
- using CRL (e.g., TOOL, HABITAT, EXPLICIT-INGREDIENT)
- using HIDDEN ROLES (e.g. DROP, HABITAT)

When both the verb and the associated object occur in the question, the system is ready to utilize this information to search for the answer in the recipe. More details of our algorithm can be found in Appendix C.

Data Extraction

Depending on the identified intent, the answer may appear in the passage either explicitly or implicitly. In the first case, the data essential for generating the answer is a direct span from the recipe and the system only needs to find an appropriate SRL and return it as the answer. However, for question categories where the answer is not explicitly mentioned in the passage, the process of data extraction is far more complicated. It requires calculating the actions, tracking object position, or collecting parts of the answer using all the information available in the annotation part: SRL, CRL, HIDDEN ROLES and the relations between them.

Response Generation

Generation of the final response is category-specific. In some cases, the gold answer contains only words annotated as a specific SRL (e.g. LOCATION, TIME). In other categories, the gold response contains the verb and the object from the question. There are categories where the system has to count occurrences of the object and return the number, as well as ones where the phrase *by using* is required at the beginning. See Appendix C for details.

3.3 DNN-Based Systems

QA is a well-established NLP task, mainly thanks to the advancements in attention-based DNN models. Thanks to fine-tuning, pre-trained BERT (Devlin et al., 2018) and its successors may be employed for downstream tasks, such as RC.

To examine how successful RC models could be for the competition, we tested the following ones: BERT, RoBERTa (Liu et al., 2019) and ELECTRA (Clark et al., 2020) in the extractive setup, i.e. taking text spans as predicted answers. We fine-tuned them on the SQuAD dataset and then on the task recipes from the train set. We used large versions of the models, and trained them for 5 (BERT), 12 (RoBERTa) and 15 (ELECTRA) epochs. The other hyperparameters used were: batch size: 8, learning rate: 1.5e-5, and max token sequence length: 512. Notably, we did not use provided annotations so that the solution was based solely on raw recipe texts.

N/A Classifier

An important part of the task is the correct identification of N/A answers in the QA pairs. The dataset contains about 9% of such, spread across all categories quite evenly. In most cases, the rule-based system was enough to identify the missing response in a cooking recipe. For more problematic situations we reached the best classification results by fine-tuning the *bert-base-multilingual-uncased* model (Wolf et al., 2020) taken from the PyTorch Hugging Face repository[4].

4 Results

Our end-to-end hybrid system reached EM scores between 80% and 100% per question category and the official result overall amounted to 92.53%. Details can be found in Table 1.

Our pipeline starts with the semantic-based system. If no answer is returned, the RC system is used if its confidence threshold exceeds 98%. This fallback mechanism produced any significant improvement only for the LOCATION (SRL) category. We additionally consider the N/A Classifier result: if it exceeds the 99% certainty threshold, the N/A answer is returned. This operation enhances the results for the EVENT ORDERING category. Adding the DNN systems in such a way leads to a 0.145 pp result increase.

In the post-evaluation phase we made further improvements, mainly in the rule-based system, and we ultimately reached the 92.969% EM result.

Human annotators reached notably low EM score of 52%. It is mainly due to the fact that the exact match metric leaves no room for human creativity. A manual review of the semantic validity of the responses gave us 73% alignment with the gold answers. This is discussed further in Section 4.2.

Manual analysis revealed that only some elements of the images associated with the recipes relate directly to recipe content. This was also mentioned by task organizers. Only 62 from 500 analyzed pictures were considered helpful in answering questions by our human evaluators. They also reported that they were often assigned to a different recipe step. For these reasons we further disregarded the images and focused only on the textual part of the data.

4.1 DNN-based Systems

Table 2 shows RC models comparison. As expected, the best Exact Match score was achieved by ELECTRA, which is currently the top-performing model on the SQuAD benchmark.

Table 3 presents the percentage of test set questions that could be answered by an oracle extractive answering system, i.e. where the answer either can be found as a span from the recipe text or it is N/A. Such examples cover 35% of the test set, meaning that this is the upper limit for any extractive QA system. The result achieved by ELECTRA (EM equal to 31%) is in line with this estimation. Another 34.6% EM could be achieved with an extractive QA system by using additional post-processing.

This leaves out 30.4% examples, mainly from categories COUNTING, LIFESPAN and EVENT ORDERING, that require non-trivial processing (e.g. rephrasing) and/or aggregation of information from various parts of the recipe.

Based on these results we claim that ELECTRA or other BERT-based systems can be considered applicable for this type of task, yet they should be able to generate answers beyond plain span extraction. It would require improvements, such as making use of a generative model, feeding the semantic annotations along with recipe texts, and perhaps adjusting the models to specific question categories.

The N/A Classifier worked better when fed with the full recipe passage (i.e. *Ingredients* and *Directions*; $F1 = 82.7\%$). If provided only with *Directions*, the result dropped to $F1 = 76.6\%$. It shows that the *Ingredients* information plays an important role in the solution.

4.2 Human benchmark

The aim of creating the human benchmark described in this subsection has no other purpose but to measure to what extent our results (as well as the gold answers) are close to human reasoning, i.e. to the answers provided by an actual person. We did so as we did not find any information on human performance in materials provided by the organizers.

We asked a group of six linguists to answer 2,000 questions selected randomly from the validation set. We maintained similar percentages of each question category for the sample to be representative. Before starting their task, the linguists had become familiar with the train dataset to grasp the main idea and the structure of questions and answers. Importantly, they did not have access to the annotation so that they based their answers solely on the recipe texts and related pictures. We decided to take this approach assuming that the semantic annotation of the recipes serves as a partial equivalent of the general knowledge that AI lacks.

As already mentioned, the manual review of the human answers revealed that 73% of them have the same meaning as the gold answers. Other re-

[4]`https://huggingface.co/models` (access Feb 20th, 2022).

Table 1: Exact Match percentage per category. For the training (**Train**), validation (**Val**) and test (**Test**) sets we present the results of our hybrid system. **Post-Eval** shows our final post-evaluation results if different than **Test**. **Size** is a percentage of the given question category in the whole validation set. **Human** results were calculated based on a sample from the validation set as described in Section 4.2. For **Electra** we took the full test set.

Category	**Size**	**Train**	**Val**	**Test**	**Post-Eval**	**Human**	**Electra**

Total		**92.7**	**93.9**	**92.5**	**93.0**	**52.0**	**31.0**

Table 2: Reading Comprehension models results for the test set (0 - 100 range). **EM** — Exact Match score.

Model	**F1**	**EM**
BERT	36.9	30.7
RoBERTa	37.7	30.7
ELECTRA	**38.5**	**31.0**

sponses are semantically close, yet not identical. However, they often differ lexically from gold answers, resulting in the low overall EM score.

It is particularly visible in the ELLIPSIS category:

> **Question:** What should be tossed?
> **Gold answer:** the rice mixture and yogurt mixture
> **Human answer:** yogurt, sour cream, mustard, sugar, salt, pepper and rice mixture

The linguists also failed to return the gold answer when the question itself was semantically ambiguous. It was mostly applicable to the METHOD category and to both LIFESPAN categories. In the former, it results from various possible ways of understanding the English word *how*:

> **Question:** How do you slice the tomatoes?
> **Gold answer:** by using a knife
> **Human answer:** slice the tomatoes thinly

The LIFESPAN questions require listing ingredients needed to obtain something. The discrepancies between the gold answer and the human answer often resulted from a different nouns ordering or using a synonym:

> **Question:** How did you get the hot chocolate?
> **Gold answer:** by mixing the hot water, milk and mixture in the mug
> **Human answer:** by mixing the mixture with hot water or milk in a mug

As linguists did not see the annotation, their proposals were often different from the gold answer in categories where it was taken from SRL or CRL, such as METHOD subcategory concerning tools or habitats, or the COUNTING categories. Moreover, e.g. in both LIFESPAN categories, gold answers either listed the ingredients explicitly or returned the DROP value (one of the HIDDEN ROLES), such as "mixture", "soup" or "dough". From the human point of view those two kinds of responses would be equally correct:

> **Question:** What's in the mixture?

Table 3: Extractive Answering usability on the task. **EA** — answers present in source texts as non-empty spans. **NA** — N/A answers in the test set. **AQ** — Answerable Questions (EA + NA); i.e. an oracle system result. **EM** — Exact Match ($\leq$ AQ) actually achieved by our ELECTRA system. All results are provided as percentage and based on the test set.

Gold answer: the egg and mixture

Human answer: the butter, sugar, tangerine zest, vanilla, baking powder, salt and egg

The linguists obtained the best results in the Event Ordering, Result, Time and Purpose categories. Apart from the last one, those are closed-form questions that leave little room for semantic ambiguity.

We treated human benchmark as an interesting experiment that confirmed two hypotheses we had. Firstly, the answers provided by our model are often semantically close to the gold answers, as stated above. The scoring criteria reject any answer that is not identical to the gold one, which leads to allegedly poor human performance and makes the answer post-processing a daunting but crucial step. Secondly, there are some patterns in the task data that are remote from human thinking. The result of the experiment did not affect the final score — it served solely for analytic purposes.

5 Conclusion and future work

Our main contribution is the hybrid system for the cooking-related QA. While we are satisfied with the result, the ~7% error rate still leaves some room for improvement.

The most challenging task for our system was the correct intent identification. This is visible in the fairly low results in the Method category. It may relate to four different intents, and we did not always distinguish them properly. Other problematic aspects were counting actions and objects and generating answers that contain all required items in the right order. These issues solely contribute to as much as 5.5 out of 7 pp constituting the whole the error rate.

The obvious question left unanswered is the possibility of SRL/CRL annotation automation, also for other competence domains. This is a missing component in a full end-to-end application of our solution.

A Dataset Analysis

One of the major problems we encountered during the linguistic analysis was question duplicates:

Semantically justified

- Semantic ambiguity resulting from the specific characteristics of the English language, so that it is not possible to distinguish question types by their syntactic structure or by other elements. For example, four groups of semantic roles as possible answers can appear in the same recipe
  Duplicated question: How do you mix the shrimp, pasta, butter and parsley?
  Answer 1: mix the shrimp, pasta, butter and parsley well
  Answer 2: by using a spatula

- With the same question structure, semantic ambiguity resulting from the content of the recipe, e.g. the same verb appearing twice in the text.
  Duplicated question: What should be added to the pan?
  Answer 1: the string beans and dressing
  Answer 2: the sauteed garlic, onions, ginger and string beans

In such cases it might be a better solution to list the correct answers instead of giving just one.

Semantically unjustified

- With the same question structure, referring to the same object in the recipe; these appeared mainly in the COUNTING category.
  Duplicated question: How many bowls are used?
  Answer 1: N/A
  Answer 2: 1

The aforementioned example of unjustified duplicates is associated with another problem. Namely, for many questions marked as unanswerable it was actually possible to find an answer in the recipe. We suppose that this was caused by selecting random questions from other recipes and assuming that they could not be answered based on the content of another recipe. Unfortunately, due to the relatively small variety of vocabulary related to cooking, this assumption was misleading. This can be seen especially in the categories: COUNTING, LIFESPAN and ELLIPSIS.

B Additional Experiments

B.1 Applicability to Another Domain QA

In this experiment we checked whether our system would work for other domains. We chose four instruction texts that are related to make-up techniques, furniture assembling and handmade Christmas decorations. We labeled these texts manually and asked linguists to write questions and answers bearing in mind the structure of questions and answers proposed by the organizers. They created 20 QA pairs for each text on average. The system achieved results in the range of 40%-50% EM (if we additionally included responses that are semantically correct, but not fully consistent with the answer suggested by the question authors, we reached approximately 60% EM). It is worth emphasizing that this was possible without any changes in our system.

B.2 Completeness and Correctness of Question Intents

The second experiment checked whether the questions provided by the organizers were semantically diverse and to what extent they corresponded to potential human intentions. We asked linguists to write questions related to five recipes from the validation set. Importantly, for the sake of an unbiased experiment, those were not the same people who worked on the human benchmark. The linguists engaged in this experiment had not seen questions and answers provided by the organizers, so the structure of independently written questions is not influenced by the existing dataset. They prepared about 100 question-answer pairs (20 for each recipe). After comparing the questions provided by the organizers to the ones created by our linguists, we concluded that some question types have not been included in the competition dataset:

- questions related to the amount of ingredients, e.g *How many tablespoons of vinegar should I add?*
- questions about the type of ingredients, e.g. *What kind of oil should I use for this recipe?*
- yes-no questions, e.g. *Is spinach required for this recipe?*
- questions about name or type of the dish, e.g. *What is this recipe for?*

Therefore, we have four extra categories not mentioned by task organizers. On the other hand, every category in Section 3.1 was covered by at least one question.

It is also noteworthy that most of the questions formulated by linguists are in the first person singular instead of the second person, as the organizers propose. Also, they respond using a whole sentence rather than a single word or a short phrase. The remaining questions written by the linguists correspond to the questions categories proposed by the task organizers. This proves that the proposed Question categories are valid and reflect real human intentions. It should be emphasized that the structure of human-written questions and answers is much more varied, but they still contain keywords that can be used without problems in our question classifier.

It must be stressed that our manual annotation concerned entirely new texts, only for the purpose of these experiments. We did not use the any of the additionally annotated data to augment the datasets provided by task organizers. Therefore, the experiments did not affect out final score.

C Implementation Details

The process of searching for information in a recipe and generating answers is presented in the Algorithm 1. It utilizes information such as types of semantic labels playing the crucial role while answering a given question category. It is summarized in Table 4, which also shows regular expressions used by our classification system.

- By *event* we usually mean a verb annotated as EVENT which should match the verb from the question. If the question also includes an adverbial, it can be used to distinguish the correct *event* in the recipe.
- By *object* we mean a word or phrase, which is annotated as DROP, PATIENT or THEME and matches the *object* from the question. In some cases no *object* is provided. Then the system relies on *event* matching.
- In the COUNTING category we need to search directly for TOOLS, HABITATS or RESULTS.

If no matching *event*, *object*, HABITAT, TOOL or RESULT can be found within the recipe, the system concludes that the question is not answerable.

Example of answering can be seen in Fig 1.

Additional Remarks

To ensure higher accuracy of the results, the system has to take into account several characteristics of

Algorithm 1: Answer generation process

```
Input    : question, recipe
Output   : generated answer
question category ← predict category using
  regex from TABLE 4 COLUMN 2
question details ← extract details from the
  question (see COLUMN 3)
relevant information ← search for relevant
  part in the recipe using question details
RC threshold ← 0.98
NA threshold ← 0.99
if relevant information was found then
    answer ← generate answer for given
      question category according to
      COLUMN 4
else
    answer ← use answer predicted by
      Electra Extractive QA[1]
    if confidence < RC threshold then
        answer ← N/A
if N/A Classifier[1,2] output = N/A and
  confidence >= NA threshold then
    answer ← N/A
return answer
```

[1] Electra Extractive QA and N/A Classifier are used only for some categories

[2] N/A Classifier was added after competition end

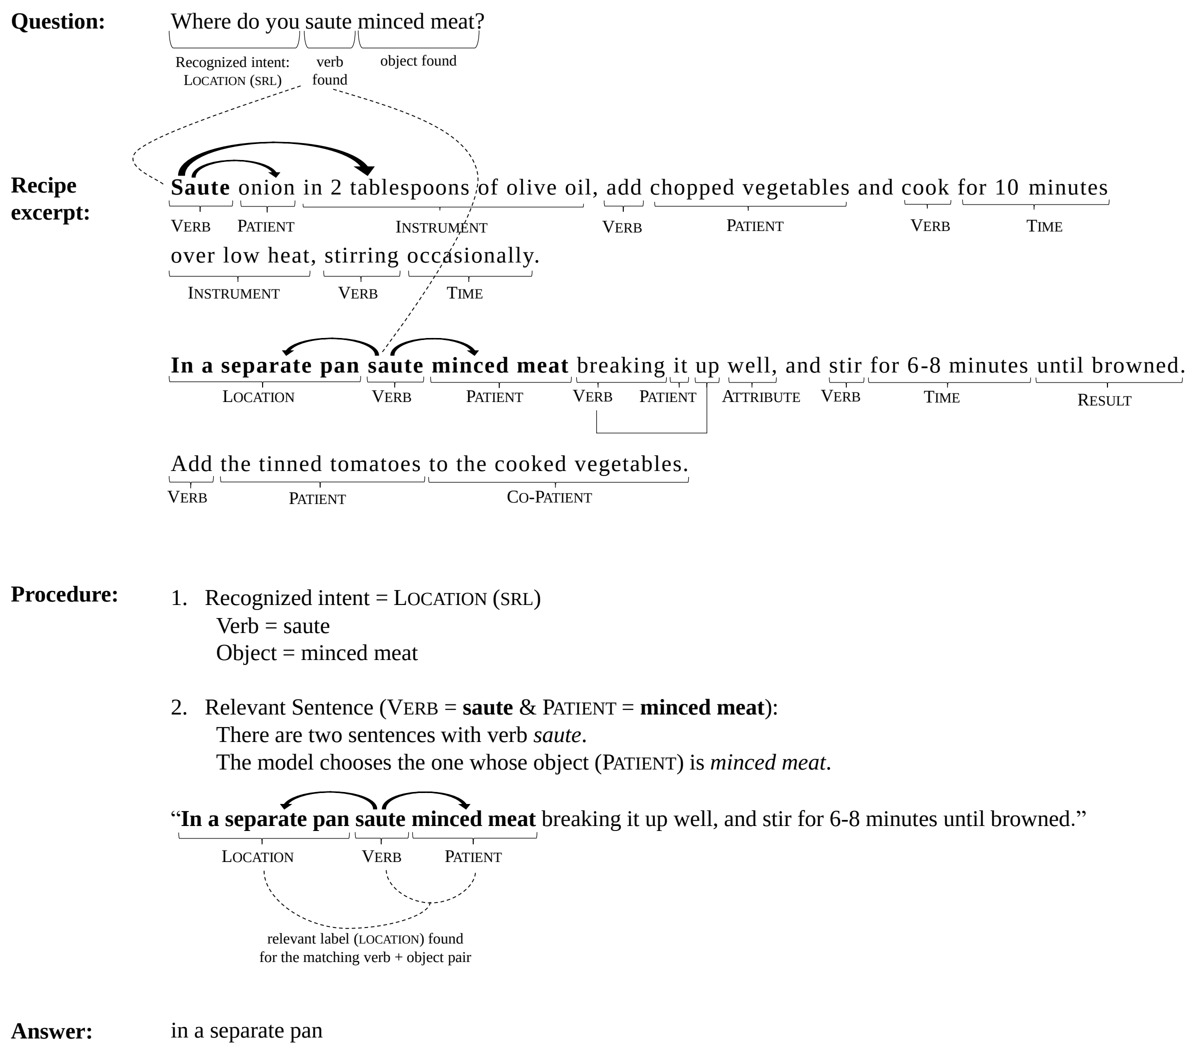
Table 4: Summary of question handling. Columns left-to-right: category, regex used for initial classification, semantic information used to search for the answer in the recipe, information used to generate the final response.

Category	Regex Pattern	Searched Label	Answer Generation
COUNTING TIMES	How many times	tools or habitats	count found occurrences
COUNTING ACTIONS	How many actions	result and corresponding event	count found occurrences
COUNTING USES	How many .* are used	tools or habitats	count found occurrences
ELLIPSIS	What should	event and (tool or habitat)	drops, ingredients
LOCATION (CRL)	Where should you	event and object	habitat
LOCATION (SRL)	Where do you	event and object	location, destination, co-patient or co-theme
METHOD	How do you	event and (object or ingredients)	verb, object, one of: tool, instrument, attribute, goal
LIFESPAN (HOW)	How did you get	result and corresponding event	verb, drops, patients, tools, habitats
LIFESPAN (WHAT)	What's in	result and corresponding event	ingredients (if patient or theme), drops
EVENT ORDERING	.* which comes first	both events	use the preceeding one
RESULT	To what extent	event and object	result
TIME	For how long	event and (object, attribute or purpose)	time
EXTENT	By how much	event and object	extent
PURPOSE	Why do you	event and object	cause or purpose
CO-PATIENT	What do you .* with	event and object	co-patient or co-theme
SOURCE	From where	event and object	source
LOCATION CHANGE	Where was .* before	event and object, and all previous events for the same object	previous habitat different from the one in the starting event

the R2VQ dataset:

- SRLs are represented as columns, within which objects are connected to the verb. Each subsequent verb within a sentence has its own column with corresponding objects. Iterating over each column separately appears to be very helpful in terms of associating verbs with proper objects.
- Each SRL starts with the head (the label starts with the letter B). If the phrase contains multiple words, the head is followed by the body (the label starts with the letter I or D). We found that concatenation of the full-length expression (using B and I as indicators) improves the quality of the identification process.
- Tokens whose CRL is TOOL, HABITAT, EXPLICITINGREDIENT or IMPLICITINGREDIENT are supplied with the index of the verb to which they relate. In some cases, using that information is extremely helpful as it allows for unambiguous identification of the relationship between the verb, the object and the answer.
- While an object in the question is created using a HIDDEN ROLE, it is needed to singularize each part of it. For example, if Drop="**limes**.3.1.9:**ginger**.3.1.1:**onions**.2.1.7" there is a great chance that it will appear in the question in the form of *the lime, ginger and onion*. On the contrary, when CRL or SRL were used to create the question, they will most likely appear as an unchanged span from the passage.

Figure 1: Example of the sematic-role-based answer generation.



Question: Where do you saute minced meat?

Recipe excerpt:

Saute onion in 2 tablespoons of olive oil, add chopped vegetables and cook for 10 minutes over low heat, stirring occasionally.

In a separate pan saute minced meat breaking it up well, and stir for 6-8 minutes until browned.

Add the tinned tomatoes to the cooked vegetables.

Procedure:

1. Recognized intent = LOCATION (SRL)
   Verb = saute
   Object = minced meat

2. Relevant Sentence (VERB = **saute** & PATIENT = **minced meat**):
   There are two sentences with verb *saute*.
   The model chooses the one whose object (PATIENT) is *minced meat*.

"**In a separate pan saute minced meat** breaking it up well, and stir for 6-8 minutes until browned."

Answer: in a separate pan

PINGAN_AI at SemEval-2022 Task 9: Recipe knowledge enhanced model applied in Competence-based Multimodal Question Answering

Abstract

This paper describes our system used in the SemEval-2022 Task 09: R2VQ - Competence-based Multimodal Question Answering. We propose a knowledge-enhanced model for predicting answer in QA task, this model use BERT as the backbone. We adopted two knowledge-enhanced methods in this model: the knowledge auxiliary text method and the knowledge embedding method. We also design an answer extraction task pipeline, which contains an extraction-based model, an automatic keyword labeling module, and an answer generation module. Our system ranked 3rd in task 9 and achieved an exact match score of 78.21 and a word-level F1 score of 82.62.

1 Introduction

In this paper, we discuss an approach to the Question Answering (QA) task for SemEval-2022 Task9(Tu et al., 2022). This task is structured as question answering pairs, querying how well a system understands the semantics of recipes derived from a collection of English cooking recipes and videos, which involve rich semantic annotation and aligned text-video objects.

In this task, a large proportion of answers can't be derived directly from the original recipe text and the information of these answers is hidden in annotated knowledge data. So we adopted two knowledge-enhanced methods in this model: the knowledge auxiliary text method and the knowledge embedding method. The knowledge auxiliary text method incorporates the hidden-roles knowledge and co-reference knowledge in generating auxiliary text. The knowledge embedding method encodes u-pos knowledge and entity knowledge into knowledge embedding.

A key evaluation measure in this task is the exact match score. Because the extraction-based model is more robust than the generative-based model, we design an answer extraction task pipeline. The pipeline contains an extraction-based model, an automatic keyword labeling module, an answer restructures module. In the training phase, we locate keywords of answers in recipe text and provide training data by labeling the keywords. In the prediction phase, we collect output keywords of the model and generate answer text by the keywords.

Our system ranked 3rd in task 9 and achieved an exact match score of 78.21 and a word-level F1 score of 82.62. We make our code publicly available on Github[1].

2 Related Work

Question Answering (QA) Liu et al. (2019) described the Span Extraction task in MRC (Machine Reading Comprehension) and Mervin (2013) described the extraction-based question answering task. BERT(Devlin et al., 2019) displayed a general extraction-based approach for the QA task.

Knowledge enhanced CoLAKE(Sun et al., 2020), ERNIE 3.0(Sun et al., 2021) and K-BERT(Liu et al., 2020) shown the method of constructing a new context by using knowledge information. Know-BERT (Peters et al., 2019) used the knowledge embedding method and Zhang et al. make some improvements.

Prompt In generating knowledge auxiliary text, we are inspired by prompt(Liu et al., 2021) learning. We focus on prompt engineering in this paper. Yuan et al. (2021) rewrite the context by replacing phrase. Davison et al. (2019) use a unidirectional LM to score the prompt patterns. Gao et al. (2021) use the T5 model to generate a template.

3 System overview

In this paper, we discuss an approach to the Question Answering (QA) task for SemEval-2022 Task9.

[1]https://github.com/archfool/SemEval2022_Task09

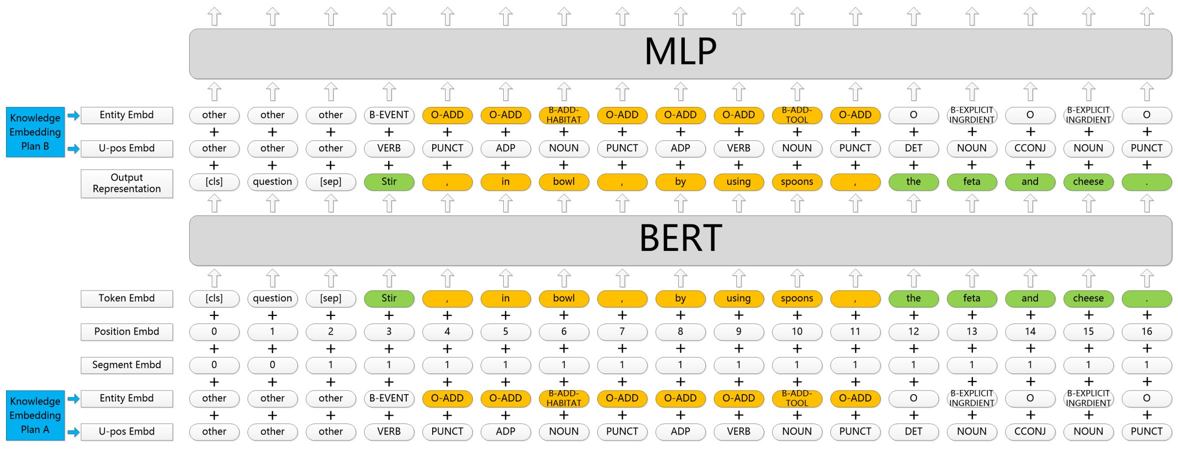

Figure 1: knowledge enhanced model

We divided the samples into 18 categories after analyzing the patterns of QA pairs. We predict answers of 6 categories by rule-based method and 12 categories by deep-learning model.

We chose BERT(Devlin et al., 2019) as the backbone of our model and chose the answer extraction method for this QA task.

Knowledge information is significant in this task, so we adopted two knowledge-enhanced methods: the knowledge auxiliary text method and the knowledge embedding method.

Knowledge auxiliary text method generating expanded text that contains original text and knowledge auxiliary text. The knowledge auxiliary text incorporates the hidden roles and co-reference knowledge.

Knowledge embedding method encoding u-pos (universal-part-of-speech) knowledge and entity knowledge into knowledge embedding.

3.1 QA datasets analysis

Following the design ideas of the FAQ task, we analyzed the patterns of QA pairs first. And we summarize QA pairs into 18 pattern categories.

With the help of divided pattern categories, we fed certain categories of data into a rule-based module. For example, some questions are about counting tasks, the rule-based method is better for these tasks than the deep-learning model method. We fed the rest QA categories into the deep-learning model module. The proportion of samples using the rule-based method was 39.87%, and the proportion of samples using the deep-learning model method was 60.13%.

The QA-pair pattern categories' example is shown in Table 2 of Appendix A.

Some more dataset information is shown in Section 4.1.

3.2 Knowledge auxiliary text

By analyzing the QA cases of the datasets, we found that a large proportion of answers can't be derived directly from the original recipe text. And the information of the answers is in the Cooking Role Labeling (CRL) annotations. So we generate knowledge auxiliary text by introducing the knowledge of the co-reference column and hidden-role column in CRL annotations. We add knowledge auxiliary text to the original text as the input of the model.

Co-reference knowledge can be regarded as a kind of entity link between the current entity token and the token where this entity is mentioned the first time. In this way, readers can search and locate the item unambiguously even though different items have the same name or one item uses different names. Knowledge auxiliary text of co-reference information is generated by easily adding the alias in the co-reference column within a couple of brackets.

For example, if the original text is "mixture" and the co-reference column has the value "small balls". Then we generate knowledge auxiliary text "(small balls)". Combined knowledge auxiliary text to the original text, and get the final text: "mixture (small balls)".

Hidden-role knowledge is a supplement to the action token that appears in the original text when some elements of the action are hidden. Inspired by prompt(Liu et al., 2021) learning, we generate knowledge auxiliary text following the pattern of the answer text from the QA-pairs. For example, we use 'by using a knife' as knowledge auxiliary text when the hidden role column has a key value of 'TOOL: knife'.

The knowledge auxiliary text method can be shown in Figure 1. In the token embedding layer, the tokens of green grids are the original text of the recipe, and the tokens of orange grids are the knowledge auxiliary text. We combined the original text and the knowledge auxiliary text as the input of the model.

3.3 Knowledge embedding

Entity knowledge and u-pos knowledge is useful in predicting answers in QA task. For example, a QA pair is: "How do you cut the carrots? by using a knife". In this case, the token of a knife is labeled as B-TOOL in the entity column. It would help predict the answer if the model gets the token's entity type information.

In our model, we adopt the knowledge embedding method to incorporate the knowledge of the u-pos column and entity column. Similar to the token embedding representation, the knowledge embedding method maps values in the u-pos column to embeddings. The size of the knowledge embedding is the same as token embedding. The entity column's knowledge embedding method is the same.

As shown in Figure 1, we have two places options to apply knowledge embedding: the embedding layer (knowledge embedding plan A in Figure 1) or the header (knowledge embedding plan B in Figure 1).

In plan A, we add knowledge embedding to the embedding layer of the model. Compared with BERT's embedding layer whose output embedding is the sum of token embedding, position embedding, and segment embedding, our model adds entity knowledge embedding and u-pos knowledge embedding to the original BERT's embedding layer.

In plan B, we add knowledge embedding to the header of the model. We first sum up the output representation of BERT's last layer, the entity knowledge embedding, and the u-pos knowledge embedding. Then fed it into a small network such as MLP(Rosenblatt, 1957).

3.4 Answer extraction method for QA task

Two common methods of predicting answers in QA tasks are the extraction-based method and the generative-based method. In our model, we chose the answer extraction method for the QA task. Here are the steps to label the data for extracting answers:

First, we filtered out keywords from the questions and answers by deleting words whose u-pos are article, preposition, pronoun, and so on.

Second, we located the keywords in the text. According to the statistics, 88.5% of the QA samples can be located successfully in one sentence, and 0.5% in two adjacent sentences. 11% samples' keywords can't be located in texts, these samples were regarded as low confidence samples and would not be used.

Third, we labeled the answers' keywords in the recipe texts. Concatenate the question and the labeled recipe texts as the input for the model.

Forth, predicting answer's keywords by model.

Fifth, generate answers based on the keywords.

3.5 Rule-based answer generation method

Some QA categories in Table 2 are more suitable for predicting using rule-based methods. For example, some categories are about counting tasks.

By analyzing the QA patterns, we assigned 6 categories to the rule-base module: cat 1, cat 6, cat 7, cat 8, cat 9, and cat 10. These samples make up 44.36% of the total samples.

A simple rule description of the 6 categories is shown in Appendix B.

4 Experimental setup

4.1 Dataset

The organizer of SemEval-2022 Task9 provided R2VQ (Recipe Reading and Video Question Answering) dataset.

R2VQ dataset is a collection of cooking recipes and videos. The R2VQ dataset provided to us has 1000 samples, and the organizer split the dataset into 3 parts: training dataset (800 samples), validation dataset (100 samples), and testing dataset (100 samples). The training dataset and validate dataset have corresponding answers to the questions while the test dataset hasn't.

Data of each sample in the R2VQ dataset is from two sources: cooking recipe text and screenshots from the videos. Each context of the recipes is consist of ingredients and directions whose labels have two annotation layers: Cooking Role Labeling (CRL) and Semantic Role Labeling (SRL). In the model of this paper, we only use the directions of recipes as the model's input.

position	**entity**	**upos**	**f1**
None	False	False	88.78
embed_layer	False	True	88.93
embed_layer	True	False	89.00
embed_layer	**True**	**True**	**89.23**
header	False	True	88.47
header	True	False	88.76
header	True	True	88.03
embed_layer	⋆	⋆	89.05
header	⋆	⋆	88.42
⋆	True	⋆	88.76
⋆	⋆	True	88.66

Table 1: Squad f1 for different knowledge-enhanced methods. Column Position means which place we add knowledge embedding to. Column Entity means whether we use entity knowledge or not. Column Upos means whether we use universal-pos knowledge or not. Column F1 means the word-level F1 score of the method.

4.2 Training Details

We implemented our model using the pre-trained language model BERT(Devlin et al., 2019) as the backbone and chose Adam-W(Loshchilov and Hutter, 2018) as the optimizer. In train phrase, the batch size is 8 and the optimizer's learning rate is 3e-5. We ran the experiment on an NVIDIA GeForce RTX 3090 GPU.

As like in the MRC task, the article is a long text while the question is a short text. We spilt the long recipe text into short texts. Concatenate the short recipe text and the question by the special token [SEP] as a tokens sequence. And added [CLS] token to the beginning of the tokens sequence. Every tokens sequence is an input of the model. We set the max sequence length of the tokens sequence as 512. We set the configuration of doc stride as 128 which indicates the token length of adjacent sentences' overlap.

5 Results

We ranked 3rd in the competition of SemEval-2022 task 9. Our model's word-level F1 score is 82.62 and the exact match score is 78.21.

In our system, parts of questions got answers by rule module while others by deep-learning model module, which is mentioned in Section 3. In this paper, we mainly focus on the deep-learning model module and word-level F1 score. The oblation experiment is about knowledge enhanced method.

The baseline of our original model is 61 of squad word-level F1 score, without knowledge auxiliary text method and knowledge embedding method. Its corresponding model is BERT and its input is the original text of the recipes without any annotation of SRL and CRL.

Then we adopt the methods of knowledge enhancement including knowledge auxiliary text and knowledge embedding. We got a squad word-level F1 score of 88.78 when we used the knowledge auxiliary text method and an F1 score of 89.23 when using both of the two knowledge enhanced methods. The ablation experiment results are shown in Table 1.

The record of knowledge auxiliary text method is shown in the first line (so as the first section) of Table 1, and the squad word-level f1 score is 88.78. In this method, we used a text which contains both original text and knowledge auxiliary text as the model's input data.

The second part of Table 1 is the records of the complete knowledge enhanced method containing both knowledge auxiliary text and knowledge embedding. We have done 6 groups of experiments. They are different in the place we put the knowledge embedding in and the specific embedding terms (entity knowledge or upos knowledge).

The best score for the second part is 89.23, its corresponding parameters are: adding knowledge embedding in the embedding layer, using both entity knowledge and upos knowledge.

The third part of Table 1 is a summary pivot table of the second part.

Some conclusions could be drawn from Table 1. 1) Knowledge embedding in the embedding layer improves the model's performance. 2) Both entity knowledge and upos knowledge benefit the performance and entity knowledge is a little more important. 3) The performance dropped if we place the knowledge embedding in the header of the model. Perhaps the parameters we set in experiments are inappropriate or the model's header we designed is too simple.

6 Conclusion

We present two knowledge-enhanced methods in this model: the knowledge auxiliary text method and the knowledge embedding method. We design an answer extraction task pipeline to accommodate SemEval-2022 Task 09. Future work will involve incorporating the video data and predicting the answer of all pattern categories by model.

Appendix

A QA-pair pattern categories

The QA pattern categories are shown in Table 1.

B Rule-based method descriptions

Follows are brief descriptions of the some categories' rule-based methods. The QA-pair pattern categories are described in Table 1.

Cat 1: locate two sentences in the text and judge whose position is in front.

Cat 6: count how many times the tool or ingredient, is mentioned in the question, appears in the text.

Cat 7: get ingredient and action information from the question, locate the ingredient before the action occurs, and get the habitat of the ingredient.

Cat 8: count how many times the habitat, which is mentioned in the question, appears in the text.

Cat 9: locate the RESULT target in the context and extract the whole sentence. Reorganize the text by the components from original text and knowledge auxiliary text.

Cat 10: locate the HABITAT target in the context and extract relevant ingredients.

ID	Question	Answer	Pct.
01	Pouring batter in and baking other side, which comes first?	the first event	15.9
02	How do you cut the stalks?	by using a knife	13.7
03	What should be added to the pan?	the kale	12.9
04	Where should you divide the dough?	floured surface	10.8
05	Where do you transfer the garlic?	to a paper towel	8.5
06	How many times is the spoon used?	2	8.3
07	Where was the quinoum before it was mixed into the wok?	bowl	5.8
08	How many teaspoons are used?	2	5.6
09	How did you get the aromatic mixture?	by adding the shallot and garlic	4.5
10	What's in the gratin?	the cheese	4.2
11	For how long do you add diced mushroom pieces?	after a few minutes	3.5
12	To what extent do you stir the pie	til syrup thickens	3.4
13	Why do you whip the egg?	to mix well	1.3
14	From where do you drain water?	potatoes	0.8
15	What do you mix sweetener with?	with 3/4 cup water	0.6
16	By how much do you cover the beans with water in a pot?	by 2 inches	0.1
17	What do you cut the rectangle into?	into 6 squares	0.05
18	How would you reduce oven temp?	slightly	0.01

Abstract

In this paper, we introduce the first SemEval shared task on *Structured Sentiment Analysis*, for which participants are required to predict all sentiment graphs in a text, where a single sentiment graph is composed of a sentiment holder, target, expression and polarity. This new shared task includes two subtracks (monolingual and cross-lingual) with seven datasets available in five languages, namely Norwegian, Catalan, Basque, Spanish and English. Participants submitted their predictions on a held-out test set and were evaluated on Sentiment Graph F_1. Overall, the task received over 200 submissions from 32 participating teams. We present the results of the 16 teams that provided system descriptions and our own expanded analysis of the test predictions.

1 Introduction

Affective computing is a fundamental step towards enabling human computer interaction (Picard, 1997), as human communication is filled with affective content which conveys a speaker's private state, *i.e.* their current mood, their emotional experiences, or their attitude towards a certain object of conversation. Along with emotion detection, sentiment analysis (Pang et al., 2002; Turney, 2002; Wiebe et al., 2005) is an important stepping stone towards this goal. On a more practical level, being able to automatically determine what people think about an idea, product, or policy is of interest to companies, governments, and private citizens.

In this paper, we describe the SemEval-2022 shared task on *Structured Sentiment Analysis*, which can be thought of as an information extraction problem in which one attempts to find all of the opinion tuples $O = O_i, \ldots, O_n$ in a text. Each opinion O_i is a tuple (h, t, e, p) where h is a **holder** who expresses a **polarity** p towards a **target** t through a **sentiment expression** e, implicitly defining pairwise relationships between elements of the same tuple. Liu (2012) argues that all of these elements are essential to fully resolve the sentiment analysis problem. Although early annotation efforts in sentiment analysis annotated for fine-grained sentiment (Wiebe et al., 2005; Toprak et al., 2010), most research on modeling sentiment *focuses either on a variety of sub-tasks* which avoid performing the full task, *e.g.* targeted (Hu and Liu, 2004), aspect-based (Pontiki et al., 2014), or end-2-end sentiment (Wang et al., 2016), *or instead relies on simplified and idealized tasks*, *e.g.* sentence-level binary polarity classification (Pang et al., 2002).

We argue that the division of fine-grained sentiment into these sub-tasks has become counterproductive, as reported experiments are often not sensitive to whether a given addition to the pipeline improves the overall resolution of sentiment, nor do they take into account the inter-dependencies of the various sub-tasks.

Motivated by this, we present the SemEval-2022 shared task on **Structured Sentiment Analysis**, which jointly predicts all elements of an opinion tuple and their relations.

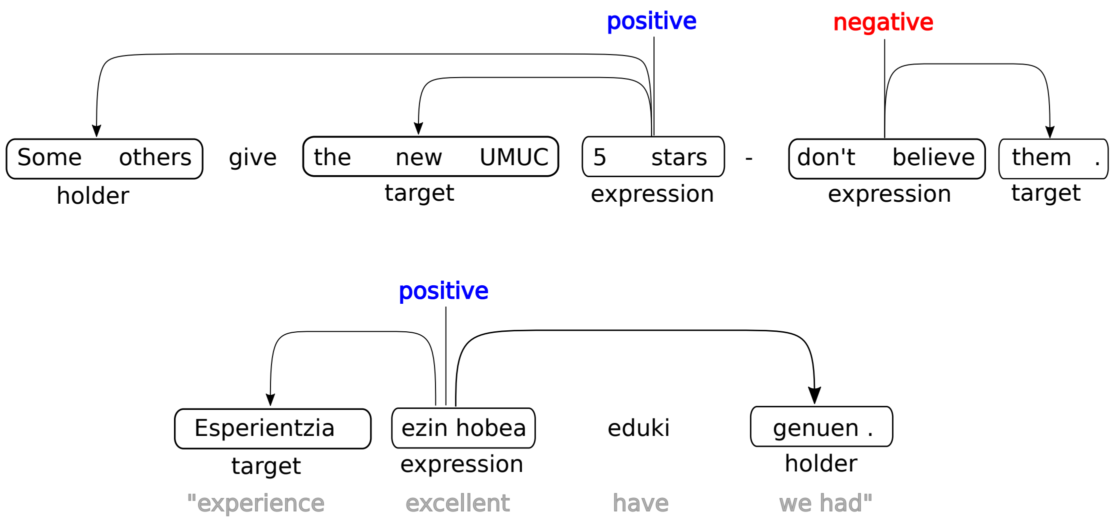

Figure 1: A structured sentiment graph (shown in English and Basque) is composed of a holder, target, sentiment expression, their relationships and a polarity attribute. Holders and targets can be null.

2 Related Work

The conceptual roots of Structured Sentiment Analysis can be found in early computational work on sentiment (Hu and Liu, 2004; Wiebe et al., 2005). Much research in the field has been motivated by the corpus compiled by Wiebe et al. (2005), who annotated English news wire documents with sentiment holders, targets, expressions, intensities, and other variables of interest. Subsets of these variables have been detected with linear (Choi et al., 2006; Yang and Cardie, 2012) and neural models (Katiyar and Cardie, 2016; Zhang et al., 2019), but the full task has never been performed simultaneously.

For instance, various SemEval shared tasks on *Aspect-Based Sentiment Analysis* (ABSA) (Pontiki et al., 2014, 2015, 2016) have focused on target extraction and polarity classification, and there have been research efforts to predict sentiment expressions as well (Wang et al., 2017). The models implemented for that purpose, however, neither resolve relations between expressions nor predict their polarity. The combination of targets, expressions and their polarity have been addressed for the recent task of *aspect sentiment triplet extraction* (Peng et al., 2019; Xu et al., 2020), but the resources that are used for this goal, which typically augment existing targeted datasets with polar expressions, suffer from a major limitation: they do not report annotation guidelines, procedures, or inter-annotator agreement, leaving the final quality of the data unclear.

To solve these issues and integrate all such perspectives, Barnes et al. (2021) proposed a holistic approach to sentiment. They cast the problem of structured sentiment as one of dependency parsing, they introduced specific metrics to evaluate automatic performance on this task, and developed a state-of-the-art structure-aware model. Further improvements were reported by Peng et al. (2021), who proposed a sparse fuzzy attention mechanism to deal with the sparseness of dependency arcs in the dependency models.

3 Task Description

The aim of this shared task is to predict all sentiment graphs in a text (see Figure 1), where a graph includes the elements of an opinion tuple (h, t, e, p). We proposed two subtasks, corresponding to monolingual structured sentiment and cross-lingual structured sentiment. Participants were free to participate in one or both setups, and they had the opportunity to submit a single run on each dataset.

Subtask 1: Monolingual structured sentiment. Models implemented for the first setup had to be trained and tested on the same language. We did not include a closed track, but we asked participants to detail all data used to train models and to make their training reproducible. This also allowed the teams to train multi-lingual models on all of the available training data for structured sentiment – a choice that was made by some of them.

Subtask 2: Cross-lingual structured sentiment. The second task required participants to train on other languages' train set and test on Spanish, Catalan, and Basque. Again, we allowed any further resource besides the train/dev sets for the test language provided with the shared task.

4 Data

The task contained seven datasets in five languages: Basque (**MultiBooked**$_{\text{EU}}$), Catalan (**MultiBooked**$_{\text{CA}}$) (Barnes et al., 2018), English, with data from **OpeNER**$_{EN}$ (Agerri et al., 2013), Multi-Perspective Question Answer corpus (Wiebe et al., 2005, **MPQA**) and Darmstadt Universities corpus (Toprak et al., 2010, **DS**$_{\text{Unis}}$), Norwegian (Øvrelid et al., 2020, **NoReC**$_{\text{Fine}}$) and Spanish (**OpeNER**$_{ES}$) (Agerri et al., 2013). We directly distributed the datasets in json format, with the exception of the last two corpora, as they have more restrictive licensing. For these, we provided links to the data such that participants could acknowledge their respective terms of use and include scripts to preprocess the data in a uniform manner. Table 1 provides an overview of the datasets and their sentiment annotations.

MultiBooked is a collection of hotel reviews in Basque and Catalan, written by users and collected from `booking.com`. The data was annotated for structured sentiment with polar expressions, targets, and holder labels, as well as polarity and intensity. Each dataset contains around 1,500 sentences, making them the smallest datasets in the shared task. However, these sentences are more densely annotated than some of the larger corpora. For guidelines and inter-annotator agreement, see Barnes et al. (2018).

OpeNER contains an opinion mining corpus of hotel reviews for six languages (de, en, es, fr, it, nl)[1]. For the purposes of the shared task, we only used the English and Spanish data (Agerri et al., 2013). The reviews were extracted from different booking sites from November 2012 to November 2013. Data collection was designed to ensure that different ratings and languages were included for a given hotel review.

The annotations regard opinion expressions, their respective holders and targets, their polarity and opinion strength. The guidelines were based on the work by Wiebe et al. (2005), which defines an opinion expression as a word (or combination of words) that expresses an attitude of the opinion holder towards a target. The corpus also specifies the relations between holders, targets and opinion expressions in opinion triplets[2].

MPQA annotates English news wire texts with a complex set of annotation types, *i.e.* *agent*, *expressive-subjectivity*, *direct-subjective*, *objective-speech-event*, *attitude*, and *target*. These types are also associated to a number of features and relations between one another. For the purpose of the shared task, we keep only the labels of *agent*, *target*, *direct-subjective*, as well as the *polarity* feature of direct-subjective, which respectively map to our holder, target, polar expression and polarity. We further normalize the polarities such that we have only *positive*, *negative*, and *neutral*. This is the second largest dataset, with a large number of holders, but relatively fewer targets and expressions.

DS$_{\text{Unis}}$ was initially published as part of the Darmstadt Service Review Corpus (DSRC) (Toprak et al., 2010). The DSRC contains reviews of online universities and services annotated with sentiment on the sentence level and fine-grained sentiment on the expression level. The **DS**$_{\text{Unis}}$ data that is part of the task contains only the university reviews, and discards the sentence-level annotations. Toprak et al. (2010) distinguish between polar facts and opinions in their annotation scheme. In order to map the data to the format of the shared task, this distinction is resolved.

NoReC$_{\text{Fine}}$ annotates a subset of the Norwegian Review Corpus (Velldal et al., 2018) for fine-grained sentiment, i.e., including polar expressions, targets and holders, as well as their polarity and intensity. The corpus contains annotations for more than 11k sentences (both subjective sentences and fact-implied ones) taken from professional reviews from a number of different domains, such as screen, music, literature, products and games (Mæhlum et al., 2019). Further details on the annotation procedure, guidelines and inter-annotator agreement can be found in Øvrelid et al. (2020).

5 Evaluation

The main metric for the task is Sentiment Graph F$_1$ (**SF**$_1$), which attempts to quantify how well a

Table 1: Statistics of the datasets, including number of sentences and average length (in tokens), as well as average and max lengths (in tokens) for holder, target, and expression annotations. Additionally, we include the distribution of polarity – restricted to positive, neutral, and negative – in each dataset.

model captures the full sentiment graph (see Figure 1). For **SF**$_1$ each sentiment graph is a tuple of (holder, target, expression, polarity). A true positive is defined as an exact match at graph-level, weighting the overlap between the predicted and gold spans for each element, averaged across all three h, t, e spans. We therefore allow some variability at the token-level (properly weighted), as long as the sentiment graph is predicted.

For precision, we weight the number of correctly predicted tokens divided by the total number of predicted tokens (for recall, we divide instead by the number of gold tokens). Correctly predicted tokens can also consist of empty holders and targets.

6 Baselines

We provided participants with two strong baselines: 1) a dependency graph prediction model, and 2) a sequence-labeling pipeline.

Dependency Graph The first baseline approaches sentiment graph prediction as a dependency graph prediction task, following Barnes et al. (2021). Each sentiment graph is converted to a head-final dependency representation, where we set the final token of the sentiment expression as a root node, the final token in each holder and token span as the head of the span, with all other tokens within that span as dependents. The labels simply denote the type of relation (target/holder) and for sentiment expressions, they additionally encode the polarity. After converting the data, we use a neural graph parsing model (Dozat and Manning, 2018), which learns to score each possible arc to predict the output structure simply as a collection of all positively scored arcs. The base of the network structure is a BiLSTM that creates contextualized representations $c_1, \ldots, c_n = \text{BiLSTM}(w_1, \ldots, w_n)$ where w_i is the concatenation of a word embedding, POS tag embedding, lemma embedding, and character embedding created by a character-based LSTM for the ith token. The contextualized embeddings are then processed by two feedforward neural networks (FNN), creating specialized representations for potential heads and dependents, and the scores for each possible arc-label combination are computed by a final bilinear transformation.

Sequence Labeling We also include a sequence labeling baseline. Specifically, this approach first trains three separate BiLSTM models to extract holders, targets, and expressions, respectively. It then trains a relation prediction model, which uses a BiLSTM with max pooling to create contextualized representations of 1) the full text, 2) the first element (either a holder or target) and 3) the sentiment expression. These three representations are then concatenated and passed to a linear layer followed by a sigmoid function. The training consists of predicting whether two elements have a relationship or not, converting the problem into a binary classification. During inference, the model starts by predicting all sub-elements. Next, it decides if these have a relationship (prediction > 0.5). Finally, the predictions are combined to form full sentiment graphs.

7 Results and Discussion

32 teams participated, with over 200 submissions in total for the evaluation period. The top 10 results for **Subtask 1** are shown in Table 2 (for **Subtask 2** in Table 3). Nearly all teams perform better than the baselines and the performance of the winning teams constitutes the new state of the art.

8 Summary of Participating Systems

In this section, we summarize the top three approaches and then further discuss some commonalities among the remaining teams.

8.1 The ZHIXIAOBAO submission

The best performing team on **Subtask 1** formulated the task similar to Barnes et al. (2021), using a dependency graph parsing approach. They deviate from the original in several important ways. First, they use either RoBERTa_Large (Liu et al., 2019) (for the English datasets) or XLM-RoBERTA_-Large (Conneau et al., 2020) (for non-English) as a feature extractor, rather than multilingual BERT base (Devlin et al., 2019) and further fine-tune the parameters of this model, rather than freezing it. Secondly, they introduce a new attention mechanism to help differentiate 'in span' and 'out of span' tokens, which helps dealing with tokens that are not a part of any sentiment span. Finally, they also use suffix masking for tokens which are broken into subtokens when computing the edge scores.

During experimentation, they found that removing the final LSTM layer from the Barnes et al. (2021) model gave improved performance. They also found that the 'in-label' approach was beneficial. Interestingly, they also found that XLM-RoBERTa often performed better than similarly sized monolingual BERT models, e.g. for Basque, Catalan, and Spanish.

8.2 The MT-Speech submission

The second best team in **Subtask 1** and best team in **Subtask 2** similarly used a dependency graph parsing approach with an XLM-RoBERTa_Large backbone. Given the rather small size of some of the datasets, this team proposes several data augmentation strategies which prove to be effective. The first is to exploit the Masked Language Modeling pre-training task of XLM-RoBERTa to augment the training data. They do this by randomly masking a small percentage of the words in a text which lie outside of the sentiment expression. They then sample up to 5 new sentences for training, putting a threshold to remove unlikely versions. Secondly, they further pre-train the language model on the training data, but using the Masked Language Model objective. They also use data from similar datasets in Portuguese and the English

Table 4: Characteristics of submissions that submitted a system description. We show the rank for subtask 1 (mono) and 2 (cross), followed by the general approach, the use of language models, and other characteristics. FT domain = Fine-tune to the domain, mono = monolingual LM, XLM-mono = multi-lingual language model used for monolingual task.

SemEval Laptop dataset which has been automatically augmented with polar expressions. This data is converted to the structured sentiment format. Finally, they include several auxiliary tasks to predict the spans in a sentiment graph as sequence labeling tasks. They include final polarity classification auxiliary task, which they perform on the Catalonia Independence Corpus (Zotova et al., 2020).

8.3 Hitachi

The third team compare a graph prediction model (Graph) and a sequence-to-sequence (Seq2Seq) approach. Specifically, Graph includes a BIO sequence labeler for span extraction, followed by relation prediction with biaffine classifiers (Dozat and Manning, 2018). For the Seq2Seq model, they serialize the tuples and use large pretrained language models to predict these serialized tuples. As the task required providing token offsets, as a post-processing step they predict the text anchors using a word-alignment tool (Jalili Sabet et al., 2020).

Generally, they find that graph prediction performs better than Seq2Seq. In an extensive analysis, they find that Seq2Seq's need for an external alignment system is a hindrance if that information is truly necessary. On OpeNER, however, Graph is clearly better. Both approaches generally perform worse on examples with more opinions, although Graph is slightly more robust. Finally, they find that Graph is much faster to train, as there is no decoder. They conclude, however, that there is not enough evidence to conclusively show that Graph is better than Seq2Seq.

8.4 General Trends

We now discuss some general trends within the submissions and their possible effect on the results. We summarize these trends in Table 4.

General Approach: In general, the teams with the best performance all use graph prediction models. The top two teams maintained the dependency graph approach of Barnes et al. (2021). Several strong submissions successfully used a pipeline approach of a sequence labeling model to extract spans, followed by a relation prediction model. Three teams preferred offset prediction to the BIO sequence labelling, while two teams formulated the task as question answering.

Language Models Nearly all teams used some form of pre-trained language models to create contextualized token representations. One important factor seems to be the size of the language model used (Base or Large), as the top teams generally used XLM-RoBERTa_Large (Conneau et al., 2020). MT-Speech find that fine-tuning this model using the masked language model task on the provided training data improves the performance. The benefits of using a monolingual model seem to be language dependent, as for English or Spanish, many submissions found monolingual models best, while for Basque or Catalan, they often found that multi-lingual language models performed better.

Others Finally, two of the top teams used a multi-task learning approach to incorporate further information into their models. Several teams further perform data augmentation to minimize the impact of the smaller datasets. This is a particularly beneficial side-effect explicitly annotating all parts of the sentiment graph, as participants were able to make changes in a controlled way, such that the opinion itself was not changed. Three teams further included ensemble approaches with less success than in other tasks.

9 Further Analysis

To gain insight into the systems' performance, we move on to analyzing their mistakes and correct predictions. We start with a quantitative analysis to understand what types of errors appear most often in the submissions, and how they vary according to the different opinion spans (e.g., h/t), settings (monolingual/cross-lingual) and datasets.

Next, we relate the predictions made in the two sub-tasks to some structural properties of the data. This qualitative analysis aims at shedding light on what makes a tuple O_i easy/difficult to find, and whether the observations that apply to a sub-task generalize well to the other.

9.1 Quantitative Analysis.

For the quantitative analysis, we group the different error types defined by Oberländer and Klinger (2020) in the following way[3]: Too early (,), Too late (,), Other (,), Multiple ( ), False Positive (/), and False Negative ( ).

Figure 2 shows relative frequencies for each error type across all 10 winning teams in the monolingual setting (left) and cross-lingual setting (right)[4]. To obtain the relative frequencies, we flatten the annotations for each span type and treat either a continuous stream of annotated or of unannotated tokens as the base of our predictions. Where a prediction exactly aligns with an annotated span, it counts as a true positive, where there is no prediction on an unannotated part, as a true negative. For all other cases we count this as another error type as grouped above. True positives and negatives are not shown in the plot, but are considered when calculating the relative frequency.

We find that, generally, predicting the correct *holder* of an opinion in the monolingual setting is easier than predicting the *target* or the *polar expression*. This is to be expected and explained by the fact that the holders of an opinion are overall shorter in length, reducing the potential of making mistakes. Interestingly, this finding does not fully hold for the cross-lingual setting where there are more False Negatives ( ) and Multiple ( ) for *holder* than for *polar expression*. A finding which holds for both the monolingual and the cross-lingual setting is that the error type that occurs the most apart from False Positives (/) and False Negatives ( ) is Multiple ( ). Multiple occurs the most when models predict *polar expressions* for the monolingual setting and *target* for the cross-lingual setting. This is likely because the *polar expression* and *target* spans are typically longer, which gives the models more options to find several predictions within the span. The other type of errors are infrequent, notable being Too early (,) and Too late (,), both error types occurring unsurprisingly mostly for the *polar expression* spans.

Now we compare the box plots across the sub-tasks. Looking at the medians, we see that these are well separated with the median for relative frequencies of False Negatives ( ) and Multiple ( ) for all span types being lower for the monolingual than for the cross-lingual setting. The same pattern for False Positives (/) can be seen, with the exception of the span type *polar expressions*. The inter-quartile ranges are not very similar to each other while looking at pairs of the same type of errors across the two sub-tasks. We see this aspect in the lengths of the boxes, which differ quite a lot, especially notable here are *holders*, for which the boxes are two times in length for the cross-lingual setting. We observe that the error frequencies are generally more spread for the cross-lingual subtask, for False Negatives ( ) and Multiple ( ) holders, and False Positives (/) targets. For other span types the trend is not as clear. Also, the overall spreads across the settings are slightly greater for the cross-lingual setup for the same span types. However, looking at the overall spreads is perhaps less informative about dispersion of the frequencies of errors than the comparison of box lengths, because of the outliers we see for the mono-

[3]The top bar shows the gold span, while the bottom corresponds to the predicted span.

[4]Error frequencies across the top 10 systems can be found in Appendix (Table 6 and Table 7).

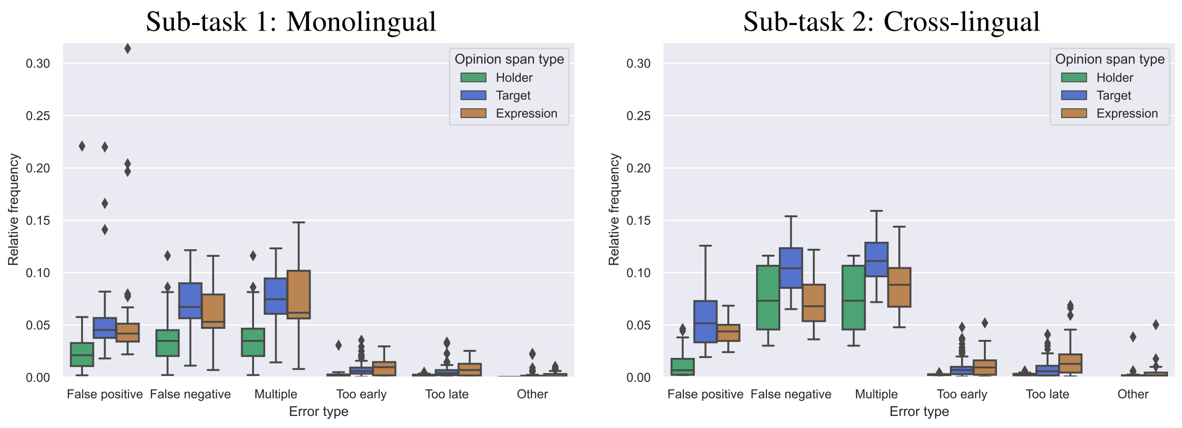

Figure 2: Relative frequencies for each error type for each span type across all teams and datasets.

lingual case. The exceptions are the box plots for the *polar expressions* in the case of the error type Multiple (▬▬). Regarding skewness, we observe generally a right-skewness for the monolingual setup, and no large skew for the cross-lingual setup. For instance, errors on *holders* are skewed to the right in the monolingual case, whereas for the cross-lingual setting, they are slightly skewed to the left. Similarly, *polar expressions* are also skewed to the left for the cross-lingual case and for *targets* the opposite effect can be noticed. Far-away outliers only exist for the monolingual setting, for False Positives (▪▫▪/▬) the far-away outliers are mostly from team ECNU_ICA and team sixsixsix for the **MPQA** and **NoReC$_{\text{Fine}}$** datasets. For the False Negatives (▭) and Multiple (▬▬), the far-away outlier is team ohhhmygosh for both error types on **MultiBooked$_{\text{EU}}$** dataset.

The analysis on the box plots evokes a further question: why are there so many False negatives (▭) for *holders* in the cross-lingual setup in comparison to the monolingual one? By inspecting the datasets, we make two observations that explain this result. First, across all datasets used for the cross-lingual sub-task there are only approximately 10% of instances annotated with *holders* and second, the fraction of non-empty *holders* is higher in the test data than in the train data (the numbers can be found in Table 5 in the Appendix).

9.2 Qualitative Analysis.

We now examine the extent to which the correct (or incorrect) identification of specific sub-parts of a sentiment graph (e.g. (h, t)) correlates with another (e.g., (e, p)), or with additional properties of the ground truth (e.g., sentiment intensity). So far, we considered a sentiment graph to be correctly predicted by one system if the system's output was a true positive (following the definition in Section 5). Now, to aggregate the results of all teams, a correctly predicted (ground-truth) graph is one which corresponds to a majority of true positives across teams. Table 8 in Appendix A reports a subsample of texts in which all O_i are predicted correctly (indicated as $+$) by most teams, and those in which most teams did not score a true positive for any of any tuple (marked as $-$).

Within-graph analysis. We begin by focusing on the predictions of h, t, and e. We observe that a successful detection of an opinion holder and target approximates the exact identification of the opinion expression. This is particularly evident in the cross-lingual setup: 75% of ground-truth opinion tuples that have a match in the holder and target for more than half the teams have an exact match in the expression (81% if also the h, t match is exact). In the monolingual setup, this happens in 70% cases (73% for exact h, t span matches).

Typically, if the spans of holder, target and expression are properly recognized, the polarity of such expression is too. It happens for 95% of correctly predicted h, t, e in the cross-lingual setting, for 93% in the monolingual one. These numbers corroborate the relational nature of the span types involved in a structured sentiment task: determining a holder and a target is crucial to establish the opinion linking the two, and hence, its polarity.

Polarity-intensity link. Going beyond the component of a graph, we investigate the relationship between O_i and the intensity of sentiment – a label that was not evaluated in the competition but which characterizes opinions in the used corpora. Figure 3 shows two example distributions of ground-truth

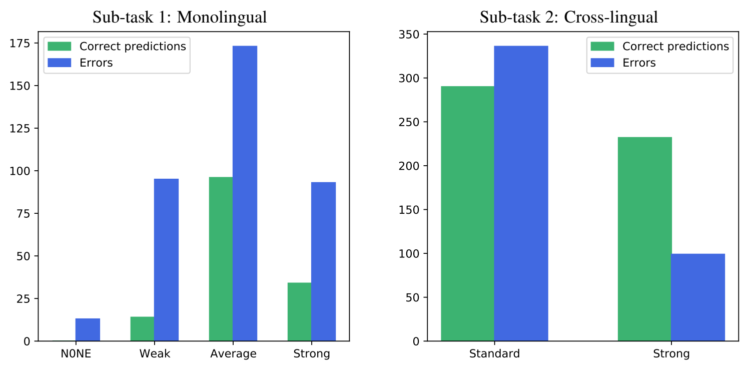

Figure 3: Counts of opinions predicted correctly (with respect to h, t, e, and p) and incorrectly (wrong p): example results from **MPQA** in Sub-task 1, and **OpeNER**$_{ES}$ in Sub-task 2.

opinions for which more than half the teams identified the right (h, t, e, p) (correct predictions), and those where for which (h, t, e) was identified but p was not (errors).

For the setups with only two strength labels, intensity seems to play a role in the prediction of polarity: the submitted systems are consistent in identifying the true polarity of most of the tuples associated to a strong sentiment expression. We see that, for instance in **OpeNER**$_{ES}$, correct predictions are 70% of opinions labelled as "Strong"; the same happens only for 46% of O_i tuples with a standard intensity level. Similar patterns are observed through all corpora in the cross-lingual setup, as well as in the monolingual task based on the same corpora, and **OpeNER**$_{EN}$ (see Appendix Figure 4). This suggests that the recognition of polarity correlates to the intensity with which sentiment is expressed: a sentiment conveyed with higher intensity tends make the prediction "easier".

The link becomes less clear for corpora with non-binary intensity annotation schemas, *i.e.* **MPQA**. Most polarities were not properly recognized across all sentiment strengths. Still, the proportion of wrong-to-correct instances is typically higher with milder intensity degrees (e.g., in **MPQA**, 87% of weak-intensity O_i tuples correspond to errors).

Opinion span sparsity. One feature that differentiates tuples is the sparsity of their spans in the text (e.g., in "*L' habitació un pèl petita per un 5 estrelles*" t and e encompass the whole sentence, while in "*La situació perquè tenim la nostra filla vivint molt a prop . segurament repetirem*", which contains no holder and target, the expression involves only the last two words). Therefore, we observe whether and how the systems' decisions change together with the sparsity of opinion spans, computed as $1 - \frac{\sum \#\,\text{tokens}(h,t,e)}{\#\,\text{tokens}(text)}$ (Figure 5 in Appendix shows the distribution of sparsity values in the two tasks).

On average, sparsity is lower for correct predictions than for errors. It is 0.73 and 0.72 for the missed h, t, and e spans in the cross-lingual and monolingual tasks, 0.67 (cross-lingual) and 0.66 (monolingual) for the predicted h, t, and e spans. This suggests that spans covering larger parts of the text are easier to predict, while errors tend to occur with labels that more scattered in the text.

A comparable observation can be drawn relative to the number of opinions in a text. Opinion tuples coming from texts with a higher number of h, t, e relations appear harder to predict: correct predictions occur for tuples that come from texts containing on average 3.4 O_is (in the cross-lingual setup, and 3 in the monolingual task), while errors arise with spans present in text that have on average 4.16 opinions (in the cross-lingual setup, and 3.27 in the other).

10 Conclusion

We proposed to cast sentiment analysis as a structured prediction problem, explicitly predicting the four main elements, and provide seven preprocessed datasets in five languages. Graph prediction models powered by pre-trained language models generally performed best, although several pipeline sequence labelling models also performed well. An analysis of the errors shows that false negatives and predicting shorter spans are the most common errors, while when models correctly predict the holder and target, they generally predict everything correctly. Finally, both more intense polar expressions and spans that cover much of the text are easier to predict.

Abstract

We describe the work carried out by AMEX AI Labs on the *structured sentiment analysis* task at SemEval-2022. This task focuses on extracting fine grained information w.r.t. to source, target and polar expressions in a given text. We propose a BERT based encoder, which utilizes a novel concatenation mechanism for combining syntactic and pretrained embeddings with BERT embeddings. Our system achieved an average rank of 14/32 systems, based on the average scores across seven datasets for five languages provided for the monolingual task. The proposed BERT based approaches outperformed BiLSTM based approaches used for structured sentiment extraction problem. We provide an in-depth analysis based on our post submission analysis.

1 Introduction

In this paper we present the work done by AMEX AI Labs on the *structured sentiment analysis* monolingual task at SemEval-2022 (Barnes et al., 2022). Structured sentiment analysis (SSA) focuses on performing fine grained analysis and extracting opinion tuples from a given input text (Barnes et al., 2021). An example is presented in Fig. 1.

Input sentence: *Some others give the new UMUC 5 stars - don't believe them*

Expected outputs are two tuples:

- **Tuple1** - ("source": *"Some others"*, "target": *"the new UMUC"*, "polar expression": *"5 stars"*)
- **Tuple2** - ("source": *""*, "target": *"them"*, "polar expression": *"don't believe"*).

Aspect based sentiment analysis is a popular and widely researched topic in the NLP community (Wagner et al., 2014; Pontiki et al., 2015; Schouten and Frasincar, 2015). However, the SSA task goes beyond traditional aspect based sentiment

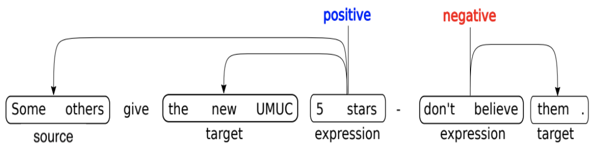

Figure 1: Sample sentence, source: (Barnes et al., 2021)

mining. The main challenges in SSA task are as follows:

- Focus is on correct **span detection** of source, targets, and polar expression elements as shown in Fig. 1.
- Correctly identifying **relationships** between source, target, and polar expression elements, as illustrated in the example above.
- Building a robust, generalized approach that is applicable *across domains* as well as *across languages*.

Most of the state-of-the-art (SOTA) approaches have explored joint learning, span based multi-task learning, BiLSTM encoders or CRF based approaches for SSA related tasks (Barnes et al., 2021; Li et al., 2019; Zhao et al., 2020; Chen et al., 2020). We propose a contextualized BERT based approach called 'CBERT', for capturing context information effectively and address the main challenges for SSA task as discussed above.

The main contributions of our work are:

- We propose a BERT based encoding approach and combine syntactic and pre-trained embeddings using a novel concatenation approach to extract and find opinion tuples effectively.
- We performed a detailed error analysis highlighting the main challenges of SSA task and suggest future directions for building a more efficient and effective system for SSA.

The outline of this paper is as follows: Section 2 describes the prior work in the area of SSA. Section 3 presents an abstract overview of our proposed system. Section 4 provides a detailed description of our CBERT system. Section 5 describes the datasets, tools and resources used for the experimental setup. Section 6 present the main results of the proposed system and describes an in-depth error analysis. Section 7 describes the main conclusions and leanings.

2 Background

Structured Sentiment Analysis (SSA) aims at capturing the natural hierarchical structure of different aspects, their corresponding sentiments in a sentence and the correlation between them. Almars et al. (2017) leveraged a hierarchical tree structure on the aspect terms, analyses the opinions on those aspect terms and connects them to the corresponding evidence for the same. Choi et al. (2006) identify two types of opinion-related entities — expressions of opinions and sources of opinions — along with the linking relation that exists between them. To identify the joint existence of opinion terms, they had utilized integer linear programming approach. Over years, this task was recognized further as Aspect Based Sentiment Analysis which focuses more on the precise identification of aspects and their corresponding sentiments (Chen et al., 2014), (Liu et al., 2012). Other intermediate works also focus on transition based end-to-end opinion extraction approaches (Zhang et al., 2019) which ignore the polarity classification subtask. Target Sentiment Analysis, which is another modified form of SSA focuses on extracting only sentiment targets and classifying their polarity (Jiang et al., 2011), (Mitchell et al., 2013).

Yang and Cardie (2012) is a strong baseline which suggests that the use of Conditional Random Fields could enhance the aspect terms prediction, given a smaller dataset with annotations, for training. During this time, some prominent research works discussed the advantage of semantic dependency parsing (Dozat and Manning, 2018), (Kurtz et al., 2020) which was leveraged for SSA task and for the establishment of the state-of-the-art SSA model which was proposed by (Barnes et al., 2021). This work formulates the SSA task as a dependency parsing problem and predicts all tuple components as a dependency graph. We aim to extend this aforementioned work and propose a modified architecture to improve the results across various language datasets.

3 Model Overview

For the SSA task, prior works have deployed separate models for detecting various elements (source, target and polar expression) (Barnes et al., 2022). However, this results in information regarding prediction of individual elements not being passed on to other element predictions.

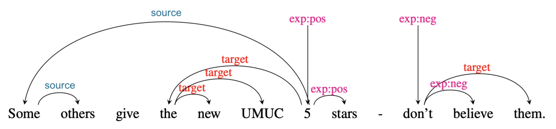

Figure 2: Sample sentence : head-first representation (Barnes et al., 2021)

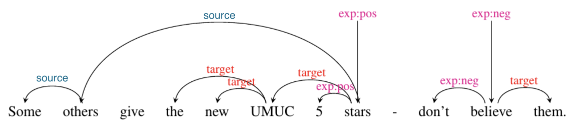

Figure 3: Sample sentence : head-final representation (Barnes et al., 2021)

For leveraging a joint learning technique, (Barnes et al., 2021) suggest two sets of approaches, *viz.*, head-first and head-final representation. *Head-first* considers spans of opinion elements using the first token of each element, *i.e.*, head token first, as shown in Fig. 2. *Head-final* considers the last token, *i.e.*, head token last, as shown in Fig. 3. Our proposed architecture was inspired by this joint learning technique and is elaborated in Section 4.

SSA task involves prediction of opinion elements along with the relationship between them, referred to as arc prediction. In this paper, we provide a comparison between two methods - VBERT, which uses only BERT embeddings and CBERT, which uses BERT embeddings along with concatenation of head and dependent BiLSTM blocks, detailed in Section 4. A comparison of results from these two approaches are provided in Section 6.

4 System Description

In this section we provide a detailed description of our proposed CBERT system. Fig. 4 presents the main architecture, comprising of seven main components, detailed below respectively.

4.1 Encoding Block

The *BERT context* shown in Fig. 4 represents BERT's role as an encoder. Our proposed model uses a BERT base multilingual cased[1] model (Devlin et al., 2018) which has t transformer layers to calculate the fine-tuned BERT vector from the input tokens, $x = (x_1, x_2, x_3, ..., x_n)$ of n padded sequence length. The output BERT fine-tuned vector is shown as, $b = (b_1^t, b_2^t, ..., b_n^t) \in R^{n*dim_b}$ where dim_b denotes it's dimension.

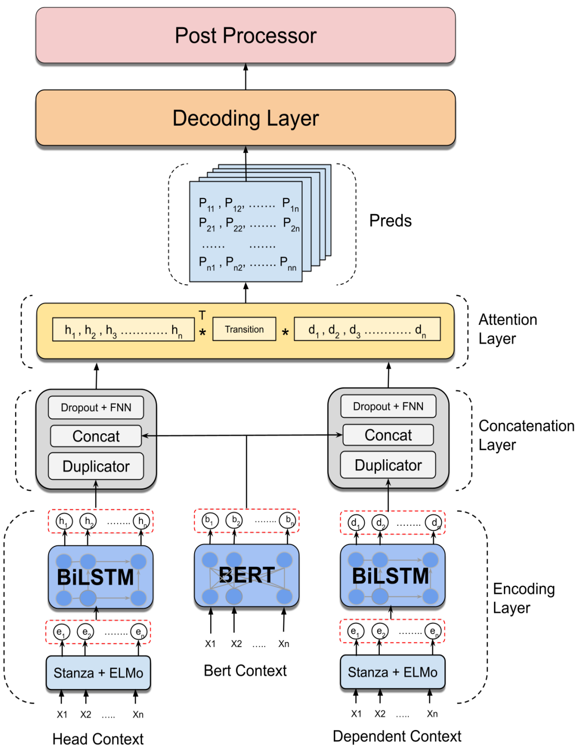

Figure 4: CBERT Architecture

The *Head Context* and *Dependent Context* as shown in Fig. 4, represent independent BiLSTM blocks where we fine-tune the syntactic and pretrained context in our CBERT system. However, in the VBERT system we do not have the aforementioned independent BiLSTM blocks (for more details refer Section A.4).

The input embedding in the BiLSTM block is a concatenation of Stanza[2] pretrained syntactic vectors (Qi et al., 2020) (U-pos, Lemma, Depparse) and ELMo[3] (Peters et al., 1802) embedding represented as, $e = (e_1, e_2, ..., e_n) \in R^{n*dim_e}$ where dim_e is the dimension of the input embedding. After passing these vectors through two independent identical BiLSTM blocks, we get the head and dependent fine-tuned vectors $h = (h_1^r, h_2^r, ..., h_n^r) \in R^{n*dim_c}$ and $d = (d_1^r, d_2^r, ..., d_n^r) \in R^{n*dim_c}$ where dim_c is the dimension of the fine-tuned vector and r is the number of recurrent layers in the BiLSTM block.

4.2 Target Encoding

We follow a head-first encoding (Barnes et al., 2021) which entails adding a label map to each position in the head-dependent 2D mapping, each label showing which category from ***(Expression-positive, Expression-negative, Source, Target, None)*** it belongs to. In the 2D mapping as shown in Fig. 5, heads are shown as rows, dependents as columns and a non ***None*** label shows if head-dependent relation exists or not. For denoting span the starting token of a certain span becomes the head and the other tokens as the dependents, as shown in Fig. 5, where *"the"* is linked to *("the","new","UMUC")*. Similarly, the head token of ***(Expression-positive, Expression-negative)*** labels point to the head tokens of ***(Source, Target)***, if a relation between them exists. For eg., *"5"* being linked to *"the"* as shown in Fig. 5. We also experimented with alternative encoding approaches mentioned in Section A.2

	Some	others	give	the	new	UMUC	5	stars	-	don't	believe	them

Figure 5: Encoding Structure

4.3 Concatenation layer

In this layer, we combine the BERT fine-tuned vector with the head and dependent fine-tuned vectors separately. The head and dependent vectors are based on a space based tokenizer while the BERT

[1]https://huggingface.co/bert-base-multilingual-cased
[2]https://stanfordnlp.github.io/stanza/index.html
[3]https://allenai.org/allennlp/software/elmo

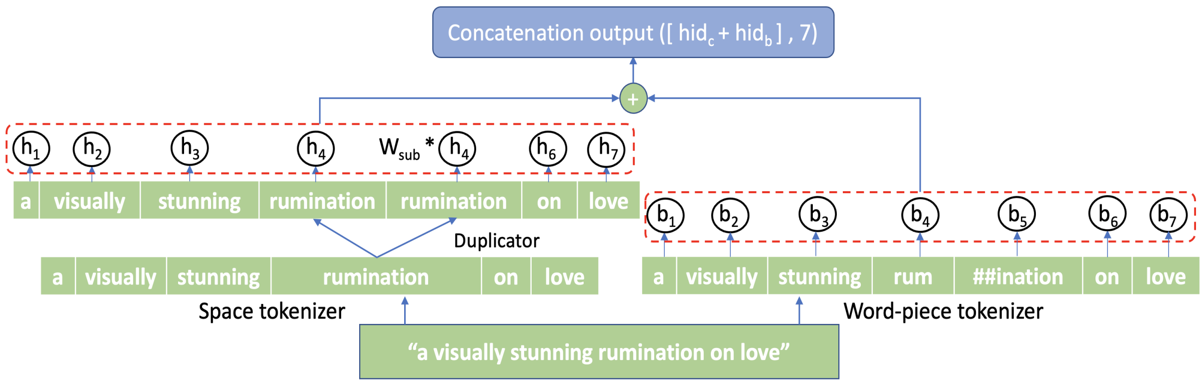

Figure 6: Concatenation of fine-tuned BERT with head and dependent fine-tuned vectors

vector is based on word-piece (Wu et al., 2016) tokenizer. Some of these space delimited tokens are further split by word-piece into sub-tokens. For eg., as shown in Fig. 6, the parent token *"rumination"* is split into sub-tokens *("rum","##ination")*. So we duplicate the parent token's vector,v as weighted vectors in the Duplicator as shown in Fig. 4. Higher weight is assigned to base-token *"rum"* and lower to sub-token *"##ination"*, as we want to put more significance on the base-token of the word for identifying span offsets correctly. Initializing sub-tokens with relatively low weighted vector instead of null vector helps us carry the base-word context till the sub-word. Following are the vector equations,

$$v = (v_1, v_2, ..., v_n)$$
$$v_{sub} = (W_{sub} * v_1, W_{sub} * v_2, ..., W_{sub} * v_n)$$
$$v_{base} = (W_{base} * v_1, W_{base} * v_2, ..., W_{base} * v_n)$$

Here v represents the parent token vector, v_{sub} the sub-token vector and v_{base} represents the base-token vector. The lower constant weight for sub-tokens is denoted by $W_{sub} \in [0, 1]$ compared to $W_{base} = 1$ assigned to base-token. The weight is decided after doing multiple runs with variations in W_{sub} as shown in Fig. 8. We choose $W_{sub} = 0.4$ empirically, as we get higher average scores in our experiments on the dev set.

4.4 Attention layer

The Concatenation layer outputs are then passed into the Attention layer which uses a transition matrix of $Shape(U) = dim_h * labels$. It transforms the head and dependent inputs to a 3D tensor matrix predicting the head-dependent relation arcs and labels jointly as represented in Fig. 4 as the Attention layer. The output is $Preds \in R^{n*n*labels}$ where $labels$ is the number of predicted labels and n is the padded sequence length. (for more details refer Section A.3)

4.5 Loss Function

We use a weighted cross-entropy function where the weights are assigned for each of the labels, l with respect to the target label frequency. We found out that the frequency of ***None*** label vs other labels was unbalanced. Hence, we conducted different runs with the following weight distribution $w = (w_{None}, 1, 1, 1, 1)$ by varying w_{None}. We choose the weights $w = (0.8, 1, 1, 1, 1)$ empirically, as we get higher average scores in our experiments on the dev set, as shown in Fig. 9.

$$loss_n = -w_{y_n} * log(\frac{exp(x_{n,y_n})}{exp(\sum_{l=1}^{L} x_{n,l})})$$
$$loss = -\sum_{n=1}^{N} \frac{loss_n}{\sum_{n=1}^{N} w_{yn}}$$

where x_n is the input probabilities, y_n is the corresponding target label, N is the batch length of input, w are the weights and L is the number of labels.

4.6 Decoding

In this subsection, we describe the methodology behind decoding the Attention layer output into the opinion pairs or tuples. As shown in Algorithm 1, in lines 2 to 12, we move along the main diagonal to find the predicted spans with labels of each category. Each of these spans have their starting offset denoted by the head pointing to itself as shown in Fig. 5. The end offset of a span is the last consecutive occurrence of the same tag as the head. For the next step shown in lines 13 to 22, we look at expression head's dependents to find if any of them are heads to other spans. This signifies a relation arc between spans.

Algorithm 1 Algorithm for Decoding the scores to tuples

Input: $Preds$, the 3D tensor output which contains the predicted label with maximum class probability for every head-dependent token pair.
Output: $Arcs$, which contain all the possible Source-Target-Expression tuples.

```
Require: $Preds \neq null$
 1: Initialize $Tar$, $Src$, $Exp$ and $Arcs$ sets to empty
 2: while Left index $l \leq length(Preds)$ and Right index $l < r \leq length(Preds)$ do
 3:     if $Preds(l,l) = T$ and all $Preds(l,r) = Preds(l,r-1)$ then
 4:         Add tokens $(t_l, ...t_r)$ to $Tar$
 5:     end if
 6:     if $Preds(l,l) = S$ and all $Preds(l,r) = Preds(l,r-1)$ then
 7:         Add tokens $(t_l, ...t_r)$ to $Src$
 8:     end if
 9:     if $Preds(l,l) \in (EN, EP)$ and all $Preds(l,r) = Preds(l,r-1)$ then
10:         Add tokens $(t_l, ...t_r)$ to $Exp$
11:     end if
12: end while
13: while Left index $l \leq length(Preds)$ and Right index $r \leq length(Preds)$ do
14:     if $Preds(l,l) \in (EN, EP)$ and $Preds(l,l) = Preds(l,r)$ and $l \neq r$ then
15:         if $t_r \in Tar$ then
16:             $Arcs \leftarrow (Tar(t_r), Exp(t_l))$
17:         end if
18:         if $t_r \in Src$ then
19:             $Arcs \leftarrow (Src(t_r), Exp(t_l))$
20:         end if
21:     end if
22: end while
```

4.7 Post processing

For post processing, in the generated tuples from the decoding layer, we remove overlapping Source or Target spans from edges of Expression spans. As shown in Example 1, "experience" is removed from the polar expression.

Example 1: *Thank you for such a wonderful experience.*
Raw tuple - ("source": "", "target": "*experience*", "polar expression": "*wonderful experience*")
Post processed tuple - ("source":"", "target": "*experience*", "polar expression": "*wonderful*").

5 Experimental Setup

5.1 Datasets & Evaluation Metric

The shared task has seven datasets across five languages that are used for final evaluation and ranking of submitted systems MPQA (Wiebe et al., 2005), NoRec (Øvrelid et al., 2020), Multi-book (Barnes et al., 2018), Opener (Agerri et al., 2013) and Darmstadt (Toprak et al., 2010). We submitted our system for monolingual task, where we fine-tuned our model for each individual dataset mentioned above.

The experiments conducted as a part of this work use Sentiment-F1 (SF1) score (Barnes et al., 2021) as the evaluation metric, as used in SemEval-2022 Shared Task 10. This metric defines true positive as an exact match for each element of the opinion terms, averaging the overlap in predicted and annotated spans for each element across source, target and polar expressions.

5.2 Experimental Settings

We use the Pytorch[4] implementation of BERT base multilingual cased model pretrained on the 104 languages. The model has $t = 12$ transformer layers, the hidden size dim_h is 768 and 12 self-attention heads. The padding length used for encoding is 128. We use ELMo embeddings which are domain-general with 256-dimensions, pre-trained with $800M$ tokens and $28M$ parameters. The Pytorch BiLSTM implementation has hidden dimension of 64, number of layers as 2 and dropout probability as 0.3. The Concatenation layer has a output dimension as 32 and dropout probability of 0.2. The batch size is set to 16 for Train and 8 for devset. We adopt an Adam optimizer (Kingma and Ba, 2014) with learning rate of $2e-5$ and 500 warmup steps. After conducting train-dev runs for maximum 100 epochs we select best epoch based on Sentiment-F1 score on dev-set. A detailed view of these experiments have been included in Fig. 7 in Appendix. We conduct these experiments on a DGX server consisting of 8 Nvidia Tesla V100-SXM2 with 16GB V-RAM. We use multiple GPU's using the DataParallel[5] Pytorch class.

6 Experimental Results and Analysis

The detailed results of final submission are as shown in Table 1. The proposed CBERT and VBERT models performed relatively better than BiLSTM based head-first and head-final approaches. CBERT performed 9% relatively better than VBERT, supporting the hypothesis that the concatenation of contextualized information with syntactic information is more effective.

Our system achieved an average rank of 14/32 systems, based on the average scores across seven datasets. An in-depth analysis reveals that although

Dataset	Head-first	Head-final	VBERT	CBERT	*Median*	*Best System*
Opener_en	0.524	0.542	0.576	**0.634**	0.623	0.760
MPQA	0.218	0.218	0.218	**0.283**	0.367	0.447
Darmstadt_unis	0.181	0.209	0.271	**0.320**	0.342	0.494
Opener_es	0.480	0.552	0.537	**0.595**	0.539	0.722
NoRec	0.254	0.272	0.315	**0.343**	0.329	0.529
Multibook_ca	0.529	0.543	0.595	**0.634**	0.525	0.728
Multibook_eu	0.501	0.536	0.564	**0.559**	0.478	0.739
Average Scores	0.384	0.410	0.439	**0.481**	0.458	0.631

Table 1: Results on the test set across seven datasets for five languages, scores of the final system is in bold face

our model performed quite good for five datasets over the median system, for two datasets *MPQA* and *Darmstadt_unis* our proposed system did not perform relatively well, thus hampering the average scores. The best system scores are also relatively quite high, than our proposed CBERT system. One of the potential reasons for relatively lower performance for two datasets could be the existence of excessive number of neutral labels in these two datasets, which was not separately handled in the experimental setup, as discussed in Section 3.2.

Following is a qualitative analysis to identify main challenges in the CBERT system.

- **Boundary Detection:** It was observed that there were differences in the source, target and polar expression boundaries based on punctuation marks, stopwords or adjectives. For eg., *It is really very basic.* contains polar expression as *very basic* in its gold annotations whereas CBERT predicted as *really very basic.*

- **Tuple Formation:** In sentences that contain a single target with multiple polar expressions, CBERT predicts them as a single tuple. For eg., *The rooms are clean and functional.* In this sentence, there is one target, *the rooms* and its two polar expressions are *clean* and *functional.* Gold annotations provided for the sentence have two separate tuples for polar expressions whereas CBERT predicts them as a single tuple.

- **Differences in Gold Annotation:** In the datasets, some data annotations exist only for texts which have an explicit indication towards the theme of the dataset. For instance, the *NoRec* dataset is a collection of restaurant reviews. Hence, the data which do not have an explicit indication towards restaurant related comments are not annotated. However, CBERT does not distinguish between themes and produces predictions for such texts as well. For eg., *As a gold member I enjoyed an upgrade to a very large room with lots of floor space* . does not have any annotations. However, CBERT predicts Source as *I*, Target as *room* and Polar Expressions as *enjoyed, very large, lots of floor space*.

A detailed set of examples are shown in Table 2.

7 Conclusion and Future Scope

This paper discusses the proposed system and experimental results on SSA task at SemEval-2022. The proposed model called CBERT, assumes a joint learning technique using BERT-base multilingual model embeddings along with contextualized embeddings created using pretrained Stanza vectors and pretrained ELMo embeddings. The arc prediction between opinion term elements are achieved using an Attention layer. The proposed CBERT approach performed relatively better than BiLSTM approaches and VBERT approach. We find that using BERT based encoding, along with concatenation of contextualized information with syntactic information is more effective for SSA task.

For improving CBERT, leveraging 2D CRFs (Zhu et al., 2005) can be explored for better span detection over longer texts. Different joint learning architecture on top of CBERT's encoding like SDRN (Chen et al., 2020) can be leveraged. Approaches to fine-tune models for specific tasks (Zhao et al., 2020) is also a potential area for exploration.

A Appendix

A.1 Additional Experimental Settings

- In Fig. 7, each of the values correspond to SF1 scores obtained over devset, post to training on Training set (train/dev). It was observed that scores are consistent at 100 epochs.

- In Fig. 8, we ran train/dev experiments for 60 epochs to record SF1 scores by varying the sub-token weight w_{sub} to find optimal w_{sub} weights to be used in the Concatenation layer.

- In Fig. 9, we conducted train/dev experiments for 60 epochs to record SF1 scores by varying weight for ***None*** label w_{None} to find optimal weight to be used in weighted cross-entropy function.

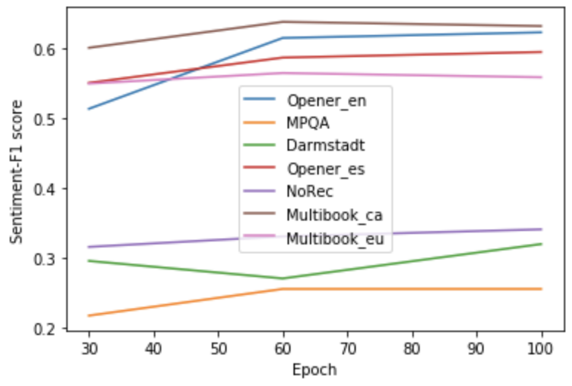

Figure 7: Graph showing Sentiment-F1 scores for our proposed model against the number of epochs.

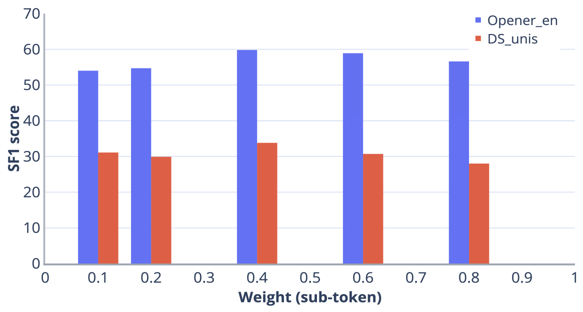

Figure 8: Sub-token weight vs devset SF1

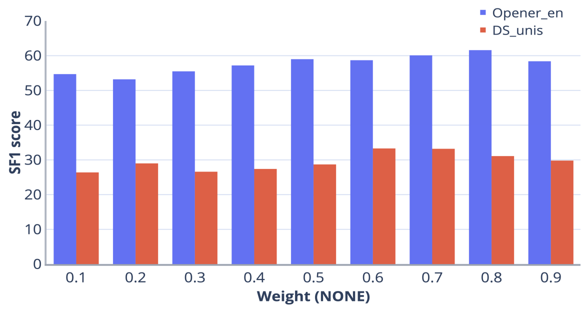

Figure 9: Weight(None) vs devset SF1

A.2 Alternative encoding schemes

We introduce another scheme for encoding where we mirror the labels of the lower triangular matrix to the upper triangular matrix along the main diagonal using results from our original encoding scheme as shown in Fig. 10. This helps us reduce the size of Attention layer's output $Preds$ by half,

Error Category	Remarks	Example
Boundary Detection	Based on Adjectives	For, *The first floor 24 hr bar was well run and no matter what time of day there was always a waiter on hand to serve .* CBERT predicts Polar Expression as *there was* whereas the annotaions contain *there was always*
	Based on Punctuations	For, *Robbed in elevator of hotel !* CBERT predicts Polar Expression as *Robbed in elevator of hotel* whereas annotations contain punctuation
	Based on Stopwords	For, *The best about this hotel is its location .* CBERT predicts Polar Expression as *The best about* whereas annotations contain *The best*
	Long Sentences	For, *There are good conference rooms with all necessary infrastructure ,good location allowing you to have nice evening , pool , restaurants , internet , 5 minutes to airport everything you need to do a business and relax after that .* CBERT predicts Source and Target efficiently but fails to detect Polar Expressions
Tuple Formation		For *Relax and enjoy* CBERT predicts two Polar Expressions separately as *Relax*, *enjoy* whereas annotations contain *Relax and enjoy* as single expression
Gold Annotations		For, *No words for this country and its people .* no annotations were provided

{yaojie2017,hongyu}@iscas.ac.cn

Abstract

ISCAS participated in both sub-tasks in SemEval-2022 Task 10: Structured Sentiment competition. We design an extraction-validation pipeline architecture to tackle both monolingual and cross-lingual sub-tasks. Experimental results show the multilingual effectiveness and cross-lingual robustness of our system. Our system is openly released on: https://github.com/luxinyu1/SemEval2022-Task10/.

1 Introduction

Aspect-based Sentiment Analysis (ABSA) aims to detect the fine-grained sentiment tendency lying underneath texts. After decades of development, this area has formed a large family of tasks. Nevertheless, many of them are too simple or overlap with each other. Meanwhile, the popular evaluation resources are limited both in number and linguistic diversity. SemEval-2022 Task 10 (Barnes et al., 2022) is proposed to unify different sub-tasks in ABSA and introduces new metrics, new datasets on different languages to better evaluate methods in this area. Task 10 challenges its participants to extract opinion quadruple $(holder, target, expression, polarity)$ from texts across English, Spanish, Basque, Catalan and Norwegian in monolingual (Sub-task 1) or cross-lingual (Sub-task 2) manners. Figure 1 provides two aspect-level annotations in a same sentence.

We applied an extraction-validation pipeline system and participated in both sub-task. Our system ranked at 10^{th} in 32 teams on the monolingual task without using extra data, and achieved competitive performance on the cross-lingual task. Besides, the proposed pipeline can be employed universally in monolingual and cross-lingual scenarios.

[*]This work was finished during their internship at ISCAS-CIP Lab.

2 Background

2.1 Task Definition

Task 10 is formalized as detecting all opinion tuples $O = O_i, ..., On$ in given text s. Concretely, each opinion O_i is a quadruple (h, t, e, p), denoting a ***holder*** who expresses a ***polarity*** $\in$ {Positive, Neutral, Negative} towards a ***target*** through a sentiment ***expression***. It's worthy to note that, *h*, *t*, *e* can be empty in this task. Following Cai et al. (2021), tuples with empty values are regard as implicit opinions in this system description paper. For the example in Figure 1, the quadruple "(–, them, don't believe negative)" is an implicit opinion.

2.2 Related Work

Aspect-based Sentiment Analysis Recently, there has been a large body of work focusing on different sub-tasks of ABSA. Generally we divide these sub-tasks into two categories: atomic and compound. Atomic ones take single element (e.g., t, e, or p) as the output and most of them can be treated as a sequence tagging problem (Li and Lam, 2017; Xu et al., 2018; Li et al., 2018; Wu et al., 2020b; Pouran Ben Veyseh et al., 2020). The compound ones need to find pairs (e.g., (t, p)), triplets (e.g., (t, e, p)) or even quadruples (e.g., (h, t, e, p)) from the inputs. Some works (Peng et al., 2020; Xu et al., 2021) use pipeline architecture to extract the elements separately and then make combinations; meanwhile some works use Seq2Seq models (Yan et al., 2021; Zhang et al., 2021) or unified tagging schemes (Mitchell et al., 2013; Zhang et al., 2015) to solve these sub-tasks in an end-to-end manner.

Pre-trained Language Models Pre-trained Language Models (PLMs) are deep neural networks pre-trained on large-scale corpora. Unlike traditional static word embedding methods, PLMs aim to learn dynamic contextual embedding of words in sentences from the unlabeled text. Recent re-

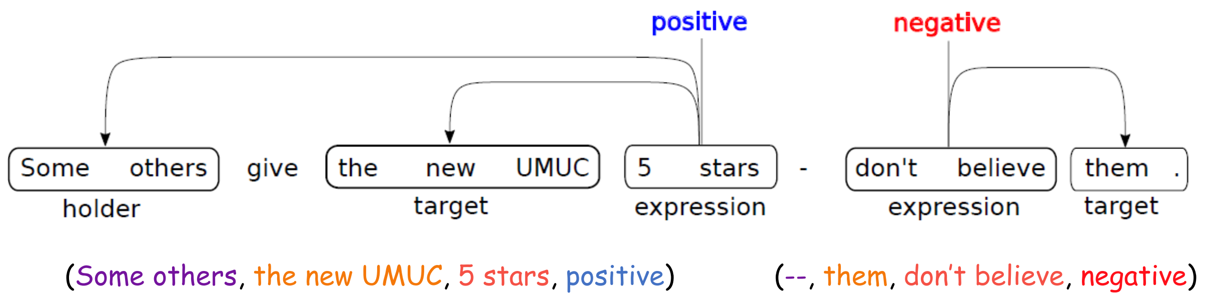

Figure 1: An example of Semeval 2022 Task 10. This figure is modified based on Figure 1 in (Barnes et al., 2021), the original sentiment graph representation is linearized to quadruple representation in this task. "–" indicates that this element in quadruple is empty.

search shows PLMs perform well in various syntactic tasks, such as POS tagging.

BERT (Devlin et al., 2019) is a typical language representation model based on the Transformer encoder architecture. It is pre-trained on two unsupervised tasks: Mask Language Modeling (MLM) and Next Sentence Prediction (NSP). mBERT[1] is a multilingual version of BERT pre-trained on the wiki dumps of 104 languages.

RoBERTa (Liu et al., 2019) removes the NSP task, which has no prominent effect in BERT pre-training and further improves BERT with dynamic masking, deeper network, longer input sequence, and larger training corpora. By virtue of these robust optimizations, RoBERTa significantly outperforms BERT on many tasks. XLM-RoBERTa (Conneau et al., 2020) extends RoBERTa architecture to the multilingual scenario by scalable pre-training on filtered CommonCrawl data containing 100 languages.

SKEP (Tian et al., 2020) incorporates sentiment knowledge into PLMs through sentiment masking and three sentiment pre-training objectives. It provides a unified contextual representation for downstream sentiment tasks.

NB-BERT (Kummervold et al., 2021) is a Norwegian instance of BERT in low-resource language. To alleviate the shortage of pre-training Norwegian corpora, OCR is conditionally used to mine good texts from digital copies.

3 System Overview

To tackle this task, we design a pipeline system that decouples this complex problem into a two-step pipeline with an extraction stage and validation stage. In the extraction stage, we first extract *target-expression-polarity* using an extended grid tagging schema, and then extract *holder* with a question answering system. In the validation stage, we employ a neural validator to determine the extracted results whether are valid in texts. Figure 2 illustrates the overall architecture of our system.

3.1 *Target-expression-polarity* co-extraction

Target-expression-polarity co-extraction aims to extract (t, e, p) triplets from text s (Peng et al., 2020). However, existing works (Peng et al., 2020; Wu et al., 2020a) usually assume that all opinions are expressed explicitly and pay little attention to implicit opinion extraction. In our system, we extend Grid Tagging Scheme (GTS) (Wu et al., 2020a) to adapt both implicit and explicit opinion extraction.

Original tagging space in GTS is an upper triangular grid, whose length and width is the tokenized sequence length l. Specifically, for $i, j \in [0, l]$, cell $(i,\ j)$ contains the tag for token-pair $(t_i,\ t_j)$ in the grid tagging. We integrate two new labels $\{\mathrm{IA}, \mathrm{IO}\}$ into the original tagging scheme and end up with a label set containing eight labels: $\mathcal{Y} = \{\mathrm{A}, \mathrm{O}, \mathrm{IA}, \mathrm{IO}, \mathrm{Pos}, \mathrm{Neu}, \mathrm{Neg}, \mathrm{N}\}$. The grid representation of implicit opinions can thus be implemented by filling IA or IO label in the cell of token-pair $(t_0,\ t_0)$ while not interfering with the representation of explict opinions. We believe this strategy is also reasonable under the perspective of sentence embedding in pretrained encoders, owing to that hidden-state of `[CLS]` (or `<s>` in RoBERTa) token which later fed into the token-level classifier, is often used as the semantic representation of the whole sentence.

We list the meanings of labels in our extended GTS separately in Table 1 and provide a tagging example for the extended GTS in Figure 3.

The decoding algorithm and inference steps we exploit are identical to the original paper.

7								N	N	Florence
8									N	.

Figure 3: The extended Grid Tagging Scheme on opinion triplet $(-, \text{Idealy situated}, \text{Positive})$ in sentence "Ideally situated in the heart of Florence.". "–" indicates this element in triplet is empty.

Model Ensemble We ensemble the different GTS models using a variety of backbones as the final predictor. Specifically, we perform an unweighted average of predicted distributions $p_{ij} \in \mathbb{R}^d$ from each model on token-pair (t_i, t_j) and get $\bar{p_{ij}}$. The final predicted label index is $\text{argmax}(\bar{p_{ij}})$.

3.2 *Target-expression* oriented *holder* extraction

After obtaining (t, e, p) triplets from the previous step, we further predict *holder* for each given triplet extracted from text s, i.e., *target-expression* oriented holder extraction. We cast this problem as a Question Answering (QA) task, where the context is text s and the answer is the holder span.

Query Construction For holder extraction, we construct the query q for the QA system with the (t, e, p) triplet. Under the multilingual setting of this task, we design different question templates in different languages. The details of the question templates are shown in Table 2.

Encoding and Inference We adopted the same setting as Devlin et al. (2019) to handle the QA task. The input query message q and text s are presented as a single packed sequence:

$$x = \begin{cases} [[\texttt{CLS}]; q; [\texttt{SEP}]; s; [\texttt{SEP}]] & \text{if BERT} \\ [\texttt{<s>}; q; \texttt{</s></s>}; s; \texttt{</s>}] & \text{if RoBERTa} \end{cases} \tag{1}$$

Language	Question Template
English	What is the holder given the aspect t and the opinion e ?
Spanish	¿Cuál es el titular de la opinión dado el aspecto t y la opinión e ?
Basque	Zein da helburu t eta e iritzia emanda iritzia duenak ?
Catalan	Quin és el titular de l'opinió donat l'aspecte t i l'opinió e ?
Norwegian	Hva er meningshaveren gitt aspektet t og meningen e ?

Table 2: The question templates we make to get query message in different languages. t denotes the target term and e denotes the expression term. When t or e is empty, the string "empty" are given to the templates as the term.

Then the context-aware representations of $\boldsymbol{x}$ are fed to a feed-forward linear layer to detect the span-start and span-end position. Note that we treat the special symbol `[CLS]` (or `<s>`) as the impossible answers for implicit opinions that without corresponding *holders*.

In detail, we feed the tokenized input sequence $\boldsymbol{x}$ into the encoder of PLMs. The last hidden-states $\mathbf{H}^x \in \mathbb{R}^{l \times d}$ can be represented by:

$$\mathbf{H}^x = \begin{cases} [\boldsymbol{h}_{[\text{CLS}]}; \boldsymbol{h}_q; \boldsymbol{h}_{[\text{SEP}]}; \boldsymbol{h}_s; \boldsymbol{h}_{[\text{SEP}]}] & \text{if BERT} \\ [\boldsymbol{h}_{\texttt{<s>}}; \boldsymbol{h}_q; \boldsymbol{h}_{\texttt{</s></s>}}; \boldsymbol{h}_s; \boldsymbol{h}_{\texttt{</s>}}] & \text{if RoBERTa} \end{cases} \tag{2}$$

where l is the length of the tokenized sentence, and d is the dimension of PLMs. The final linear span prediction network takes $\mathbf{H}^x$ as the input and outputs two probabilities $p_s, p_e \in \mathbb{R}^l$ for span-start and span-end prediction:

$$p^s, p^e \propto \text{softmax}(\text{Linear}(\mathbf{H}^x)) \tag{3}$$

For model learning, the whole parameters in the QA model are optimized by maximizing the likelihood of span-start and span-end positions:

$$\mathcal{L}_{QA} = -\frac{1}{N}\sum_{i=1}^{N}\left[\log\left(p^s_{y^s_i}\right) + \log\left(p^e_{y^e_i}\right)\right] \tag{4}$$

where N is the number of spans in a single batch, y^s_i and y^e_i are ground-truth span-start and span-end positions respectively.

3.3 Quadruple Validation

To reduce the errors accumulated in previous steps, we design a binary classifier that determines if a combination of *holder*, *target*, and *expression* is valid in text s. The valid triplets predicted by this sub-system are kept along with their corresponding *polarity*, while the others are discarded.

Encoding and Inference We utilize the pre-trained transformers to obtain the representation of text and triplets. Since BERT-like models are more sensitive to sentence-pair input, we concatenate h, t, e with a special symbol `[PAD]` and treat them together as sentence `B`. Concretely, we build the sequence pack in the form of:

$$\boldsymbol{x} = [[\texttt{CLS}]; s; [\texttt{SEP}]; h\,\texttt{[PAD]}\,t\,\texttt{[PAD]}\,e; [\texttt{SEP}]] \tag{5}$$

Under the circumstances of implicit opinion, the empty h, t, e terms are replaced with a special token `[EMP]`.

The validator network takes the representation of $\boldsymbol{x}_{\texttt{[CLS]}}$ as the input and returns the binary validation result. We implement the validator with a linear feed-forward layer.

Span Manipulation Considering that the combinations from sub-spans of the golden *holder*, *target*, and *opinion* terms are also treated as weighted correct predictions, we perform span manipulation to build a more robust classifier. For each ground-truth *holder*, *target*, *expression* term in triplet, we enumerate all the sub-spans and the original term in their corresponding set $\mathbf{H}, \mathbf{T}, \mathbf{E}$, the final triplet candidate pool is the Cartesian product of the three set: $\mathbf{H} \times \mathbf{T} \times \mathbf{E}$.

Finally, for each golden triplet, we randomly select at most k triplets (must include the original one) from the candidate pool as positive samples.

Negative Sampling We further design several rules to mine the negative (i.e., invalid) samples from raw datasets and manipulated golden triplets, including:

1.1. If a golden triplet has a holder, remove the holder and keep other elements.

1.2. If a golden triplet doesn't have a holder, use a holder dictionary to mine pseudo holders from text, packaging the mined holders (if there exist any) with the golden triplet.

2. If a text has multiple golden triplets, exchange the holder / target / expression terms in one with the other.

3. Randomly sample triplets.

Rules $1 \to 3$ are sequentially executed until q samples have been harvested, where q is in positive correlation with the number of positive samples. Meanwhile, we remove all the weighted true and true samples from the mined pseudo negative samples.

4 Experimental setup

4.1 Data Splits

Monolingual Sub-task This sub-task contains 7 different datasets (Agerri et al., 2013; Wiebe et al., 2005; Toprak et al., 2010; Barnes et al., 2018; Øvrelid et al., 2020) across 5 languages. We leveraged the origin splits provided by the organizer and did not include any extra data. The details of data splits are shown in Table 3.

Dataset	Splits		
	Train	Dev	Test
OpeNER$_{en}$	1,744	249	499
OpeNER$_{es}$	1,438	206	410
NoReC$_{Fine}$	8,634	1,531	1,272
MPQA	5,873	2,063	2,112
DS$_{unis}$	2,253	232	318
MultiB$_{ca}$	1,174	167	335
MultiB$_{eu}$	1,063	152	305

Table 3: Data splits.

Cross-lingual Sub-task This sub-task uses a zero-shot setting in which models are trained on the resource that does not contain annotations in the target language. For each target language, we combine all the training sets of OpeNER$_*$, MPQA, and MultiB$_*$ in other languages.

4.2 Implementation and Hyperparameters

This section generally describes the system implementation details and the selection of parameters. The detailed settings can be found in Appendix A.

Monolingual Sub-task For extended GTS and QA part in our pipeline, we tune and select models based on SF$_1$ (Sentiment Graph F1 (Barnes et al., 2021)) scores on the development splits. For the validator part, the models are tuned based on the classification accuracy on the manipulated and sampled development datasets.

In order to maximize the advantages of our system, we test a number of high-performing PLMs and finally RoBERTa$_{large}$, XLM-RoBERTa$_{large}$, NB-BERT$_{large}$, SKEP-ERNIE$_{large}$ and ensemble model [BERT$_{large}$+SKEP-ERNIE$_{large}$] are adopted to the training on different datasets in extended GTS. The max sequence length is set to the max of training and development sets, and meanwhile, the number of hops is chosen in 2 and 3 for GPU memory limitation. The large extended GTS models are trained on a single A100 80G GPU.

For QA sub-system, we use several task-pre-trained PLMs as backbones, such as XLM-RoBERTa$_{large}$-SQuAD[2], distilBERT$_{base}$-SQuAD[3] and RoBERTa$_{large}$-SQuAD[4].

For the validation step, we add LaBSE[5], which is a PLM focusing on language-agnostic sentence embedding and mBERT to the model pools in GTS training.

We fine-tuned all models on the training data using linear learning rate scheduler and the warming up strategy with the learning rate of 3e-5/3e-6 and the batch size of 8~64. We set all random seeds to 1 for reproducibility.

Cross-lingual Sub-task We set all holder positions in tuples to empty instead of leveraging the QA sub-system to extract holders. This is because the QA sub-system requires extra enhancements to fitting the cross-lingual setting (Cui et al., 2019).

The cross-lingual backbone in extended GTS is XLM-RoBERTa$_{large}$, and LaBSE for the validator.

5 Results

In this section, we report the scores on the development and test datasets of two sub-tasks separately. We use *SF*$_1$ (Sentiment Graph F1), *SP* (Sentiment Graph Precision) and *SR* (Sentiment Graph Recall) to evaluate the performance of our system.

5.1 Monolingual Sub-task

Table 4 reports the results of the monolingual sub-task, which ranks 10th in 32 teams. Table 5 shows the ablation analysis of different components on the development set of monolingual tasks. We can see that: 1) Grid-tagging-scheme based target-expression-polarity co-extraction achieves good performance in different languages. 2) The proposed validator can effectively filter out invalid

triples and significantly improve the precision of the model.

5.2 Cross-lingual Sub-task

Table 6 shows the results on the cross-lingual sub-task. Compared to the monolingual sub-task, the experimental results shows that the proposed cross-lingual system still performs competitively without training on the target language.

6 Conclusion

In this paper, we propose a pipeline system for $(holder, target, expression, polarity)$ quadruple extraction in ABSA, and adopt a verity of pre-trained language models in distinct parts of system. The evaluation results demonstrate the effectiveness and robustness of our system.

Abstract

Structured Sentiment Analysis is the task of extracting sentiment tuples in a graph structure commonly from review texts. We adapt the Aspect-Based Sentiment Analysis pointer network BARTABSA to model this tuple extraction as a sequence prediction task and extend their output grammar to account for the increased complexity of Structured Sentiment Analysis. To predict structured sentiment tuples in languages other than English we swap BART for a multilingual mT5 and introduce a novel Output Length Regularization to mitigate overfitting to common target sequence lengths, thereby improving the performance of the model by up to 70%. We evaluate our approach on seven datasets in five languages including a zero shot crosslingual setting.

1 Introduction

The goal of sentiment analysis is to understand a writer's opinions expressed in a text. In recent years, this topic became of particular research interest since with the advent of social media platforms, users were encouraged to share their opinions about a wide range of subjects with the world. For example, websites like Yelp collect and share opinions about restaurant visits and various online retailers allow customers to publish their reviews about items in their assortment. Consequently, various text corpora emerged that made it feasible to apply machine learning based approaches to this task (Yadav and Vishwakarma, 2020).

Sentiment analysis can be approached with various degrees of granularity. It is possible to only classify the overall polarity of a sentence as positive or negative, or a more precise intermediate value (Nguyen et al., 2020; Devlin et al., 2019).

Furthermore, the sentiment can be predicted in a more fine-grained manner, like with regard to the various targets addressed in the sentence. This can be of particular interest if the writer is ambiguous in their review and no overall sentiment label can be assigned to a sentence. For example, a customer might describe the service or the interior of a restaurant as unpleasant but the food itself as good. This can be extended to more complex sentence structures, taking into account not only the aspects or the sentiment, but also its holder (i.e. who is expressing the sentiment) or the opinion term itself, e.g. (Yan et al., 2021; Mukherjee et al., 2021).

In this paper, we work on the challenge described by Barnes et al. (2022). Here, the goal is to extract an arbitrary number of opinion tuples from a text. Each tuple can consist of a *holder*, a *target*, a *sentiment expression*, and a *polarity*. However, it is also possible that some of these mentioned *entities* are not present in a certain tuple. Moreover, a sentence may include no sentiment and hence no tuples should be extracted.

The challenge spans data from five different languages, namely English, Spanish, Catalan, Basque, and Norwegian and two different subtasks. First, there is the monolingual setting in which you are allowed to train on all sentiment data, including those in the language that is subsequently used to test the model's capability of extracting sentiment. Moreover, in the crosslingual setting the models are tested on Spanish, Catalan and Basque sentiment data while being trained on any of the other languages. It was also allowed to train on Spanish, Catalan and Basque data as long as it does not contain any annotated sentiment information. This makes the crosslingual structured sentiment analysis task a zero shot setting.

Our approach is based on BARTABSA (Yan et al., 2021), who leverage a *pointer network* to predict sentiment tuples (aspect, opinion, sentiment) by representing them using a custom output grammar. They extend a BART model with a pointer generator network which is thus able to predict token *indices* from the input sequence as output.

Our contributions are as follows: (i) we introduce a new, flexible grammar to model structured sentiment graphs as a pointer sequence, (ii) we explore mT5 as base model allowing us to make cross-lingual predictions, (iii) we introduce a new length regularizer to prevent overfitting to common sequence lengths.

2 Preliminaries

2.1 BART & mT5

BART (Lewis et al., 2020) is a sequence-to-sequence model built using transformer (Vaswani et al., 2017) neural networks. In its default configuration BART consists of 6 encoder and 6 decoder transformer layers. BART is trained as a denoising autoencoder. Hence, the input to its encoder are sentences which are noised using five different methods like masking or permutation of tokens. Consequently, the decoder is trained to restore the original sentence like defined in Equation 1.

mT5 (Xue et al., 2021; Raffel et al., 2020) is another sequence-to-sequence model based on the transformer architecture. It is trained on 101 languages at the same time using the span corruption objective and at time of publication achieved state of the art on many multi-lingual benchmarks. Its training corpus includes all languages used in this challenge (section 1).

2.2 BARTABSA

We model the Structured-Sentiment Analysis task as a seq2seq-task by adopting the framework introduced in BARTABSA. It encodes sentiment tuples (section 1) as a sequence of token indices (pointers) and special tokens.

2.2.1 Output Grammar

In BARTABSA, the target sequence consists of tuples with a fixed size of five:

$$\ldots, a_i^s, a_i^e, o_i^s, o_i^e, s_i^p, \ldots$$

which allows them to express the i^{th} aspect term (a) and its opinion term (o) in an input sentence by their respective start^s and end^e integer *token-index* in the input token sequence, as well as the sentiment polarity class s^p associated with this combination of aspect and opinion terms. Sequences structured like this can be unambiguously converted to aspect-based sentiment tuples as they occur in fixed sequence lengths of five: four token indices and one sentiment class.

2.2.2 Model

Sequences of this *output grammar* can be predicted by the model by *pointing* to the tokens in the input sequence in this fixed order and finally completing the triplet of aspect, opinion and sentiment by predicting the associated sentiment class.

Thus, the task is modelled as an auto-regressive decoding task where the probability of the next output token $P(Y|X)$ depends on both the input X as well as the previously decoded tokens $Y_{<t}$. For a sequence of length m the decoding process is hence given as

$$P(Y|X) = \prod_{t=1}^{m} P(y_t|X, Y_{<t}) \quad (1)$$

Usually, the decoding is stopped as soon as the End-Of-Sequence token `EOS` is predicted.

An architecture to generate such output was introduced as BARTABSA (Yan et al., 2021). BARTABSA is based on BART (Lewis et al., 2020) and uses a pretrained BART encoder to encode the input sentence. Hence, given an input sequence of n tokens $s = [x_1, \ldots, x_n]$, BARTABSA first applies the encoder to obtain the input representation

$$H_e = \text{BARTEncoder}(s) \quad (2)$$

with $H_e \in \mathbf{R}^{n \times d}$ (d denotes the embedding size).

Since the goal of BARTABSA is to predict indices to tokens in the input sequence, its decoder is augmented with a pointing mechanism (Vinyals et al., 2015) to generate these indices (Yan et al., 2021) instead of tokens from a vocabulary (see Equation 5 – 8). To be able to predict l additional sentiment class labels C, they are concatenated to the input and treated as tokens of the input sentence. However, to train and inference the neural network in an auto-regressive manner, i.e. feeding the previous output back into the decoder, the yet generated pointers must be mapped back to their indexed tokens first using the following mapping:

$$\hat{y}_t = \begin{cases} X_{y_t} & \text{if } y_t \in X \\ C_{y_t - n} & \text{if } y_t \text{ is an index of a class label} \end{cases} \quad (3)$$

The BART decoder is then applied to the mapped pointers:

$$h_t^d = \text{BARTDecoder}(H^e; \hat{Y}_{<t}) \quad (4)$$

Using h_t^d, the distribution for pointing to the input sequence is then calculated as:

$$E^e = \text{BARTTokenEmbed}(X) \quad (5)$$

$$C^d = \text{BARTTokenEmbed}(\text{C}) \tag{6}$$

BARTTokenEmbed is a shared embedding layer which is used to embed both the tokens from the input sequence X as well as the class labels C.

$$\bar{H}^e = \alpha\ \text{MLP}(H^e) + (1-\alpha)E^e \tag{7}$$

Finally, the embedded input sequence is concatenated with the embedded class labels. The pointing distribution is then given as the softmax over the concantenated sequence multiplied with the hidden representation h_t^d obtained from the BART decoder:

$$\begin{aligned} P_t &= \text{softmax}([\bar{H}^e; C^d]h_t^d) \\ &= P(y_t|X, Y_{<t}) \end{aligned} \tag{8}$$

where $E^e, H^e, \bar{H}^e \in \mathbb{R}^{n\times d}$, $C^d \in \mathbb{R}^{l\times d}$, $P_t \in \mathbb{R}^{n+l}$. Teacher forcing (Williams and Zipser, 1989) is used during training together with negative log-likelihood as optimization criterion.

3 Methodology

Our approach to predicting sentiment graphs on the given datasets is grounded on BARTABSA (2.2). We adopt and extend their framework to not only be able to predict aspect-based sentiment but also structured sentiment. For this we introduce a new output grammar which is able to model and represent the sentiment tuples as required for this task.

We adapt their sequential pointer representation for *Triplet Extraction* (aspect, opinion, sentiment) to the task at hand.

3.1 Extensions to the Output Grammar

We extend the expressive power of their output grammar in several ways to account for the increased target complexity of the structured sentiment task: Each entity (can be a or o for Triplet Extraction) for structured sentiment analysis can...

- be optional
- consist of arbitrarily many discontiguous parts
- be “source”/“holder” of the sentiment

Defining such an enhanced output grammar which can model these properties enables us to unambiguously represent the sentiment tuples required for the structured sentiment task. In the following we adapt the notion of BARTABSA from “aspect term” to the sentiment *target* and “opinion term” to the polar *expression*.

3.1.1 Entity Absence

First we account for *optional absence* of entities by introducing a special token for each type of entity indicating the begin of its respective entity. This prevents ambiguity if an entity is absent and transforms the previous example from subsubsection 2.2.1 to the following sequence:

$$\ldots, \text{TGT}_{BEG}, t_i^s, t_i^e, \text{EXP}_{BEG}, e_i^s, e_i^e, s_i^p, \ldots$$

where XYZ_{BEG} is the unique class token for each entity type indicating the begin of entity XYZ, t_i and e_i are *integers* referring to token positions in the input sequence and s_i^p is the sentiment class token (see Figure 1 for example). This way if, e.g., there is no target term to be predicted for the i^{th} sentiment tuple the sequence becomes

$$\ldots, \text{EXP}_{BEG}, e_i^s, e_i^e, s_i^p, \ldots$$

and thereby stays unambiguous as it is still well defined that the tokens between e_i^s and e_i^e resemble the expression term and not the missing target term. This can be clearly interpreted although e_i^s and e_i^e are the first two predicted indices of the i^{th} sentiment tuple which were allocated to target entity indices before.

3.1.2 Entity Splitting

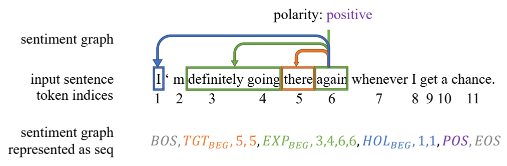
Second we allow for *split entities* as described in subsection 4.3 by further extending the output grammar. After every begin-of-entity special token (XYZ_{BEG}) we do not only allow for a single start^s and end^e index tuple but arbitrarily many such tuples. Therefore a two-part target term in the i^{th} triplet is represented like this:

$$\ldots, \text{TGT}_{BEG}, t_i^{s1}, t_i^{e1}, t_i^{s2}, t_i^{e2}, \text{EXP}_{BEG}, e_i^s, \ldots$$

In this syntax the first part of the i^{th} target term can be found between t_i^{s1} and t_i^{e1} and the second part between t_i^{s2} and t_i^{e2} (see Figure 1 for example). Every entity can be modeled by arbitrarily many such pointer tuples and due to the special tokens (XYZ_{BEG}) indicating transitions between the predicted entities the association between pointer indices and entity type stays unambiguous.

3.1.3 Sentiment Source

Last we enable the prediction of the *sentiment holder* or source. Given the previous modifications to the output grammar this can be easily achieved by introducing a new special token HOL_{BEG}.



polarity: positive
sentiment graph
input sentence
token indices
I ' m definitely going there again whenever I get a chance.
1 2 3 4 5 6 7 8 9 10 11
sentiment graph
represented as seq
BOS, TGT_BEG, 5, 5, EXP_BEG, 3,4,6,6, HOL_BEG, 1,1, POS, EOS

Figure 1: Exemplary input sentence, its associated sentiment graph (target, expression, holder, sentiment) as well as the sentiment graph modeled using our grammar.

3.1.4 Constructing the Output Grammar

Combining all our extensions to the output grammar introduced above we are able to unambiguously represent structured sentiment tuples in a sentence as a sequence consisting of pointers and special tokens.

First we sort all sentiment tuples per sentence ascending by their token index in the input sentence. For this we only look at the index of the start token of each entity. We first sort the tuples by the start index of the target term, if they are equal by their expression term and lastly on equality we fall back to their holder term. This is done the same way in BARTABSA and PASTE as it is shown that predicting the sentiment tuples of a sentence in a strict order boosts the performance of the final model (Yan et al., 2021; Mukherjee et al., 2021).

A sentiment graph for an input sentence is modelled as follows using our output grammar (example in Figure 1): After the `BOS`-token we encode the sentiment tuples in the order described above. First if the i^{th} sentiment tuple contains an target term we insert an TGT_{BEG}-token followed by a sequence of tuples of start (t_i^s) and end (t_i^e) indices, one for every discontiguous part of the target term. We repeat this for the expression and holder terms of the sentiment tuple. The representation of the i^{th} sentiment tuple is completed by its sentiment polarity token (pos, neu, neg). This process is repeated for every sentiment tuple of the input sentence. After the last sentiment polarity token the output sequence is closed with an `EOS`-token.

If a sentence has no sentiment tuples it is represented by the empty sequence $[BOS, EOS]$.

3.2 Output Length Regularizer

Predicting the structured sentiment graph for an input sentence using our above (3.1.4) defined output grammar is naturally very sensitive to the placement of the `EOS`-token. If our model predicts the `EOS`-token e.g. only a single token too early the last sentiment tuple — consisting of target, expression, holder and sentiment class — becomes incomplete as it lacks at least the sentiment class for the entire tuple. Therefore it can no longer be correctly interpreted or converted to the sentiment graph structure. A missplaced `EOS`-token can lead us to miss an entire sentiment tuple or even more if the `EOS`-token is off by more than the length of a tuple.

During our experiments we noticed some models being prone to overfitting to common positions of the `EOS`-token (also see Newman et al. (2020)) in the train set (5.1). When analysing the predictions of such a model during training we found that often the `EOS`-token was predicted not only at the correct location in the sequence, but also once more, earlier at the most-common `EOS`-token position in the train set. Usually this is right after the `BOS`-token. As we convert the output sequence to the sentiment graph up to the first `EOS`-token (3.1.4) this results in an empty graph. Such an incorrect sequence consisting of an otherwise correctly predicted sentiment unit with a target and an expression exemplarily looks like this:

$$[BOS, EOS], t_i^s, t_i^o, \mathrm{EXP}_{BEG}, e_i^s, e_i^e, s_i^p, EOS$$

In this case the TGT_{BEG}-token got erroneously replaced by an overfitted `EOS`-token, thereby stopping the output sequence early — as indicated by the gray font. As can be clearly deducted from Figure 1 such a token replacement would result in an empty sequence and thereby no extracted sentiment graph. We cannot just ignore/fix such a misplaced `EOS`-token automatically because we cannot decide whether such an error occurred at all or which begin-of-entity (XYZ_{BEG}) got replaced by the first `EOS`.

Therefore we have to prevent these errors from occurring in the first place. To encourage the model to predict the `EOS`-token at the correct location only, we extended the loss function to make it more sensitive to the placement of the `EOS`-token.

We realize this by introducing an additional loss component $\mathcal{L}_{\mathcal{RE}}$. The predictions $\hat{y}$ of our model during training have the shape $\mathbb{R}^{s \times \hat{t}}$, where $\hat{t}$ and s is the length of the prediction $\mathcal{P}$ and source sequence $\mathcal{S}$ respectively, as we predict t *target* indices pointing to tokens in the source sequence of length s (including special tokens).

Now, along every column $j \in 1 \ldots \hat{t}$ of $\hat{y}$ we calculate the softmax to decide the token probability distribution at prediction step j. From this matrix we now extract the row $o = \hat{y}_i \in \mathbb{R}^{\hat{t}}$, $i \in 1 \ldots s$ corresponding to the EOS-token. Then, $\mathrm{softmax}(o)$ at position j represents the probability that the j-th token in the target sequence is an EOS-token over all positions in the target sequence.

We calculate the cross entropy between this resulting vector o and the correct position for the EOS-token in the target sequence.This loss addition penalizes high-probabilities for EOS-tokens in the wrong locations:

$$\mathcal{L}_{\mathcal{RE}}(y, \hat{y}) = \mathrm{CE}(t, \mathrm{softmax}(\hat{y}_i)) \qquad (9)$$

where t is the length of the target sequence y — thereby the correct position of the EOS-token — and i is the vocabulary index of EOS.

We add our Output Length Regularization to the Cross Entropy loss:

$$\mathcal{L}(y, \hat{y}) = \mathrm{CE}(y, \hat{y}) + \mathcal{L}_{\mathcal{RE}}(y, \hat{y}) \qquad (10)$$

4 Experiments

We base our model on two different but related architectures depending on the subtask. For both tasks, we build a model similar to BARTABSA (Yan et al., 2021)[1] consisting of a transformer encoder-decoder model augmented with a pointer layer for predicting indices in the input sequence.

We always train for 75 epochs and select the best model based on the best performance on the validation set. This strategy is in line with BARTABSA but we increased the maximum number of epochs from 50 to 75 as we found in preliminary experiments that mT5 sometimes was able to improve slightly on the validation set beyond 50 epochs. If we train on multiple datasets at the same time we also validate on a concatenation of their respective validation sets. We finetune the models once with and once without the Output Length Regularization (3.2). We select model dependent learning rates, learning rate schedules and optimizers as suggested in their respective original papers or BARTABSA. Therefore we finetune BART models using Adam with a peak learningrate of $5e^{-5}$ in a triangular learning rate schedule and mT5 using AdaFactor with a constant learningrate schedule and a learningrate of 0.001.

The results are evaluated using the Sentiment Graph F_1 introduced by Barnes et al. (2021). For this metric they calculate the true positives by averaging the overlap for exact token-level matches between predicted and gold spans over all three entities. To obtain precision and recall they now divide the number of correctly predicted tokens by the total number of predicted tokens and gold tokens respectively.

4.1 Subtask 1: Monolingual

For the monolingual task we divide between English and non-English datasets. For the English datasets we select a pretrained monolingual English BART model as our transformer architecture as suggested in BARTABSA. As there are no BART models publicly available for all non-English languages from our datasets, we choose a pretrained mT5 model for those instead which was pretrained on 101 languages including all languages present in our datasets. We do not train a separate mT5 for every single dataset or language since finetuning mT5 on small datasets lead to significant instabilities during training (5.1) which we counteract by concatenating all datasets available to us.

We compare our approach against the baselines provided by the task organizers[2]. They provide a sequence labelling approach which consists of three separate BiLSTM models, one each for extracting the holders, targets, and expressions followed by another BiLSTM-based relation prediction model. On top of the concatenation of these three outputs a classification task is trained to predict whether two predicted elements are related or not. The second baseline is a graph parsing model described by Barnes et al. (2021). It works by modelling the sentiment tuples as dependency graphs and then predicting those using the neural dependency parser introduced by Dozat and Manning (2018).

4.2 Subtask 2: Crosslingual

In the crosslingual setting it is important for our model to be able to generalize and transfer well between languages. Therefore we once again select mT5 as our basemodel and train it on English and Norwegian at the same time as these are the only languages available for training in this setting. We train on both available languages at the same time since we expect this to improve generalization between languages.

[1]For our experiments we reuse their codebase making use of torch, transformers and fastNLP.

[2]https://github.com/jerbarnes/semeval22_structured_sentiment

4.3 Datasets

The datasets provided for this challenge can be split into five languages: English (darmstadt (Toprak et al., 2010), mpqa (Wiebe et al., 2005), opener (Agerri et al., 2013)), Spanish (opener), Catalan (multibooked (Barnes et al., 2018)), Basque (multibooked) and Norwegian (norec (Øvrelid et al., 2020)). All datasets are structured identically consisting of a source sentence and its annotated sentiment graphs, which are represented by their sentiment tuples (target, expression, holder, polarity) as introduced in section 1. Additional complexity is added by the fact that every sentiment tuple entity can be either completely missing or even consist of arbitrarily many discontiguous parts as described in subsubsection 3.1.4: e.g. in "[. . .] have degraded the image of the University severely" the opinion term consists of two parts: "degraded" and "severly".

4.4 Dataset Sampling

During preliminary experiments we observed stability problems while finetuning mT5 (5.1) which we were only able to mitigate by training on the concatenation of different datasets and sampling the training dataset. We were able to address this instability by undersampling the training set in such a way that *at most* one fifth of the training set consists of empty samples. We implemented this sampling by first ensuring this ratio for all datasets separately and concatenating them afterwards. We kept this sampling strategy for all experiments using mT5 except when training only on the concatenation of the English datasets where we found that a maximum of one fourth empty samples achieved better results on the validation set.

We ran the same experiments with BART and found it to be not nearly as susceptible to a sampling strategy compared to mT5. Nevertheless we found that BART is able to gain small improvements on the validation set only when training on the concatenation of all English datasets without Output Length Regulatization while sampling the training datasets such that at most half of the samples are empty. So we sampled the training dataset only in this specific case when finetuning BART.

5 Results & Evaluation

5.1 Training Instability of mT5

While finetuning mT5 on our datasets during preliminary runs we noticed that the model is not only generally very unstable during training but also that the resulting performance is very sensitive to different dataset splits. When training on individual training datasets including all samples the model was not able to achieve sentiment-F_1-scores above 5% on the validation set. For this it did not matter whether we included the Output Length Regularization (3.2) or not. We only managed to achieve competitive results using mT5 after we significantly undersampled the empty sentiment tuples in the dataset as described in subsection 4.4. We believe this to be already first signs of EOS-token location overfitting (3.2) as all empty samples are represented by the sequence $[BOS, EOS]$.

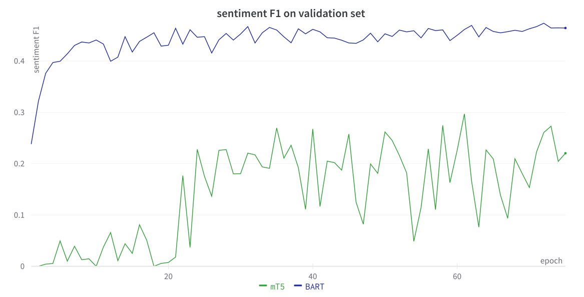


Figure 2: Comparison of two representative English validation set sentiment-F_1 curves for BART and mT5 during training. The models got evaluated in each of the 75 training epochs.

Training instabilities of mT5 become evident when looking at the F_1-scores on the validation set during training as representatively plotted in Figure 2 (green). For comparison we rerun the same setup using BART (blue). While the training loss of the mT5-models descends during training without large jumps or spikes the F_1-score on the validation set oscillates heavily. Although all mT5-models we trained contained such frequent and huge jumps in the F_1-score, there became no common pattern apparent between different runs. Even the slightest change e.g. different dataset sampling can result in a completely different F_1-score curve on the validation set. At the same time the loss during training on the same dataset remained smooth. This is not surprising given the fact that a wrongly placed EOS-token can invalidate the entire prediction as described in subsection 3.2, while in comparison according to the cross entropy loss a higher probability for the EOS-token at the e.g. second position only slightly decreases the measured performance. In other words the final evaluation metric is way more sensitive to the placement of the EOS-token

Table 1: Submitted results for the monolingual subtask as described in subsection 4.1.

		ours		baselines	
dataset	model	sent-F_1	place	seq. label	graph parser
opener_en	BART	0.651	12	0.33	0.52
mpqa	BART	0.338	11	0.02	0.12
ds_uni	BART	0.417	6	0.06	0.20
average		0.469	—	0.14	0.28
opener_es	mT5	0.504	17	0.24	0.50
norec	mT5	0.280	18	0.20	0.36
multib_ca	mT5	0.517	16	0.34	0.52
multib_eu	mT5	0.439	18	0.37	0.55
average		0.435	—	0.29	0.64
overall avg		0.449	16	0.22	0.40

than the training objective. This is the core issue we are addressing by introducing the additional loss component (3.2). We did not observe a similar phenomenon during training of any BART model.

5.2 Subtask 1: Monolingual

As we approached the monolingual setting using two different base-models we also analyse them separately. Overall for this monolingual subtask we placed 16^{th} out of 31 teams on the leaderboard at the time the challenge ended.

For mT5 we report the results for finetuning on all datasets on all languages at the same time using our Output Length Regularization, as training mT5 became slightly more stable on a larger dataset.

For the English results we finetune BART with our Output Length Regularization only on the respective dataset the model was tested on except when testing on the darmstadt dataset. For darmstadt we trained BART on a combination of all English datasets and without Output Length Regularization. If we train only on the darmstadt dataset itself and with Output Length Regularization like for the other datasets, we achieve an F_1-score of only 0.389. We chose this strategy for all BART runs in general and the darmstadt dataset in specific as it resulted in the highest scores on the respective validation datasets. The results for the other datasets when training BART on all english datasets at the same time is included in Table 2.

In Table 1 we report our performance on the monolingual task and compare it against the baselines provided by the task organizers. On English datasets using BART we achieved in general a considerably higher placement (6,11,12) than our over all placement (16) and are able to comfortably beat the employed baselines (subsection 4.1). This indicates that our method works comparatively better using BART as base model than mT5 (16, 17, 18, 18) where our approach consistently beats the sequence labelling approach but matches the performance of the graph parser only on some datasets.

Table 2: Comparison of a single BART and a single mT5 trained on all English datasets at the same time.

	sent-F_1	
dataset	BART	mT5
opener_en	0.493	0.471
mpqa	0.326	0.159
darmstadt_uni	0.365	0.218
average	0.395	0.283

5.2.1 BART vs. mT5 Performance

To further evaluate this presumed performance discrepancy between BART and mT5 we compare our approach using both base models on the English datasets as this is the only language both models have in common. We train both models using the Output Length Regularization and only differing by their respective optimal sampling strategy as laid out in subsection 4.4. For a fair comparison we train both models on all datasets at the same time as a larger dataset reduces training instabilities of mT5 (5.1). The results are visible in Table 2.

We find the performance to be drastically dropping overall when we switch from a BART to an mT5 model. The overall validation loss for both models in every epoch is reported in Figure 2. We assume this drop is hugely driven by the training instabilities (5.1) we observed, although we also suspect the differences in pretraining (2.1) to lead to this discrepancy. This explains our comparatively better placement in Table 1 when we are able to use BART instead of mT5 to solve the task.

5.2.2 Ablation: Output Length Regularization

In order to evaluate how well our novel Output Length Regularization (3.2) is able to improve model performance we finetune a separate BART for every English dataset once with and once with-

Table 3: Comparison of performance for models trained with and without length regularization. BART models were trained on the dataset they are tested on while mT5 models were trained on all languages at the same time.

		sent-F_1	
model	dataset	w/ lenreg	w/o lenreg
BART	opener_en	0.651	0.635
	mpqa	0.338	0.320
	darmstadt_uni	0.389	0.320
	average	0.459	0.425
mT5	opener_es	0.504	0.410
	norec	0.280	0.251
	multibooked_ca	0.517	0.374
	multibooked_eu	0.439	0.353
	average	0.435	0.347
	overall average	0.449	0.367

Table 4: Average number of predicted sentiment tuples per sentence compared to actual average number of sentiment tuples per sentence in the testset.

		lenreg		
	dataset	w/	w/o	testset
BART	opener_en	1.77	1.88	1.73
	mpqa	0.21	0.29	0.24
	darmstadt_uni	0.31	0.47	0.41
mT5	opener_es	2.02	1.49	2.33
	norec	1.28	0.77	0.97
	multibooked_ca	1.39	1.00	1.56
	multibooked_eu	1.19	0.76	1.43

out length regularization. We repeat this setup for mT5 but train a single common mT5 on all datasets together as we found mT5 to be more stable during training with increasing dataset sizes.

We compare the results in Table 3. It is apparent that for all runs for both base models on all datasets and languages the sentiment F_1 score improves when adding our length regularization. Therefore we conclude that our Output Length Regularization (3.2) does indeed help the model learn where to place the EOS-token and thereby decide how many sentiment tuples are present in the sentence. This results in better predictions for this task especially for the mT5 model.

Originally we introduced the Output Length Regularization to fix an overfitted EOS-token at the second position for the mT5 model as exemplarily indicated by the colors in subsection 3.2. This led the mT5 model to predict too few (commonly zero) sentiment tuples. When analysing the differences in length of the output sequences (see Table 4) we found that for the mT5 model it consistently increased the number of sentiment tuples predicted by the model and thereby almost always moves the average number of predicted tuples per sentence closer to the average number of sentiment tuples present in the dataset splits. Only for norec the average number of predicted tuples on the testset overshoots the average number of sentiment tuples on the testset.

Table 5: Performance of BART per dataset (columns) when finetuning only on a single dataset (rows). All models trained with Output Length Regularization.

	op_en	mpqa	ds_uni
opener_en	0.651	0.007	0.195
mpqa	0.008	0.338	0.050
darmstadt_uni	0.300	0.005	0.389
all English	0.493	0.326	0.365

5.2.3 Crossdomain Performance

The crosslingual subtask of this challenge primarily evaluates how well a model is able to generalize between different languages and different domains at the same time. We also analyze the performance of our BART model when we change only the target domain by crossdomain zero shot evaluating on a different english dataset. Therefore we finetune a separate BART model with Output Length Regularization on each of the three English datasets separately and then use each model to predict all other English datasets.

In Table 5 we find BART to be able to generalize between darmstadt_uni and opener_en albeit this comes at the cost of a significant performance loss in both directions. Meanwhile mpqa does not seem to be similar enough to either of the other two English datasets for the model to output meaningful crossdomain predictions. This can be explained as both darmstadt_uni and opener_en datasets consist of reviews of universities and hotels respectively, while mpqa is a dataset focused around political opinion expression. It is likely that the model benefits from the more similar phrasing used in both review datasets compared to political opinions.

Table 6: Submitted results for the crosslingual subtask as described in subsection 4.2. We finetuned mT5 with Output Length Regularization on all datasets at once.

dataset	sent-F_1	place
opener_es	0.315	14
multibooked_ca	0.259	15
multibooked_eu	0.243	14
average	0.272	15

Table 7: Comparison of an mT5 trained with and without Output Length Regularization (3.2).

	sent-F_1	
dataset	w/ lenreg	w/o lenreg
opener_es	0.315	0.245
multibooked_ca	0.259	0.105
multibooked_eu	0.243	0.131
average	0.272	0.160

5.3 Subtask 2: Crosslingual

For the crosslingual task (Table 6) we predict structured sentiment tuples in Spanish, Catalan and Basque without prior training on any sentiment annotations in any of these languages. We again finetune an mT5, but for this subtask on all languages at once which are not in the set of target languages: English & Norwegian. Training on a larger dataset consisting of multiple languages not only stabilizes training but also possibly helps the model to generalize between languages to predict structured sentiment in unseen languages. Compared to the monolingual subtask where mT5 was trained using sentiment annotations in the target languages (Table 1), here mT5 loses on average over 40% of performance in this zero shot crosslingual setting. Therefore we are able to show that despite a significant performance loss pointer prediction models are able to zero shot generalize between languages and domains at the same time.

5.3.1 Ablation: Output Length Regularization

Again we evaluate our Output Length Regularization by finetuning two mT5 on all English and Norwegian datasets at the same time, once with and once without Output Length Regularization. We find the same results as already described in 5.2.2: Output Length Regularization is able to improve the zero shot crosslingual generalization significantly as can be found in Table 7. Finetuning mT5 for pointer prediction using this length regularization increases the performance by 70% averaged over all target datasets.

6 Related Works

The PASTE framework (Mukherjee et al., 2021) also uses pointer networks to solve the task of aspect-based sentiment analysis. Instead of Transformers, they use an LSTM (Hochreiter and Schmidhuber, 1997) as decoder and two additional Bi-LSTMs as pointer networks — one for pointing to aspect and opinion term each.

Peng et al. (2020) propose an approach to extract opinion triplets from text in a generative manner without using pointers. However, their output grammar is also less flexible meaning that all of the entities (target, aspect, and sentiment) have to be present in each triple. They also introduced one of the data sets used to train BARTABSA and PASTE.

Apart from structured sentiment analysis, pointer networks were also successfully applied to various further NLP tasks where it is beneficial to directly transfer parts of the input sequence to the output. This includes automatic summarization (See et al., 2017; Enarvi et al., 2020) and entity extraction (Nayak and Ng, 2020).

7 Conclusion

In this work, we adapted BARTABSA, a pointer network based on BART, for the task of structured sentiment analysis. In particular, we introduced a new output grammar which is able to model the increased complexity of this task by taking into account new entity types, split entities and missing entities in sentiment tuples.

We also experimented replacing BART with an mT5 network to allow for input sequences in languages other than English. We found that using the approach of BARTABSA it is possible to swap out BART for another base model but in the case of mT5 this comes with a significant performance hit which we suspect is mainly driven by training instabilities we encountered. Moreover, we introduced a output length regularizer to reduce overfitting to common sequence output lengths from the trainset. We found this to be very beneficial consistently on all data sets and to increase relative performance by up to 70%.

Abstract

Task 10 in SemEval 2022 is a composite task which entails analysis of opinion tuples, and recognition and demarcation of their nature. In this paper, we will elaborate on how such a methodology is implemented, how it is undertaken for a Structured Sentiment Analysis, and the results obtained thereof. To achieve this objective, we have adopted a bi-layered BiLSTM approach. In our research, a variation on the norm has been effected towards enhancement of accuracy, by basing the categorization meted out to an individual member as a by-product of its adjacent members, using specialized algorithms to ensure the veracity of the output, which has been modelled to be the holistically most accurate label for the entire sequence.Such a strategy is superior in terms of its parsing accuracy and requires less time. This manner of action has yielded an SF1 of 0.33 in the highest-performing configuration.

1 Introduction

Sentiment Analysis is a specialized area under Natural Language Processing which deals with the extraction of opinions and emotions from text which may include reviews, social media posts, forums or news. Sentiment Analysis has become a powerful tool for detecting the public opinion on any topic.
This research article evinces how the sentiments and opinions expressed by people in various environments could be understood by means of a structured sentiment analysis (SSA) approach. There are conventional means to this end, in transition-based and graph-based techniques, but a potent alternative is the novel way to envision dependency parsing tasks as algorithmic pattern-recognition by way of sequence labelling. Sequence labeling is essentially an agglomeration of multiple discrete categorizations, extended on to each element of the entire sequence. The model is trained on 7 seven data sets with 5 different languages English, Spanish, Basque, Norwegian and Catalan.

In Subtask-A we try to separately identify the holder and target in the text, along with the sentiment expression used using a Sequence Labelling Approach.

In Subtask-B we predict whether the extracted tokens have a relation or the lack of one.

Subtask-C involves the concatenation of the results of Subtask-A and Subtask-B to provide the final predictions.

2 Background

2.1 Definitions

The following contains descriptions of the models made use of, and related terminology. Namely we will define LSTM, BiLSTM, Sigmoid, Linear, Max Pooling Layers and Word Embeddings and the BIO Sequence Labelling approach.

Long Short-Term Memory(LSTM)

Speech-recognition language models, among numerous other activities, have seen encouraging levels of success by availing Recurrent Neural Networks (RNN) (Mikolov et al., 2010, 2011) (Graves and Schmidhuber, 2005). The model is made to predict the current output by analysing the long-distance features, by virtue of how history information is incorporated into an RNN. Long-range dependencies are better detected and processed by LSTMs than RNNs (Graves and Schmidhuber, 2005) by virtue of their difference in terms of how the latter has purpose-built memory cells in lieu of the hidden layer updates in the former (Hochreiter and Schmidhuber, 1997). Aside from this striking feature, LSTMs and RNNs are essentially the same.

BiDirectional Long Short-Term Memory(BiLSTM) - It a sequence processing model that comprises of one LSTM receiving input in the forward direction, and another which drives input backwards. BiLSTMs are used to enhance the subject and context to be used by the network, by proliferating the quantity of data that could be accessed by the algorithm (e.g. cognizance of the words in front of, and following a certain word that is to be analyzed).

Sigmoid Layer The sigmoid layer is responsible for making sure that the output remains confined within the interval (0,1), through subjecting a sigmoid function on the input.

$$S(x) = \frac{1}{1 + e^{-x}}$$

Linear Layer Mathematically, this module is designed to calculate the linear equation $Ax = b$ where x is input, b is output, A is weight.

Max Pooling Layer Max pooling task results in a map output in which the significant features from the preceding feature map is reflected, considering how it extracts the most crucial constituents of the feature map under the purview of the filter.

Word Embeddings It refers to a specialized means of representation for input text, dependent on its connotation, thus attributing the same representation to words who depict a similar meaning. In this paper we use GloVe and FastText embeddings.

BIO Sequence Labelling - "B-I-O" is a tagging scheme, where either of "B" (Beginning), "I" (Inside), or "O" (Outside) labels denote the relative position of the part of speech. If none of these three assignments could be meted out to the text in question, a special label denoting that case could be assigned.

2.2 Related Work

Sentiment analysis constitutes five operations in sequence as i) sentiment expression extraction, ii) sentiment target extraction, iii) sentiment-holder extraction, iv) definition of relationships between elements, v) assignment of polarity. (Yadav and Vishwakarma, 2020) compares various SOTA DL techniques which have been applied to this problem, including CNNs, Recursive Neural Nets, RNNs, LSTM, GRU and Deep Belief Networks, concluding that LSTMs give better results compared to other models. (Xu et al., 2019) explored the possibility of using BiLSTMs for sentiment analysis on comments, and found improved accuracy. (Phan et al., 2020) proposed an ensemble model of various feature vectors to form embeddings which were fed to a CNN, this method greatly improved accuracy on sentences with fuzzy sentiment. A Bidirectional RNN-CNN (Basiri et al., 2021) was also found to achieve SOTA results. Thus, emphasizing the fact that bidirectional models capture context better in textual data.

Sequence Labeling Typically, it would be advantageous to formulate an NLP operation akin to a general sequence-labeling task. Each element from a defined input sequence is considered, and a collection of labels is scrutinized to pick out one relevant to the text, and an assignment is made with the aforementioned. In this paper we propose a Part of Speech tagging approach. (Akhundov et al., 2018) have shown how BiLSTM-CRF can be used for this task. (Prasad and Kan, 2017) shows the extraction of keyphrases and relation prediction using CRFs for sequence labeling.

2.3 Data

The seven datasets in question encompass five different languages of which the expressions are composed of, to be subjected to structured sentiment analysis. They are made such as to typify the way in which the particular approach to this study performs, as necessitated by the task. The datasets are similar in terms of possessing holders, expressions and targets, while dissimilarities are by virtue of their frequency and distribution.

The maximum number of holders in an individual dataset would be the 2,054, featured in MPQA (Wiebe et al., 2005), while the lion's share of targets (8,293) and expressions (11,115) both are allocated to NoReCFine (Øvrelid et al., 2020). The set DSUnis (Toprak et al., 2010) possesses the least amount of all among holders, targets, and expressions in 94, 1601, and 1082 respectively.

The dataset provided by opeNER project (Agerri et al., 2013) are opener_en and opener_es . The number of targets and expressions in opener_en, opener_es are 1286, 1760 , 1062 and 1625 respectively.

All the groups carry markers for polarity of the text, which shows the positive or negative connotation carried by each member. MPQA and DSUnis are distinctive in how they also include instances of "neutrality", beside the extremities. In DSUnis, this feature is utilized while dealing with clauses that showcase varying degrees of both polarities, with contextual variance. The neutralities in MPQA are much less complicated, as they only vouch for words that are subjective, and may not necessarily have a polarizing effect.

MPQA is entirely in English, and carries text from news agencies. The two datasets involving critiques of hotels are MultiBEU and MultiBCA (Barnes et al., 2018), which are Basque and Catalan, respectively. They include markers that further qualify each polarity, as "strong positive" or "strong negative". DSUnis is essentially an agglomeration of user reviews in English from the internet towards e-commerce and educational institutions, with only the latter being considered as part of this research. This is a consequence of the e-commerce reviews mostly comprising only the relevant polar targets that account for polarity, without holding the expressions themselves. NoReCFine is a Norwegian dataset made up of professional reviews belonging to a multitude of domains, and is also the most voluminous set of the lot. It additionally shows the intensity of the polarity for each expression, as in slight, normal or strong, which is deemed beyond the scope of the study.

3 System Overview

Here we provide a model that first learns to extract the sub-elements (holders, targets, expressions) using sequence labelers, and then tries to classify whether or not they have a relationship.

Specifically, we first train three separate BiLSTM models to extract holders, targets, and expressions, respectively. We then train a relation prediction model, which uses a BiLSTM + max pooling to create contextualized representations of 1) the full text, 2) the first element (either a holder or target) and 3) the sentiment expression.

These three depictions are concatenated and sent to a linear layer, followed by a sigmoid function. The training consists of predicting whether two elements have a relationship or not, converting the problem in binary classification.

4 Experimental Setup

The sequence labelling model employed in our research essentially attempts to divaricate and demarcate various elements of the input text into tuples. To begin with, the starting file Get_baseline.sh is executed in order to call the subsequent files in convert-to-bio.py, and

Convert-to-rels.py. The former is responsible for converting the given statements into the workable format, as in the stratification of data into holder, target and expression parts, with "B-I-O" labels. The labels are also carriers of the polarity (positive, negative, or neutral) of each text. Next up, the Convert-to-rels.py file is called, upon which, it extracts the target/expression pairs and holder/expression pairs, and creates 2 new fields e1, e2. Furthermore, the BiLSTMs are trained to extract holder, target and expression from the data. Pretrained GloVe or FastText embeddings are also provided to the model for the operation of labeling. After passing the input through the aforementioned processing stages, the vocabulary obtained in the end is stored in a vocabulary dictionary. 3 BiLSTMs are trained separately for each labeling task, following which, is the relation prediction model trained. The full sentence, in addition to e1 and e2, are all scanned for relations. If relations are present, then predictions are made accordingly. Finally to get a consolidated prediction.json terminal output file, the inference.py file is called. The holders, targets, and expressions have been extracted using the trained BiLSTMs already and the polarity is available from the expression labelling. The data is formatted accordingly and lastly packed into a neat json format. The following model incorporates a learning rate of 0.01. We have run it for upto 10 epochs, to arrive at a considerable amount of accuracy. The number of hidden layers in this model is kept as 1 by default.

5 Results

The efficacy of the sentiment analysis model towards encapsulating the full sentiment graph can be depicted in terms of the criteria as enumerated by two benchmarks, in Sentiment Graph F1 (SF1) and Non-polar Sentiment Graph F1 (NSF1). The sentiment graphs are considered in terms of holder, target, expression, and polarity, for evaluation by SF1, whereas NSF1 takes into account all elements of the tuple, except polarity for scrutinization. In this case, a perfect match on the graph, with respect to the mean of all three spans, and including weights pertaining to the gold and expected spans for each member is considered as a true positive. The precision value is a ratio where the numerator is the sum of predicted tokens that are found to be right, with the denominator being the total sum of all predicted tokens (amount of gold tokens is the denominator in case of recall). Empty targets and tokens are also taken into consideration.

Dataset	SF1-Score
norec	0.191
multibooked_ca	0.323

darmstadt_unis	0.104
average	0.218

Table 1: Results

6 Conclusion

In summation, our research work presents the three-tier model which we constructed, and is found to have the best accuracy of 0.33. The model has been proven to consume significantly less time as opposed to graph parsing. An inconsistency however has been documented, with regard to the processing of complex sentences carrying multiple expressions, in how it considers only the polarity attributed to the terminal element. Going forward, the component BiLSTM could be supplanted with BiLSTM CRF and run, owing to the nature of the latter to be robust and independent of word embedding, and capability to provide superior accuracy levels on Parts of Speech tagging, Name Entity Recognition of data sets and chunking.

MT-Speech at SemEval-2022 Task 10: Incorporating Data Augmentation and Auxiliary Task with Cross-Lingual Pretrained Language Model for Structured Sentiment Analysis

Cong Chen, Jiansong Chen, Cao Liu, Fan Yang, Guanglu Wan, Jinxiong Xia,
Meituan, Beijing, China
{chencong29, chenjiansong, liucao}@meituan.com

Abstract

Structured Sentiment Analysis (SSA) is an important component of sentiment analysis, which is a critical task in NLP. Traditional SSA methods cannot capture the cross-lingual interactions between different language and there is insufficient annotated data, especially in the cross-lingual settings. In this paper, we use the pre-trained language models with two auxiliary tasks and adopt data augmentation to address the above problems. Specifically, we employ XLM-RoBERTa to capture the cross-lingual knowledge interactions and enhance the generalization in multilingual/cross-lingual settings. Furthermore, we leverage two data augmentation techniques and propose two auxiliary tasks to improve the performance on the few-shot and zero-shot settings. Experiments demonstrate that our model ranks first on the cross-lingual sub-task and second on the monolingual sub-task of SemEval-2022 task 10.

1 Introduction

Structured Sentiment Analysis (SSA) is an important task in sentiment analysis (Barnes et al., 2021; Liu, 2012; Mitchell et al., 2013). The goal of SSA is to extract all opinion tuples from given texts. The opinion tuple (h, t, e, p) consists of a holder (h) which expresses a polarity (p) towards a target (t) by a textual sentiment expression (e). Benefiting a variety of business applications, such as human-machine dialogue and recommendation systems, SSA has attracted much more attention from both academia and industry (Pang et al., 2008; Mitchell et al., 2013; Xu et al., 2020; Ovrelid et al., 2020; Li et al., 2019).

The mainstream method for SSA is to adopt a pipeline approach by separately performing the subtasks including holder extraction and target extraction. However, such methods can not capture dependencies of multiple sub-tasks. To address this problem, Barnes et al. (2021) leverages graph-based dependency parsing to capture the dependencies among opinion tuples, where sentiment holders, targets and expressions are the nodes, and the relations of them as the arcs. This model has obtained state-of-the-art performance on SSA.

However, the aforementioned methods still suffer from some important issues. Firstly, the knowledge of the pre-trained language models (PLMs) has not been fully exploited. In fact, the cross-lingual PLMs contain rich knowledge of the interactions among different languages. Secondly, the above data-driven models rely on a large amount of annotation data, but there is insufficient or even no annotated data in the real scene. For example, in SemEval-2022 shared task 10 (Barnes et al., 2022), the **MultiB**$_{EU}$ (Barnes et al., 2018) dataset has only 1215 sentences and the **MultiB**$_{CA}$ (Barnes et al., 2018) dataset have only 1341 sentences, and there is no training data for the target language in the cross-lingual setting, which heavily hinders the performance on SSA.

To address the above problems, we propose a unified and end-to-end model for SSA, which performs data augmentation and adopts auxiliary tasks with cross-lingual PLMs. Specifically, we employ XLM-RoBERTa (Conneau and Lample, 2019; Conneau et al., 2019) as the backbone encoder to make use of its multilingual/cross-lingual knowledge. To alleviate the problem of insufficiency or lack of annotated data, we adopt two data augmentation methods: the one is to add in-domain annotated data of the same task under the training stage, and the other is to employ Masked Language Model (MLM) (Devlin et al., 2018) for generating similar texts. Furthermore, in addition to predicting each tuple in the dependency parsing graph simultaneously, we add two auxiliary tasks: 1) sequence labeling to predict the span of the holder / target / expression, and 2) sentiment polarity classification. Note that both of them do not need additional

Table 2: Comparisons on cross-lingual evaluation leader board.

annotations.

We conduct experiments on subtask 1 and subtask 2 of SemEval-2022 shared task on SSA. Experimental results demonstrate that our method outperforms strong baselines. We rank first on the cross-lingual sub-task and rank second on the monolingual subtask in SemEval-2022 task 10[1].

To summarize, our contributions are as follows.

- We leverage cross-lingual pre-trained language models to capture the interactive information knowledge among different languages.
- We combine existing in-domain training data and produce new training data by MLM to alleviate the problem of insufficiency or lack of annotated data.
- We propose two auxiliary tasks that do not require additional annotations to further improve the performance.
- Experimental results demonstrate the effectiveness of our proposed model, and we rank first on the subtask 2 and rank second on the subtask 1 on SemEval-2022 task 10.

2 Method

We incorporate the dependency graph parsing approach (Barnes et al., 2021) into our model. The general architecture is a pre-trained language model (e.g BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), etc..) followed by a three-layers BiLSTMs (Schuster and Paliwal, 1997; Cross and Huang, 2016) and the bilinear (Kiperwasser and Goldberg, 2016; Dozat and Manning, 2016) attention as the decoding component. Hence, we can take advantage of the knowledge of large-scale PLMs (Vaswani et al., 2017; Radford et al., 2019; Raffel et al., 2020; Yang et al., 2019; Wolf et al., 2019) and deep semantic dependency parsing (Dozat and Manning, 2016; Oepen et al., 2020; Kurtz et al., 2020).

2.1 Encoder

We consider several state-of-the-art models as the candidates of our model's backbone, such as Multilingual BERT (mBERT) (Devlin et al., 2018), XLM-RoBERTa (Conneau et al., 2019), and info-XLM(Chi et al., 2021). Particularly, we choose the XLM-RoBERTa backbone as the baseline. Because subtask 1 is a multilingual problem and subtask 2 is a cross-lingual zero-shot problem. They both benefit from the Translation Language Modeling (TLM) objective in XLM-RoBERTa. The TLM and Masked Language Modeling (MLM) objectives in the XLM-family models perform better than mBERT, which is simply trained on multilingual corpus with the MLM objective. Additionally, XLM-RoBERTa is trained on more data, which makes it more robust. Another reason we choose XLM-RoBERTa is that it is a large open-source model for downstream applications. We did not employ info-XLM as it is trained with the sentence-level classification objective, which is not suited for this task.

Table 3: Monolingual task performances with different encoders. All models use the same bilinear attention decoder. All results are evaluated on the official released development set.

2.2 Data Augmentation

We provide two data augmentation methods to further boost the performance of our model. First is the in-domain data enhancement (DA1) to better make use of the data in different languages. The second is the MLM data augmentation (DA2).

2.2.1 In-domain Data Enhancement

We combined different dataset that belong to the same domain in the training phase, to help improve generalization. Noticed that the four datasets **MultiB**$_{EU}$, **MultiB**$_{CA}$, **Opener**$_{ES}$, and **Opener**$_{EN}$ (Agerri et al., 2013) are all from the hotel review corpus. We observe these datasets share some common features even though they are of different languages. These languages share the same or similar words for the same objects or concepts. For example, the "hotel" word in Catalan and Spanish are also "hotel", and in Basque it is a similar word "hotela". Besides, the people who use these languages share the same sentiment polarity tendency on the hotel review domain. Combining the four language datasets together as a whole training set will improve the overall performance. We additionally add the Portuguese hotel review dataset (BOTE-rehol)(Barros and Bona, 2021) and the English laptops review dataset (RES14) (Pontiki et al., 2014; Xu et al., 2020) for extra training, which needs to be converted to the same format as this task.

2.2.2 Data Augmentation by Masked Word Generation

The Masked Language Model corrupts the input texts by randomly replacing the tokens with the [MASK] tokens, and predicts the original token at the [MASK] positions. For each sample with valid opinion tuples, by randomly masking a small portion of the tokens in the text, we obtain a new sample whose meaning is similar as the original with the same labels. Note that in this task we do not mask the sentiment expression words as the PLMs may generate words of different polarities which are inconsistent with the original labels.

2.3 Auxiliary Tasks

SSA consists of structure prediction and sentiment polarity classification, and to handle these two tasks in an end-to-end manner is non-trivial. We propose two auxiliary tasks to provide more training signals to the model to better handle structure prediction and polarity classification. For structure prediction, we add a sequence labeling task to explicitly predict the type (target, holder, or expression) of each token. For polarity classification, we add more sentiment polarity classification data as extra tasks. Specifically, we use the average pooling of the model's BiLSTM hidden-states as sentence-level representations. The representation is fed to a multilayer perceptron(MLP) for sentence-level sentiment polarity classification. The total loss is the weighted sum of the main loss and the auxiliary losses:

$$\mathcal{L} = \mathcal{L}^p + (\mathcal{L}^s + \mathcal{L}^c)/2 \quad (1)$$

where $\mathcal{L}^p$ is the primary loss of the SSA task. $\mathcal{L}^s$ and $\mathcal{L}^c$ are the losses for sequence-labeling and classification task, respectively.

3 Experiments

3.1 Experimental data

We use the officially released development set as the test set, and randomly split the original training set into the training and development sets. We keep the size of the split development sets the same as the official released development set.

We transform the BOTE-rehol and RES14 datasets into the graph format and leave the opinion tuples' holders empty since the two datasets do not contain holder labels.

For each dataset, we convert the sentiment graph labels to sequence labeling labels, which will be added as an auxiliary task during training. Additionally, for the **MultiB**$_{CA}$ and **Opener**$_{ES}$ datasets, we make use of the Catalonia Independence Corpus (CIC) (Zotova et al., 2020) as the extra training

Methods	**MultiB**$_{CA}$	**MultiB**$_{EU}$	**OpeNer**$_{ES}$	**OpeNer**$_{EN}$
baseline	0.685	0.650	0.654	0.712
w / DA1	0.727	0.670	0.711	0.729

Methods	**MultiB**$_{CA}$	**MultiB**$_{EU}$	**OpeNer**$_{ES}$
OpeNer$_{EN}$	0.574	0.438	0.630
w / DA1	0.600	0.550	0.620
w / DA1-2	0.623	0.567	0.657

Table 5: Cross-lingual performances of data augment (DA) on official released development set.

data of the polarity classification task.

3.2 Implementation details

We adopt the head-first setting (Barnes et al., 2021) which sets the first token within each span as the head of the span with all other tokens within that span as dependents. The root node is represented by the first token within the sentiment expression. For any word that is tokenized into a head-token followed by several sub-tokens, we set the head-token as the head and its following sub-tokens as the dependents. We use *holder, targ, exp-Positive, exp-Negative, exp-Neutral, None* as labels to denote different node types. The relation between each node is expressed by the attention value between the head-tokens of the nodes.

We try different combinations to get the best results for different subtasks. With XLM-RoBERTa-large as the backbone, details combinations are listed in Table 6 for the four hotel review datasets (**MultiB**$_{EU}$, **MultiB**$_{CA}$, **Opener**$_{ES}$ and **Opener**$_{EN}$). For **DS**$_{Unis}$ dataset (Toprak et al., 2010), we chose English RES14 dataset which also has few holders elements as its in-domain dataset. As most of the sentences in the two dataset are expressed without holders elements.

When generating new samples via MLM, for each sentence with at least one valid sentiment tuple, we mask one position i at a time and feed the masked sentence to the XLM-RoBERTa-large model. The PLM generates a word based on the highest probability p_i. We pick the top 5 most confident samples ranked by the PLM's output probability P_i for $i \in n$, where n denotes the possible masked positions. And set a threshold p as 0.85 to filter out any samples with a probability lower than the threshold. Repeated samples are not considered valid. The generated samples are treated as supplementary data to the original dataset.

For domain adaptation, we further pre-trained XLM-RoBERTa-large with all the data from the released datasets via Mask Language Modeling (MLM)(Devlin et al., 2018). We pick the best checkpoint according to the lowest perplexity on the development set.

3.3 Overall Comparisons

Comparison Settings. Firstly, we compare our model with other participant teams on the leader board of the structured sentiment competition. Table 1 and Table 2 record the comparison results of the monolingual and cross-lingual evaluation, respectively.

Comparison Results. (1) Our methods rank second and first on the monolingual and cross-lingual evaluation, respectively, which demonstrates the effectiveness of our proposed model. (2) Our model remarkably outperforms the top2 team in the cross-lingual subtask, which indicates our model has better generalization on the zero-shot cross-lingual settings.

3.4 Effectiveness of Cross-lingual Pre-trained Language Model

Comparison Settings. To prove the effectiveness of XLM-RoBERTa[2], a cross-lingual pre-trained language model, we compare it with the following baselines: 1) w2v + BiLSTM, BiLSTMs with word2vec (Mikolov et al., 2013) word embeddings; 2) mBERT, the Multilingual BERT (Devlin et al., 2018); 3) mBERT + BiLSTM; 4) XLM-RoBERTa + BiLSTM.

Comparison Results. (1) Table 3 demonstrates that XLM-RoBERTa + BiLSTM obtains the best performance among all of the benchmarks, and the average score outperforms the strongest baseline (mBERT + BiLSTM) by 6.7%. It proves that our model has great generalization ability. (2) BiLSTM can improve the performance by 3.7%, which indicates the BiLSTM layer can capture sequence information, which is beneficial to sequence encoding (Cross and Huang, 2016).

[2]We leverage the large version of XLM-RoBERTa to improve performances.

Methods	**MultiB**$_{CA}$	**MultiB**$_{EU}$	**OpeNer**$_{ES}$
Data combination	**OpeNer**$_{ES}$ **MultiB**$_{EU}$	**OpeNer**$_{EN}$ **MultiB**$_{CA}$ **OpeNer**$_{ES}$ bote-rehol	**OpeNer**$_{EN}$ **MultiB**$_{CA}$

Table 6: In domain data combination for cross-lingual evaluation. No target language data is participated in training and development.

Methods	**MPQA**	**DS**$_{Unis}$	**OpeNer**$_{EN}$	**OpeNer**$_{ES}$	**MultiB**$_{CA}$	**MultiB**$_{EU}$	**NoReC**$_{Fine}$
baseline	0.296	0.337	0.648	0.641	0.662	0.647	0.400
w / Auxiliary-task	0.305	0.346	0.674	0.660	0.687	0.657	0.411

Table 7: Performances on the official released development set with auxiliary tasks. We use RoBERTa-base (Liu et al., 2019) for **MPQA** (Wiebe et al., 2005), **DS**$_{Unis}$ and **OpeNer**$_{EN}$, bert-base-spanish-wwm-cased (Cañete et al., 2020) for **OpeNer**$_{ES}$, RoBERTa-base-ca (Armengol-Estapé et al., 2021) for **MultiB**$_{CA}$, berteus-base-cased (Agerri et al., 2020) for **MultiB**$_{EU}$, and norwegian-RoBERTa-base `https://huggingface.co/patrickvonplaten/norwegian-roberta-base` for **NoReC**$_{Fine}$ (Øvrelid et al., 2020).

3.5 Effectiveness of Data Augmentation

Comparison Settings. In order to demonstrate the effectiveness of data augmentation, we utilize existing training data for data augmentation (DA1) including **MultiB**$_{EU}$ **MultiB**$_{CA}$, **OpeNer**$_{ES}$ and **OpeNer**$_{EN}$. Furthermore, we leverage MLM to generate new training data for data augmentation (DA2). We record the performance in Table 4 and Table 5, where "w/" means "with", and "DA1-2" means "DA1 combined with DA2".

Comparison Results. We can conclude the following from Table 4 and Table 5: both DA1 and DA2 contribute to performance improvement, with performance increases on almost every benchmark. Specifically, the performance has remarkably improved in the cross-lingual settings, and data augmentation is more helpful on the few-shot and zero-shot settings.

3.6 The Effectiveness of Auxiliary Tasks

As shown in Table 7, we leverage the auxiliary tasks including sequence labeling and sentiment polarity classification to improve the performances. We can observe that the auxiliary tasks improve performances on all of the datasets, which demonstrate the effectiveness of the two auxiliary tasks.

4 Conclusion

This paper studies the task of structured sentiment analysis. In order to deal with the problems of poor interactions of different languages and lack of annotation data, we adopt the cross-lingual pre-trained language model and adopt data augmentation and auxiliary tasks. Specifically, we employ XLM to capture the interactive information in the pre-training stage. Furthermore, we leverage two data augmentation strategies and two auxiliary tasks to improve the performance for lack of training data. Experiments demonstrate the effectiveness of our models. Our models rank first on the cross-lingual sub-task and rank second on the monolingual sub-task of SemEval-2022 task 10.

Abstract

In this paper, we focus on the structured sentiment analysis task that is released on SemEval-2022 Task 10. The task aims to extract the structured sentiment information (e.g., holder, target, expression and sentiment polarity) in a text. We propose a simple and unified model for both the monolingual and crosslingual structured sentiment analysis tasks. We translate this task into an event extraction task by regarding the expression as the trigger word and the other elements as the arguments of the event. Particularly, we first extract the expression by judging its start and end indices. Then, to consider the expression, we design a conditional layer normalization algorithm to extract the holder and target based on the extracted expression. Finally, we infer the sentiment polarity based on the extracted structured information. We conduct the experiments on seven datasets in five languages. It attracted 233 submissions in monolingual subtask and crosslingual subtask from 32 teams. Finally, we obtain the top 5 place on crosslingual tasks.

1 Introduction

The identification of sentiment in the text is an important field of study. Users' opinions on products, events, topics, and so on are valuable for both the company and government to improve products or policies. Recently, more and more researchers focus on fine-grained sentiment analysis tasks, such as structured sentiment analysis, which can be formulated into tuple extraction from the context (Wiebe et al., 2005).

We focus on structured sentiment analysis, which is released by SemEval 2022 task 10. Formally, the task aims to extract all of the opinion tuples $O = \{O_i, ..., O_n\}$ in a text. A tuple (h, t, e, p) can represent the structure of sentiment in context. As shown in Figure 1, "Some other " (h) is a holder who expresses a polarity "positive" (p)

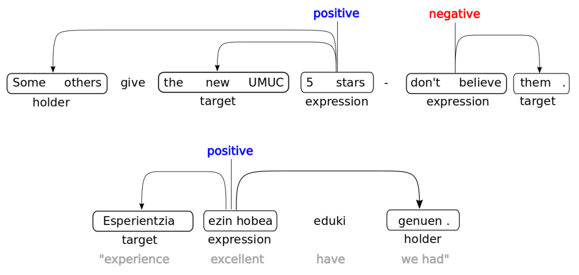

Figure 1: A structured sentiment graph is composed of a holder, target, sentiment expression, their relationships and a polarity attribute. Holders and targets can be null.

towards a target "the new UMUC" (t) through a sentiment expression "5 stars" (e), implicitly defining the relationships between the elements of a sentiment graph. Moreover, the SemEval task 10 is divided into two settings of increasing complexity: **Setting A** trains and predicts the sentiment polarity on monolingual. **Setting B** trains on the source language and tests on the target language. Particularly, we can train on any of the other datasets, as well as any other resource that does not contain sentiment annotations in the target language. The datasets used for this task are provided by the competition organizers, who collected and annotated the corpus (Barnes et al., 2021).

Structured sentiment analysis can be resolved down into four sub-tasks: a) expression extraction, b) target extraction, c) holder extraction, and d) sentiment polarity classification. Previous work on information extraction has used pipeline methods that extract the holders, targets, and expressions (tasks a-c). Most of the works conduct experiments on the MPQA dataset (Wiebe et al., 2005). Choi et al. (2006); Yang and Cardie (2012) used CRFs with the extracted features (e.g., named-entity tagger, sentiment lexicons, and dependency parsers), which results in a very strong baseline. For a complicated task with a small size of the training data, these feature-based mechanism learning techniques often still perform better than neural-based models,

[*] Jie Zhou is the corresponding author of this paper.

such as Bi-LSTMs (Katiyar and Cardie, 2016). The end-to-end approaches have shown some potential by learning the relationships among the multiple subtasks (Zhang et al., 2019; Zhou et al., 2020a). However, all of these studies ignore the sentiment polarity classification subtask. Barnes et al. (2021) regarded the structured sentiment analysis task as a dependency parsing task to model the relationships among the elements.

In this paper, we transform this task into an event extraction framework. Because we found the expression word is the same as the trigger word in the event extraction, both of them can uniquely represent the whole structured tuple. Besides, we regard the other elements (e.g., holder and targets) as the arguments of the sentiment structured information. Above all, we propose a pipeline model for this task. The key problem for this task is how to model the relationships among the targets, holders and expressions. To take the expressions into account, we introduce a conditional layer normalization method to extract the holders and targets w.r.t. the expression. Our simple and unified model is appropriate for both monolingual and crosslingual tasks. Experiments on datasets of monolingual and crosslingual tasks show our approach is capable to improve performance significantly on structured sentiment analysis as event extraction.

2 Related Work

2.1 Structured Sentiment Analysis

The goal of structured sentiment analysis is to extract the holders, expressions, and polarities w.r.t. the targets (Zhou et al., 2019). Early researches formulated the subtasks of structured sentiment analysis into independent span extraction or relation extraction. Choi et al. (2006) investigated a joint approach to extract entities and relations at the same time for opinion recognition and analysis. Yang and Cardie (2012) proposed semi-Markov conditional random fields (semi-CRFs) to extract opinion expressions at segment level. Katiyar and Cardie (2016) used deep bidirectional LSTMs for joint extraction of opinion entities and relations (e.g., the IS-FROM, IS-ABOUT) that connect the entities to extract expressions with their associated holders and targets. Zhang et al. (2019) presented a transition-based end-to-end method to extract the elements (e.g., holders, targets, and expressions) with their relationships. Then, to take the sentiment polarity into account, systems like IMN (He et al., 2019), SK-GCN (Zhou et al., 2020b) and RACL (Chen and Qian, 2020) have been developed.

Moreover, Barnes et al. (2021) introduced a parsing-based algorithm that implements a real unified structured sentiment analysis. They regarded structured sentiment analysis as a dependent parsing problem to model the relatedness among the holder, target, expression, and polarity. Different from these works, we translate structured sentiment analysis to an event-extraction framework.

2.2 Multilingual Sentiment Classification

Traditional methods for multilingual sentiment analysis are based on machine translation. Then, neural-based models product the source and target languages into a common space via parallel data or dictionaries. Lample and Conneau (2019) proposed two methods to learn cross-lingual language models: one unsupervised that uses cross language modeling to learn cross language representation. And one supervised that leverages parallel data with a new cross-lingual language model objective. Tellez et al. (2017) trained an SVM classifier by leveraging language-dependent and independent features. However, these machine learning approaches also require a feature extraction phase. We eliminate by incorporating deep learning approaches since they can learn features automatically. Furthermore, (Wan, 2008) designed a new approach to improve Chinese sentiment analysis using reliable English datasets. Recently, multi-lingual pre-trained language models (e.g., mBert (Devlin et al., 2019)) obtains state-of-the-art performance for crosslingual tasks.

3 Our Approach

In this paper, we propose a simple and unified model to extract the structured sentiment analysis. This section describes how we redefine the sentiment classification task to an event extraction task, detail the pipeline method. Fig. 3 shows the framework of our model, which consists of three components, expression extraction, arguments extraction (including holder extraction and target extraction), sentiment classification. First, we extract the expression based on (multi-lingual) pretrained language models (PLMs) (See Subsection 3.2). Second, we design a conditional layer normalization strategy to extract the holders and targets by incorporating the expression. Finally, we perform sentiment classification tasks based on the sentence

representation learned by the previous part (See Subsection 3.3 and 3.4).

3.1 Task Definition

Given a sentence $s = \{w_1, ..., w_{|s|}\}$, where w_i is the i-th word in the sentence s, which contains $|s|$ words. The goal of this task is to extract all the sentiment tuples $O = \{\mathrm{O}_1, ..., \mathrm{O}_{|O|}\}$ in the text, where the tuple (e, a, p) consists of expression e, arguments a (target t, holder h) and sentiment polarities c tuple. The event sentiment polarity class $c \in \{P, N, O\}$, which represents positive, negative and neutral.

3.2 Expression Extraction

Through the data analysis, we found that the expression uniquely identifies the tuple O since the targets and holders may not exist in the text. Thus, we extract the expression first by regarding it as the trigger. We first obtain the contextual word embedding based on the PLMs. For the monolingual setting, we use language-specific PLMs. For crossligual setting, we use the multi-lingual PLMs. Particularly, we input the sentence s into PLMs to obtain the word embedding $X = \{x_1, x_2, ..., x_{|s|}\}$,

$$X = \mathrm{PLM}(s) \tag{1}$$

Then, we extract the expression by two token-level binary classifiers to predict the start and end indices of the expression. A linear layer with an activation function is adopted as the classifier,

$$\begin{aligned} p_e^s &= \mathrm{Sigmoid}(W_e^s X + b_e^s) \\ p_e^e &= \mathrm{Sigmoid}(W_e^e X + b_e^e) \end{aligned} \tag{2}$$

where p_e^s and p_e^e are the predicted probability distribution of expression e's start and end indices, $W_e^s, W_e^e, b_e^s, b_e^e$ are the learnable weights.

3.3 Argument Extraction

The key challenge for extracting targets and holders with respect to the extracted expression is how to integrate the expression into the extractor model. Inspired by (De Vries et al., 2017), we design a conditional layer normalization method to take the expression into account 3. Specifically, we use the representation of the expression to control the β and γ in the layer normalization. In this way, we can obtain the expression-aware representation for target and holder extraction. The word representation h_i after the conditional layer normalization (CLN) is computed as,

$$\begin{aligned} h_i &= \mathrm{CLN}(x_i) = \gamma \frac{e_i - \mu}{\sigma} + \beta, \\ \gamma &= W_\gamma [x_{e^s}; x_{e^e}], \\ \beta &= W_\beta [x_{e^s}; x_{e^e}], \end{aligned} \tag{3}$$

where μ, σ are the mean and standard deviation of the elements in x_i, e^s and e^e are the start and end indices of the expression e, W_γ and W_β are the trainable parameters. We use the concatenation of the expression's start and end word representation as the expression representation.

Based on the expression-aware representation $H = \{h_1, h_2, ..., h_{|s|}\}$, we train two classifiers to predict the probability distribution of the start and end indices for targets and holders respectively.

$$\begin{aligned} p_t^s &= \mathrm{Sigmoid}(W_t^s H + b_t^s) \\ p_t^e &= \mathrm{Sigmoid}(W_t^e H + b_t^e) \\ p_h^s &= \mathrm{Sigmoid}(W_h^s H + b_h^s) \\ p_h^e &= \mathrm{Sigmoid}(W_h^e H + b_h^e) \end{aligned} \tag{4}$$

where p_t^s/p_h^s and p_t^e/p_h^e are the predicted probability distribution of target t/holder h's start and end in-

dices, W_t^s, W_t^e, b_t^s, b_t^e/W_h^s, W_h^e, b_h^s, b_h^e are the learnable weights.

3.4 Sentiment Classification

Finally, we infer the sentiment polarity of the structured tuple (h, t, e). Since the text representation contains the expression information that can represent the tuple, we use a max pooling operator based on H to obtain the tuple representation r,

$$r = \text{MaxPooling}(H) \tag{5}$$

We input the tuple representation r into a sentiment classifier to predict the sentiment polarity distribution towards the target,

$$p_c = \text{Softmax}(W_c r + b_c) \tag{6}$$

where W_c and b_c are the parameters.

4 Experiments

In this section, we first give the experimental setup, including datasets, implementation details and evaluation metrics (Section 4.1). Then, we present the experimental results and analysis on both the monolingual and multilingual settings (See Section 4.2).

4.1 Experimental Setup

Datasets To evaluate the effectiveness of our model, we conduct our experiments on datasets of multiple languages, including English, Basque, Catalan, Norwegian. MultiB$_{\text{EU}}$, MultiB$_{\text{CA}}$ (Barnes et al., 2018) and NoReC$_{\text{Fine}}$ (Øvrelid et al., 2020) are the reviews data in Basque, Catalan, and Norwegian. MPQA (Wiebe et al., 2005) is a English dataset that contains expressions, holders, targets and their relationships. DS$_{\text{Unis}}$ (Toprak et al., 2010) contains labeled opinions for user reviews about universities and services. The OpenNER dataset consists of labeled reviews of hotels from the guests. And it's divided into two languages: OpeNer$_{\text{en}}$ in English, OpeNer$_{\text{es}}$ in Spanish. The statistics of the datasets are shown in Table 1. We can find that the size of the labeled data is limited, especially the number of labeled holders. For example, in DS$_{\text{Unis}}$ dataset, there are only 86 holders, which limits the performance of the neural models largely.

Implementation Details For the monolingual setting, we utilize the language-specific pre-trained language models (PLMs) as the word embedding, which are downloaded from Huggling Face [1]. We finetune the parameters on the training data for this setting. For the crosslingual setting, we use the multi-lingual PLMs (e.g., mBEER, XLM) and fix the parameters on the training phase. We use Adam optimizer with the learning rates of 1e-5. The dimensions of word embedding are 128. The max sequence length is 512. The dropout is 0.1. We train all models for 100 epochs and keep the model that performs best regarding F1 on the dev set. We use default hyperparameters from Kurtz et al. (2020) and run all of our models five times with different random seeds. The reported test results are based on the parameters that obtain the best performance on the development.

Evaluation Metrics Following the previous works (Barnes et al., 2021), as we are interested not only in extraction or classification but rather in the full structured sentiment task, we use Sentiment Graph F1 as the final metric.

4.2 Experimental Results and Analysis

For experimental results, we report the majority baseline for each language. Our unified model can perform on both the monolingual and crosslingual settings and obtain good performance on these tasks, our main experimental results are presented in Table 2 and 3. We follow metrics in (Barnes

et al., 2021) to use Graph F1 scores to evaluate structured sentiment extraction and classification.

In detail, Table 2 shows the results of the monolingual setting. For English, the top 15 participants lie between 62.6% and 76.0%, 30.9% and 44.7%, 28.0% and 49.4% F1 score on the OpeNer$_{\text{en}}$, MPQA, DS$_{\text{Unis}}$ datasets. For the Spanish dataset, the top 15 F1 scores lie between 62.2% and 72.2%. The participants in the middle of the table are quite close to each other. For Catalan, F1 scores range from 58.3% to 72.8%. For the Basque language, F1 scores range from 50.6% to 73.9% , with a gap of 20 points between first and last place. For the Basque dataset, F1 scores range from 50.6% to 73.9%, and most are in mid 60%. In this setting, we obtain ninth place based on the average score of all the datasets.

Table 3 shows the performance of crosslingual setting, which trains on English datasets and tests on the target languages including MultiBooked datasets and the OpeNER Spanish dataset. For Spanish, the top 15 F1 scores between 32.1% and 64.4%. For Catalan, F1 scores between 26.9% and 64.3%, which span a wide range. For the Basque dataset, the F1 scores range from 30.3% to 63.2%. Particularly, our model obtains the second and third places on the MultiB$_{\text{CA}}$ and MultiB$_{\text{EU}}$ languages.

5 Conclusions

In this paper, we propose a simple and unified model for both the monolingual and crosslingual structured sentiment analysis tasks. Different from the previous studies, we transform this task into an event extraction task. Mainly, we first design an expression extraction for extracting the expression, just like extracting the trigger words in the event extraction task. Then we predict the holder and target based on the extraction results of the previous step. The model performs well on seven datasets in five languages.

Abstract

This paper presents our submission to task 10, Structured Sentiment Analysis of the SemEval 2022 competition. The task aims to extract all elements of the fine-grained sentiment in a text. We cast structured sentiment analysis to the prediction of the sentiment graphs following (Barnes et al., 2021), where nodes are spans of sentiment holders, targets and expressions, and directed edges denote the relation types between them. Our approach closely follows that of semantic dependency parsing (Dozat and Manning, 2018). The difference is that we use pre-trained language models (e.g., BERT and RoBERTa) as text encoder to solve the problem of limited annotated data. Additionally, we make improvements on the computation of cross attention and present the suffix masking technique to make further performance improvement. Substantially, our model achieved the **Top-1** average Sentiment Graph F1 score on seven datasets in five different languages in the monolingual subtask.

1 Introduction

SemEval 2022 task 10 is a structured sentiment analysis task, aiming to predict all of the opinion tuples in a text. Each opinion O is a tuple (t, h, e, p), where h is a holder who expresses a polarity p towards a target t through a sentiment expression e. In practical, the task of structured sentiment analysis can help machines understand how people perceive ideas, policy etc.

This paper describes the system developed by the team ZHIXIAOBAO for SemEval-2022 Task 10. We follow the work of (Barnes et al., 2021) to cast the task as dependency graph parsing problem. The predicted opinion tuples are denoted by a directed graph, $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, for each sentence. As shown in Figure 1, all tokens in a sentence are presented as nodes and there are directed edges between the nodes to represent their relations. Each node in $\mathcal{V}$ can point to multiple nodes, and can have multiple incoming edges too. Sentiment expressions are regarded as roots in the structured sentiment graph (e.g., the token "5" and "don't" in Figure 1). Notice that not all nodes connect to the other nodes (e.g., the token "give" in Figure 1). The isolated tokens are the none-sentiment elements in the sentence, thus we should be able to predict the edge type of "null" in our model. Original edge types are defined as *holder*, *target*, and *expression*. Following the work of (Barnes et al., 2021), we also tried the **"+inlabel"** style of definition, where none-"null" edge types consist of $holder_{in}$, $holder_{out}$, $target_{in}$, $target_{out}$, $expression_{in}$, $expression_{out}$. Foot markers *in*, *out* denotes the in-span and out-span edges respectively. For example, the edge from "5" to "some" belongs to $holder_{out}$, while the edge from "Some" to "others" belongs to $holder_{in}$.

As demonstrated in previous work (Barnes et al., 2021), formulating the task as a graph structure prediction problem is superior to that of solving it by the span extraction and relation prediction approaches. The former can better extract overlapping spans than the latter. Thus, our model mainly follows the solution of dependency parsing to directly predict between-word relations. The model consists of a text encoder to extract contextual features of tokens, and a classifier to predict edges between each pair of tokens. A bilinear or biaffine cross attention is applied in the classifier layer to make multiplicative interactions between the features of a pair of tokens. In our model, pre-trained language models (e.g., BERT and RoBERTa) are used as the text encoder. We discover that fine-tuning the pre-trained language model brings huge enhancements in our experiments. In addition, as the meaning of in-span and out-span edge types are totally different, we leverage two cross attention for in-span edge types and out-span edge types prediction respectively. We also present a suffix mask-

ing technique to reduce noise in the data. These techniques greatly improve the performance of our model compared with the original dependency parsing model.

Our model ranked **1st** out of 32 participating teams on monolingual subtask and got the highest average F1 score on 4 datasets.

2 Task Description

SemEval task 10 focuses on predicting all elements of the structured sentiment in a text, represented by opinion tuples (t, h, e, p), where h is a holder who expresses a polarity p towards a target t through a sentiment expression e. The evaluation is on seven datasets in five languages, the statistics of which are shown in Table 1.

NoReC$_{\text{Fine}}$ (Øvrelid et al., 2019) is the largest structured sentiment multi-domain dataset with professional reviews in Norwegian. **MultiB**$_{\text{EU}}$ and **MultiB**$_{\text{CA}}$ (Barnes et al., 2018) are hotel reviews datasets in Basque and Catalan, respectively. **OpeNER**$_{\text{EN}}$ and **OpeNER**$_{\text{ES}}$ (Agerri et al., 2013) are polarity-enhanced datasets with customer reviews in Spanish and English respectively. **MPQA** (Wiebe et al., 2005) annotates news articles in English from the world press. Finally, **DS**$_{\text{Unis}}$ (Toprak et al., 2010) is an annotated English reviews dataset of online universities and e-commerce.

Previous shared tasks on Aspect-Based Sentiment Analysis (ABSA) focus on extracting sentiment targets and classifying the polarity directly. Most previous methods follow the information extraction pipeline, which firstly extract the span of holders, targets, expressions and subsequently predict the relations. However, splitting structured sentiment analysis into subtasks may cause the error propagation problem. We follow the work that solving the problem by dependency graph parsing (Barnes et al., 2021) to achieve better performance in our model.

3 System Overview

The overview of our system is shown in Figure 1. We use a pre-trained language model to extract text information as the node features in the graph. Then, a cross attention layer is used to compute the predicted score of each edge type. After we get the edge score for each token pair, a graph parsing algorithm is presented to transform the predicted score to opinion tuples.

3.1 Text Encoder

We use the pre-trained language models, **BERT** and **RoBERTa**, to generate the contextual features of the text in multiple languages. Both of them are Transformer-based language models using a huge amount of text with a masked language model objective. These pre-trained language models have shown great superiority in a low-resource scenario like this task. Compared with BERT, RoBERTa removes next sentence prediction(NSP) loss and applies larger batch size and sequence length during the pre-training step, leading to a better performance in most cases. We tried the monolingual version of **RoBERTa**$_{\text{LARGE}}$ (Liu et al., 2019a) and **BERT**$_{\text{LARGE}}$ (Devlin et al., 2019) for each dataset, as our feature extractor. Our experimental results demonstrate that **RoBERTa**$_{\text{LARGE}}$ performs better than **BERT**$_{\text{LARGE}}$ in all the datasets.

3.2 Discrete Cross Attention

After extracting the text features, we can then use bilinear or biaffine attention to produce a score for each pair of tokens. The score includes multiplicative interactions among pairs, and can be used to predict edge types. Different from the previous work (Barnes et al., 2021), we model heads and dependents of in-span and out-span separately, because we think it is better to cast the in-span and out-span label prediction as two "different" tasks. According to our observation, they have different properties in the corpus. Thus, inspired by the multi-task learning framework, we propose to use **Discrete Cross Attention (DCA)** to make them share same bottom features in the text encoder, but have non-shared parameters in the computation of cross attention.

The contextual features C extracted from text encoder are processed with four layers of the feed-forward neural networks(FNN), FNN$^{in}_{head}$, FNN$^{in}_{dep}$, FNN$^{out}_{head}$ and FNN$^{out}_{dep}$ creating representations of potential heads and dependents for in-span and out-span respectively. And then a bilinear score is computed for each kind of edge types using a trainable parameter matrix A. The discrete cross attention can be formulated as bellow,

$$h_i^{in} = FNN_{head}^{in}(c_i) \tag{1}$$

$$d_i^{in} = FNN_{dep}^{in}(c_i) \tag{2}$$

$$score_{ij}^{in} = h_i^{inT} A_{in} d_j^{in} \tag{3}$$

$$h_i^{out} = FNN_{head}^{out}(c_i) \tag{4}$$

$$d_i^{out} = FNN_{dep}^{out}(c_i) \tag{5}$$

$$score_{ij}^{out} = h_i^{outT} A_{out} d_j^{out} \tag{6}$$

$$score_{ij} = softmax(score_{ij}^{in} \oplus score_{ij}^{out}) \tag{7}$$

$score_{ij}$ represents the final score list for each edge type, which is the softmax score of the concatenation of in-span edge scores $score_{ij}^{in}$ and out-span scores $score_{ij}^{out}$.

3.3 Graph Parsing

We set a threshold θ to determine whether the edge exists, i.e., if $max(score_{ij}) > \theta$, we set the predicted edge type to be $argmax(score_{ij})$, or we make the predicted edge to be "null". We

Algorithm 1: Graph parsing

```
Input: Sentiment graph $\mathcal{G}$
Output: Opinion Tuples $(H, T, E)$
Data: Opinion set $Op_{set}$
1  for $e_{r,i}$ in $\mathcal{G}$ do
2      if $e_{r,i} \in ExpTypes$ then
3          E ← $FindSpan(i, Type(e_{r,i}))$;
           new $H_{set}, T_{set}$;
4          for $e_{i,j}$ in $\mathcal{G}$ do
5              if $Type(e_{i,j}) \in HolTypes$ then
6                  $H_{set} \leftarrow FindSpan(j, hol)$
7              if $Type(e_{i,j}) \in TrgTypes$ then
8                  $T_{set} \leftarrow FindSpan(j, trg)$
9          for $H$ in $H_{set}$ do
10             for $T$ in $T_{set}$ do
11                 $Op_{set} \leftarrow (H, T, E)$
```

set $\theta = 0.5$ in our experiments. We use two kinds of graph parsing representations, head-first and head-final, following (Barnes et al., 2021). For head-first, we use the first token in the target/holder/expression spans as the head of the span and the other tokens within the span as the dependent. For head-final, we take the opposite way, i.e., set the final token of the target/holder/expression spans as the heads.

The algorithm of converting structured sentiment graph to opinion tuples (H, T, E) is in shown in **Algorithm 1**. H, T, E denote $holder$, $target$ and $expression$ respectively. $ExpTypes$, $HolTypes$, $TrgTypes$ are the edge type sets for $expression$, $holder$, $target$ respectively. $e_{i,j}$ denotes the predicted edge type between token i and token j, and r is the root nodes. $FindSpan(\cdot)$ is a function to find the complete span for a certain edge type, which can be simply implemented by merging linked tokens with the same edge type. As shown in **Algorithm 1**, we should first find the expressions, and then add the linked holders and targets for each expression to the opinion tuples. Notice that if we cannot find holder or target spans for an expression, we shall append an empty token into H_{set} or T_{set}.

3.4 Suffix Masking Trick

In both training and predicting procedure, a sentence is first tokenized by byte-pair encoding (BPE) before it is inputted into the text encoder, i.e., BERT

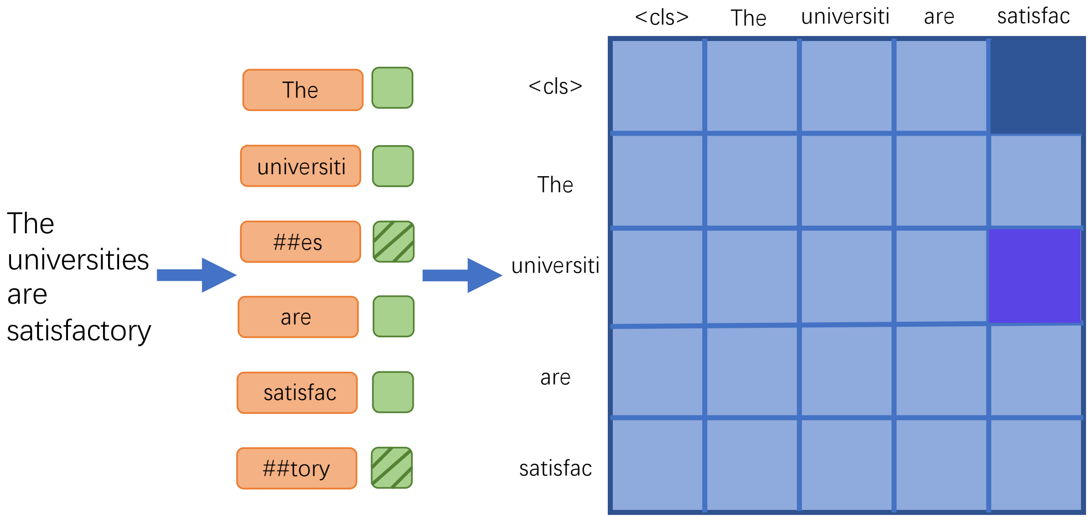

Figure 2: Suffix masking.

and RoBERTa. Some words are splitted into prefixes and suffixes in the procedure. For example, "universities" is tokenized to "universiti", "##es" as shown in Figure 2. We think these suffixes are often noises and provide few supervision signals for the edge prediction, since they are shared by many distinguished words. Inspired by this intuition, we mask these suffixes in the computation of edge scores. As shown in Figure 2, we mask the suffix, "##es" and "##tory", before the prediction of edges. In this way, the edges only exist between the pair of $(< cls >, satisfac)$ and $(universiti, satisfac)$.

4 Experiments

The experiments details and main results are shown in this section.

4.1 Experiment Details

The implementation of our model depends on pytorch and huggingface. In our experiments, **BERT**$_{\text{LARGE}}$ represents the monolingual version for each dataset, which all can be found in the huggingface website. As for **RoBERTa**$_{\text{LARGE}}$, the version of *xlm-roberta-large* (Conneau et al., 2019) is used on models for **MultiB**$_{\text{CA}}$, **MultiB**$_{\text{EU}}$ and **OpeNER**$_{\text{ES}}$, and *roberta-large-en-cased* (Liu et al., 2019b) is used on the English datasets, i.e., **MPQA**, **OpeNER**$_{\text{EN}}$ and **DS**$_{\text{Unis}}$.

We use Adam as our optimizer with the learning rate to be 1e-5 for the fine-tuning of pre-trained language models and 1e-4 for the other parameters in the model. The batch size is set to 12 with the gradient accumulation steps to be 48. The dropout rate is 0.3 and the hidden state size of FNN layers is set to 256. Our models are run on a maximum of 1000 epochs. We train all the models with 5 different seeds on the training set released by the orginizer and choose the best results based on the performance on development datasets. The training run on two Tesla V100 GPUs with 32G memory.

It has to be noted that we add a “<cls>” token when encoding the sentences and set the “<cls>” token as the root of the sentiment graph. In Figure 1, there actually exists an edge between <cls> token and the head of expression spans.

4.2 Metrics

To measure how well a system is able to capture the full sentiment graph, submitted systems are evaluated on sentiment graph F_1 (SF_1) following (Barnes et al., 2021). A true positive is defined as an exact match at graph-level, weighting the overlap in predicted and gold spans for each sentiment element, averaged across all three kinds of spans, i.e., expression, holder, target. For precision we weight the number of correctly predicted tokens divided by the total number of predicted tokens (for recall, we divide instead by the number of gold tokens).

4.3 Main Results

The main experimental results are shown in Table 2. It can be seen that using monolingual **BERT**$_{\text{LARGE}}$ pre-trained on larger language-specific corpus as text encoder is better than the multilingual **BERT**$_{\text{base}}$ used in (Barnes et al., 2021), and fine-tuning the pre-trained language models brings more improvements than freezing the parameters. An in-

Methods	NoReC$_{\text{Fine}}$	MultiB$_{\text{CA}}$	MultiB$_{\text{EU}}$	OpeNER$_{\text{ES}}$	OpeNER$_{\text{EN}}$	MPQA	DS$_{\text{Unis}}$
mBERT$_{\text{base}}$ w/o fine-tune + lstm (Barnes et al., 2021)	39.4	55.8	57.4	-	-	18.8	27.3
BERT$_{\text{LARGE}}$ w/o fine-tune + lstm	42.9	63.7	62.1	65.4	65.0	33.5	36.7
BERT$_{\text{LARGE}}$ fine-tune + lstm	50.4	69.1	65.2	67.1	69.2	42.1	40.8
BERT$_{\text{LARGE}}$ fine-tune	50.8	70.7	65.7	68.6	70.8	43.5	42.4
BERT$_{\text{LARGE}}$ fine-tune + inlabel	50.9	70.5	65.9	68.4	71.5	43.3	42.8
BERT$_{\text{LARGE}}$ fine-tune + inlabel + DCA	51.7	71.1	67.3	69.1	73.1	43.6	44.5
BERT$_{\text{LARGE}}$ fine-tune + inlabel + DCA + mask	**52.9**	71.7	70.5	71.6	75.4	43.9	47.2
RoBERTa$_{\text{LARGE}}$ fine-tune + inlabel + DCA + mask	-	**72.8**	**73.9**	**72.2**	**76.0**	**44.7**	**49.4**

Table 2: Main results. **mBERT**$_{\text{base}}$ denotes the multilingual BERT (Xu et al., 2019). "+lstm" denotes adding an LSTM layer after the text encoder. "+inlabel", "DCA" and "mask" denote the "+inlabel" style of edge types, the discrete cross attention and the suffix masking technique presented in last section.

teresting discovery is that adding an LSTM layer between text encoder and cross attention leads the decreasing of SF_1 score. Thus, we remove the LSTM layer in our final submitted models. In addition, we can see that the **"+inlabel"** style definition of edge types is indeed helpful in this task. Furthermore, the presented discrete cross attention and suffix masking technique significantly improve the performance of our model.

The results prove the effectiveness of fine-tuning **RoBERTa** in this task. As shown in the Table 2, methods with **RoBERTa**$_{\text{LARGE}}$ as the text encoder on six datasets achieve the best performance. The best SF_1 scores on **MPQA**, **OpeNER**$_{\text{EN}}$ and **DS**$_{\text{Unis}}$ are 44.7, 76.0, and 49.4, where *roberta-large-en-cased* is used in the model. For **MultiB**$_{\text{CA}}$, **MultiB**$_{\text{EU}}$ and **OpeNER**$_{\text{ES}}$, *xlm-roberta-large* (Conneau et al., 2019) outperforms **BERT**$_{\text{LARGE}}$ and we have 72.8 on **MultiB**$_{\text{CA}}$, 73.9 on **MultiB**$_{\text{EU}}$ and 72.2 on **OpeNER**$_{\text{ES}}$. The results demonstrate that a pre-trained language model with more parameters and trained on the larger corpus performs very well in downstream tasks as feature extractor. For **NoReC**$_{\text{Fine}}$, we use *nb-bert-large* (Kummervold et al., 2021) and the SF_1 score is 52.9. We do not get results on **NoReC**$_{\text{Fine}}$ in the last line of the table because monolingual **RoBERTa**$_{\text{LARGE}}$ for Norwegian is not available at the time of our experiments. We guess that the model on **NoReC**$_{\text{Fine}}$ using **RoBERTa**$_{\text{LARGE}}$ will achieve a better result.

There are some failed attempt during the period of competition, too. We tried to enrich the contextual features of a sentence with word embedding, POS tag embedding, lemma embedding by using tools like SpaCy (Honnibal et al., 2020), Stanza (Qi et al., 2020) and UDPipe (Straka and Straková, 2017). But, we find that it is not superior to directly fine-tuning the pre-trained language model. We also tried to pre-train the RoBERTa-large on a Norwegian corpus, then the SF_1 score continuously grows with the increasing of training steps. However, due to the limitation of computation resources and time, we only trained the model with 2M steps. The final version does not outperform that using **BERT**$_{\text{LARGE}}$ because of the inadequate training.

5 Conclusion

In this paper, we have presented the implementation of the ZHIXIAOBAO system submitted to the SemEval-2022 Task 10. We propose an enhanced dependency parsing model for sentiment graph analysis. We leverage the fine-tuning technique of pre-trained language models, **BERT**$_{\text{LARGE}}$ and **RoBERTa**$_{\text{LARGE}}$ to increase the ability of model generalization. Furthermore, we present the discrete cross attention and suffix masking technique to achieve a significant performance improvement. Our model ranked **1st** out of 32 participating teams on the monolingual subtask with the highest SF_1 score on 4 datasets.

Abstract

This paper describes our participation in SemEval-2022 Task 10, a structured sentiment analysis. In this task, we have to parse opinions considering both structure- and context-dependent subjective aspects, which is different from typical dependency parsing. Some of the major parser types have recently been used for semantic and syntactic parsing, while it is still unknown which type can capture structured sentiments well due to their subjective aspects. To this end, we compared two different types of state-of-the-art parser, namely graph-based and seq2seq-based. Our in-depth analyses suggest that, even though graph-based parser generally outperforms the seq2seq-based one, with strong pre-trained language models both parsers can essentially output acceptable and reasonable predictions. The analyses highlight that the difficulty derived from subjective aspects in structured sentiment analysis remains an essential challenge.

1 Introduction

SemEval-2022 Task 10 (Barnes et al., 2022) aims at extracting structured sentiment from a given sentence. Different from other sentiment analysis tasks, structured sentiment analysis is formulated as an information extraction problem with at least three elements, namely a holder, a target and a sentiment expression. The shared task has two subtasks. In Subtask 1 (monolingual), we evaluate the performance on seven monolingual corpora, i.e., `MPQA` (Wiebe et al., 2005), `OpeNER`, `OpeNER_es` (Agerri et al., 2013), `DSu` (Toprak et al., 2010), `MultiB_ca`, `MultiB_eu` (Barnes et al., 2018) and `NoReC` (Øvrelid et al., 2020). In Subtask 2 (crosslingual), we evaluate the zero-shot prediction performance on three non-English corpora, i.e., `OpeNER_es`, `MultiB_ca` and `MultiB_eu`, generated by a model trained with an English corpus. One significant difference between syntactic parsing and structured sentiment analysis is that

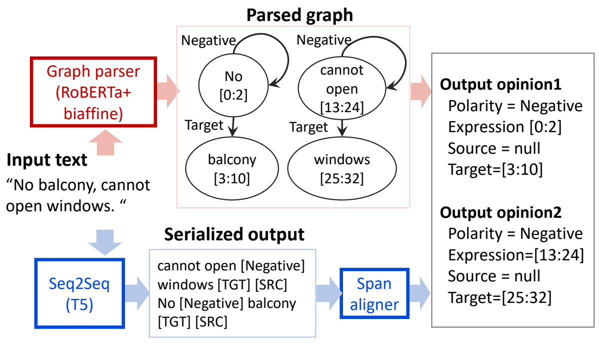

Figure 1: Overview of the two parsers: (Top) Graph and (Bottom) Seq2Seq.

the former is based on certain well-defined rules, whereas the latter forms an information structure on the basis of subjective opinions. Given the nature of the sentiment structure, Barnes et al. (2021) formulated the problem as a dependency parsing task.

Our motivation here is to throw light upon how subjective opinions affect parsing performance and how well recent strong parsing models can capture them. To this end, we compare two types of parsing model: graph- and generation-based[1] models. Though these parsers have shown competitive performance under various conditions (Oepen et al., 2020; Ozaki et al., 2020; Samuel and Straka, 2020), each of them has its own advantages and disadvantages. Graph-based parsers (McDonald et al., 2005) directly model token-to-token relations; therefore, they are suitable for modeling structured sentiment with surface anchors. On the other hand, generation-based parsers output a sequence to reconstruct the graph structure of the target meaning representation. Recent advances in deep neural networks have allowed us to generate a serialized graph directly from an input sentence by using pre-trained generation models (Ozaki et al.,

[1]We regard a transition-based parser (Dyer et al., 2015) to be a kind of seq2seq-based parser, as it generates an action sequence based on its states.

2020; Procopio et al., 2021). Specifically, we focus on state-of-the-art seq2seq-based models like T5 (Raffel et al., 2020). Because pre-trained generation models (e.g. text summarization models) have been trained to generate a summarized statement from a given input sentence, it may be easier for the generation-based parsers to model semantic relations including subjective opinions than the graph-based ones.

In this paper, we briefly introduce our approaches together with a comparison of the two different parsers: (i) **Graph**: We use a model that jointly solves two different problems, namely span identification, and relation extraction of spans. (ii) **Seq2Seq**: We design a serialization for sentiment structures generated by our seq2seq-based parser. We simply use pre-trained text generation models and fine-tune them with the serialized sentiment structures.

Experiments showed that Graph and Seq2Seq achieved reasonable levels of performance on both subtasks. Our submitted systems are based on Graph and ranked third in both the monolingual and cross-lingual tasks. We further conducted in-depth analyses for the two parsers. Our findings are twofold:

1. Multilingual performance tends to depend more on the type of pre-trained model used than on the model architecture, while Graph outperformed Seq2Seq in non-English corpora.

2. Graph is somewhat recall-focused, whereas Seq2Seq is more precision-focused in specific corpora.

The first finding suggests that Graph with a strong pre-trained model has an advantage for multilingual training when compared to Seq2Seq. Given that mT5 (Xue et al., 2021) is not trained on any supervised tasks such as translation or summarization, it may be difficult for multilingual Seq2Seq to generate (and possibly copy) sentiment tokens from the input text. Other considerations such as the decoder architecture and training time of Seq2Seq seem to favor Graph.

Regarding the second finding, we found that Graph performs well on complex structured opinions. However, on the other side of the coin, it suggests that Graph sometimes causes over-detection (though these over detected opinions may be acceptable to humans). We found that this happens particularly for `MPQA` polar expressions. This could be due to the nature of `MPQA`, which usually includes context-dependent expressions.

As a result, we argue that it is difficult to decide which type of parser is better because: (i) the decision criteria rely on how we define the sentiment structure, e.g., structured sentiments in some corpora are semantically complex and context-dependent, while those in other corpora are not, making the corpus less context-dependent. (2) Whether to use Graph or Seq2Seq depends on whether we want to cover as much of the structured sentiments as possible or whether we want to emphasize precision. (3) In regard to metric-dependent choices, Seq2Seq is at a disadvantage in the shared task because the metric requires anchoring to the surface of the input text. We also have to decide which parser to use from various other perspectives, such as (4) whether or not we are targeting English, and (5) whether the training speed is important. These considerations make structured sentiment analysis challenging.[2]

2 Models

This section explains the Graph and Seq2Seq methods used in this work.

2.1 Graph model

We formulate the problem as a joint task of span identification and relation extraction. This approach can be classified as a graph-based approach (Dozat et al., 2017; Falenska et al., 2020), which is known to perform well in fields such as syntactic dependency parsing. Although there are various approaches to this problem, we simply use the architecture of Morio et al. (2022). The architecture generates BIO tags to predict spans using pre-trained language models such as Longformer (Beltagy et al., 2020). The span representation of each predicted span is generated by average pooling of the predicted span and subsequently fed into biaffine classifiers (Dozat and Manning, 2017) to predict relations.

Because the architecture was originally designed to predict argument structures (Lawrence and Reed, 2019), so-called argument mining, it needs a little tweaking. We thus designed a dedicated encoding for structured sentiment analysis. As shown in Figure 1 (Top), the opinions for the input text can

[2]We plan to release our code at `https://github.com/hitachi-nlp/graph_parser`

be represented as a graph. We represent a representative polarity expression as a root node, and its polarity as a self-loop (e.g., a *no* node and its negative self-loop). We represent the other polarity expressions, target and source via child nodes linked to the polarity nodes (e.g., *balcony* is a child node for the *no* node). Overlapping spans are divided up using the start and end indexes of the overlap, and each span can have multiple labels (e.g., *Positive_Source* is a combined label for positive and source spans). Although this graph encoding cannot fully represent structured sentiments[3], we confirmed that the data reconstructed from the graph encoding achieves about 99% F-score (so there is practically no problem.) We convert all the given datasets using this graph encoding, and given a text input, the model is trained to parse the graph.

2.2 Seq2Seq model

Seq2Seq Generation Here, we formulate the problem as a summarization task to output serialized tuples of structured sentiment. We preferably utilize pre-trained summarization language models, such as T5 (Raffel et al., 2020), and fine-tune them with the serialized tuples.

Serialization system A seq2seq model outputs serialized tuples of structured sentiment regardless of their position on the surface (see Figure 1). For example, when an input text is “No balcony, cannot open windows”, we have two tuples of structured sentiment; each of them is serialized as follows:

```
No[NEG] balcony[TGT] [SRC]
cannot open[NEG] windows[TGT] [SRC]
```

We serialize a tuple into a polar expression, a target, and a holder order. The polar expression ends with `[NEG]`, `[NEU]` or `[POS]` tokens according to its polarity. The target and holder expressions end with `[TGT]` and `[SRC]`, respectively. If multiple spans are in a tuple, we concatenate them with a special separator (`[SEP]`) token. Since each expression is marked with these special tokens, we can simply concatenate all tuples without confusing them with each other.

Reconstruction from serialization Although our serialization preserves semantically sufficient information on sentiment structures, there is a piece of missing information, i.e., anchors. To reconstruct the anchor information, we utilize a word aligner based on a pre-trained language model: SimAlign (Jalili Sabet et al., 2020). Because SimAlign provides a zero-shot alignment model, we utilize it for obtaining the alignment between the input text and its serialized sentiment structure. For ease of explanation, we define *span* $s = [t_i, t_{i+1}, \ldots, t_{i+j}]$ as a single phrase appearing as a holder, a target, or a polar expression, where t is a generated token. First, we pick a single opinion; then, we extract all tokens in the opinion and form a token sequence $[t_1, \ldots, t_n]$. Second, we calculate the token alignments $[a_1, \ldots, a_n]$ between the input text and the token sequence to point out the corresponding tokens in the input, where $a > 0$ and $a \in \mathbb{N}$. Lastly, we recover the span $s = [t_i, \ldots, t_{i+j}]$ location by $[\min(a_i, \ldots, a_{i+j}), \max(a_i, \ldots, a_{i+j})]$ [4].

Furthermore, we add a heuristic procedure to improve the reconstruction accuracy. When an expression extracted from a reconstructed anchor is different from its original generated expression, we apply a greedy search to find the part where the original expression appears *as is* in the input text. If we find the part, we use an anchor that points to the part instead of the reconstructed anchor. With this heuristic, we achieved an F-score of around 97% between gold and reconstructed opinions from the serialized outputs[5].

3 Experiments

3.1 Experimental setup

Implementation details We implemented Seq2Seq and Graph with PyTorch (Paszke et al., 2019) and the Huggingface Transformers library (Wolf et al., 2020). All models were trained with a fixed number of steps (about 10,000 steps). We used a learning rate of 2e-5 for Graph and 5e-5 for Seq2Seq, with a warmup (Howard and Ruder, 2018) ratio of 0.1. The batch size was set to 16 for Graph and 32 for Seq2Seq. We set the beam width to 5 for Seq2Seq. We did not conduct hyperparameter tuning or model selection and did not use any development data during training and validation.

Pre-trained models To fully utilize the representative power of Graph and Seq2Seq, we used

[3]Our graph encoding cannot distinguish a case where one polar expression forms a single opinion with multiple targets from a case where a polar expression forms multiple opinions with a single target.

[4]Because actual anchors are character-level, we need to convert the spans from the token level to the character level.

[5]Without this heuristic, the F-score is about 91%.

pre-trained language models based on Transformer (Vaswani et al., 2017). For Graph, we used RoBERTa-large (Liu et al., 2019) in Subtask 1 (monolingual) and InfoXLM-large (Chi et al., 2021) in Subtask 2 (cross-lingual). RoBERTa is a well-tuned model based on BERT (Devlin et al., 2019), and it has shown state-of-the-art performance in various classification tasks. InfoXLM is a recently proposed model, which is pre-trained with contrastive learning. For Seq2Seq, we used T5-large (Raffel et al., 2020) in Subtask 1 and mT5-large (Xue et al., 2021) in Subtask 2. T5 uses a unified text-to-text framework to deal with various text-based tasks.

Submitted models In our preliminary experiments, we found that the development scores of the monolingual Graph models were slightly better than those of the Seq2Seq ones (the reasons will be discussed later). Thus, we only used Graph models for our submission. However, to discuss Graph and Seq2Seq in detail, we show the results of both Graph and Seq2Seq below.

3.2 Main results

Table 1 shows the overall results of Subtask 1 (i.e., monolingual), including the scores for the development and test data in Sentiment Graph F1 (SF_1) (Barnes et al., 2021). We tried three different seeds for each model to minimize the effects of random seeds and averaged the scores. For the ensemble methods, the scores are those from the ensemble of models with the three seeds. For reference, we also include the results of the best-performing team for the test data. Overall, Graph mostly outperformed Seq2Seq with significant differences observed in non-English corpora, such as OpeNER_es and MultiB_eu. This suggests that Graph has an advantage for multilingual training when compared to Seq2Seq. That is, while T5 is trained on summarization and its related tasks, mT5 is not. This difference might cause a disadvantage

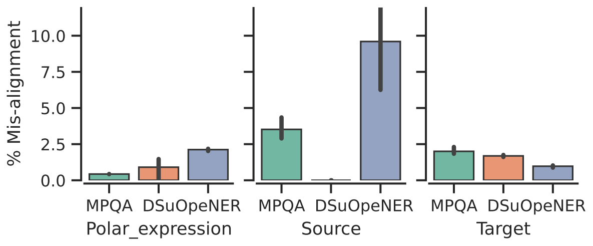

Figure 2: Misalignment ratio of Seq2Seq, where misalignment means Seq2Seq predicted correct surface tokens, but the aligned spans for the original text were incorrect.

wherein Seq2Seq generates (and possibly copies) sentiment tokens from the input text.

Although not surprising, Table 1 indicates that the ensemble models of Graph outperform the non-ensemble ones. The submitted ensemble models have comparable SF_1 to those of the best team on the test set of some corpora.

Subtask 2 In this subtask, we used `OpeNER` English for training and conducted zero-shot prediction for `OpeNER_es`, `MultiB_eu`, and `MultiB_ca`. Table 2 shows SF_1 of Subtask 2 (i.e., cross-lingual zero-shot). Overall, it seems that Graph is still a better choice than Seq2Seq. There is a significant difference in `MultiB_eu`, i.e., Seq2Seq (44.7) and Graph (51.6). This difference may be due to the pre-trained language models (i.e., InfoXLM vs. mT5) and the misalignment problem of Seq2Seq. On the other hand, Graph and Seq2Seq performed poorly compared with the top-performing team, so neither model seems suitable for the zero-shot setting.

3.3 Analysis and Discussion

This section compares Seq2Seq and Graph and points out that one is not superior to the other. Our argument is supported by an analysis of the alignment errors of Seq2Seq and the structural/semantic properties of the parsers. To simplify the discussion, we focus only on non-ensemble and monolingual models for the English corpora (i.e., `MPQA`, `DSu` and `OpeNER`).

3.3.1 Does Graph really outperform Seq2Seq?

Alignment error in Seq2Seq A major drawback of Seq2Seq is the alignment error caused by the aligner. That is, Seq2Seq can produce the correct surface tokens of the polar expression, source or target, but the aligner may align incorrect spans

Figure 2 shows the misalignment ratio (i.e., the ratio of predicted elements where the surface tokens generated by Seq2Seq are correct, but the spans generated by the aligner are incorrect). There is a certain amount of alignment error in `MPQA`, `DSu` and `OpeNER`. We can see that the ratio of `OpeNER` is larger than those of the others. We explain this in Table 3. In case #1, a polar expression *chic!* was correctly predicted, but the aligner did not include the exclamation mark. In #2, *minutes from numerous...* was correctly predicted, but the beginning word *minutes* was unfortunately not included in the span. We found that the large misalignment ratio of the source in `OpeNER` was caused by pronoun words, as illustrated in #3, where our system could not resolve which *I* (i.e., the former or the latter in the two *I* tokens) to align. Case #4 shows a similar phenomenon for the term *hate*.

If we had remedied some of the misalignments, Seq2Seq would have produced 41.8 SF_1 and 42.6 SF_1 on the test data of `DSu` and `MPQA`, respectively. These results are comparable or better than those of the Graph models shown in Table 1; thus, we can not simply conclude that Graph is better than Seq2Seq. Moreover, Seq2Seq might be the best choice for an evaluation metric that does not emphasize anchoring spans of the input sentence (which may be enough for practical purposes). On the other hand, it seems that Seq2Seq for `OpeNER` still has a significant performance gap against Graph, as shown in Table 1. We focus on this aspect below.

3.3.2 How do Graph and Seq2Seq differ from each other?

Here, we discuss the differences between Graph and Seq2Seq on the basis of structural and semantic complexity. We also discuss the limitations of the parsers.

Complexity of sentiment structure We suppose that the number of opinions in an input text can be used as a proxy metric showing the complexity of the sentiment structure. Figure 3 shows the relationship between the number of opinions in an input sentence and SF_1. Overall, the two parsers exhibit similar trends; that is, the more opinion numbers there are, the harder the prediction becomes. However, the performance of Graph seems to be less dependent on the number of opinions, while Seq2Seq generally exhibits a negative trend, especially for `OpeNER`. These results suggest that Graph is a good choice for handling complicated

#	Corpus	Text	Gold span (and its text)	Generated surface by Seq2Seq	Mis-aligned span (and its text)
1	`OpeNER`	hotel chic !	[6:12] (chic !)	chic!	[6:10] (chic)
2	`OpeNER`	It is minutes from numerous restaurants , bars , etc. and centrally located between the Prado and the Palace · · great for walking .	[6:53] (minutes from numerous restaurants, bars, etc.)	minutes from numerous restaurants, bars, etc.	[14:53] (from numerous restaurants , bars , etc.)
3	`OpeNER`	I was forced to stay in this area due to my business reason , but oterwise I would not suggest to come here to spend your holidys .	[75:76] (I)	I	[0:1] (I)
4	`MPQA`	" We do n't hate the sinner , " he says , " but we hate the sin . "	[51:55] (hate)	hate	[12:16] (hate)

Table 3: Case study of misalignments where Seq2Seq produced correct surface tokens but the reconstruction system aligned incorrect spans.

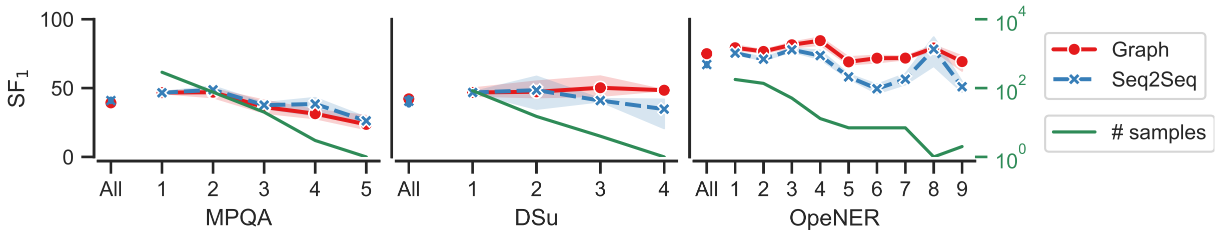

Figure 3: Relationship between the number of opinions included in a sentence (X-axis) and SF$_1$ (Y-axis). The green line shows the total number of samples in the evaluation set; it is evident that the larger the number of opinions is, the fewer the number of samples is. Note that *All* indicates the evaluation for full sentences, for reference.

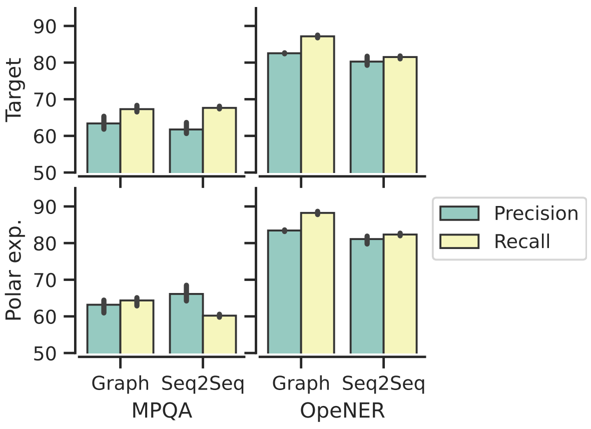

Figure 4: Precision and recall of Graph and Seq2Seq for target (top) and polar expression (bottom) outputs.

structures.

However, Graph has another disadvantage: over-detection. Figure 4 shows the precision and recall values for target and polar expression in `MPQA` and `OpeNER`. As shown, there is a possible trend that Graph is more recall-focused, and Seq2Seq is more precision-focused. In other words, Graph may over-detect opinion fragments for specific corpora. Case #1 in Table 4 shows an example of over-detection. The over-detected phrases are a *means* of "threatened" and may not be a target.

However, we find that, even for complex structures with multiple opinions, both Graph and Seq2Seq produce reasonable predictions. In case #1 in Table 4, the *means* of "threatened" is semantically a target; thus, this would be an acceptable case. Case #2 shows a long polar expression which does not appear in the gold standard, i.e., *let alone the 4 stars*, while the prediction seems to be correct in a sense. Through these observations, both Graph and Seq2Seq seem to try to output plausible outputs.

Semantic complexity Here, we begin by focusing on the difference between corpora (i.e., `MPQA` and `OpeNER`), because it is difficult to evaluate the semantic complexity directly. `MPQA` is annotated on the basis of the private state frame and distinguishes subjective information from material presented as fact (Wiebe et al., 2005). This makes `MPQA` semantically complex and context-dependent. On the other hand, `OpeNER` project originally focuses on lexicon creation (Agerri et al., 2013), making the corpus probably less context-dependent.

Again, let us investigate the precision and recall in Figure 4. A significant score gap between precision and recall in the figure can be found in

#	Corpus	Text	Method	Polarity	Polar exp.	Source	Target
1	MPQA	But after the Chinese side released all the US crew members , major US political figures changed their stance immediately and threatened to use human rights , trade , and Olympics hosting issues to " retaliate " against China .	Gold	Negative	threatened	major US political figures	China
			Graph	Negative	threatened	major US political figures	1. China, 2. trade , and Olympics hosting
			Seq2Seq	Negative	threatened	major US political figures	China
2	OpeNER	I would never ever come back to this hotel even if they paid me. simply it 's not worth the money , let alone the 4 stars .	Gold	Negative	would never ever come back	I	this hotel
				Negative	not worth		the money
			Graph	Negative	would never ever come back	I	this hotel
				Negative	not worth		the money
			Seq2Seq	Negative	never ever come back	I	this hotel
				Negative	not worth	I	the money
				Negative	let alone the 4 stars		it
3	MPQA	AOL would never have existed if it had been founded here , I am sure , since its employees would have been mocked into obscurity by the digerati .	Gold	Negative	mocked into obscurity	digerati	its employees
			Graph	Negative	mocked	the digerati	its employees
			Seq2Seq	⊥	⊥	⊥	⊥
4	MPQA	In the complaint , Hobeika had not yet been called by name .	Gold	Negative	the complaint		
			Graph	Negative	complaint		
			Seq2Seq	⊥	⊥		
5	DSu	I had a programming class with no lectures which is always fun for beginners to try to learn concepts without any sort of interactivity .	Gold	Negative	1.always, 2.fun for beginners	everyone	no lectures
			Graph	⊥	⊥	⊥	⊥
			Seq2Seq	⊥	⊥	⊥	⊥

Table 4: Case study of outputs by graph-based and seq2seq-based models. Magenta colored text indicates incorrect outputs. For visibility, we have omitted some of the outputs. ⊥ represents a false-negative prediction.

the polar expression of MPQA; i.e., for Seq2Seq, the polar expression's precision of MPQA is quite higher than its recall. Interestingly, the gap was not so large in the polar expression of OpeNER. We presume that this is due the semantic complexity (or context-dependent nature) of MPQA. That is, since Seq2Seq always refers to the context of the input side when generating an output, the output could be more context-dependent, and as a result, Seq2Seq may not output less-confident opinions.

Since it is difficult to test the hypothesis that Seq2Seq may not output less-confident opinions in a statistical manner, we present several case studies. Cases #3 and #4 in Table 4 show errors where Graph predicted correct or incorrect opinions but Seq2Seq did not. In #3, the term *mocked* is a negative word *as is*, and can be predicted only with a lexical perspective. However, the polar expression is located in a fictional speculation in insubstantial text, which may have confused Seq2Seq. In #4, Graph predicted *complaint* as a negative polar expression, since the complaint could be a negative lexicon *as is*, while Seq2Seq did not output any opinions. Considering the context in the entire article, it might be difficult to for Seq2Seq to determine if the complaint is an opinion. In this way, Seq2Seq might enable more context-aware predictions, but may not be suitable for structured sentiment analysis based on lexicons. Graph seems to be good at handling lexicons and context-independent phrases.

Limitation of both parsers Another semantically complex case illustrates an interesting error that neither Graph nor Seq2Seq could parse. Case #5 in Table 4 shows an irony expression that might illustrate a limitation of pre-trained models.

Which is superior? As discussed above, each model has its own advantages depending on the perspective. However, we cannot decide which is better, because the decision criteria rely on how we define the sentiment structure. MPQA defines structured sentiment on the basis of private state frames, while OpeNER focuses more on lexical

↓ Sec. per **step**		DSu	OpeNER	MPQA
		en	en	en
Graph	RoBERTa-large	**0.2**	**0.2**	**0.3**
Seq2Seq	T5-large	2.0	2.0	1.8

(Peng et al., 2021)	mBERT	31.9
PERIN NC (Samuel et al., 2022)	XLM-R-base	39.3
PERIN LE (Samuel et al., 2022)	XLM-R-base	40.4
PERIN OT (Samuel et al., 2022)	XLM-R-base	41.6
Graph (ours)	XLM-R-base	**44.8**

Table 6: Comparison with state-of-the-art methods for `NoReC` test data. Note that NC, LE, and OT mean the node-centric, labeled edge, and opinion-tuple variants of PERIN.

semantics. This would make a difference with syntactic parsing, which is based on a certain type of well-defined grammar, and would cause the parsing performance to be lower than that of syntactic parsers. To cover the variety of definitions of structured sentiment, an abstraction of the sentiment structure might be needed, as is done in abstract meaning representation (AMR; Banarescu et al. 2013).

3.3.3 Energy efficiency approximated by training time

Finally, we discuss the energy efficiency of Graph and Seq2Seq as an estimate of their financial and environmental impact (Strubell et al., 2019). We evaluated the approximated energy consumption in terms of the training time on NVIDIA V100 GPUs. Table 5 shows step-normalized and epoch-normalized training speed in seconds, given that a different batch size was used for Graph and Seq2Seq. As shown, Graph is usually faster than Seq2Seq on all English corpora. We suppose this is because Seq2Seq has a decoder part, which has a computational cost. The results suggest that Graph is preferable in terms of energy efficiency.

4 Related work and state-of-the-art

Sentiment analysis, such as aspect-based sentiment analysis (Chen and Qian, 2020), is a popular research area in natural language processing. Most recently, we have seen attention focusing on parsing full representations of sentiment from text, i.e., structured sentiment analysis (Barnes et al., 2021), as we have tackled in this study. Most methods (Barnes et al., 2021; Peng et al., 2021) for this task are motivated by graph-based parsers that can parse the structured sentiment using a technique similar to dependency parsing. On the other hand, the state-of-the-art graph-based parser, PERIN (Samuel et al., 2022), utilizes the idea of meaning representation parsing (Oepen et al., 2020; Samuel and Straka, 2020), which remedies the lossy dependency graphs of the previous work (Barnes et al., 2021). Our graph-based method (i.e., Graph) is one such study. The differences between Graph and the related literature are in the graph encoding method and model architecture.

To directly compare our Graph with the state-of-the-art methods, we trained Graph with XLM-RoBERTa-base (XLM-R; Conneau et al. (2020)). We tried three different seeds and averaged the scores. Because the corpora provided in the shared task were slightly modified from those used in the related studies, it is difficult to make a direct comparison. Thus, we evaluated only on the unaffected `NoReC`. Table 6 suggests that our Graph outperforms state-of-the-art baselines; however, we cannot conclude that our method is state-of-the-art based solely on an evaluation on `NoReC`. We hope that more extensive studies will clarify this situation.

On the other hand, an alternative to the traditional graph-based methods, we proposed a generation-based method (i.e., Seq2Seq) that showed promising results. Generation-based methods have been recently utilized in meaning representation parsing (Ozaki et al., 2020; Procopio et al., 2021); this framework offers more research options in terms of architecture and graph encodings for structured sentiment analysis. Our study can be positioned within this framework.

5 Conclusion

This paper showed two different parsers (i.e., graph-based and seq2seq-based parsers) for SemEval-2022 Task 10, structured sentiment analysis. The parsers were compared in various aspects such as complexity in structure and semantics. Experiments and analyses showed that both parsers output reasonable predictions, but that it is hard to decide which is better. This could be because the decision criteria rely on how the sentiment structure is defined. This makes structured sentiment analysis challenging. To deal with this difficulty, it may be helpful to apply an abstract representation of structured sentiment.

Acknowledgements

The computational resources of the AI Bridging Cloud Infrastructure (ABCI) provided by the National Institute of Advanced Industrial Science and Technology (AIST) were used. We would like to thank Dr. Masaaki Shimizu for maintenance and management of the large computational resources.

Abstract

This paper describes the system submitted by our team (UFRGSent) to SemEval-2022 Task 10: Structured Sentiment Analysis. We propose a multilingual approach that relies on a Question Answering model to find tuples consisting of holder, target, and opinion expression. The approach starts from general questions and uses the extracted tuple elements to find the remaining components. Finally, we employ an aspect sentiment classification model to classify the polarity of the entire tuple. Despite our method being in a mid-rank position in the SemEval competition, we show that the question-answering approach can achieve good coverage retrieving sentiment tuples, allowing room for improvements in the technique.

1 Introduction

Opinions abound on the Internet nowadays. They are a valuable source of information since people often rely on them for making purchases. Companies can also benefit from this vast amount of opinions, as they do not need to conduct opinion polls or focus groups to measure the acceptance of a particular product (Liu, 2011). The large volume of opinions available becomes hard for humans to process. This leads to the study of ways of automating the processing of opinions, in order to summarize them.

Sentiment Analysis is the field of study which aims at processing the information conveyed by unstructured texts, providing structured information that facilitates the understanding of the opinions, attitudes, or emotions towards a particular entity (Liu, 2011). Sentiment Analysis can be performed at different levels of granularity (entire review, sentence, or aspect). Aspect-Based Sentiment Analysis (ABSA) aims to identify and rate the features (or aspects) of the entity being evaluated. Typically, ABSA involves the following phases: (i) identify and extract entities in reviews; (ii) identify and extract the aspects of an entity; (iii) cluster similar aspects; and (iv) determine the polarity of the sentiment over the entities and the aspects. Most of the research in Sentiment Analysis focuses on solving only one of these phases at a time.

Task 10 in SemEval 2022 – Structured Sentiment Analysis (Barnes et al., 2022) proposes a new approach to tackle the Sentiment Analysis problem, where the elements that constitute an opinion are identified together, in a structured way through a graph. Thus, Structured Sentiment Analysis can be seen as an information extraction task since we want to find the text spans where opinions about a particular feature are expressed (Barnes et al., 2021).

In this paper, we describe UFRGSent, a multilingual approach that relies on a question answering system to find the elements of an opinion present in review texts and a fine-tuned model to classify the polarity of the sentiment tuple. Our average results ranked 20th out of 31 participating systems. Nevertheless, we believe there is room for improvement in our technique.

2 Background and Related Work

An opinion can be defined as a tuple $O = (h, t, e, p)$, where h represents the opinion holder (person who emits the opinion), t is the aspect target of the entity being reviewed, e is the opinion that is being expressed, and p is the sentiment related to the aspect expressed on the review (Liu, 2012).

While many works treat each opinion component separately, some approaches extract them all together, taking advantage of the components being interconnected. Graph neural networks (Barnes et al., 2021; Qian et al., 2021), transition-based neural models (Zhang et al., 2019), and multi-task learning (Chen and Qian, 2020) can be used to accomplish this task. There are also works applying co-extraction to find correlated opinion components, such as aspect words and corresponding polarities (Luo et al., 2019; He et al., 2019), aspect and opinion terms (Wu et al., 2020), or aspects, opinions, and polarities (Wang et al., 2017; Chen et al., 2021).

Question Answering is a challenging and well-studied problem in the Natural Language Processing field, gaining attention in the last years due to the use of pre-trained Language Models. One of the most popular subtasks of question answering is the Machine Reading Comprehension task. This task consists of, from a text piece (also known as context) and a question, finding the answer to the question in context (Zeng et al., 2020). Chen et al. (2021) proposed using a machine reading comprehension system to solve the problem of aspect sentiment triplet extraction. They use three-turn questions to extract aspects and opinions (in the first two turns) and sentiments (in the last turn), achieving state-of-the-art performance on standard Aspect-Based Sentiment Analysis (ABSA) datasets.

3 UFRGSent

3.1 Task Description

The Structured Sentiment Analysis task consists in identifying a sentiment graph from a review text r. Such graph can be seen as tuple $t = (h, t, e, p)$, composed by the the holder (h), the target (t), the opinion expression (e), and the sentiment polarity (p). Components h, t, and p are text spans over r, while $s \in \{\text{Positive}, \text{Negative}, \text{Neutral}\}$. A review r can contain none or multiple sentiment tuples.

3.2 Solution Overview

An overview of UFRGSent can be seen in Figure 1. A two-phase process was employed to identify sentiment tuples in a review text r. First, we use a pre-trained question answering model fine-tuned with opinionated texts in order to identify the spans in r that correspond to holder, targets, and opinion expressions. Next, we use another pre-trained aspect sentiment classification model fine-tuned on the training datasets, in order to predict the polarity of each extracted sentiment tuple.

The extraction of sentiment tuples from the review text was made using a question answering model. We iteratively submit three kinds of questions to the model, in order to extract candidates to sentiment tuples.

Tier 1 Questions: the following questions were the first questions posed to the model. As shown,

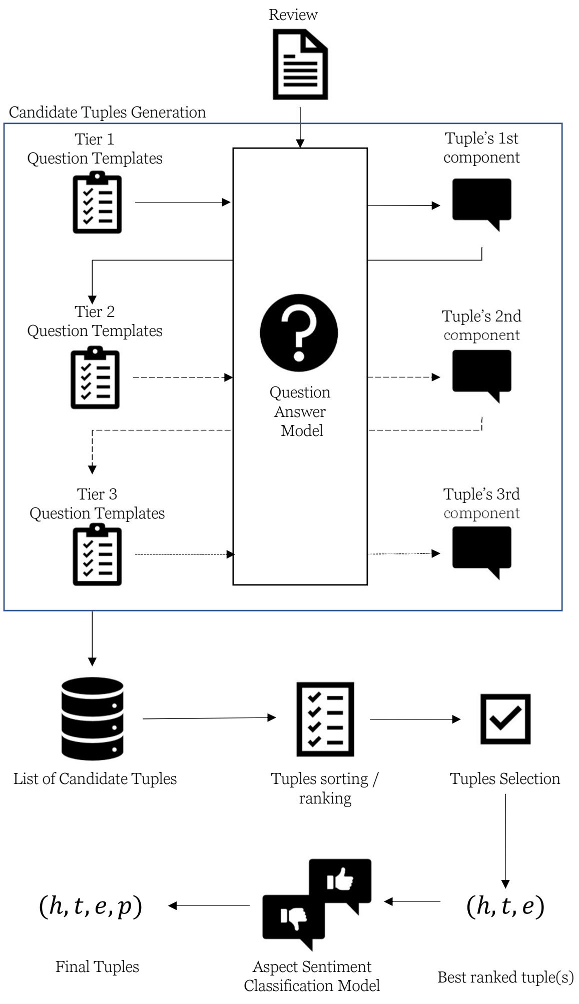

Figure 1: Overview of UFRGSent

each of the questions allows us to obtain one component of the sentiment tuple.

```
Who is the holder?
  Answer: (h, __, __)
What is the aspect expression?
  Answer: (__, t, __)
What is the opinion word?
  Answer: (__, __, e)
```

We extract the n most likely answers predicted by the model for each question. The model can also predict that the question has no answer on r. When this happens, we interpret it as the absence of sentiment in the sentence and produce the null tuple $(\_\_, \_\_, \_\_)$ as a candidate.

Tier 2 Questions: after the first extraction iteration, we obtain a list of candidate tuples containing just one component. This step aims to extract the second tuple component based on the existing one. These are the templates of questions used in this step, and the candidate tuples that were generated in this phase.

```
Who has an opinion about <target>?
  Answer: (h, t, __)
What is the feeling about <target>?
  Answer: (__, t, e)
What is <holder> opining about?
  Answer: (h, t, __)
What is the opinion expressed by
<holder>?
  Answer: (h, __, e)
What is <opinion> about?
  Answer: (__, t, e)
Who thinks <opinion>?
  Answer: (h, __, e)
```

We do not use the null tuple in this iteration. If the QA Model returns that a question has no answer in this phase, we create a tuple without the remaining components, which will not be used in the next phase.

Tier 3 Questions: finally, we use the candidate tuples obtained in the previous step, with two components of the tuple, to obtain the remaining expression. These are the templates of questions for this step.

```
How <holder> feels about <target>?
Who thinks <target> is <opinion>?
What <holder> expressed <opinion>
about?
```

There are two possible outcomes for this phase – a complete tuple (h, t, e) or a tuple with two components, for the cases in which the question produces no answer.

Candidate Ranking and Selection: At the end of the Tier 3 questions, UFRGSent produces a list of candidate tuples, containing all answers generated by the iterative procedure previously described. The next step is ranking these tuples according to some criteria. Finally, based on the final ranking, we select the top-k answers to find the subset of tuples that best represent the structured sentiment on that review. If the null tuple were selected as the best answer in this phase, we conclude that the review has no sentiment.

Aspect Sentiment Classification: After determining the first three components of the sentiment tuple, we use an aspect sentiment classification model. This model receives the review and the aspect-phrase as inputs and outputs the polarity of the aspect in the review.

4 Experimental Setup

4.1 Question Answering Model

We fine-tuned BERT multilingual (Devlin et al., 2019) for the Question Answering task using the training data provided. To convert the original data into a question-answer dataset, we employed the following technique: Each sentence becomes a context. For each sentence, we generate the questions following the templates presented in Section 3.2. If a sentence does not have any sentiment annotation, we only generate Tier-1 questions with the null answer. Otherwise, we generate the three tiers of questions for the sentences containing structured sentiment annotations. For the sentences whose tuples do not contain some component (*i.e.,* part of the sentiment graph is not in the sentence), we do not generate questions with the missing component. For example, we only include the question `Who has an opinion about <target>?` for the sentences that have the aspect annotations.

The QA model was fine-tuned for two epochs, using the script provided by HuggingFace Transformers (Wolf et al., 2020)[1]. We tested the final model over dev datasets provided in the task, obtaining an F-1 score of 74.68.

4.2 Aspect Sentiment Classification Model

For the polarity prediction task, we used LCF-BERT (Zeng et al., 2019), which is provided by PyABSA[2]. We used an existing trained model created over 14 datasets in two languages (English and Chinese) as our base model. The base model was fine-tuned for ten epochs on the training dataset. The tests over the dev datasets yielded an F1 score of 75.13% and an Accuracy of 88.54%. The model only accepts as input a review and an aspect. In the case of sentences which not contain the target component, we feed the model with the opinion expression. The holder information is not used in this task.

4.3 Ranking and Tuple Selection

Our team employed two simple heuristics to sort the candidate tuples and select the final tuples. To sort the candidate tuples, we ranked them according to the number of times that the tuple was generated by the question answering procedure. Since we make multiple questions, it is common for an answer to be generated many times.

Once the candidate tuples are sorted, we selected the most frequent answers as our final tuples. If the most frequent was the null answer, we assume

[1]https://github.com/huggingface/transformers/tree/main/examples/pytorch/question-answering

[2]https://github.com/yangheng95/PyABSA

the review has no sentiment. On the other hand, if our technique generated more than one answer, we prune the answer set by removing the occurrence of the null tuple and removing overlapping tuples, *i.e.,* the tuples that have conflicting spans over the review. For example, in the sentence "I love the food." the spans "food" and "the food" overlap. In that case, we only keep the first tuple that appears in the ranking.

4.4 Datasets

We evaluated UFRGSent using seven datasets, namely NoReC (Øvrelid et al., 2020) that contains professional reviews in Norwegian; MultiBooked_eu and MultiBooked_ca (Barnes et al., 2018) with hotel reviews in Basque and Catalan, respectively; OpeNER_en and OpeNER_es (Agerri et al., 2013) that contain hotel reviews in English and Spanish, respectively; MPQA (Wiebe et al., 2005) a dataset of news wires in English; and Darmstadt Service Reviews (Toprak et al., 2010) with English reviews from online universities. Table 1 shows statistics of the datasets.

Dataset	Lang	# sent	# h	# t	# e
NoReC	NO	11,437	1,128	8,923	11,115
MultiBooked_eu	EU	1,521	296	1,775	2,328
MultiBooked_ca	CA	1,678	235	2,336	2,756
OpeNER_es	ES	2,057	255	3,980	4,388
OpeNER_en	EN	2,494	413	3,850	4,150
MPQA	EN	10,048	2,279	2,452	2,814
Darmstadt_unis	EN	2,803	86	1,119	1,119

Table 1: Statistics of Datasets (obtained from `https://github.com/jerbarnes/semeval22_structured_sentiment`).

4.5 Evaluation Metric

The evaluation metric used to assess the quality of the participating systems was the Sentiment Graph F_1 (Barnes et al., 2021). This metric evaluates an entire tuple (h, t, e, p). A true positive is an exact match between the predicted and golden graphs, weighting the overlaps of the spans for each tuple component, averaged across the three spans. *Precision* is calculated by weighting the number of correctly predicted tokens divided by the total predicted tokens, while *Recall* is the ratio between the number of correctly predicted tokens and the number of golden tokens.

5 Results

Table 2 shows the official results of UFRGSent. We varied two parameters of our method during the runs – the types of questions used in the question-answering model to extract tuple candidates and the number of answers retrieved for each question. The run that achieved the best average result uses the target and opinion questions and one answer to generate the candidate tuples. The same result was obtained when we generated five or ten answers. This run produced the best result in four out of seven datasets – MultiBooked_ca, NoReC, OpeNER_es, and OpeNER_en.

Considering the Darmstadt_unis dataset, the best result was when we just considered the aspect questions and generated one answer. On the other hand, the best results for MPQA and MultiBooked_eu datasets were obtained using the three types of questions and one, five, or ten answers.

We noticed a significant loss in performance when generating three answers. We conclude that this happened because the first answer generated is the expected response most of the time. Producing additional answers tends to introduce noise in the candidate tuples. However, increasing the number of answers makes the correct answer be generated more times, yielding the right tuple choice.

In comparison with other participants, our average score was the 20^{th} result out of 31 participating systems. The dataset in which we achieved the best rank was MultiBooked_ca (15^{th}), while our worst results were Darmstadt_unis and MPQA datasets (20^{th} out of 31). Although our team did not submit results for the cross-lingual task, we emphasize that our solution is entirely multilingual – there is only one model, which extracted sentiment tuples for all datasets simultaneously. Therefore, our solution can be extended to any other language among the 104 languages present in multilingual BERT.

In order to assess the quality of our candidate tuple extraction, we measured the coverage of the question-answering results (*i.e.,* the percentage of gold tuples present in the set of candidate tuples). This measurement was done on the development dataset, for which we know beforehand the gold sentiment graphs. The results of the experiment can be seen in Table 3.

We set the hyper-parameter k to one, extracting only one answer per question. The evaluation was made in two ways – the exact match between gold tuple and candidates and the overlap, in which a pair of tuples containing an overlap between their tokens is considered a correct match. The experiment was repeated, varying the type of questions

Configuration		Dataset							Avg. Score

OpeNER_es	35.8%	72.8%	27.7%	50.4%	27.4%	57.8%	0.1%	26.0%

Table 3: Coverage of Extraction for Question-Answering System

used to extract the candidates. We first use the three types of questions together, and then we evaluate the coverage achieved by each type of question individually.

The results show that our question-answering technique provides good coverage of sentiment tuples. For darmstadt_unis and mpqa, we have an exact match with over 65% coverage. We also improved the measure on datasets with less coverage in the exact match experiments, considering tuple overlap. All datasets achieved at least 70% coverage in the overlap experiments.

Using only one component to extract candidate tuples reduces coverage for the question answering for all datasets. While the mpqa dataset was less affected by removing the components (loss of 2.9% in coverage using targets, 3.9% using opinion expressions, and 2.4% using holder questions). Other datasets had significant drops in coverage, especially when just holder questions were considered.

6 Conclusion

In this paper, we described our system submitted to SemEval-2022 Task 10. We designed a multilingual approach that relies on a QA system and an ASC model to find the Sentiment Graphs. The key idea is that the joint and incremental extraction of holder, target, and opinion helps to achieve a good coverage for UFRGSent.

In these preliminary experiments, we could not establish the quality of our tuple ranking and selection methods and we leave it for future work. Additionally, we are interested in understanding how well our multilingual model performs against a monolingual version of our technique, and how other state-of-the-art QA models can improve the extraction of sentiment tuples.

OPI at SemEval-2022 Task 10: Transformer-based Sequence Tagging with Relation Classification for Structured Sentiment Analysis

Rafał Poświata
National Information Processing Institute, 00-608 Warsaw, Poland
rposwiata@opi.org.pl

Abstract

This paper presents our solution for SemEval-2022 Task 10: Structured Sentiment Analysis. The solution consisted of two modules: the first for sequence tagging and the second for relation classification. In both modules we used transformer-based language models. In addition to utilizing language models specific to each of the five competition languages, we also adopted multilingual models. This approach allowed us to apply the solution to both monolingual and cross-lingual sub-tasks, where we obtained average Sentiment Graph F1 of 54.5% and 53.1%, respectively. The source code of the prepared solution is available at https://github.com/rafalposwiata/structured-sentiment-analysis.

1 Introduction

Structured Sentiment Analysis (SSA) can be formulated as an information extraction task in which one attempts to find all of the opinion tuples $O = O_i, ..., O_n$ in a text. Each opinion O_i is a tuple (h, t, e, p) where h is a **holder** who expresses a **polarity** p towards a **target** t through a **sentiment expression** e, implicitly defining pairwise relationships between elements of the same tuple (Barnes et al., 2021). An example of such tuples as a structure sentiment graph was shown in Figure 1. This problem is relatively new and there has been little work published on the subject to date. To stimulate interest in this issue among the NLP community the SemEval-2022 Task 10: Structured Sentiment Analysis (Barnes et al., 2022) competition was organized. The contest consisted of two sub-tasks: monolingual and cross-lingual. In the monolingual sub-task, the systems were trained and then tested on the datasets in the same languages. In the cross-lingual sub-task, systems had to be prepared for Catalan, Basque and Spanish datasets, while data in these languages could not be used for training. This setup is often known as zero-shot cross-lingual transfer (Hu et al., 2020).

In this paper we present our system for this competition. We mainly focused on the solution for the monolingual track, however, it has also been successfully applied to the cross-lingual. The rest of the paper is organized as follows. Section 2 briefly describes related work. Section 3 shows an overview of used datasets. Section 4 elaborates on our solution. Experiments showing the effectiveness of the created system performed on development and test sets are presented in Section 5. The next section briefly describes the mistakes and limitations of our system. Finally, Section 7 concludes this paper.

2 Related Work

Structured Sentiment Analysis can be broken down into five sub-tasks: a) expression (opinion) extraction, b) target (aspect) extraction, c) holder extraction, d) defining the relationship between these elements, and e) assigning polarity (Barnes et al., 2021).[2]

A few years ago, the main focus was on **Aspect-Based Sentiment Analysis (ABSA)**, which only concerned on targets extraction (task b) and classifying the polarity towards them (task e) (Pontiki et al., 2014, 2015, 2016). Sequence tagging solutions have proven to be effective in this issue (Li et al., 2019a). An extension of this problem was **End2End Aspect-Based Sentiment Analysis (E2E-ABSA)**, which adds the issue of expression extraction (task a). He et al. (2019) propose an interactive multi-task learning network (IMN) which is able to jointly learn multiple related tasks simultaneously, to resolve this problem. Chen and Qian (2020) also use multi-task learning, but with relation propagation mechanisms and create Relation-Aware Collaborative Learning (RACL) framework. Tagging-based solutions also work well in this case

[1]Picture based on figure from Barnes et al. 2021.

[2]Phrases in parentheses indicate alternative names used interchangeably in the sentiment analysis literature.

Table 1: Statistics of the datasets. Mixed tags means a situation where a given term in different opinions plays a different role, e.g. once it is a target and once it is a holder. Nested tags are when a term in one opinion is part of a term in another opinion. Opposite polarity expressions refers to the case where a sentence contains an expression that has a different sentiment depending on the opinion.

(Li et al., 2019b; Hu et al., 2019). The tasks listed above did not require resolving relationships between extracted tags.

The recently proposed, **Aspect Sentiment Triplet Extraction (ASTE)** fill this gap (Peng et al., 2020). The task is to extracting all aspects terms with their corresponding opinion terms and sentiment polarity (tasks a, b, d and e). Peng et al. (2020) propose two stage model. In the first stage, it extracts opinions and aspects along with sentiment using sequence tagging based on the unified BIO scheme. The second stage pairs up the predicted terms from the first stage to output triplets. ASTE is most similar to SSA, missing only the holder extraction.

For SSA, the subject of the competition, there are few solutions. Barnes et al. (2021) cast the structured sentiment problem as dependency graph parsing. Peng et al. (2021) extend this work and propose a sparse and fuzzy attention scorer with pooling layers which improves parser performance.

3 Datasets

Seven structured sentiment datasets in five languages were selected for the competition. The **MPQA** dataset (Wiebe et al., 2005) contains news documents from the world press in English. **DS$_{\text{Unis}}$** (Toprak et al., 2010) are English reviews of online universities and e-commerce. **OpeNER$_{\text{en}}$** and **OpeNER$_{\text{es}}$** (Agerri et al., 2013) consist of hotel reviews in English and Spanish, respectively. **MultiB$_{\text{eu}}$** and **MultiB$_{\text{ca}}$** (Barnes et al., 2018) are also hotel reviews, but in Basque and Catalan. The last dataset is **NoReC$_{\text{Fine}}$** (Øvrelid et al., 2020), a multi-domain dataset of professional reviews in Norwegian. The statistics of each dataset are sum-

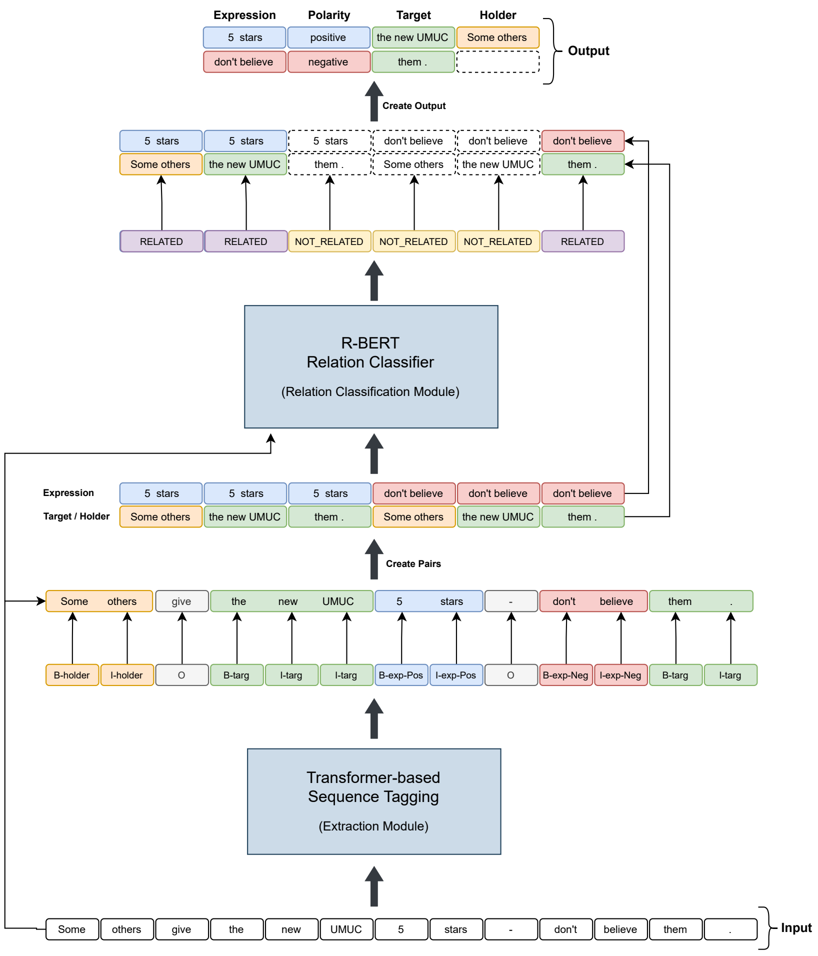

Figure 2: Architecture of the proposed solution.

marized in Table 1.

4 System Overview

The architecture of our solution is shown in Figure 2. This solution was inspired by the works of Li et al. (2019a,b); Hu et al. (2019), and especially the work of Peng et al. (2020). It consists of two main components: Extraction Module and Relation Classification Module. The first module is based on sequence tagging and is used to extract targets, holders and expressions with polarity. This is accomplished by using a suitable tagset which is a modification of the BIO scheme, consisting of the following tags: *{B-holder, B-targ, B-exp-Neg, B-exp-Neu, B-exp-Pos, I-holder, I-targ, I-exp-Neg, I-exp-Neu, I-exp-Pos, O}*. Transformer-based Language Model with a linear classification layer was used as an implementation. Having already extracted entities, the role of the second module is to classify whether there is a relationship between them. Specifically, it is about verifying that there is a holder and/or target associated with a particular expression. We utilized the R-BERT (Wu and He, 2019) model to accomplish this task. Based on a sentence with two appropriately marked entities (expression and holder/target), it determines whether or not they are related.[3] Entities that are related are combined and form an output. Extraction and Relation Classification modules are trained independently.

5 Experiments

5.1 Experimental Setup

To conduct the experiments, we first utilized the Simple Transformers library (Rajapakse, 2019) for the implementation of the Extraction Module. For the Relation Classification Module we modify publicly available source code of R-BERT.[4] The hyperparameters used in learning each of these modules are presented in Table 2. All models were run five times on a single GPU Tesla V100.

[3]For all the details, we would refer you to Wu and He 2019 paper.

Parameter	Extraction	Relation Classification
Optimizer	AdamW	AdamW
Learning rate	5e-5	2e-5
Batch size	32	16
Dropout	0.1	0.1
Epochs	10	12
Validation after no. steps	200	200

Table 2: Parameter used for Extraction and Relation Classification modules during training.

5.2 Pretrained Language Models

We chose two types of language models based on transformer architecture for experiments: monolingual (at least one for each of the five competition languages) and multilingual. The use of multilingual models allowed us to obtain a more general solution and was necessary for the cross-lingual sub-task. Table 3 gives a brief summary of the models used. All models were downloaded from the Hugging Face hub[5].

Language	Model	Size	Source
English	BERT	base	Devlin et al. 2019
	RoBERTa	large	Liu et al. 2019
	XLNet	large	Yang et al. 2019
Spanish	BERTIN	base	de la Rosa et al. 2021
	RoBERTa-BNE	large	Gutiérrez-Fandiño et al. 2021
Catalan	Catalan-BERTa	base	Armengol-Estapé et al. 2021
Basque	BERTeus	base	Agerri et al. 2020
Norwegian	NorBERT	base	Kutuzov et al. 2021
	NB-BERT	large	Kummervold et al. 2021
Multilingual	mBERT	base	Devlin et al. 2019
	XLM-R	large	Conneau et al. 2020

Table 3: Transformer-based language models used in experiments.

5.3 Metrics

Following the works on Named Entity Recognition problem (Akbik et al., 2018; Yamada et al., 2020; Zhou and Chen, 2021), we used micro-average F1 score as our main measure for the Extraction Module. In addition for this module we added a detailed measure for each tag type i.e. F1 score for holders, targets and expressions with sentiment classes, separately. For the Relation Classification Module, we used Accuracy and macro-average F1 measures. Evaluation of the overall system was based on the official competition metric i.e. Sentiment Graph F1.

[5]https://huggingface.co/models

5.4 Development Results

Table 4 shows the results on the development sets for each module. For the Extraction Module, the **XLM-R** model was the best on five of the seven datasets. In only two cases (**MPQA** and **$\mathbf{DS_{Unis}}$**) language-specific models were found to be superior: **XLNet** and **RoBERTa**, respectively. For the Relation Classification Module, we only used models based on the BERT architecture, following the original R-BERT work (Wu and He, 2019). The **mBERT** usually proved to be the best (5/7 cases), except for two cases (**$\mathbf{MultiB_{eu}}$** and **$\mathbf{NoReC_{Fine}}$**) where **BERTeus** and **NB-BERT** were the best. The best models for each module were used to test the overall system. A summary of this experiment can be found in Table 5. The average Sentiment Graph F1 was 55.0%.

5.5 Test Results

The best models verified on the development sets were used on the test sets which are the official competition sets. For the monolingual sub-task, we used exactly the same configuration of models as in Table 5. For the cross-lingual sub-task, we used models trained on the **$\mathbf{OpeNER_{en}}$** set, namely **XLM-R** for extraction and **mBERT** for relation classification. There were two reasons for this choice. First is the use of multilingual models in both modules. Second, from the fact that the results on the development sets were high compared to the results for other models trained on English language sets. The results are summarized in Table 6. We achieved average SF1 scores of 54.5% and 53.1% for the monolingual and cross-lingual sub-tasks, respectively. This allowed us to rank 11th and 9th out of the 32 teams in these sub-tasks.

6 Errors Analysis

As a result of the used architecture, most errors are due to incorrect tagging. In particular, this is relevant to expressions where a correct sentiment is additionally required. The results were significantly worse for expressions limited in a given set, e.g., neutrals in the MPQA or DS_{Unis} sets. Furthermore, by using a single extraction model, the solution is not able to correctly handle more complicated cases such as mixed or nested tags or opposite polarity expressions. This is most noticeable in the **$\mathbf{NoReC_{Fine}}$** dataset.

		Extraction						Relation Classification	
Dataset	**Model**	**Holder F1**	**Target F1**	**Exp. F1**			**F1**	**Acc**	**F1**

7 Conclusion

In this paper, we presented a solution to the SemEval-2022 Task 10: Structured Sentiment Analysis. A simple architecture based on sequence tagging and relation classification achieved good results. The use of multilingual language models enabled the solution to be used for monolingual and cross-lingual sub-tasks. At the same time it can be easily extended e.g. by using an additional CRF layer (Souza et al., 2019) in the Extraction

Module or by using other multilingual language models e.g. InfoXLM (Chi et al., 2021).

ETMS@IITKGP at SemEval-2022 Task 10: Structured Sentiment Analysis Using A Generative Approach

R Raghav* and **Adarsh Vemali*** and **Rajdeep Mukherjee**
Indian Institute of Technology Kharagpur, India
{rraghav5600, adarsh.vemali, rajdeep1989}@iitkgp.ac.in

Abstract

Structured Sentiment Analysis (SSA) deals with extracting opinion tuples in a text, where each tuple (h, e, t, p) consists of h, the holder, who expresses a sentiment polarity p towards a target t through a sentiment expression e. While prior works explore graph-based or sequence labeling-based approaches for the task, we in this paper present a novel unified generative method to solve SSA, a SemEval-2022 shared task. We leverage a BART-based encoder-decoder architecture and suitably modify it to generate, given a sentence, a sequence of opinion tuples. Each generated tuple consists of seven integers respectively representing the indices corresponding to the start and end positions of the holder, target, and expression spans, followed by the sentiment polarity class associated between the target and the sentiment expression. We perform rigorous experiments for both Monolingual and Cross-lingual subtasks, and achieve competitive Sentiment F1 scores on the leaderboard in both settings.

1 Introduction

Structured Sentiment Analysis (SSA) is the task of extracting structured information around sentiment expressions present in text in the form of opinion tuples $O = \{O_1, O_2, ..., O_n\}$, where each opinion tuple $O_i = (h, t, e, p)$ consists of h, the *holder* (or *source*, used interchangeably) who expresses a sentiment polarity p towards a *target* (or *aspect*) t using an opinion or sentiment expression e (Barnes et al., 2021a). Prior works (Liu, 2012; Peng et al., 2020) have highlighted the importance of addressing sentiment analysis as a structured prediction problem in order to capture the complete information around various opinions expressed in the text. The task of SSA thus expects to exploit the pairwise interactions between the members of the same opinion tuple during the extraction process.

*Equal contribution

With the exponential growth of online marketplaces and user-generated content therein, SSA or near similar tasks of aspect-sentiment-opinion triplet extraction (Peng et al., 2020; Mukherjee et al., 2021a; Yan et al., 2021), and aspect-category-sentiment-opinion quad extraction (Cai et al., 2021), the newest additions under the broader umbrella of aspect-based sentiment analysis (ABSA) (Pontiki et al., 2014a,b) have become more important than ever (Mukherjee et al., 2021b). In the face of ever-expanding choices, it becomes a challenging necessity to take educated explainable decisions from past user reviews. SSA guides the learning in the proper direction by facilitating an automated way to focus on major sentiment or opinion indicators. As a result, the task has wide applications in various market segments, such as e-commerce, food delivery, healthcare, ride sharing, travel and hospitality, to name a few.

Previous efforts on SSA have primarily focused on two approaches: sequence labeling-based (He et al., 2019), and graph-based (Barnes et al., 2021b). The former tries to first predict the presence/absence of targets and expressions in the text by sequentially labeling each text token using BIOES[1] tags, before modeling their interaction to predict the sentiment polarity. The latter models the task as a dependency graph parsing problem, where the sentiment expression is considered as the root node, and the other elements are connected via arcs that represent their relationships. Different from these, we present a novel generative approach to solve SSA. More specifically, we take motivation from a unified generative framework recently proposed by Yan et al. (2021) to solve several ABSA tasks. We suitable modify their BART-based encoder-decoder architecture to adapt it for SSA. Given a sentence, the model is

[1]BIOES is a tagging scheme commonly used for sequence labeling tasks. B, I, E, O, and S respectively denote the *begin, inside, outside, end*, and *single* tags corresponding to an entity.

Dataset Name	Language	% Null (Train, Dev)	Size (Train, Dev, Test)

Figure 1: Annotation Format. The value of "opinions" in the JSON is a list of opinion tuples present in the "text". Each item in the list is a dictionary, with keys being the tuple elements, and the values corresponding to their representation in the text. *Source, Target* and *Polar_expression* are annotated with the the actual word spans appearing in the text along and their respective character indices. *Polarity* represents the sentiment expressed in the tuple, and *Intensity* represents its strength.

trained to generate a sequence of tuples, each consisting of seven integer outputs corresponding to the start and end indices of the holder, target and sentiment expression spans appearing in the text, and finally the polarity class. An example is shown and described in Figure 2.

We participate in the SemEval 2022 Task 10: Structured Sentiment Analysis (Barnes et al., 2022) hosted on CodaLab. In order to demonstrate the efficacy of our proposed solution, we attempt both the *monolingual* and *cross-lingual* subtasks and achieve competitive performance on the leaderboard in both settings. As part of the (sub)tasks, we testify our approach on multiple datasets spanning across five different languages - *English* (Darmstadt_unis, OpeNER_en, MPQA), Basque (MultiBooked_eu), *Catalan* (MultiBooked_ca), *Norwegian* (NoReC_fine) and *Spanish* (OpeNER_es). A summary of dataset statistics is reported in Table 1. While the evaluation scripts were made available to us by the task organizers to analyze our performance, the final leaderboard scores were obtained on a hidden test set.

2 Task Overview

2.1 Task Definition

SSA aims to predict all the structured sentiment graphs present in a given text. A graph is formally represented by opinion tuples $O = O_1, O_2, ..., O_n$, where each opinion tuple O_i consists of a quadruple of the holder h, the target t, the sentiment expression e, and the sentiment polarity p.

2.2 Datasets

As summarized in Table 1, we are provided with a total of 7 datasets, as part of the shared task, spanning across 5 different languages. Each dataset is a collection of sentences, along with their corresponding annotated opinion tuples, each consisting of (*Source, Target, Polar Expression*, and *Polarity*).

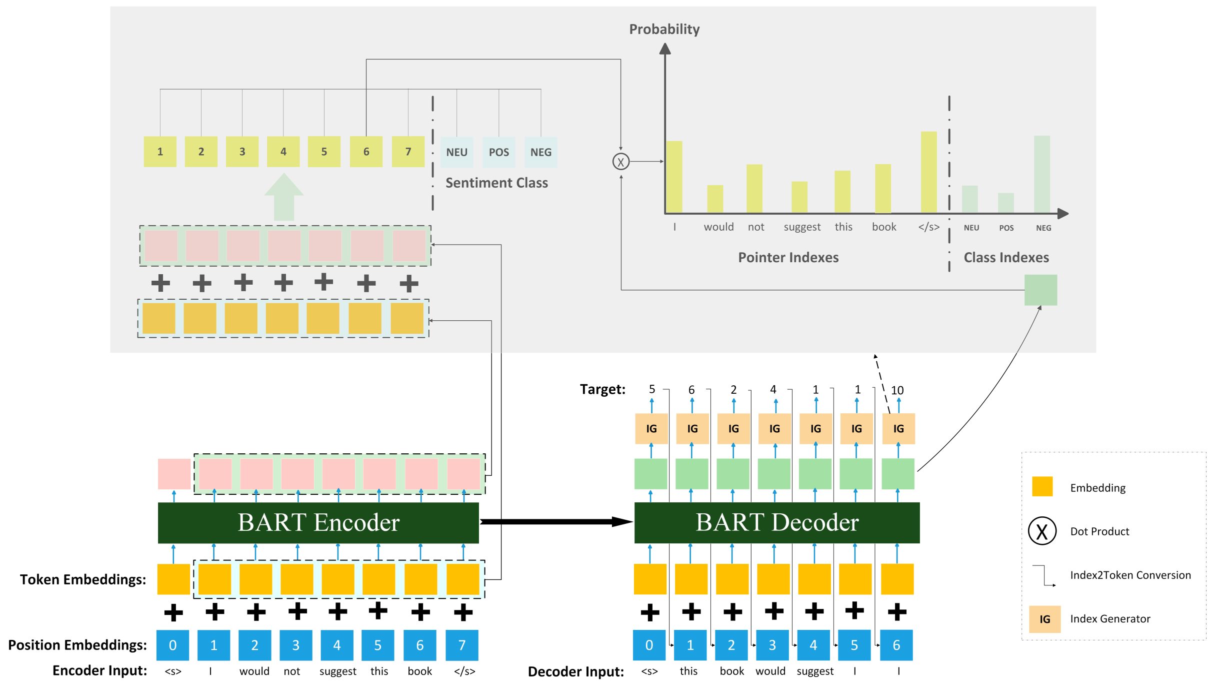

Figure 2: Model Architecture. The above figure shows an example where the input is "<s> I would not suggest this book </s>", and the corresponding output is "5, 6, 2, 4, 1, 1, 10" (Only partial decoder sequence is shown. Here, 7 (</s>) should be the next generation index). The "Index2Token Conversion" module converts the pointer indices back to the corresponding tokens in the source text, and the class index to the corresponding sentiment polarity.

While the *Intensity* of the expressed sentiment is also provided as part of the annotations, intensity classification/regression is not included as part of the task. An example is shown in Figure 1. All the data is provided through CodaLab, and GitHub.

3 Methodology

3.1 Task Formulation

We take a generative approach to formulate SSA as a structured prediction problem. We note here that predicting the holder (source), target (aspect), and polar expression spans correspond to extraction tasks, whereas sentiment polarity prediction is a classification task. Following (Yan et al., 2021), we model both these tasks in a unified generative framework by representing span entities with their start and end pointer indices corresponding to the text, and sentiment polarity with a class index.

We denote the holder, target, polar expression and sentiment polarity as *h*, *t*, *pe*, and *sp* respectively. The start and end index of each term is represented using superscripts ^{s} and ^{e}. For an input $X = [x_1, ..., x_n]$, where x_i is the i^{th} word in the text, the target $Y = [t_i^s, t_i^e, pe_i^s, pe_i^e, h_i^s, h_i^e, sp_i, ...]$ is defined as a sequence of tuples, each consisting of seven indices corresponding to an opinion tuple (h, t, pe, sp). An example sentence along with its target sequence are shown in Figure 2.

3.2 System Overview

Our model, as shown in Figure 2, consists of an encoder-decoder architecture with BART (Lewis et al., 2019) as its backbone. Given an input $X = [x_1, ..., x_n]$, the model is trained to produce an output $Y = [y_1, ..., y_m]$ (with y_0 representing the start-of-sequence token, $< s >$). The probability distribution is modeled as:

$$P(Y|X) = \prod_{t=1}^{m} P_t \quad (1)$$

Here $P_t = P(y_t|X, Y_{<t})$ represents the index probability distribution for the t^{th} time step.

3.2.1 Encoder

BART comprises of a bi-directional encoder. We denote the encoded vector of the input sentence X as H^e. For the sake of simplicity, we ignore the start-of-sequence token ($< s >$) in the equations.

$$H^e = BARTEncoder([x_1, ..., x_n]) \quad (2)$$

Here $H^e \in R^{n \times d}$, with d as the hidden dimension.

Dataset	% Null Instances
NoReC_fine	47.24% (As in the dataset)
MultiBooked_eu	10%
MultiBooked_ca	14.65 % (As in the dataset)
OpeNER_es	4%
OpeNER_en	14%
MPQA	50%
Darmstadt_unis	69.77 % (As in the dataset)

Table 2: % null instances in processed train sets.

3.2.2 Index2Token Conversion

Since the entity spans are decoded as corresponding start and end indices, and the sentiment polarity is decoded as corresponding class index, the indices need to be converted back to tokens before the BART Decoder can use them along with the encoder hidden state H^e for generating the next token (index) in the t^{th} time step. For each $y_t \in Y_{<t}$, we therefore use the following conversion strategy:

$$\hat{y}_t = \begin{cases} X_{y_t} & \text{if } y_t \text{ is a pointer index,} \\ Pol_{y_t - n} & \text{if } y_t \text{ is a class index} \end{cases} \quad (3)$$

where $Pol = [p_1, p_2, p_3]$ is the list of polarity classes. In our implementation, $y_t \in [1, n+3]$. The first sentence token x_1 has the pointer index 1.

3.2.3 Decoder

Our BART decoder now uses H^e and the converted decoder outputs $\hat{Y}_{<t}$ to obtain the t^{th} decoder hidden state:

$$H_t^d = BARTDecoder(H^e, \hat{Y}_{<t}) \quad (4)$$

where $H_t^d \in R^d$. Finally, H_t^d is used to predict the token probability distribution P_t. We request our readers to refer to (Yan et al., 2021) for additional details.

3.2.4 Training and Workflow

Teacher forcing with negative log likelihood as the loss function is used to train the model. During inference, beam search is used to generate the target sequence Y in an auto-regressive manner. Finally, the generated sequence is translated back into the phrase spans and sentiment polarity. As shown in Figure 2, we now illustrate the working of our proposed method using an example sentence:
I would not suggest this book .

1. The input <s> I would not suggest this book </s> is sent as input to the BART Encoder. As specified in Section 3.2.2, the word "I" is mapped to position index 1. Accordingly, </s> is mapped to index 7. Thereafter, each sentiment polarity is assigned a class index in sequence. In this case, the polarity values neutral, positive, and negative, are assigned class indices 8, 9 and 10 respectively.

2. The BART Decoder is trained to generate a sequence of indices till the end-of-sequence index (here 7) is generated. Corresponding to each opinion tuple, the decoder respectively predicts the start and end word indices for the target, polar expression, and source and finally, the polarity class index.

3. In our case, the expected target sequence is 5, 6, 2, 4, 1, 1, 10, 7. Here, (5, 6) represents the *target* phrase "this book", (2, 4) represents the *polarity expression* phrase "would not suggest", (1, 1) represents the *holder* phrase "I", and 10 represents the *negative* polarity class.

4. During inference, a decoding algorithm is employed making use of the *Index2Token Conversion* module to respectively convert the indices back to the text tokens and polarities before presenting to the end user.

4 Experiments

4.1 Data Preprocessing

In addition to fully annotated sentences, we observe the following two kinds of instances in all the datasets: (a) no opinion tuples at all - hereby referred to as the null examples, and (b) few empty entities in a single opinion tuple. We note here that our tuple representation scheme expects position indices of words appearing in the sentence. In order to accommodate for the above mentioned cases, we add a string *None* in the beginning of every sentence. This helps us to map the missing entities (e.g. holder or aspect in an opinion tuple) to a phrase present in the sentence.

After rigorous experiments, we set an optimal threshold for the proportion of null examples to be used for training in each of the datasets as reported in Table 2. During training, we found that limiting the proportion of null examples to the reported values significantly helped us in achieving the best performance on the respective datasets across monolingual and cross-lingual settings.

Dataset	% null	Batch Size	LR	F1 Score	Best Epoch

Table 4: Null Parameter Tuning for each dataset

4.2 Experimental Setup

For the *monolingual* setting, we used the train, validation, and test splits of the same datasets. While experimenting on the *English* datasets (Darmstadt_unis, MPQA, and OpeNER_en), we use BART-base[2] as the backbone. For the *Non-English* datasets (OpeNER_es, Multibooked_eu, Multibooked_ca, and NoReC_fine), we use BART-large-MNLI [3] as the backbone. In the *cross-lingual* setting, we trained our models using the combined training data from all *English* datasets and evaluated them on the test sets of respective *Non-English* datasets (NoReC_fine not included as part of this setting). Here, we used BART-large-MNLI as the backbone for all our cross-lingual experiments.

Although predicting the intensities of sentiment polarities was not included as part of the shared task, we hypothesized that additionally learning the intensity prediction task would help the model in predicting the other entities (h, t, e, p) better in a multi-task setting. We performed additional experiments to verify our hypothesis. However, we observed little to no difference in the final results. Accordingly, we excluded intensity prediction from further consideration while performing our final experiments. We make our code repository publicly available at https://github.com/Sherlock-Jerry/SSA-SemEval.

4.3 Hyperparameter Tuning

We train all our models on Tesla P100-PCIE 16GB GPU. We perform extensive tuning experiments to

Table 6: Monolingual SubTask: Test Set SG-F1 Scores.

obtain the optimal set of hyperparameters. To determine the optimal learning rate, we ran monolingual experiments on two English and Non-English datasets respectively, as elucidated in Table 3. Based on our observations, we fixed a common learning rate of $5e-5$ for our final experiments across both the settings, monolingual as well as cross-lingual. For obtaining the optimal proportion of null instances to be used for training the final models, we perform three iterations of monolingual experiments on each dataset, each time with a different proportion of null instances used for training the models, as reported in Table 4. The final null thresholds are reported in Table 2. Table 5 summarizes the set of hyperparameters used for reporting our final results for both the subtasks. For all our experiments, the model selected according to the best F1 score on the validation data was used to evaluate on the test data.

4.4 Evaluation Metrics

Sentiment Graph F1 (SG-F1) is used to evaluate the models. *True Positive* is defined as an exact match (including polarity) at graph-level, weighted by the token-level overlap between the gold and predicted spans for holder, target, and polar expression, averaged across all three spans. *Precision* is calculated by weighting the number of correctly predicted tokens divided by the total number of predicted tokens. *Recall* is calculated by dividing the number of correctly predicted tokens by the number of gold tokens, thereby allowing for empty holders and targets which exist in the gold standard.

5 Results

5.1 Monolingual Subtask

We report the results for our monolingual experiments in Table 6 and compare them with the existing state-of-the-art (SOTA) results reported in Barnes et al. (2021b). Amongst the given datasets, our model performs the best on OpeNER_en and OpeNER_es, and has a relatively poor performance on MPQA, Darmstadt_unis and NoReC_fine. Despite this, we comfortably outperform the existing SOTA on these datasets. On the public leaderboard hosted on CodaLab, we achieved 18th rank out of 32 entries for this task.

5.2 Crosslingual Subtask

We report the results for our crosslingual experiments in Table 7. In this paradigm, we used all the English datasets for training our model, and tested our best trained models on the test sets of the respective Non-English datasets.

Dataset	SG-F1
EN-EU (MultiBooked_eu)	0.431
EN-CA (MultiBooked_ca)	0.506
EN-ES (OpeNER_es)	0.542

Table 7: Corsslingual SubTask: Test Set SG-F1 Scores.

Here, we achieved 11th rank out of 32 entries.

5.3 Qualitative Analysis

- In the monolingual subtask, we observed that our model performs poorly on the datasets with large proportions of empty opinion tuples (null instances). As can be confirmed from Table 2, MPQA, Darmstadt_unis, and NoRec_fine have high empty tuple proportion as against OpeNER_en, and OpeNER_es with low proportion of null instances.

- We observed that for datasets having lengthy sentences, our model performs relatively poor. A comparison between the distribution of test sentence lengths and the Sentiment Graph F1 scores for each dataset is shown in Figure 3.

- We also observed annotation errors in the datasets. For instance, given the test sentence

Label Type	Source	Target	Polar Expression	Polarity
Gold	-	The size of room	reasonable	Positive
Prediction	-	The size	reasonable	Positive
Gold	-	walls	in very poor conditions	Negative
Prediction	-	walls	very poor	Negative
Gold	-	floor	in very poor conditions	Negative
Prediction	-	floor	in very poor conditions	Negative
Gold	-	ceiling	in very poor conditions	Negative
Prediction	-	ceiling	in very poor conditions	Negative

Table 8: Ground truth opinion tuples and model predictions for the sentence: "The size of room is reasonable , but floor , walls and ceiling are in very poor conditions".

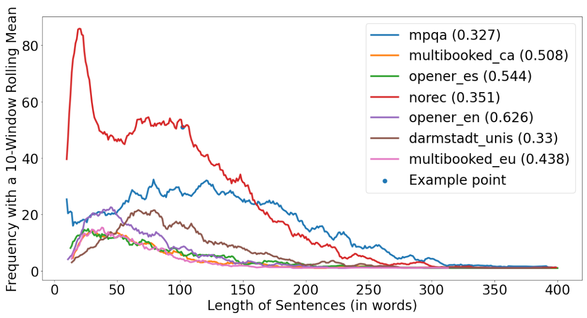

Figure 3: Comparing the distribution of test sentence lengths with best-obtained SG-F1 scores for each dataset. The "Example point" shows that there 51 sentences in the test set for NoRec_fine with length 100.

"So wonderful to see people go to work smiling and leave work still smiling and happy.", our trained generative model correctly predicts an opinion tuple with "see people go to work" as the target, and "So wonderful" as the opinion expression with a "Positive" sentiment. However, no ground truth opinion tuples are associated with the sentence.

- As reported in Table 8, we found a few instances where our model correctly predicts the necessary entities; but due to ambiguity in labelling (even at human level), we saw a mismatch. Here, our model predicts "The size" as the *target* whereas the gold standard expects "The size of room". Similar is the case with "in very poor conditions" (gold standard) versus the predicted phrase "very poor".

6 Related Work

Previous efforts on SSA have primarily focused on two approaches: sequence labeling-based (He et al., 2019), and graph-based (Barnes et al., 2021b). The corresponding scores for both these approaches are considered as baselines by the task organizers.

6.1 Sequence Labelling

In this approach, (He et al., 2019) propose a pipeline of sequence labelling and relation classification tasks. More specifically, three different sequence labellers based on BIOES tags are trained to predict the three span-based opinion entities, i.e. the holder, the target, and the polar expression. Finally, their relationship is exploited using a separate classification layer on top to predict the connecting sentiment polarity. However, such an approach inherently suffers from error propagation between the steps. Also, the inter-dependency especially between the target and the polar expression is not captured when the spans are predicted in isolation.

6.2 Dependency Graph Parsing

(Barnes et al., 2021b) have treated this task as a bilexical dependency graph prediction problem. They present two different versions of their proposed approach - (a) head-first and (b) head-final, as shown in Figure 4.

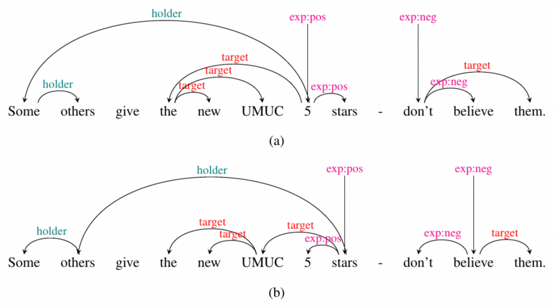

Figure 4: Dependency Graph Parsing

In both cases, the sentiment expression is considered as the root node, and the other elements are connected via arcs that represent their relationships. This approach builds upon the Dozat and Manning parser, implemented in (Kurtz et al., 2020).

7 Conclusion

Different from prior methods, we in this work present a novel generative approach to tackle the task of Structured Sentiment Analysis. We formulate the task as a structured prediction problem. Our BART-based encoder-decoder architecture is trained to predict a sequence of indices corresponding to each opinion tuple present in the text. The generated indices suitably represent the holder, target, and polar expression spans by their start and end token positions, and the sentiment polarity by its corresponding class. As part of SemEval 2022 Task 10, we participate in both monolingual and crosslingual subtasks, and achieve competitive performance on the leaderboard for both settings. In future, we would like to explore paraphrasing-based generative methods for the task.

SLPL-Sentiment at SemEval-2022 Task 10: Making Use of Pre-Trained Model's Attention Values in Structured Sentiment Analysis

Sadrodin Barikbin
Speech and Language Processing Lab
Sharif University of Technology

barikbin@ce.sharif.edu

Abstract

Sentiment analysis is a useful problem which could serve a variety of fields from business intelligence to social studies and even health studies. Using SemEval 2022 Task 10 formulation of this problem and taking sequence labelling as our approach, we propose a model which learns the task by finetuning a pretrained transformer, introducing as few parameters (150k) as possible and making use of precomputed attention values in the transformer. Our model improves shared task baselines on all task datasets.

1 Introduction

Sentiment analysis has many applications in different fields. From social and political studies (Rodríguez-Ibáñez et al., 2021) to business intelligence and even health studies (Alamoodi et al., 2021). SemEval 2022 Task 10 (Barnes et al., 2022) formulates this problem as to extract a graph of sentiment-related entities and names that, **Structured Sentiment Analysis**. An example of such graph is depicted in figure2 Specifically given an input sentence, one should extract a list of quadruples. Each quadruple consists of a sentiment expression, a target expression, a holder expression and the polarity. SemEval 2022 Task 10 has two subtasks, monolingual and cross-lingual. We participated in the first track. Shared task data is consisted of seven datasets in English, Spanish, Norwegian, Catalan and Basque. We trained and evaluated our model on each of these datasets.[1]

2 Related Work

Structured sentiment analysis aims to extract sentiment, target and holder expressions along with their relations and also sentiment polarities. (Barnes et al., 2021) solves this problem by taking dependency graph parsing approach. It uses BiLSTM and multilingual BERT (Devlin et al., 2019) to encode input sentence and a neural dependency parser to jointly predict expressions and relations. Every sentiment, target or holder expression in the sentence would become a star-shaped subtree in the output graph, with last token of expression as its root and its edges labelled with type of entity. Relation between a sentiment expression and a target or holder expression is also represented with an edge from the former's root to that of the latter. This work evaluates its model on five datasets in four languages namely, NoReC$_{\text{Fine}}$ (Øvrelid et al., 2020), Multibooked$_{\text{EU}}$, Multibooked$_{\text{CA}}$ (Barnes et al., 2018), MPQA (Wiebe et al., 2005) and Darmstadt$_{\text{Unis}}$ (Toprak et al., 2010). Its main evaluation metrics are Targeted F1 and Sentiment Graph F1. First one measures exact prediction of target expression and polarity, and the second one measures exact match at graph level, weighting overlap between gold and predicted entities, averaged across three entity types.

A less comprehensive formulation of sentiment analysis is **End2End** sentiment analysis which aims to predict target and sentiment expression along with polarity but does not consider relation between expressions. (He et al., 2019) uses this formulation. Taking sequence labelling as its approach, it predicts target expression together with sentiment expression by one module and polarity by another one. Both modules along with a feature extraction module make use of a CNN to make their specific and shared latent vectors respectively. Furthermore, polarity prediction module has a self-attention layer which gets predicted probability of tokens' being in sentiment expression from the other module and incorporates it in computing attention values so as to tokens with higher proba-

[1] Our code is available at https://github.com/sadra-barikbin/novel-solutions-for-sentiment-analysis

bility get more attention. Beside its main task, this work employs two auxiliary document-level tasks to enjoy the benefits of multi-task learning. This work also uses a mechanism called message passing in which, predicted probabilities of all modules is iteratively fed back into model to make the model like a RNN. For data, they use review datasets from (Pontiki et al., 2014) and (Pontiki et al., 2015) which are annotated with sentiment expressions by (Wang et al., 2016, 2017). Among their evaluation metrics, F1-I is equivalent with Targeted-F1 of (Barnes et al., 2021).

(Chen and Qian, 2020), similarly attempts to solve end2end sentiment analysis and takes sequence labelling approach. It introduces a layer called RACL which consists of three separate but interconnected modules for sentiment and target extraction and polarity prediction. Each module makes a module-specific representation of input using a CNN and information is exchanged among them through attention mechanism. The work uses a stack of RACL layers as its model in which features in a layer is fed to upper layer and finally prediction is done by average pooling over prediction of all layers. This work has used same data and evaluation metrics as (He et al., 2019).

Finally (Li et al., 2019) solves **targeted sentiment analysis** which aims to extract only target expression and polarity. To this end, it has used BERT (Devlin et al., 2019) along with a task specific layer. Here BERT makes a contextual and rich representation of input words and the task-specific layer performs sequence labelling. For this layer, different types such as fully connected, CRF (Lafferty et al., 2001), GRU and self-attention layer are examined that the last two outperformed the others.

3 Datasets and Evaluation

Shared task is on seven datasets in five languages. We trained and evaluated our model on each one separately. General and detailed information of datasets is shown in table1 and table2 respectively. **NoReC**$_{\text{Fine}}$ is norwegian professional reviews in multiple domains. **MultiB**$_{\text{CA}}$, **MultiB**$_{\text{EU}}$, **Opener**$_{\text{EN}}$ and **Opener**$_{\text{ES}}$ (Agerri et al., 2013) are hotel reviews in Catalan, Basque, English and Spanish respectively. **Darmstadt**$_{\text{Unis}}$ consists of English online university reviews and finally **MPQA** contains annotated news articles in English. Evaluation metric of the task is ***Sentiment Graph F1***. Prediction and gold answer of problem are a list of quadroples $q = (q_s, q_t, q_h, q_{pol})$ in which the first three entities are sets of tokens for sentiment, target, and holder expressions respectively. q_pol is polarity with value among $Negative, Neutral, Positive$. Match score of two given source and target quadroples namely, $score(src, tgt)$ is as follows.

$$\frac{\sum_{e\in\{s,t,h\}} \frac{|src_e \cap tgt_e|}{|src_e|}}{3} * 1\{src_{pol} = tgt_{pol}\} \quad (1)$$

As it can be seen, this is a weighted match over amount of overlap between entities, averaged across three entity types. Polarities should be strictly equal. Denominator $|src_e|$ is for score to be comparable with another one having different source quadrople. As target and holder expressions could be empty, $|src_e|$ is replaced with 1 in the case src_e is empty. $|src_e \cap tgt_e|$ is also set to 1 when $|src_e|$ and $|tgt_e|$ are empty. Given N input sentences, $pred_n$ as the list of predicted quadroples for n-th sentence and $gold_n$ as its gold counterpart, ***Precision*** is computed as follows.

$$\frac{\sum_{n=1}^{N} \sum_{p\in pred_n} \max_{q\in gold_n} score(p, q)}{\sum_{n=1}^{N} |pred_n|} \quad (2)$$

max is to select score of best matching gold quadrople for a given predicted one. Similarly, ***Recall*** is computed as follows.

$$\frac{\sum_{n=1}^{N} \sum_{q\in gold_n} \max_{p\in pred_n} score(q, p)}{\sum_{n=1}^{N} |gold_n|} \quad (3)$$

Finally, ***Sentiment Graph F1*** is measured as follows.

$$GraphF1 = \frac{2 * Precision * Recall}{Precision + Recall} \quad (4)$$

4 System Description

Our model is comprised of a base pre-trained model that is supposed to extract rich contextualized features and two separate modules for extracting expressions and predicting edges. For english datasets (Opener$_{\text{EN}}$, Darmstadt$_{\text{Unis}}$ and MPQA) we used RoBERTa$_{\text{base}}$ (Liu et al., 2019) model and for non-english ones (Opener$_{\text{ES}}$, Norec$_{\text{Fine}}$,

		#	avg.	max

	dev	206	18.9	108

Table 1: General information of shared task datasets. First five datasets are used in (Barnes et al., 2021). Max and average are measures of tokens' counts.

Multibooked$_{\text{CA}}$ and Multibooked$_{\text{EU}}$), we used LaBSE (Feng et al., 2020) as model's base.

We treat quadruples in a sentence as a graph which its nodes are expressions and its edges connect expressions within a quadruple. We name the module for extracting expression, **Node Extractor** and the module for determining edges, **Edge Predictor**. System structure is depicted in figure 1. Firstly, input sentence is fed into model base. Then node extractor gets the encoded input and for each one of three entity types, predicts expressions in the sentence. Polarities are also predicted by this module. Edge predictor, then, gets the expressions and for every pair of sentiment-target and sentiment-holder expressions, predicts if there is an edge between them. Finally a sentiment expression plus its polarity along with all of target and holder expressions connected thereto would become one of predicted quadroples.

4.1 Node Extractor

This module consists of three feed forward neural networks for predicting label of each token in BIO scheme, each network for an entity type. Using these three networks, sequence tokens are labeled for sentiment, target and holder expressions independently. In this networks, ReLU is used as activation and each network has less than 50k parameters. Loss function of the module is cross entropy. We integrate predicting polarity of sentiment expressions in sequence labelling task by replicating BIO labels for negative, neutral and positive polarities.

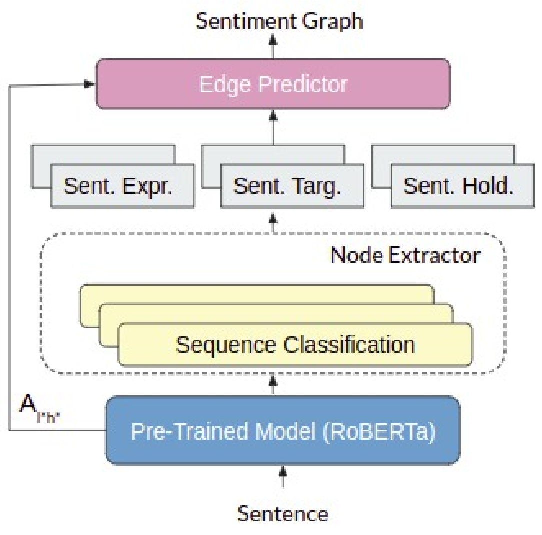

Figure 1: System architecture

Note that node extractor and jointly predicting sentiment expression and polarity is inspired of what is being used in one of our baselines, the one using sequence labelling approach.

4.2 Edge Predictor

Aimed for leveraging pretrained model's knowledge as much as possible, we simply used its computed attentions to predict edges. To this end, we examined different settings that are as follows:

Base: This is the base setting of edge predictor. We use attention values of a predetermined head in a specific layer in this way that we compute sum of attentions of two given expressions to each other and apply sigmoid to predict being an edge between them. More specifically, we choose head 7 in layer 8 of RoBERTa$_{\text{base}}$ for english datasets and head 9 layer 11 of LaBSE for others. This choice was based on the observation that those heads were more semantic-aware in the sense that sentiment expression tokens attend more to target expression tokens. Those heads are also less position dependant, meaning that a token's attention distribution does not lean toward a specific position in the sequence.

Consider two nodes a and b which span intervals (a_{begin}, a_{end}) and (b_{begin}, b_{end}) in the sentence respectively. Probability of being an edge being between a and b, $P_{e_{ab}}$ in the is computed as follows:

$$P_{e_{ab}} = \sigma\Big(\sum_{i=a_{begin}}^{a_{end}} \sum_{j=b_{begin}}^{b_{end}} A_{l^*h^*ij} + A_{l^*h^*ji}\Big) \quad (5)$$

		holders			targets			sent. expr.			polarity

	dev	49	1.0	2	371	2.0	10	400	2.6	14	284	0	116
Opener$_{\text{ES}}$	train	176	1.0	3	2748	2.4	13	3042	2.6	16	2472	0	570
	dev	23	1.0	2	363	2.6	11	387	2.6	17	317	0	70

Table 2: Details of shared task datasets. First five datasets are used in (Barnes et al., 2021). Max and average are measures of tokens' counts in expressions.

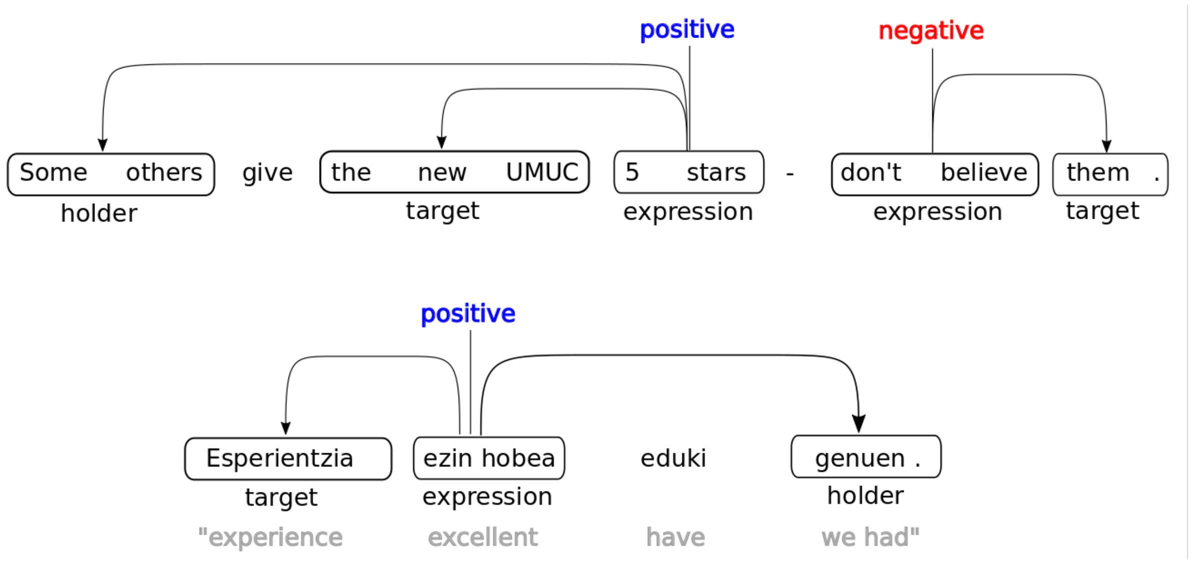

Figure 2: A sentiment graph example. Entities of a quadrople are connected with edges and sentiment expressions are labeled with polarity. Image is from (Barnes et al., 2022)

A is the pretrained model's computed attention. l^* and h^* determine prespecified head and layer respectively. σ is the sigmoid function. This equation simply means attention of two nodes to each other determines probability of being an edge between them.

+AvgH: In this setting we do not rely only on specific heads and use attention values of all heads in all layers. To this end we introduce new learnable weights, one for each head, and compute linear combination of attention values across all heads. Total number of new weights is number of layers times number of heads in each layer, which is 144 in both RoBERTa$_{\text{base}}$ and LaBSE. So in this setting, $P_{e_{ab}}$ becomes

$$\sigma(\sum_{l,h=1}^{n_l,h_l} \sum_{i=a_{begin}}^{a_{end}} \sum_{j=b_{begin}}^{b_{end}} w_{lh} * (A_{lhij} + A_{lhji})) \quad (6)$$

in which n_l and n_h are number of layers and heads in the pretrained Model respectively. w is the learned weight assigned to each head. At training start w is set to 1 in setting one head and 0 in other heads.

+SepH: We use separate heads for predicting edges for sentiment-target expression pair and sentiment-holder expression pair. Specifically, for predicting and edge between a sentiment and a target expression, we use head 7 in layer 8 for english datasets and head 9 in layer 11 for non-english

	$\text{Opener}_{\text{EN}}$	$\text{Opener}_{\text{ES}}$	$\text{Norec}_{\text{Fine}}$	$\text{Darmstadt}_{\text{Unis}}$	$\text{MultiB}_{\text{EU}}$	$\text{MultiB}_{\text{CA}}$	MPQA	Average
base	0.64	0.65	0.44	0.45	0.67	0.64	0.38	0.55
+AvgH	-0.03	-0.02	-0.05	-0.14	0.02	0.01	-0.31	-0.07
+SepH	0.03	0.02	-0.05	-0.03	-0.00	-0.02	-0.08	-0.02
+SepH+AvgH	0.01	-0.00	-0.03	-0.07	-0.02	-0.00	-0.24	-0.05

Table 3: Performance of different variants of our model. First row is the default variant and numbers in other rows show increase or decrease in comparison with the default variant. Results are based on evaluation on development data.

ones. For predicting an edge between a sentiment expression and a holder expression, we use head 10 in layer 11 for english datasets and head 4 in layer 11 for non-english ones.

+SepH+AvgH: This is the mixture of last two settings. We use all heads in all layers but we consider separate linear combinations of them for sentiment-target and sentiment-holder expression pairs. So the number of introduced weights is doubled to 288 in this setting.

5 Experiments

5.1 Baselines

We compare our model with two baselines proposed in the shared task. First one is basically (Barnes et al., 2021) which is described in section 2. The second one takes sequence labelling approach. It sets two modules for predicting expressions and relations respectively. Expression prediction module consists of three BiLSTMs which predict sentiment, target and holder expressions respectively. This module is fed by an embedding layer which is initialized with pretrained word embeddings. Relation prediction module, given two extracted expressions and the input sentence, uses separate BiLSTMs and max pooling to make contextualized representations from them. Then it feeds concatenation of three max pooling layers to a linear layer and sigmoid to predict if there is relation between two expressions or not. In the comparisons we call the baselines, **GP** (for graph parsing) and **SL-BiLSTM** (for sequence labelling) respectively.

5.2 Settings

We trained each variant of our model 5 times, each with different random seed on every dataset for at most 20 epochs. learning rate was 1e-4 and 1e-3 for pretrained model and newly introduced weights respectively. We did warm-up in epoch 1 and applied step LR scheduling with gamma as .1 and step size as 9. Baselines were also trained using script given by shared task organizers. Evaluation measure being used was Sentiment Graph F1. Evaluation was done using the script given by shared task organizers. We used PyTorch (Paszke et al., 2019) plus Pytorch-Ignite (Fomin et al., 2020) as training framework and WandB (Biewald, 2020) as Experiment Tracking tool.

Dataset	Attentionist	GP	SL-BiLSTM
$\textbf{NoReC}_{\text{Fine}}$	**0.32**	0.28	0.19
$\textbf{MultiB}_{\text{CA}}$	**0.61**	0.54	0.33
$\textbf{MultiB}_{\text{EU}}$	**0.59**	0.57	0.34
MPQA	**0.26**	0.15	0.02
$\textbf{Darmstadt}_{\text{Unis}}$	**0.25**	0.21	0.13
$\textbf{Opener}_{\text{EN}}$	**0.58**	0.52	0.31
$\textbf{Opener}_{\text{ES}}$	**0.55**	0.50	0.26

Table 4: Test results of our model and baselines. Evaluation metric is Sentiment Graph F1

6 Results

Results are shown in table4. **Attentionist** is our proposed model. For our model, only result of the best variant is shown. As it can be seen, our model outperforms the baseline in all datasets.

7 Ablation Study

In order to assess and compare performance of different variants of our model, we trained each variant four times using different random seeds on each dataset and compared them on development data. Results are depicted in table3.

Abstract

This paper addressed the problem of structured sentiment analysis using a bi-affine semantic dependency parser, large pre-trained language models, and publicly available translation models. For the monolingual setup, we considered: (i) training on a single treebank, and (ii) relaxing the setup by training on treebanks coming from different languages that can be adequately processed by cross-lingual language models. For the zero-shot setup and a given target treebank, we relied on: (i) a word-level translation of available treebanks in other languages to get noisy, unlikely-grammatical, but annotated data (we release as much of it as licenses allow), and (ii) merging those translated treebanks to obtain training data. In the post-evaluation phase, we also trained cross-lingual models that simply merged all the English treebanks and did not use word-level translations, and yet obtained better results. According to the official results, we ranked 8th and 9th in the monolingual and cross-lingual setups.

1 Introduction

Sentiment Analysis (SA, Pang and Lee, 2008) deals with the automatic processing of subjective information in natural language texts. Early work on SA focused on conceptually simpler tasks, such as polarity classification at the sentence or document level. With the advances in natural language processing (NLP), more fine-grained and complex tasks have been proposed, such as detecting the entity that expresses an opinionated chunk of text, or the entity that was targeted. More particularly, Barnes et al. (2021) consider sentiment analysis as a (graph) structured task, and discuss up to five subtasks: (i) sentiment expression extraction, (ii) sentiment target extraction, (iii) sentiment holder extraction, (iv) defining the relationship between these elements, and (v) assigning a polarity label. They discuss that although these tasks have been extensively studied by different authors (Turney, 2002; Pontiki et al., 2015; Zhang et al., 2019, *inter alia*), they are not addressed all together. They also discuss that such subdivision into subtasks might have a negative impact in the general analysis of the sentence, and that a joint analysis could translate into a holistic approach. To do so, they propose to encapsulate all these tasks in the form of a sentiment graph. Formally, the goal is to find the set of opinion tuples $\{O_1, \ldots, O_i, \ldots, O_n\}$ in a given text, where each opinion O_i is a tuple of the form (h, t, e, p) where h is a holder who expresses a polarity p towards a target t through a sentiment expression e, implicitly defining pairwise relationships between elements of the same tuple. We illustrate an example in Figure 1.

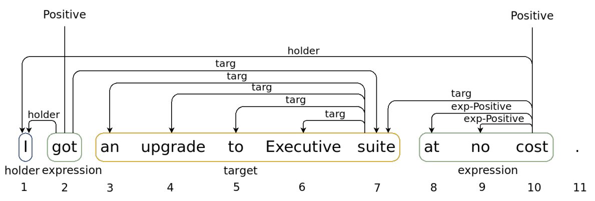

Figure 1: An example of sentiment graph as defined by Barnes et al. (2021). The sentence has a holder ('I'), two sentiment expressions ('got' and 'at no cost') and one target ('an upgrade to Executive suite')

More particularly, for the SemEval-2022 Task 10 (Barnes et al., 2022), the organizers proposed both a monolingual[1] and a cross-lingual (zero-shot) setup. They considered 5 languages (and 7 treebanks): English, Spanish, Catalan, Basque, and Norwegian. For the zero-shot setup Basque, Catalan, and Spanish were the target languages.

Our approach is based on the idea of viewing this task as semantic dependency parsing (Oepen et al., 2015), since both tasks are structurally similar even if the graphs have different meaning. More

[1]We use the term monolingual as it was the term used by the organizers, but this setup allowed the use of any resource, including resources in different languages.

specifically, we rely on a bi-affine graph-based parser (Dozat and Manning, 2018) and different large pre-trained language models (LM), such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) or XLM-R (Conneau et al., 2020). For the monolingual setup we train a semantic parsing model on single and merged treebanks, and compare the performance using different LMs. For the cross-lingual setup, we first do a word-level translation of the datasets in a different language than the target treebank, and then proceed similarly to the monolingual setup. Overall, the approach relies on off-the-shelf tools already available, but traditionally used for other purposes. We here re-purpose them for their use for sentiment analysis as graph-based parsing.

2 The role of parsing in SA

Parsing has been used in the past for SA, with different motivations, such as integrating syntactic knowledge as a component of the model's architecture, or producing structured sentiment outputs.

Polarity classification. Since early times, authors have studied the importance of language structure to deal with relevant linguistic phenomena for polarity classification, first focusing on simpler strategies such as the use of n-grams or lexical rules (Pang et al., 2002; Taboada et al., 2011). Later on, more complex syntactic structures were incorporated as well, both for rule-based and machine learning approaches.

For instance, for the rule-based paradigm, Poria et al. (2014) used dependency relations for concept-level sentiment analysis, so sentiment could flow from one concept to another to better contextualize polarity. Vilares et al. (2015a, 2017) proposed a model to compute the sentiment of sentences that was driven by syntax-based rules to deal with specific relevant phenomena in SA, and that could be easily re-purposed for any language for which a dependency parser was available. Kanayama and Iwamoto (2020) built on top of Vilares et al.'s idea, and proposed a multilingual syntax-based system that achieved a high precision for 17 languages.

From the machine learning perspective, Joshi and Rosé (2009); Vilares et al. (2015b) used dependency triplets to train data-driven (pre-neural) models and obtain slight improvements over purely lexical approaches. Socher et al. (2013) collected sentiment labels for phrases and sentences that were previously automatically represented as constituent (sub)trees, to then train a compositional model that used a recursive neural network. This work has some relevant resemblances with Barnes et al. (2021)'s proposal for structured sentiment analysis. Socher et al. were among the first to provide tree-shaped annotated sentiment data (in this case just for polarity classification), while most of previous work had focused on using tree knowledge as external information to the models, but with sentiment annotations only associated with plain texts. This publicly available data later encouraged many authors to design models that could exploit tree-shaped annotated data to obtain better performing models (Tai et al., 2015; Zhang and Zhang, 2019, *inter alia*).

Aspect-based sentiment analysis (ABSA). ABSA is a task that is particularly suitable for the integration of syntactic information, since its main goal is to associate sentiment with specific entities and aspects that occur in the sentence (Pontiki et al., 2015). Related to this, Popescu and Etzioni (2005) already used dependency trees to constrain an unsupervised sentiment analysis system that extracted a set of product features and their sentiment, given a particular item. More recently, with the wide adoption of neural networks in NLP, different authors have integrated syntactic knowledge and syntactic structures in different network architectures, such as long short-term memory networks (LSTMs, Tang et al., 2016), recursive neural networks (Nguyen and Shirai, 2015), convolutional networks (Xue and Li, 2018), and graph attention networks (Huang et al., 2020; Sun et al., 2019).

Overall, it is clear that parsing has had a high relevance in SA. Yet, the novelty of the shared task is in using graphs to represent richer annotations. This makes it possible to use parsing algorithms as sentiment models, i.e. not just to use them as a component of the model architecture, but as the model responsible of producing the whole sentiment structure of the chunk of text. Also, this is especially relevant in the era of large neural models, where the utility of parsers for downstream tasks is sometimes questioned, with some studies questioning its need in the presence of pretrained models that implicitly learn syntax (Tenney et al., 2019; Glavaš and Vulić, 2021; Dai et al., 2021) while others still achieve extra accuracy from their use in conjuntion with such models (Sachan et al., 2021; Xu et al., 2021; Li et al., 2021; Zhang et al., 2022). In any case, tasks like this one show that graph structures can be also useful to re-purpose traditional tasks such as SA, while taking advantage of research that the NLP community has done on parsing algorithms for decades.

3 Brief overview of the shared task

The goal of the task is to produce graph structures that reflect the sentiment of a sentence, as we showed in Figure 1. More particularly, the organizers released 7 treebanks in 5 different languages: OpeNER (Agerri et al., 2013, English and Spanish), MPQA (Wiebe et al., 2005, English), Darmstadt_unis (Toprak et al., 2010, English), MultiBooked (Barnes et al., 2018, Basque and Catalan), and NoReC_fine (Øvrelid et al., 2020, Norwegian).[2] Table 1 details the main statistics for the datasets.

Dataset	Language	# sents	# holders	# targets	# expr.
NoReC_fine	Norwegian	11437	1128	8923	11115
MultiBooked	Basque	1521	296	1775	2328
MultiBooked	Catalan	1678	235	2336	2756
OpeNER	Spanish	2057	255	3980	4388
OpeNER	English	2494	413	3850	4150
MPQA	English	10048	2279	2452	2814
Darmstadt_unis	English	2803	86	1119	1119

Table 1: General statistics of the treebanks used in the shared task.

The sentiment of a sentence is composed of all the opinions, O_i, that make it up. Each opinion can have up to four elements: a holder (h) who expresses a polarity (p) towards a target (t) through a sentiment expression (e). These four elements implicitly define the pairwise relationships between the elements of a tuple. The previous example, Figure 1, shows a sentence with two sentiment expressions (*got* and *at no cost*) that express the polarity (*Positive*) of the sentiment that a holder (I) has towards one target (*an upgrade to Executive suite*).

Preprocessing The organizers of the shared task proposed two possible ways to address the task: as a sequence labeling or as graph-based parsing problem. As mentioned above, we opted for the latter. We use the scripts available in the official repository to transform the JSON files to the CoNLL-U based format and *vice versa*, and we applied the needed changes to make it compatible with `supar` (see §4).[3] Under the graph-based paradigm, the problem is approached as a bilexical dependency graph prediction task, with some assumptions. To convert the data, the organizers suggest two possible conversions, namely *head-first* and *head-final*. In *head-first*, it is assumed that the first token of the sentiment expression is a root node, and that the first token of each holder or target spans is the head node of such span, while the other ones are dependents. Meanwhile, in *head-final*, the final token of the holder and target spans is set as the head of the span, and the final token of the sentiment expression as a root node (Figure 1 is a head-final example). In this work, we have chosen *head-final*, which is the default option for the shared task and also delivered better results than *head-first* in the experiments carried out by Barnes et al. (2021) (see Table 3 in that paper).

Subtasks More in detail, the challenge is divided into two subtasks:

1. Monolingual setup: When training and development data is available for the same treebank/language, i.e. the goal is to train one model per treebank. It was allowed to use extra resources or tools that could boost performance, even from different languages.

2. Cross-lingual, zero-shot setup: It is assumed that there is no gold training data in the language of the target treebank. The organizers specified that it is possible to use treebanks in other languages, translation tools, and any other resources that do not include sentiment annotations in the target language.

Metrics Each subtask is evaluated independently, and the ranking metric was *sentiment graph F1* (Barnes et al., 2021), where true positives are exact matches at the graph level, weighting the overlap between the predicted and gold spans for each element, and averaged across all three spans. To compute precision, it weights the number of correctly predicted tokens divided by the total number of predicted tokens, while for recall it weights the number of correctly predicted tokens divided by the total number of gold tokens. Also, as mentioned earlier, it is possible to have tuples with empty holders and targets.

4 Our model

We rely on the Dozat and Manning (2018) parser, a widely used state-of-the-art model both for syntactic and semantic dependency parsing. Inspired in previous graph-based parsers (McDonald et al., 2005; Kiperwasser and Goldberg, 2016), the parser first computes contextualized representations for each word using bidirectional LSTMs (biLSTMs; Hochreiter and Schmidhuber, 1997; Schuster and Paliwal, 1997). After that, the model computes a *head* and a *dependent* representation for each term, to establish through a bi-affine attention whether an edge exists between each pair of tokens, and if so, what is the semantic relationship between them. In particular, in this paper we follow the implementation used in the `supar`[4] package, as it has been widely adopted by the community and it is available for other flavors of parsing as well, such as constituent or dependency parsing. We preferred this implementation over the graph-based baseline provided in the SemEval repository, since early experiments showed a superior performance, and it also offered a simpler integration of large language models. We left the parser hyperparameters, except the learning rate, at their default value.

Pre-trained language models For each language we looked for avaliable monolingual and multilingual pre-trained LMs at `https://huggingface.co/`. Specifically, for each language, we included:

- `Basque`: berteus-base-cased, RoBasquERTa.
- `Catalan`: julibert, roberta-base-ca, calbert-base-uncased.
- `English`: bert-base-cased, bert-base-uncased, bert-large-cased, bert-large-uncased, roberta-base, roberta-large, albert-base-v2, albert-large-v2, xlnet-base-cased, xlnet-large-cased, electra-base-discriminator, electra-large-discriminator, electra-base-generator, electra-large-generator.
- `Norwegian`: norbert, nb-bert-base, nb-bert-large, electra-base-norwegian-uncased-discriminator.
- `Spanish`: bio-bert-base-spanish-wwm-uncased, bert-base-spanish-wwm-cased, roberta-base-bne, roberta-large-bne, selectra_medium, zeroshot_selectra_medium.

[4]`https://github.com/yzhangcs/parser`

With respect to the cross-lingual LMs, we considered: xlm-roberta-base and xlm-roberta-large.

4.1 Monolingual models

For this task, we use: (i) pre-trained language models, (ii) `supar`, and (iii) the official training and development files to build our models. Also note that we train end-to-end models, using words as the only input (later tokenized into subword pieces by the language models), but ignoring the part-of-speech tags and syntactic information provided in the sentiment treebanks. We did not use part-of-speech tags (or other morphosyntactic annotations) since these are not used in `supar` together with BERT encoders, and using them would require to adapt the code, which was exactly what we tried to avoid in this work.

Training procedure We fine-tuned parsing models considering for each treebank the proposed LMs, and combining them with `supar`. Since training is time-consuming, many model configurations are proposed, and the performance of `supar` is stable independently of the seed, we decided to train a single model per LM. Specifically, all models have been trained with the default seed used by `supar`, which is 1. The only parameter that was modified was the learning rate (l_r), as we observed that for some models (specially the larger language models) the fine-tuning process did not converge. We started with $5 \cdot 10^{-5}$, and did a small grid search down to $1 \cdot 10^{-6}$, where if a model still did not converge it was discarded.[5] Additionally, to train the parsing models, we considered three strategies:

1. Single monolingual training and development files: We train each model on a single treebank and validate its performance in the corresponding dev set, i.e., the standard monolingual training and development methodology.

For the best model obtained for each treebank according to strategy 1, we explored a couple of harmonized training strategies (harmonized in the sense that different treebanks follow the same annotation guidelines):

2. Merged training and development files from different treebanks: We considered to merge

[5]For both monolingual and cross-lingual subtasks, all the selected models used a l_r of $5 \cdot 10^{-5}$. The only exception is Norwegian in the monolingual subtask, for which we used $5 \cdot 10^{-6}$.

all the available training files and all the available development files, treating them as a single dataset. Thus, we trained a single model that could predict all test files, but with the disadvantage that model selection is based on multilingual performance, which could hurt the performance in this setup.

3. Merged training files, single development file: Similar to 2, but merging only the training files. For the development phase, we proceeded as in 1 and used each dataset's dev file for model selection. The idea was to have training data that can benefit from multilingual information, but that still considers a monolingual file for a language-dependent model selection, i.e., given n treebanks, we still need to train n models, one per treebank.

We detail the experimental results for the training/development phase in §5.

4.2 Cross-lingual (zero-shot) models

In this setup, we rely on two main components: (i) available translation systems to perform word-level translations from source language to target language treebanks, and (ii) both monolingual and cross-lingual language models. Our goal with (i) is to obtain noisy, unlikely-grammatical data, but that still can provide sentiment annotations for a given target language, exploring the viability of this approach. Regarding the learning rate, we used $5 \cdot 10^{-5}$ in all cases.

Auxiliary translation models From the CoNLLU converted files[6], we translated the sentences at the word level using the Helsinki-NLP translation models[7] (Tiedemann and Thottingal, 2020) available at `huggingface`. Table 2 lists the language pairs for which we could obtain translated versions for the cross-lingual setup.

Dataset	Language	Basque	Catalan	Spanish
NoReC_fine	Norwegian			✓
MultiBooked	Basque			✓
MultiBooked	Catalan			✓
OpeNER	Spanish	✓	✓	
OpeNER	English	✓	✓	✓
MPQA	English	✓	✓	✓
Darmstadt_unis	English	✓	✓	✓

Table 2: Treebanks and the languages to which they were translated for the cross-lingual experiments.

[6] https://github.com/MinionAttack/corpus-translator
[7] https://huggingface.co/Helsinki-NLP

Then, to train the models we proceeded similarly to strategy 2 used in the monolingual setup: we combined the translated training and validation files coming from treebanks in other languages, and used the micro-averaged F1-score on the translated development set for model selection.

Post-evaluation (and better) baseline After the deadline to submit proposals, we also tested a baseline consisting on training, using an XLM-RoBERTa LM as the base component, a cross-lingual model that uses all the English datasets (without any kind of translation) as the source data. We discuss these results as well in §5.2.

5 Results

Here, we detail and discuss the results that we got for both subtasks (see §5.1 and 5.2) on: (i) the official development sets, and (ii) the official test sets of the shared tasks.

5.1 Monolingual setup

Tables 3 and 4 show the results for the development phase on the English and non-English datasets, respectively, including different LMs and training setups.

With respect to the results on the English treebanks, an interesting trend is that despite being the monolingual setup, using cross-lingual language models, and in particular XLM-RoBERTa, performed surprisingly well. Combined with the training strategy 3 (merged training sets, single development set), such models obtained the best results for 2 out of 3 English corpora (OpeNER and Darmstadt), while they still ranked well in the other dataset (MPQA). Across monolingual LMs, we also observe trends: electra-base-discriminator and (both base and large) RoBERTa models obtain overall the best results. On the other hand, we did not obtain equally robust results with ALBERT, and to a lesser extent, with BERT architectures. This is not totally surprising, since among the tested LMs, BERT is among the oldest ones, and ALBERT is a lite BERT, so some computational power is lost and it is understandable that this translates into some performance loss too, compared to larger LMs.

With respect to the experiments on the non-English datasets, we observe certain similarities, although the number of available models is much smaller than in the English cases. Again, XLM-RoBERTa overall obtains the best results. The only

exception is the Norwegian dataset, where we obtained the best results with a BERT architecture.

Yet, a more thoughtful discussion would be needed to determine if some architectures truly behave better than others. Note that all these LMs are usually pre-trained using different and heterogeneous text sources, and specially for the less-resourced languages, some constraints are usually imposed during training. For instance, it is hard to conclude that berteus-base-cased (BERT) (Agerri et al., 2020) is worse than XLM-RoBERTa (Conneau et al., 2020), since the amount of resources to

train the former was more constrained.

Finally, a few days before the submission deadline, the training files of some treebanks were slightly updated by the organizers, due to minor bugs in the segmentation process that corrupted some sentences. As we did not have time to re-run all models and update the results, we chose to re-train only the model that obtained the best performance on the previous version of the treebanks. Therefore, all the outputs submitted for the test sets correspond to models trained on the updated, uncorrupted files. In Table 5 we compare the performance of the models trained on the updated and deprecated versions of the training files. Overall, we observed relatively small, but non-negligible differences, usually obtaining a better performance with the updated version of the treebank.

Official results on the test sets In Table 6 we show the performance on the test sets of our submitted models, i.e. those that achieved the highest score in the corresponding development phase. The performance is stable across different test sets, obtaining slightly better results for Iberian languages. For a detailed comparison against the rest of participants, we refer the users to Appendix 11 and the

OpeNER_en	xlm-roberta-large	3	0.714	0.716
MPQA	roberta-base	1	0.374	0.374
Darmstadt_unis	xlm-roberta-large	3	0.329	0.357

Table 5: Scores on the development set for the models trained on the corrupted and uncorrupted versions of the training files, on the monolingual setup. For each treebank, we only did the comparison for the best performing model, based on the performance on the corrupted version.

Dataset	Model	Strategy	Score
NoReC_fine	nb-bert-large	1	$0.462_{(10)}$
MultiBooked_eu	xlm-roberta-large	2	$0.680_{(7)}$
MultiBooked_ca	xlm-roberta-base	1	$0.653_{(8)}$
OpeNER_es	xlm-roberta-large	3	$0.692_{(6)}$
OpeNER_en	xlm-roberta-large	3	$0.698_{(9)}$
MPQA	roberta-base	1	$0.349_{(10)}$
Darmstadt_unis	xlm-roberta-large	3	$0.414_{(8)}$

Table 6: Scores of our models, for the monolingual subtask, on each test set. Our ranking on the shared task for each test set is indicated as a subscript.

official shared task paper (Barnes et al., 2022).

The datasets of the shared task belong to different domains: OpeNER and MultiBooked deal with hotel reviews, NoReC with professional reviews in multiple domains, Darmstadt_unis (the dataset for which we obtain the second lowest scores) contains English online university reviews, and MPQA (the dataset for which we obtain the lowest scores) is about news articles annotated with opinions and other private states (i.e., beliefs, emotions, sentiments, speculations, . . .). For the two lowest-scoring datasets, they have in common that they mostly contain single-opinion sentences, whereas the other datasets tend to have more variety in the number of opinions and their distribution. For instance, ∼85% and ∼74% of the training sentences of the Darmstadt_unis and MPQA datasets have only one opinion, while the next most 'single-opinion' dataset is multibooked_eu with only ∼53% of the sentences. However, we need to perform more detailed analysis as future work to extract more robust conclusions.

5.2 Cross-lingual setup

Table 7 shows the results for the development phase for the three target languages and their datasets. Again, XLM-RoBERTa models obtain overall the best performance, although in this case it is less surprising since cross-lingual LMs are expected to suit well this kind of challenges. Similar to the case of the monolingual setup, we decided to retrain the best-performing model with the updated versions of the training files. In Table 8, we show the comparison between the corrupted and uncorrupted versions of the datasets, which contrarily to the monolingual setup, often turned out into worse performing models.

Finally, Table 9 shows the scores for the post-evaluation baseline (model trained on the English datasets with XLM-RoBERTa) on the dev set. Very interestingly, the results show that this baseline outperformed our word-level translation approaches. We need more analysis to understand why this happens, but we hypothesize that the larger amount of English texts XLM-RoBERTa was pre-trained on could be playing an important role.

Corpus	Model	F1
Basque	xlm-roberta-base	0.434
	berteus-base-cased	0.416

	xlm-roberta-large	$0.638_{(2)*}$

Table 10: Scores of our models, for the cross-lingual subtask, on each test set. Our ranking on the shared task for each test set is indicated as a subscript. * indicates the ranking that we would obtain in the shared task using the post-evaluation baseline models.

6 Conclusion

This paper describes our participation at the SemEval Shared Task 10 on structured sentiment analysis. We participated both in the monolingual and cross-lingual (zero-shot) setups. We applied a simple, but effective approach, relying on off-the-shelf tools, traditionally used for other purposes, and used them to predict sentiment graphs instead. More particularly, for the monolingual setup, we linked pre-trained language models with bi-affine graph parsing and training over single and multiple treebanks. In the zero-shot setup, we followed a similar approach, but relied on publicly available translation models to obtain training data, by applying a word-level translation of treebanks, to then train models similarly to the monolingual setup.

SPDB Innovation Lab at SemEval-2022 Task 10: A Novel End-to-End Structured Sentiment Analysis Model based on the ERNIE-M

Yalong Jia, Zhenghui Ou, Yang Yang
Shanghai Pudong Development Bank
{jiayl2, ouzh, yangy103}@spdb.com.cn

Abstract

Sentiment analysis is a classical problem of natural language processing. SemEval 2022 sets a problem on the structured sentiment analysis in task 10, which is also a study-worthy topic in research area. In this paper, we propose a method which can predict structured sentiment information on multiple languages with limited data. The ERNIE-M pretrained language model is employed as a lingual feature extractor which works well on multiple language processing, followed by a graph parser as a opinion extractor. The method can predict structured sentiment information with high interpretability. We apply data augmentation as the given datasets are so small. Furthermore, we use K-fold cross-validation and DeBERTaV3 pretrained model as extra English embedding generator to train multiple models as our ensemble strategies. Experimental results show that the proposed model has considerable performance on both monolingual and cross-lingual tasks.

1 Introduction

Sentiment analysis (Liu, 2012) is widely used in many aspects of computer science nowadays, such as human computer interaction, lingual feature extraction, etc. Affective computing techniques enable us to explore the sentiment message, which depicts the preference, emotion or even idea of people, behind the sentence itself.

Sentiment analysis task can be classified into text level, sentence level, entity level and opinion tuple level. The goal of text or sentence level sentiment analysis is to predict sentiments of given documents or sentences. On the other hand, entity level sentiment analysis needs to consider sentiments between each entity in given sentence. Furthermore, a sentence may contain multiple entities with different sentiments (positive or negative). Therefore, in comparison to entity level sentiment analysis, opinion tuple level sentiment analysis requires additional extraction of relations between entities and opinions.

Structured sentiment analysis (Barnes et al., 2022) is a task to predict a sentiment graph for given sentences. It can be theoretically cast as an information extraction problem in which one attempts to find all of the opinion tuples $O = O_1, ..., O_n$ in a text. As we can see in Figure 1, each opinion O_i is a tuple (h, t, e, p) where h is a holder who expresses a polarity p towards a target t through a sentiment expression e, implicitly defining pairwise relationships between elements of the same tuple.

The structure of the paper is as follows. Section 2 briefly reviews recent works on similar tasks; Section 3 describes our model structure in detail. Section 4 shows the analysis of the given datasets; Section 5 introduces our experimental setting and results. And finally in Section 6, we make a conclusion and give the ideas about future works.

2 Background

Dividing structured sentiment analysis into multiple subtasks is a traditional approach, by first identifying holders, targets and expressions through Named Entity Recognition (NER) module, then predicting relations among the entities. (Peng et al., 2020; Li et al., 2019) are baselines with good performance. On the other hand, the end-to-end sentiment analysis is a straight-forward approach, which directly extracts target and expression without splitting them into sub-tasks. (He et al., 2019) presents an interactive multi-task learning network(IMN) implemented by a series of a multi-layer CNN modules. Recently, (Barnes et al., 2021) cast the structured sentiment problem as the dependency graph parsing problem, and proposed a method that outperforms the SOTA(state-of-the-art) baselines on

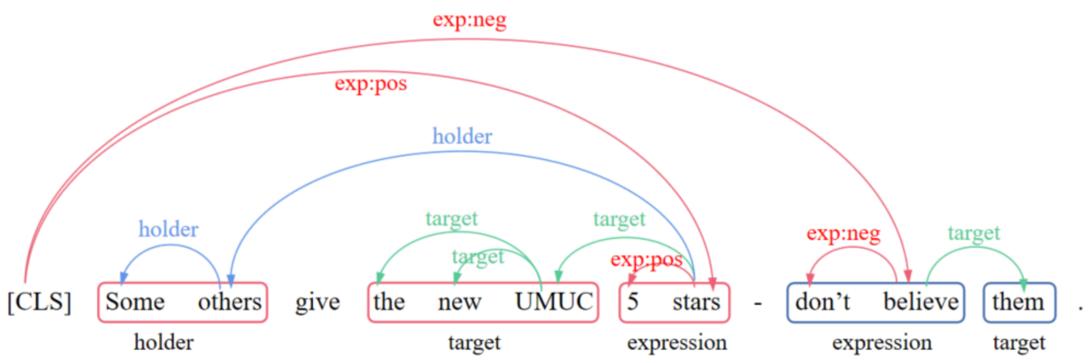

Figure 1: A structured sentiment graph is composed of a holder, target, sentiment expression, their relationships and a polarity attribute. Holders and targets can be none.

extensive experimental results.

In this task, 7 small datasets involving 5 different languages are given, which means our method needs to support multiple languages with limited data. Therefore, in this work, we use ERNIE-M pretrained model as word embedding generator, as it shows SOTA performances in various of NLP tasks in multiple languages. Because of the outstanding performance of (Barnes et al., 2021), we employ a similar network structure to extract the sentiment information.

3 Model structure

The model structure is similar to the head-final model structure in (Barnes et al., 2021), while we use a pretrained model in this work. A bert-style (ERNIE-M (Ouyang et al., 2020)) pretrained model takes sentences starting with "[CLS]" token as input. We connect "[CLS]" token with the last word of the expression, which is the root node of the tuple (h, t, e). The connection type is related to the sentiment polarity, "exp:pos" for positive polarity, "exp:neu" for neutral polarity, and "exp:neg" for negative corresponding to polarity, such that we are able to predict sentence polarity based on the connection type. As shown in Figure 1, a connection from "[CLS]" to "stars" and a connection from "[CLS]" to "believe" are established, with a connection type of "exp:pos" and "exp:neg" respectively. We describe the model structure in detail below.

For a given sentence $\overrightarrow{x} = (x_1, x_2, ..., x_n)$, where $x_i (1 \leq i \leq n)$ represents a single word. In this work, we use ERNIE-M pretrained model as a text feature extractor, which takes subword tokens as the model input. We apply subword-based tokenization on the input words.

As shown in Figure 2, we apply subword-based tokenization on the input sentence, getting $\overrightarrow{t} = (t_1, t_2, ..., t_m)$ for any $t_j (1 \leq j \leq m)$ representing a subword token. For instance, word "restful" will be split into "rest" and "##ful", where "##" indicates that the token is not the start of a word. And the process can be easily inversed by these special characters, such as we can restore ["Great", "and", "rest", "##ful", "place", "to", "stay", "."] to its original status ["Great", "and", "restful", "place", "to", "stay" "."]. After that, we input the subword tokens into the ERNIE-M model and get the embedding of the subword tokens. Then, we apply average pooling on the subword embeddings($\overrightarrow{v}$ in equation 1) which belong to a same original word to get the word representation $\overrightarrow{c} = (c_1, c_2, ..., c_n)$.

After obtaining the word representations of the sentence, we perform a position-wise feed-forward networks to obtain the representation of the heads and dependents, where heads represent head nodes, and the dependents represent follower nodes. Then we use Bilinear Attention Network (Kim et al., 2018) to calculate the pairwise correlation between each two words in the sentence.

$$\overrightarrow{v} = (v_1, ..., v_m) = \text{ERNIE-M}(t_1, ..., t_m) \quad (1)$$

$$h_i^{head} = FFN^{head}(c_i) \quad (2)$$

$$h_j^{dep} = FFN^{dep}(c_j) \quad (3)$$

$$score_{i,j} = Bilinear(h_i^{head}, h_j^{dep}) \quad (4)$$

In equation 4, we obtain a score matrix that indicates the relationship between each word in the input sentence pair-wisely, by passing head and

4 Data

SemEval-2022 task 10 provides a total of 7 datasets: NoRec_fine(Øvrelid et al., 2020), MultiBooked_eu(Barnes et al., 2018), MultiBooked_ca(Barnes et al., 2018), OpeNER_es(Agerri et al., 2013), OpeNER_en(Agerri et al., 2013), MPQA(Wiebe et al., 2005), Darmstadt_unis(Toprak et al., 2010), involving different languages (en, ca, eu, no, es) and a couple of domains. MultiBooked_ca (Catalan), MultiBooked_eu (Basque), Opener_en(English), and Opener_es(Spanish) belong to hotel reviews domain. NoRec is a Norwegian dataset in literature, movies, video games, restaurants, music and theater domains. Darmstadt_unis is an English dataset in university domain, and MPQA is an English dataset in news domain. Our data analysis on the given datasets is shown in Table 1.

We can see that there are three different types of sentiment(positive, neutral, negative) in the opinions of Darmstadt_unis and MPQA, while others only contain Positive and Negative sentiments. In addition, we find that the number of expressions is always larger than or equal to the number of holders and targets for all datasets, which means there is at least one expression in each opinion. We can draw a conclusion that in a quadruple (h, t, e, p), both h and t may be missing, but e and p are not. Therefore, the expression(more precisely, the last word of expression) is defined as the root node of a (h, t, e) triplet.

5 Experiment and result

5.1 Data preprocessing

We process the labels of the original data into the format that the model required. Taking the sentence shown in Figure 1 as an example, the preprocessed result is shown in Table 2. We truncated the sentence due to the length of the sentence.

5.2 Experiments

In model validation period, we introduce two strategies, i.e., data augmentation and focal loss, which

	[CLS]	Some	others	give	the	new	UMUC	5	stars	.

EN-CA	0.543
EN-EU	0.527

Table 4: The left table is the result of monolingual, and the right table is the result of cross-lingual.

are described in detail below.

Data augmentation As shown in Table 1, the dataset is small. The largest dataset given is the NoRec dataset with 8,634 pieces of data, and only 4,555 pieces of data are left after removing the samples with empty opinions. Therefore, we use all datasets with the same polarity types for training with the help of ERNIE-M model, which supports multiple languages. For instance, we find that the Darmstadt_unis and MPQA have three categories of sentiment polarity, while the others have two categories of sentiment polarity. Hence, we merge Darmstadt_unis and MPQA into one dataset, and merge the others into another dataset. The results are shown in Table 3, and the evaluation method[1] is based on (Barnes et al., 2021). There is an average improvement of 2.36% after training the model with merged dataset, and a most significant improvement on the Opener_es at 4.44%.

[1]https://github.com/jerbarnes/semeval22_structured_sentiment

Focal loss As shown in Table 2, we can see the imbalance of the labels. The relationship between most words are none. Therefore, we introduce focal loss strategy, which reduces the loss weight of the "none" and increases the loss weight of the other labels. Because of the baseline scores on the MPQA and Darmstadt_unis are relatively lower, we test focal loss strategy on these two datasets. However, as we can see in Table 3, the performance is not good on Darmstadt_unis. Therefore, we do not use the focal loss strategy in the Darmstadt_unis solution.

5.3 Ensemble

We apply K-fold cross-validation and ensemble on the results of different pretrained models.

K-fold cross-validation For each dataset, we merge the original training set and the validation set, and perform K-fold segmentation after shuffling. The selection of K is related to the proportion of the original dataset training set and validation set. Notice that the proportion of the training set and the validation set after the segmentation should be approximated to their original proportion. We repeat this operation K times and obtain K different models. Finally, we ensemble K different models to get the final model.

Usage of other pretrained models For English datasets (Darmstadt_unis, MPQA, Opener_en), we train additional model by replacing the ERNIE-M model with the DeBERTaV3(He et al., 2021) model as the lingual feature extractor, and keep the other parts unchanged. Then we perform K-fold cross-validation strategy on both models and ensemble them in the same way. The results are shown in Table 4.

6 Conclusion

In order to solve the issues of small dataset and cross language in SemEval-2022 task 10, we introduce a multilingual pretrained model ERNIE-M as a lingual feature extractor to the given baseline model. Furthermore, we use multiple strategies such as data augmentation, K-fold cross-validation, focal loss and ensemble to improve the model performance. In the future, we can take other techniques to do further optimization, such as different data augmentation technieques, fine-tuning the pretrained model with the in-domain dataset, and changing the label from word level to subword level to fit the subword representation of the pretrained model.

xuruifeng@hit.edu.cn

Abstract

This paper describes our system that participated in the SemEval-2022 Task 10: Structured Sentiment Analysis, which aims to extract opinion tuples from texts. A full opinion tuple generally contains an opinion holder, an opinion target, the sentiment expression, and the corresponding polarity. The complex structure of the opinion tuple makes the task challenging. To address this task, we formalize it as a span-relation extraction problem and propose a two-stage extraction framework accordingly. In the first stage, we employ the span module to enumerate spans and then recognize the type of every span. In the second stage, we employ the relation module to determine the relation between spans. Our system achieves competitive results and ranks among the top-10 systems in almost subtasks.

1 Introduction

Sentiment analysis, also called opinion mining, aims to analysis people's attitudes and emotions towards specific targets, such as products, organizations, events, etc (Liu, 2012). It has become an important research field in natural language processing (Medhat et al., 2014; Hussein, 2018; Zhang et al., 2018).

Structured sentiment analysis. Barnes et al. (2021) formally defines a complete opinion as a quadruple (h, t, e, p) where h is a holder who expresses a polarity p towards a target t through a sentiment expression e. Figure 1 presents examples of opinion quadruples. On the basis of this definition, Barnes et al. (2022) formally establishes a benchmark for structured sentiment analysis. This benchmark consists of two tracks, the monolingual track and the crosslingual track, and we participate the monolingual track.

In this paper, we cast this task as a span-relation extraction problem (Jiang et al., 2020), which is a formalization that has been widely used in many

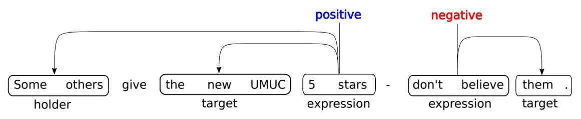

Figure 1: Examples of opinion quadruples (Barnes et al., 2021).

information extraction tasks (Eberts and Ulges, 2019; Xu et al., 2021; Lu and Ng, 2021; Li et al., 2021). With the span-relation formalization, opinion quadruple extraction is divided into two stages.

- In the first stage, we extract "meaningful" text spans and recognize their types. Specifically for this task, the type space is $\{h, t, e\}$. For those spans classified as e, we additionally detect the sentiment polarity they express.
- In the second stage, we determine the relations between spans. The relation space is set to $\{eh, et, ee, \text{none}\}$. eh and eh are used to facilitate the matching of sentiment expressions, holders, and targets during the decoding process. ee is used to deal with discontinuous sentiment expressions, which is inspired by (Li et al., 2021).

In addition, we employ span pruning (Xu et al., 2021) to reduce the computation of the second stage. Finally, opinion quadruples are decoding from the results of two stages. Our system achieves competitive results and ranks among the top-10 systems in almost subtasks.

2 Related Work

Span extraction is a fundamental method for many tasks, such as named entity recognition, aspect-level sentiment analysis, etc. This method performs element extraction by enumerating all possible spans and then determining the type of spans. Xu et al. (2017) attempts to determine the type of spans by encoding all possible spans into a representation of the same size. Sohrab and Miwa (2018) also enumerate all potential spans and then use a deep network to classify them. Luan et al. (2019) leverage the coreference and relation type confidences to enhance the representation of spans. Tan et al. (2020) added the task of span boundary detection to improve the sensitivity of the model to span boundaries. This approach was able to produce higher quality candidate spans.

Span-relation extraction for sentiment tasks focuses on extracting categories of spans and relationships between spans, such as extracting relationships between entities and extracting aspect sentiment triplet. Peng et al. (2020) try to solve the aspect sentiment triplet extraction problem using a two-stage pipeline. The first stage extracts the target as well as its polarity and opinion, using the BIOES annotation method.The second stage then couples the extracted target and opinion terms to determine their paired sentiment relation. However, This method may suffer from the problem of error propagation. End-to-end methods(Wu et al., 2020; Xu et al., 2020) can extract both span and their relationships. However, previous work has usually used word-to-word interactions to predict sentiment relationships. The disadvantage of this approach is that it ignores the sentiment consistency of the entire span. The method proposed by Xu et al. (2021) can accurately enumerate all the span representations with high likelihood and then predict the sentiment relationship between them. This approach can mitigate the impact of errors in the span extraction step on subsequent relationship prediction, while it also preserves the sentiment consistency of the entire span when predicting relationships

3 Our System

Given the input text, we first obtain its contextualized representation through a pre-trained language model, BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019). Then we input the contextualized representation into the span module and the relation module in turn to extract spans and detect relations.

3.1 Span Module

Span module roughly follows the idea of Tan et al. (2020). First we employ two binary classifiers to detect the start and end position of the “meaningful” spans respectively. Then another classifier is adopted to match the start and end positions and determine the category.

3.1.1 Start and End Prediction

Suppose $H \in \mathbb{R}^{n\times d}$ is the contextualized representation output by the language model, where n is the length of the input text. Then We calculate the probability of each position being the start or end position:

$$P_{start} = \text{sigmoid}(H \cdot W_{start}) \in \mathbb{R}^{n\times 1}, \quad (1)$$
$$P_{end} = \text{sigmoid}(H \cdot W_{end}) \in \mathbb{R}^{n\times 1}. \quad (2)$$

where $W_{start}, W_{end} \in \mathbb{R}^{d\times 1}$ are learnable parameters. Afterwards, we can decode the candidate start and end positions:

$$I_{start(>t)} = \{i \mid P^{(i)}_{start} > t, i = 1, \cdots, n\}, \quad (3)$$
$$I_{end(>t)} = \{i \mid P^{(i)}_{end} > t, i = 1, \cdots, n\}, \quad (4)$$

where threshold $t \in (0, 0.5]$ is hyper-parameter.

3.1.2 Start-End Matching and Classification

We adopt a classifier to match the start and end positions and determine the category. If the start position $i \in I_{start(>t)}$ and the end position $j \in I_{end(>t)}$ satisfy $i \leq j$, then we predict the category of span (i, j):

$$r_{ij} = [h_i; h_j; f_{width}(i, j)] \in \mathbb{R}^{3d}, \quad (5)$$
$$P^{(i,j)}_{span} = \text{softmax}(\text{FFNN}_s(r_{ij})) \in \mathbb{R}^4, \quad (6)$$

where $f_{width}(i, j) \in \mathbb{R}^d$ denotes a learnable embedding based on width $j - i$, and FFNN denotes a feed-forward neural network with non-linear activation. The span category space is $\{h, t, e, \text{invalid}\}$, where h denotes the opinion holder, t denotes the opinion target, and e denotes the sentiment expression.

For those spans classified as e, we predict its sentiment polarity additionally:

$$P^{(i,j)}_{polarity} = \text{softmax}(\text{FFNN}_p(r_{ij})) \in \mathbb{R}^3, \quad (7)$$

where the polarity space is $\{\text{POS}, \text{NEG}, \text{NEU}\}$.

3.2 Relation Module

Relation module aims to determine the relations between spans. For a span pair, we first construct a relation representation based on the span representations and then feed it into a relation classifier. Notice that we employ span pruning (Xu et al., 2021) to reduce the computation.

Language	Pretrained Model
English	roberta-large (Liu et al., 2019)
Spanish	BSC-TeMU/roberta-base-bne (Gutiérrez-Fandiño et al., 2021)
Norwegian	pere/norwegian-roberta-base
Basque	ixa-ehu/berteus-base-cased (Agerri et al., 2020)
Catalan	BSC-TeMU/roberta-base-ca (Armengol-Estapé et al., 2021)

Table 1: Pretrained language model for 5 different languages.

3.2.1 Span Pruning

Considering the large number of the predicted spans, it is not computationally practical to consider all possible pairwise relations. Following Xu et al. (2021), we prune spans in the relation classification stage. The holder, target, and sentiment expression candidates are selected based on the scores of the mention types for each span:

$$\Phi^{(i,j)}_{holder} = P^{(i,j)}_{span}(m = h), \tag{8}$$

$$\Phi^{(i,j)}_{target} = P^{(i,j)}_{span}(m = t), \tag{9}$$

$$\Phi^{(i,j)}_{expression} = P^{(i,j)}_{span}(m = e). \tag{10}$$

We use the mention scores Φ_{source}, Φ_{target} and $\Phi_{expression}$to select the top k candidates and obtain the holder candidate pool S^h, the target candidate pool S^t, and the sentiment expression candidate pool S^e, respectively. The value of k is related to the length of the sentence n:

$$k = \max(n \cdot z, k_{min}), \tag{11}$$

where z, k_{min} are hyper-parameters.

3.3 Datasets

	Language	Domain	Train	Dev	Test
MPQA	English	news	5873	2063	2112
DS$_{\text{Unis}}$	English	e-commerce	2252	232	318
OpenNER$_{\text{EN}}$	English	hotel	1745	250	499
OpenNER$_{\text{ES}}$	Spanish	hotel	1439	206	410
NoReC$_{\text{Fine}}$	Norwegian	multi-domain	8634	1531	1272
MultiB$_{\text{EU}}$	Basque	hotel	1064	152	305
MultiB$_{\text{CA}}$	Catalan	hotel	1174	168	335

Table 2: Data statistics.

3.3.1 Relation Classification

For most datasets, we only detect two relations, `expression-holder` and `expression-holder`. For datasets with discontinuous sentiment expressions, we detect `expression-expression` relation additionally. We obtain the candidate pair representation by coupling each expression candidate representation $s^e_{a,b}$ with the other candidate representation. For an expression candidate $(a, b) \in S^e$ and a holder candidate $(c, d) \in S^h$, their pair representation is:

$$g^{e,h}_{(a,b),(c,d)} = [r_{a,b}; r_{c,d}; f_{distance}(a, b, c, d) \\ f_{context}(a, b, c, d); f_{type}(e); f_{type}(h)]$$

where $f_{distance} \in R^d$ denotes a learnable embedding based distance $min(|b-c|, |a-d|)$, $f_{context} \in R^d$ is obtained by performing max-pooling operation on the context between the two spans, and f_{type} is a learnable embedding for indicating the span type. We construct $g^{e,t}$, $g^{e,e}$ in a similar way.

Then we input the pair representation to a feed-forward neural network to determine the sentiment relation:

$$P^{((a,b),(c,d))}_{relation} = \text{softmax}(\text{FFNN}_r(g^{e,h}_{(a,b),(c,d)})),$$

where the relation space is $\{eh, et, ee, \text{none}\}$.

3.4 Training

During training, we utilize the cross-entropy function to calculate the loss of start & end prediction, span classification(SC), polarity classification(PC), and relation classification(RC). The overall optimization objective is to minimize the summation of these losses:

$$\mathcal{L} = \mathcal{L}_S + \mathcal{L}_E + \mathcal{L}_{SC} + \mathcal{L}_{PC} + \mathcal{L}_{RC}. \tag{12}$$

3.5 Sentiment Structure Decoding

We first decode the sentiment expressions and their sentiment polarities from the results of the span module. Then we obtain the holder candidate pool and the target candidate pool by span pruning. For each sentiment expression, we determine whether it has a relation with each holder candidate and target candidate. Finally, the opinion quadruplets are produced based on the result of the relation classification. In addition, for discontinuous sentiment expressions, sentiment expressions are merged according to the relation between sentiment expressions.

Model	**MPQA**	**DS$_{\text{Unis}}$**	**OpenNER$_{\text{EN}}$**	**OpenNER$_{\text{ES}}$**	**NoReC$_{\text{Fine}}$**	**MultiB$_{\text{EU}}$**	**MultiB$_{\text{CA}}$**
head first	17.40	25.00	-	-	29.50	56.80	54.70
head final	18.80	26.50	-	-	**31.20**	53.70	54.70
Span-Relation	**35.00**(9)	**44.90**(4)	**70.30**(8)	**64.20**(10)	21.30(21)	**63.90**(10)	**63.50**(12)

Table 3: Results on the test dataset (Sentiment Graph F_1, %).

4 Experiments

The monolingual track (Barnes et al., 2022) provides 7 structured sentiment datasets in five languages. Their statistics are listed on Table 2.

It is worth noting that there are discontinuous spans in the NoReC$_{\text{Fine}}$ and DS$_{\text{Unis}}$ datasets. For example, in "*It looks again like UMUC will do anything for money*", "*looks again*" and "*do anything*" are annotated as the same sentiment expression.

4.1 Experiment Settings

We use BERT or RoBERTa as the text encoders. Since this task has datasets in different languages, different pre-training models are used for different language, which is detailed in Table 1.

We used Adam as our optimizer. The maximum number of epochs is set to 15, z is set to 0.3, and k_{min} is set to 5. We train our model on the training set and keep the model that performs best on the validation set. We evaluate our model on Sentiment Graph F_1 (Barnes et al., 2021) and compare our model with sentiment graph approaches (Head-first/Head-final) (Barnes et al., 2021).

4.2 Main Results

The comparison results of opinion quadruple extraction are listed in Table 3. According to these results, our approach achieves better performance on most datasets than baselines, especially on MPQA exceeding baseline by 16.2%. This demonstrates the effectiveness of our approach for opinion quadruple extraction.

4.3 Ablation Study

Model	**MPQA**	**DS$_{\text{Unis}}$**	**OpenNER$_{\text{EN}}$**
Full Model	40.67	40.04	72.38
w/o f_{width}	37.50	37.40	71.14
w/o $f_{distance}$	38.83	36.42	71.46
w/o $f_{context}$	37.54	39.47	69.39

Table 4: Ablation results on the dev dataset.

We conduct an ablation study to examine the impact of some components in the proposed model and list the results in Table 4. It can be observed that the removal of width embedding, position embedding, and context all degrade the performance, indicating their necessity.

Model	**OpenNER$_{\text{ES}}$**	**NoReC$_{\text{Fine}}$**	**MultiB$_{\text{EU}}$**	**MultiB$_{\text{CA}}$**
	62.40	23.26	61.53	54.26
w mBERT	61.62	36.22	57.17	63.35

Table 5: Effect of mBERT representations.

In addition, we also compare the performance of the multilingual pre-trained model mBERT(bert-base-multilingual-cased)(Devlin et al., 2019) for this task. To this end, we compare the experimental performance of monolingual pre-trained models with mBERT on minor language datasets and list the results in Table 5. It can be observed that mBERT achieves similar performance to the monolingual pre-trained model for most minor languages. In addition, for the Norwegian and Catalan datasets, the performance of the models with mBERT improves considerably, which may be due to the lack of corpus in these two languages when training the monolingual pre-trained models.

5 Conclusions

This paper describes our system for structured sentiment analysis. We formalize the task as a span-relation extraction problem and propose a two-stage extraction approach, which consists of a span module and a relation module. Experimental results demonstrate the effectiveness of our approach.

Amazon.com, Inc.
Seattle, WA, USA
{malmasi,njfn,besnikf,sudipkar,olegro}@amazon.com

Abstract

We present the findings of SemEval-2022 Task 11 on Multilingual Complex Named Entity Recognition MULTICONER.[1] Divided into 13 tracks, the task focused on methods to identify complex named entities (like media titles, products, and groups) in 11 languages in both monolingual and multi-lingual scenarios. Eleven tracks were for building monolingual NER models for individual languages, one track focused on multilingual models able to work on all languages, and the last track featured code-mixed texts within any of these languages. The task used the MULTICONER dataset, composed of 2.3 million instances in Bangla, Chinese, Dutch, English, Farsi, German, Hindi, Korean, Russian, Spanish, and Turkish. Results showed that methods fusing external knowledge into transformer models achieved the best performance. The largest gains were on the Creative Work and Group entity classes, which are still challenging even with external knowledge. MULTICONER was one of the most popular tasks in SemEval-2022 and it attracted 377 participants during the practice phase. The final test phase had 236 participants, and 55 teams submitted their systems.

1 Introduction

Processing complex and ambiguous Named Entities (NEs) is a challenging NLP task in practical and open-domain settings but has not received sufficient attention from the research community. Complex NEs, like the titles of creative works (movie/book/song/software names) are not simple nouns and are harder to recognize (Ashwini and Choi, 2014). They can take the form of any linguistic constituent, like an imperative clause ("Dial M for Murder"), and do not look like traditional NEs (Person names, locations, organizations). This ambiguity makes it challenging to recognize them based on their context. Such titles can also be semantically ambiguous, e.g. "On the Beach" can be a preposition or refer to a movie.[2] Finally, such entities usually grow at a faster rate than traditional categories, and emerging entities pose yet another challenge.

Neural models (e.g. Transformers) have produced high scores on benchmark datasets like CoNLL03/OntoNotes (Devlin et al., 2018). However, as noted by Augenstein et al. (2017), these scores are driven by the use of well-formed news text, the presence of "easy" entities (e.g. person names), and memorization due to entity overlap between train/test sets; these models perform significantly worse on complex/unseen entities (Meng et al., 2021; Fetahu et al., 2021). Researchers using NER on downstream tasks have also noted that a significant proportion of their errors are due to NER systems failing to recognize complex entities (Luken et al., 2018; Hanselowski et al., 2018). Examples of such challenges are highlighted in Table 1.

For this task, we created the MULTICONER dataset (Malmasi et al., 2022) to address the aforementioned challenges. MULTICONER provides data from three domains (Wikipedia sentences, questions, and search queries) across 11 different languages, which are used to define 11 monolingual subsets of the shared task. Additionally, the dataset has multilingual and code-mixed subsets.

We received 1,884 submissions from 55 teams during the test phase and 34 system description papers were submitted. Results showed that usage of external data and ensemble strategies played a crucial role in the strong performance on in-domain data and also contributed to domain adaptation. External knowledge brought large improvements on classes containing names of creative works and groups, allowing these systems to achieve the best overall performance.

Challenge	Description
Complex Entities Relevant to all domains	Not all entities are proper names: some types (e.g. creative works) can be linguistically complex. They can be complex noun phrases (`Eternal Sunshine of the Spotless Mind`), gerunds (`Saving Private Ryan`), infinitives (`To Kill a Mockingbird`), or full clauses (`Mr.Smith Goes to Washington`). Syntactic parsing of such nouns is hard, and most current parsers/NER systems fail to recognize them. The top system from WNUT 2017 achieved 8% recall for creative work entities (Aguilar et al., 2017). Effective evaluation requires corpora with many such entities.
Ambiguous Entities and Contexts Particularly for voice and search domains	Some NEs are ambiguous: they are not always entities, e.g. "`Inside Out`", "`Among Us`", and "`Bonanza`" may refer to NEs (a movie, video game, and TV show) in some contexts, but not in others. Such NEs often resemble regular syntactic constituents. News texts have long sentences discussing many entities, but other use cases (search queries, questions) have shorter inputs. Data with minimal context is needed to assess performance of such use cases. Capitalization/punctuation features are large drivers of success in NER (Mayhew et al., 2019), but short inputs (ASR, queries) often lack such surface features. An uncased evaluation is needed to assess model performance.
Emerging Entities For domains with growing entities	All entity types are open classes (new ones are added), but some groups have a faster growth rate, e.g. new books/songs/movies are released weekly resulting in a long-tail distribution. Assessing true generalization requires test sets with many unseen entities, to mimic an open-world setting.

Table 1: Challenges not tackled by current work/datasets, but addressed by the MULTICONER task and data.

2 MultiCoNER Dataset

The MULTICONER dataset was designed to address the NER challenges described in §1. It represents three domains (wiki sentences, questions, and search queries) and includes 11 languages, plus multilingual and code-mixed subsets. For a detailed description of the MultiCoNER dataset, we refer the reader to the dataset paper (Malmasi et al., 2022). The dataset is publicly available.[3]

2.1 NER Taxonomy

MULTICONER leverages the WNUT 2017 (Derczynski et al., 2017a) taxonomy entity types, which defines the following NER tag-set with six classes:

1. PER: Names of people
2. LOC: Location or physical facilities
3. CORP: Corporations and businesses
4. GRP: All other groups
5. PROD: Consumer products
6. CW: Titles of creative works like movie, song, and book titles

This taxonomy allows us to capture a wide array of entities, including those with more complex entity structures, such as creative works.

2.2 Languages and Subsets

Eleven languages are included in MULTICONER:

1. Bangla (`BN`)
2. Chinese (`ZH`)
3. Dutch (`NL`)
4. English (`EN`)
5. Farsi (`FA`)
6. German (`DE`)
7. Hindi (`HI`)
8. Korean (`KO`)
9. Russian (`RU`)
10. Spanish (`ES`)
11. Turkish (`TR`)

[3]`https://registry.opendata.aws/multiconer`

These languages were chosen to include a diverse typology of languages and writing systems, and range from well-resourced (`EN`) to low-resourced ones (`FA`).

MULTICONER contains 13 different subsets: 11 monolingual subsets for the above languages, a multilingual subset (denoted as `MULTI`), and a code-mixed one (`MIX`).

Monolingual Subsets Each of the 11 languages has its own subset, which includes data from all three domains.

Multilingual Subset This contains randomly sampled data from all the languages mixed into a single subset. This subset is designed for evaluating multilingual models, and should ideally be used under the assumption that the language for each sentence is unknown.

Code-mixed Subset This subset contains code-mixed instances, where the entity is from one language and the rest of the text is written in another language. Like the multilingual subset, this subset should also be used under the assumption that the languages present in an instance are unknown.

Class	Split	EN	DE	ES	RU	NL	KO	FA	ZH	HI	TR	BN	MULTI	MIX
PER	Train	5,397	5,288	4,706	3,683	4,408	4,536	4,270	2,225	2,418	4,414	2,606	43,951	296
	Dev	290	296	247	192	212	267	201	129	133	231	144	2,342	96

Table 2: MultiCoNER dataset statistics for the different languages for the Train/Dev/Test splits. For each NER class we show the total number of entity instances per class on the different data splits. The bottom three rows show the total number of sentences for each language.

2.3 Dataset Creation

The MultiCoNER dataset consists of 11 languages, and three domains (encyclopedia sentences, questions from QA, and Web queries). A detailed overview of the MultiCoNER dataset is provided in the dataset paper (Malmasi et al., 2022).

Lowner: represents the encyclopedic sentences extracted from the different localized versions of Wikipedia. We select low-context sentences and the *interlinked* entities are resolved to the *entity types* using Wikidata as a reference, according to the NER class taxonomy from (Derczynski et al., 2017b). Manual inspection of 400 sampled English sentences shows that the NER gold labels are 94% accurate.

Msq-Ner: from the MS-MARCO Q&A corpus (Bajaj et al., 2016) *question templates* are extracted by replacing the *entities* with their NER *type* (from the MultiCoNER NER taxonomy). Entities in a question are identified using spaCy.[4] The templates are translated from English into the rest of the languages.

Orcas-Ner: similar ot Msq-Ner, templates from Web user queries are extracted from the ORCAS dataset (Craswell et al., 2020). The templates are translated into the respective languages, and finally, multiple instances are constructed from each template by simply replacing the template slots with actual named entities in the target languages.

[4]https://spacy.io/

2.4 Dataset Statistics

Table 2 shows some statistics of the dataset. For all the tracks, we have released 15,300 training and 800 development instances. In the training splits, the absolute majority of instances are from the Wikipedia domain (i.e. Lowner), whereas a small number of 100 instances are domain-adaptation data, with 50 instances coming from the Web Questions (i.e. Msq-Ner) and Web Query (i.e. Orcas-Ner) domains, respectively.

The test splits on the other hand are much larger. This is done for mainly two reasons: (1) to be able to assess the generalizability of NER models on unseen and complex entities, and (2) to assess the cross-domain adaptation performance of NER models. For practical reasons, we cap the number of test instances to be at a maximum of 200k per subset, with the exception of the Code-Mixed and Multilingual subsets. The Multilingual test split was generated from the language-specific test splits and was downsampled to contain only 471k instances. On the other hand, for the Code-Mixed subset, we sample test sentences from the language-specific test split, and replace the original entity surface forms with the surface form of the entity in another language, picked at random.

More details on the dataset construction process are available in Malmasi et al. (2022).

3 Task Description and Evaluation

The shared task is composed of 11 monolingual and 2 multilingual tracks. The monolingual tracks invited participants to build monolingual models for 11 languages addressed by the shared task. The multilingual track invited multilingual models capable of identifying entities from monolingual texts from any of the 11 languages. The code-mixed track called for models to identify entities in mixed-language texts (any language pair from the 11 languages). That means the multilingual models for multilingual and code mixed tracks should be able to process texts from any language and show competitive performance for all the languages.

We used the macro-averaged F1 scores to evaluate and rank systems. Additionally, we report precision, recall, and per-domain performance.

4 Baseline System

We train and evaluate a baseline NER system using on XLM-RoBERTa (XLM-R) (Conneau et al., 2020), a multilingual Transformer model. The XLM-R model computes a representation for each token, which is then used to predict the token tag using a CRF classification layer (Sutton et al., 2012).

The XLM-R baseline is highly suited for multilingual application scenarios, such as our. It supports up to 100 languages and provides a solid baseline upon which the participants can build. The baseline was trained with a learning rate of $2e-5$ and a maximum number of 50 epochs, with an early stopping criterion of a non-decreasing validation loss for 5 epochs. The code and scripts for the baseline system were provided to the participants to use its functionalities and further extend it with their approaches.[5]

5 Participating Systems and Results

We have received submissions from 55 different teams. Among the monolingual tracks, we have observed the highest participation of 30 teams in the `English` track. Ordered by the number of participating teams, the other monolingual tracks are `Chinese` (21), `Bangla` (18), `Spanish` (18), `Hindi` (17), `Korean` (17), `German` (16), `Dutch` (15), `Farsi` (15), `Turkish` (15), and `Russian` (14). The number of participating teams for the Multilingual and Code-mixed tracks are 25 and 21, respectively. Table 3 shows the final rankings for all tracks. Detailed performance breakdown is available in Appendix A.

Most of the top-performing teams aimed at building their system targeting the multilingual track, and then retrained it for the other tracks separately and made submissions to all the 13 tracks. Therefore, in the rest of this section, we will first discuss the approaches by focusing on the multilingual track. Then, we will discuss teams that built their systems for one or more monolingual tracks. Finally, we will summarize the methods (e.g. language models, toolkits) and resources used.

5.1 Top Multilingual Systems

DAMO-NLP (Wang et al., 2022) ranked 1st in the multilingual (`MULTI`) track and all the monolingual tracks except `BN` (2nd) and `ZH` (4th). Given a text, they used a knowledge retrieval module to retrieve K most relevant paragraphs from a knowledge base (i.e. Wikipedia). Paragraphs were concatenated together with the input, and token representations were passed through a CRF to predict the labels. They employed multiple such XLM-RoBERTa models with random seeds and then used a voting strategy to make the final prediction.

USTC-NELSLIP (Chen et al., 2022a) ranked 1st in three tracks (`MIX`, `ZH`, `BN`), and 2nd for all the other tracks. The average performance gap between USTC-NELSLIP and DAMO-NLP is $\approx$3% for all the 13 tracks. USTC-NELSLIP aimed at fine-tuning a Gazetteer enhanced BiLSTM network in such a way that the representation produced for an entity has similarity with the representation produced by a pre-trained language model (LM). They developed a two-step process with two parallel networks, where a Gazetteer-BiLSTM uses a Gazetteer search to produce one-hot labels for each token in a given text and a BiLSTM produces a dense vector representation for each token. Another network uses a frozen XLM-RoBERTa to produce an embedding vector for each token. A KL divergence loss is applied to make the Gazetteer network's output similar to the LM. These two networks are jointly trained together again and their outputs are fused together for the final prediction.

QTrade AI (Gan et al., 2022) ranked 3rd in `MULTI`, 4th in `MIX`, and 8th in `ZH`. They used an XLM-RoBERTa encoder and applied sample mixing for data augmentation, along with adversarial training through data noising. For the multilingual

Table 3: Ranking for all of the tracks based on Macro F1. Full forms of the team names “B.E.P.” and “SPDB I.L.” are BaselineExtendinPokemons and SPDB Innovation Lab, respectively.

track, they leveraged an architecture with shared and per-language representations. Finally, they created an ensemble of models trained with different approaches.

SeqL (Hassan et al., 2022) ranked 4^{th} in MULTI 5^{th} in MIX. They train seven XLM-RoBERTa-large and Infoxlm-large models and then used an ensemble approach with voting and score fusion to predict the final labels. They found that the ensemble approach is slightly better than the best single model, and score fusion worked better than simple voting.

CMB AI Lab (PU et al., 2022) ranked 5^{th} in MULTI, 3^{rd} in MIX, 4^{th} in KO, and 6^{th} in ZH. They first utilized a biaffine layer to identify potential entity spans in a sentence, and the extracted spans are then processed with another classifier to obtain their class label. Finally, an ensemble is created by combining different pre-trained encoders and data augmentation techniques based on translations of the original training data. In terms of pre-trained LMs, they used XLM-RoBERTa and mT5.

5.2 Other Noteworthy Systems

RACAI (Pais, 2022) (3^{rd} in ES, NL, RU, KO, FA, DE, HI; 4^{th} in BN, TR; 5^{th} in EN; 7^{th} in MULTI, MIX; 16^{th} in ZH) used XLM-RoBERTa as pre-trained LM and a lateral inhibition layer inspired by the biological mechanism of lateral inhibition. They achieved strong performance in most of the tracks without using any external data.

Sliced (Plank, 2022) (4^{th} in NL, RU, FA, DE, HI; 5^{th} in KO, TR; 6^{th} in ES; 7^{th} in BN; 8^{th} in EN; 9^{th} in MULTI; 12^{th} in ZH; 15^{th} in MIX) used the MaChAmp toolkit (van der Goot et al., 2021) that enables easy exchange of pre-trained LMs for fine-tuning as well as multi-task learning. Within this framework, they have experimented with four different pre-trained LMs and found that XLM-RoBERTa is more efficient for training their system and provides stronger performance.

MaChAmp (van der Goot, 2022) (5^{th} in DE, ES, NL; 6^{th} in RU, TR; 9^{th} in EN; 10^{th} in FA, BN, HI; 11^{th} in KO; 14^{th} in ZH, MIX; 18^{th} in MULTI) first trained a multi-task model on 7 SemEval tasks and then fine-tuned for each task individually. They report that such a multi-tasking and fine-tuning approach is beneficial for a subset of the tasks.

OPDAI (Chen et al., 2022b) (3^{rd} in ZH; 9^{th} in HI; 10^{th} in MIX; 12^{th} in MULTI) used a hybrid technique with multiple stages involving model ensemble using neural model, soft templates, and Wikipedia lexicons. Their strong performance in ZH is powered by RoBERTa-wwm (Cui et al., 2021) pre-trained on Chinese data and Chinese word embeddings (Song et al., 2018).

CASIA (Fu et al., 2022) only participated in ZH and ranked 2^{nd}. They built a hybrid system based on RoBERTa-wwm and used three training mechanisms (adversarial training, child-Tuning training, and continued pre-training). Additionally, they performed a series of data augmentation steps.

PAI (Ma et al., 2022) (3^{rd} in EN) used string matching to retrieve entities with types from the LUKE entity dictionary (Yamada et al., 2020) for a given text. Then they concatenated the entity information with the input text and fed it to a pre-trained BERT model to build the NER system.

SU-NLP (Çarık et al., 2022) only participated in TR and ranked 3^{rd}. Given an input text, they query an information retrieval (IR) system that indexes Wikipedia articles. Retrieved documents are used as context and a Turkish BERT variant (BERTurk) is used to encode the context and candidate mentions, with classifier heads for NER.

Infrrd.ai (He et al., 2022) participated in nine tracks (EN, ES, NL, KO, DE, ZH, HI, BN, MULTI) and their best rank is 4^{th} for ES. They trained a multilingual model with an XLM-RoBERTa base encoder, whose embeddings were passed into a BiLSTM encoder, which finally passed the encoded tokens to a CRF layer for classification. They also used an ensemble strategy with majority voting.

UM6P-CS (Mekki et al., 2022) ranked 6^{th} in MULTI and 8^{th} in MIX. They introduced several self-training and auxiliary tasks that aim to improve NER classification performance on top of XLM-RoBERTa. The auxiliary task of span classification focused on addressing the mention detection performance of the model, which essentially ensures that the model has good coverage of all named entities, regardless of their type. In terms of self-training, the authors predicted weak labels on the unlabelled test set and concatenated both datasets into one. The impact of self-training seems to have a significant impact with 3% improvement in terms of Precision, and 2.24% in terms of F1 score.

Multilinguals (Pandey et al., 2022a,b) participated in EN, ES, and ZH and best rank is 10^{th} in ZH. They applied a BERT encoder with different classification heads: a linear layer, a CRF layer, and a BiLSTM-CRF. BERT and linear approach worked best for EN. For ES and ZH, they pre-trained BERT using the Whole Word Masking (WWM) learning objective over Wikipedia data and the CRF classification head worked best for these tracks.

L3i (Boros et al., 2022) participated in all tracks and best rank is 7th in DE. They used Sentence-BERT (Reimers and Gurevych, 2019) to retrieve the most similar sentence from the training set and used it as context by adding it to the test text. Their model consists of a BERT encoder with a Transformer layer and a CRF head for classification.

MarSan (Tavan and Najafi, 2022) participated in all tracks and best rank is 9th in FA. They used T5 (monolingual and multilingual) to create feature vector for an input text. Then they performed a subtoken check step to mark the first subword as 1 and others as 0 (Subtoken check increased 4% F1). At the final stage, a Transformer layer is followed by a token prediction layer to perform NER.

TEAM-Atreides (Tasnim et al., 2022) only participated in BN and ranked 8th. They used an ensemble of mono-lingual ELECTRA-based models with majority voting. They also used data augmentation using translation and conducted experiments with non-contextual word embeddings.

UA-KO (Song and Bethard, 2022) ranked 8th in the KO track. They used GeoNames and the Encyclopedia of Korean Culture to incorporate entity names in the training set. Their model uses an ensemble approach with a soft-voting mechanism, combining the monolingual and multilingual models' predictions.

CSECU-DSG (Aziz et al., 2022) participated in all tracks and the best rank is 9th for ZH. The authors propose two approaches: (1) a BiLSTM-CRF that leverages stacked token embeddings from different sources, and (2) a Transformer-based encoder with a feed-forward classification head.

PA Ph&Tech (Lin et al., 2022) participated in ES, DE, and NL and best rank is 9th for NL. They used ensemble embedding from multiple transformers and reinforcement learning was also applied to maximize model accuracy. In an additional setting (Hou et al., 2022), they experimented with an ensemble approach, where they leveraged multiple transformers by assigning different weights in the transformer layers. Meanwhile, data augmentation is also applied to enlarge the training data.

Raccoons (Dogra et al., 2022) ranked 10th in the EN track. They focused on improving word representations for NER through a reinforcement trainer. This was done through a task model and controller that repeatedly interact to update the embeddings.

AaltoNLP (Pietiläinen and Ji, 2022) participated in five tracks (EN, DE, FA, BN, KO) and the best rank is 11th for FA. Their approach consists of an ensemble strategy where they train two encoders jointly, allowing the models to combine the scores from the different encoders via a linear layer. Different models used different random seeds.

LMN (Lai, 2022) ranked 12th in the EN track. They applied a transfer-based encoder with a feed-forward classification head with a CRF layer. Their best variant used the ALBERT-xxlarge model. They also experimented with entity linking with Wikipedia and augmenting data with entities of the same type.

UC3M-PUCPR (Schneider et al., 2022) participated in EN, ES, MIX, and their best rank is 12th for MIX. They have used an ensemble of language-specific pre-trained LMs with soft-voting to make the final predictions.

NamedEntityRangers (Miftahova et al., 2022) ranked 16th in the MULTI track. They used RemBERT and mT5 to experiment with two approaches, where the first approach is the classical token classification method and the second method uses a template-free paradigm in which an encoder-decoder model translates the input sequence of words to a special output, encoding named entities with the predefined label.

CMNEROne (Dowlagar and Mamidi, 2022) ranked 16th in MIX. Their approach involves fine-tuning multilingual BERT on code-mixed data. To learn language-agnostic features, they pre-trained the model for a downstream task of language identification using the multilingual dataset.

KDDIE (Martin et al., 2022) only participated in the EN track and ranked 16th. They experimented by fine-tuning BERT and DeBERTa-based models and their best system is a fine-tuned DeBERTa-XLarge model.

DS4DH (Rouhizadeh and Teodoro, 2022) ranked 20th in the MULTI track. Their approach involves fine-tuning different pre-trained LMs (Multilingual-BERT, XLM-RoBERTa-base, XLM-RoBERTa-Large, Distilbert-Multilingual) with different classification heads like CRF and fully-connected layer.

NCUEE-NLP (Lee et al., 2022) ranked 7th in the ZH track. They used external data collected from MSRA, Weibo, People Daily, Boson,

Class	Baseline	DAMO-NLP	USTC-NELSLIP	QTrade AI
PER	63.88	92.07 (+28)	90.76 (+27)	87.20 (+23)
LOC	51.87	86.52 (+35)	86.81 (+35)	80.79 (+29)
CORP	49.61	84.55 (+35)	87.86 (+38)	77.23 (+28)
PROD	44.36	84.32 (+40)	81.05 (+37)	75.23 (+31)
GRP	39.28	79.90 (+41)	81.52 (+42)	71.66 (+32)
CW	37.68	84.49 (+47)	83.81 (+46)	73.85 (+36)

Table 4: F1 scores of the baseline and top three systems in the MULTI track for each class.

CLUNER, and LG, and trained a BiLSTM-CRF model with embeddings from a BERT model pre-trained on Chinese data.

DANGNT-SGU (Nguyen and Huynh, 2022) ranked 25th in the EN track by fine-tuning RoBERTa on the training data.

silpa_nlp (Singh et al., 2022) ranked 14th in HI and BN by fine-tuning XLM-R on the training set.

6 Insights from the Systems

6.1 Advancing the State of the Art

Identifying Complex Entities From the ranking in Table 3, we see that almost all the teams could outperform the official baseline system described in Section 4 in all the tracks. For most of the tracks, the top two teams DAMO-NLP and USTC-NELSLIP's performance gap is very small compared to third place. To btter understand this difference, we look at per-class performance. In Table 4, we show per-class F1 scores for the top three teams in the MULTI track. Although the systems performed better than the official baseline by a large margin, complex entities like creative works, products, and groups are still the most difficult ones to identify. This analysis shows that the largest gains by the top systems leveraging external knowledge came from classes containing complex NEs, e.g. CW and GRP.

Domain Adaptation The official baseline system performed poorly in terms of domain adaptation and achieved much lower F1 in MSQ-NER and ORCAS-NER compared to LOWNER. Intuitively, augmenting the training data with interrogative sentences could be a way to perform better in these domains. However, we observe that the participants could overcome the challenge of domain adaptation without especially including questions and queries

in their external data. For example, DAMO-NLP found that their approach of retrieving Wikipedia paragraphs not only provided a strong performance on LOWNER, but also helped with cross-domain transferability.

Adapting to MSQ was easier compared to ORCAS-NER for all the tracks except Bangla. The top systems like DAMO-NLP and USTC-NELSLIP struggled in MSQ-NER for Bangla, while they typically had higher F1 scores for MSQ-NER than ORCAS-NER for the other tracks. This could be an interesting direction to explore in the future.

6.2 Other Insights

External Data In Section 5 we observe that such superior performance by these top systems became possible by exploiting external knowledge during learning and inference. While USTC-NELSLIP used knowledge from pre-trained language models to fine-tune Gazetteer presentations, DAMO-NLP directly used raw texts from Wikipedia to inject context and it gave them an advantage over USTC-NELSLIP in most tracks.

As the availability of external data is higher for English compared to other languages, most of the teams participating in other languages used publicly available pre-trained models for other languages, or translated data from other languages. For example, CASIA augmented data from other languages with translation, and it helped them to secure second place in the Chinese track. In general, a large portion of the participating teams showed that they can do better if they can go beyond the provided training data, and use external data or pre-trained language models for different languages to inject external knowledge in some way.

Modeling Approaches Almost all participating systems relied on publicly available Transformer (Vaswani et al., 2017) based pre-trained language models (Table 5). XLM-RoBERTa (a.k.a. XLM-R) was the most popular choice for building multilingual models. Most of the teams participating in non-English monolingual tracks preferred this particular model to the multilingual variant of BERT.

Other recent language models like T5, ELECTRA, XLNet, and ALBERT were used by some of the teams, but mostly for English. We observed that for non-English languages, many teams used community-developed pre-trained models for other languages like Chinese, Hindi, Spanish, Korean, Bangla, Turkish, Russian, Farsi, Dutch, and German. Most of such models are trained using the BERT architecture with data for the respective languages. A lot of teams relied on the strength of Conditional Random Field (CRF; Lafferty et al. 2001) for sequence labeling problems and adopted it to gain stronger performance. Very few teams used architectures like LSTMs.

Teams that simply fine-tuned pre-trained language models performed similarly to the baseline system for most of the tracks. Apart from the previously mentioned role of external data, another vital component for strong performance is using ensemble learning strategies. Almost all the strong performing teams trained multiple models and ensembled them for making the final predictions. We have also observed some teams experimenting with adversarial training and reinforcement learning.

7 Conclusion

In this paper, we have presented an overview of the SemEval shared task on identifying complex entities in multiple languages. In this shared task, we have received system submissions from 55 competing teams, and 34 system description papers. On average, the wining systems for all the tracks outperformed the baseline system by a large margin of 35% F1.

Most of the top-performing teams in MULTICONER utilized external knowledge bases like Wikipedia and Gazetteer. They also tend to use XLM-RoBERTa as the pre-trained language model. In terms of modeling approaches, ensemble strategies helped the systems to achieve strong performance. Results from the top teams indicate that identifying complex entities like creative works is still difficult among all the classes even with the usage of external data.

Appendix

In this section, we provide the domain specific performance of the teams on each track. For each team, we report precision, recall, and F1 for the three domains, i.e., LOWNER, ORCAS, and MSQ. We also highlight the baseline system's performance breakdown for each track. Each track's result is presented in its individual table as listed here:

- Table 6 Bangla (BN)
- Table 7 German (DE)
- Table 8 English (EN)
- Table 9 Spanish (ES)
- Table 10 Farsi (FA)
- Table 11 Hindi (HI)
- Table 12 Korean (KO)
- Table 13 Dutch (NL)
- Table 14 Russian (RU)
- Table 15 Turkish (TR)
- Table 16 Chinese (ZH)
- Table 17 Code-Mixed (MIX)
- Table 18 Multi-lingual (MULTI)

A Detailed Results

LMN at SemEval-2022 Task 11: A Transformer-based System for English Named Entity Recognition

Ngoc Minh Lai
Van Ho Middle School
`nl834771@gmail.com`

Abstract

Processing complex and ambiguous named entities is a challenging research problem, but it has not received sufficient attention from the natural language processing community. In this short paper, we present our participation in the English track of SemEval-2022 Task 11: Multilingual Complex Named Entity Recognition. Inspired by the recent advances in pretrained Transformer language models, we propose a simple yet effective Transformer-based baseline for the task. Despite its simplicity, our proposed approach shows competitive results in the leaderboard as we ranked 12 over 30 teams. Our system achieved a macro F1 score of 72.50% on the held-out test set. We have also explored a data augmentation approach using entity linking. While the approach does not improve the final performance, we also discuss it in this paper.

1 Introduction

Recognizing complex named entities (NEs) is a challenging research problem, but it has not received sufficient attention from the natural language processing community (Meng et al., 2021a; Fetahu et al., 2021). Complex NEs can be complex noun phrases (e.g., *National Baseball Hall of Fame and Museum*), gerunds (e.g., *Saving Private Ryan*), infinitives (e.g., *To Build a Fire*), or even full clauses (e.g., *I Capture The Castle*). This ambiguity makes it difficult to recognize them based on their context (Aguilar et al., 2017; Luken et al., 2018; Hanselowski et al., 2018).

In this paper, we describe our participation in the English track of SemEval-2022 Task 11: Multilingual Complex Named Entity Recognition (Malmasi et al., 2022a,b). Inspired by the recent success of Transformer-based pre-trained language models in many NLP tasks (Devlin et al., 2019; Joshi et al., 2019; Lai et al., 2019; Joshi et al., 2020; Tran et al., 2020; Yu et al., 2020; Wen et al., 2021; Lai et al., 2021; Monaikul et al., 2021), we propose a simple but effective Transformer-based baseline for the task. Despite its simplicity, our proposed approach shows promising results: the official ranking indicated that our system achieved a macro F_1 score of 72.50% on the test set and ranked 12th out of 30 teams. We have also explored a data augmentation approach using entity linking. While the approach does not improve the final performance, we also discuss it in this paper.

In the following sections, we first describe the related work in Section 2 and the proposed method in Section 3. We then describe the experiments and their results in Section 4. Finally, Section 5 concludes this work and discusses potential future research directions.

2 Related Work

Many previous named entity recognition (NER) methods are based on the sequence labeling approach (Collobert et al., 2011; Ma and Hovy, 2016; Lample et al., 2016; Chiu and Nichols, 2016; Lee et al., 2019; Yang et al., 2018; Yang and Zhang, 2018; Lai et al., 2020a; Li et al., 2020). For example, Collobert et al. (2011) introduced a neural architecture that uses convolutional neural networks (CNNs) to encode tokens combined with a CRF layer for the classification. Many other studies used recurrent neural networks (RNNs) instead of CNNs to encode the input and a CRF for the prediction (Ma and Hovy, 2016; Lample et al., 2016). With the recent rise of pre-trained language models, recent NER models typically make use of context-dependent embeddings such as ELMo (Peters et al., 2018) or BERT (Devlin et al., 2019).

While neural-based models have achieved impressive results on popular benchmark datasets like CoNLL03 and OntoNotes (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003; Pradhan et al., 2012), these models typically do not perform well on complex/unseen entities (Augenstein et al., 2017). Complex named entities (e.g., titles

of creative works) are typically not simple nouns and are harder to recognize. The challenges of NER for recognizing complex entities and in low-context situations was recently outlined by Meng et al. (2021b). Other work has extended this to multilingual and code-mixed settings (Fetahu et al., 2021).

3 Method

3.1 Baseline model

Similar to many previous studies (Lample et al., 2016; Chiu and Nichols, 2016), we formulate the task as a sequence labeling problem. Given an input sequence consisting of n tokens $(x_1, ..., x_n)$, the goal is to predict a sequence of labels $(y_1, ..., y_n)$, where y_i is the label corresponding to token x_i. Table 1 describes the label set. We follow the BIO format: `B` denotes the beginning of a named entity, `I` denotes the continuation of a named entity, and `O` corresponds to tokens that are not part of any named entity.

Figure 1 shows a high-level overview of our Transformer-based model. Our model first forms a contextualized representation for each input token using a Transformer encoder (Devlin et al., 2019). Let $\mathbf{H} = (\mathbf{h}_1, ..., \mathbf{h}_n)$ be the output of the encoder where $\mathbf{h}_i \in \mathbb{R}^d$. After that, we can predict the final label y_i for each input token x_i:

$$\begin{aligned} \mathbf{y}_i &= \text{softmax}(\text{FFNN}_\theta(\mathbf{h}_i)) \\ y_i &= \arg\max_j \mathbf{y}_{ij} \end{aligned} \tag{1}$$

where FFNN_θ is a trainable feedforward network. $\mathbf{y}_i$ is the predicted probability distribution over the label set for the token x_i. The model is fine-tuned end-to-end via minimizing the typical cross-entropy loss.

Unlike many previous studies (Lample et al., 2016; Chiu and Nichols, 2016), our model does not have a CRF layer (Lafferty et al., 2001). A recent paper suggested that when using a pretrained Transformer language model for sequence labeling, adding a CRF layer may not improve the performance substantially (Chen et al., 2019).

3.2 Data Augmentation

To increase the size of the training set, we have also experimented with a simple data augmentation approach (Figure 2). For example, consider the sentence "*The main contractor was Ssangyong Engineering and Construction.*", which is an example in the training set of the English track of MultiCoNER. In this case, "*Ssangyong Engineering and Construction*" is a named mention referring to a Korean corporation. To create a new training example, we can replace the named mention with a different entity that is also a corporation.

More specifically, in this example, we first use an entity linker[1] to link the named mention to its corresponding entity in Wikidata, a large-scale knowledge graph. From the found Wikidata page, we

SSANGYONG Engineering & Construction Co., Ltd.
Replace the original named entity with an entity that is also an instance of business
New Example
The main contractor was Yazd Tire.

Figure 2: Our data augmentation approach.

can extract all types of information about the entity. We can utilize these types of information to find a new entity that is different but highly similar to the original entity. For simplicity, in this work, we simply try to find a new entity of the same Wikidata type as the original entity. At the end, we will have a new example (e.g., "*The main contractor was Yazd Tire.*").

4 Results

4.1 Data and Experimental Setup

The learning rate is set to be 2e-5, and the batch size is 32. We experimented with different numbers of training epochs, 10 and 20. We use Huggingface's Transformer library (Wolf et al., 2020) to experiment with various Transformer language models:

- **BERT**. Devlin et al. (2019) introduced a language representation model named BERT, which is pre-trained using two tasks: masked language modeling (MLM) and next sentence prediction (NSP). We used the large version of BERT (i.e., bert-large-uncased) in this work.

- **RoBERTa**. Liu et al. (2019) proposed an improved recipe for training BERT models. The modifications include: (1) training the model longer, with bigger batches, over more data; (2) removing the NSP objective; (3) training on longer sequences; and (4) dynamically changing the masking pattern applied to the training data. We used the large version of RoBERTa (i.e., roberta-large) in this work.

- **ALBERT**. Lan et al. (2020) introduced ALBERT, a BERT-based model with two parameter reduction techniques: factorized embedding parameterization and cross-layer parameter sharing. We used the xxlarge version of ALBERT (i.e., albert-xxlarge-v2) in this work.

4.2 Results on the Development Set

Table 3 shows the overall results on the development set of the English track of MultiCoNER. We see that ALBERT-xxlarge trained with 20 epochs outperforms all other baseline models on the development set. As such, we use this model to generate predictions for the test set. The model achieved a

Table 3: Overall results on the development set. Macro scores (%) are shown.

macro F1 score of 72.50% on the held-out test set. Note that the baseline models shown in Table 3 are trained using only the original training set (without any data augmentation).

4.3 Analysis of the Data Augmentation Approach

For each example in the training set, we used the data augmentation approach (Section 3.2) to generate a new example. Table 2 shows some of the newly generated examples.

We used all of the original and newly generated examples to train a new RoBERTa-large model (the number of epochs is 10). The model performs worst than the RoBERTa-large model trained with only the original examples. Nevertheless, we still believe the approach has a lot of potential, and we leave further exploration to future work.

5 Conclusion

In future work, we plan to conduct a thorough error analysis and apply visualization techniques to understand our models better (Murugesan et al., 2019). In addition, as pretrained Transformer models are typically computationally expensive and have many parameters, we are also interested in reducing the computational complexity of our baseline models using compression techniques (Sanh et al., 2019; Lai et al., 2020b; Sun et al., 2020).

Abstract

From pretrained contextual embedding to document-level embedding, the selection and construction of embedding have drawn more and more attention in the NER domain in recent research. This paper aims to discuss the performance of ensemble embeddings on complex NER tasks. Enlightened by Wang's methodology, we try to replicate the dominating power of ensemble models with reinforcement learning optimizor on plain NER tasks to complex ones. Based on the composition of semeval dataset, the performance of the applied model is tested on lower-context, QA, and search query scenarios together with its zero-shot learning ability. Results show that with abundant training data, the model can achieve similar performance on lower-context cases compared to plain NER cases, but can barely transfer the performance to other scenarios in the test phase.

1 Introduction

Named Entity Recognition (NER) as a typical topic in the NLP field, has displayed numerous outstanding outcomes in recent years, especially benefiting from development of pretrained models. However, there are still challenging aspects that remain to be tackled, such as short texts (low-context), emerging entities, and complex entities. In this task, corpus from low-context, QA and search query scenarios are collected to represent different complex NER tasks (Meng et al., 2021). Wang et al. (2021) proposed an automated concatenation model on plain NER tasks with benchmark dataset like CONLL03, which automatically generates optimized concatenation of stack embeddings with reinforcement learning strategies for structure prediction tasks like NER. A similar methodology is applied on the given dataset to test if the challenges mentioned above can be properly addressed.

2 Related Work

The development of sequence tagging models can be concluded mainly into two separate parts: encoder and decoder. Ever since the BiLSTM-CRF model (Ma and Hovy, 2016) was brought up, it has been widely used as the decoder end of NER models, while researchers shifted increasing attention to the structure of encoder. Various categories of embeddings have been raised, including character embeddings, non-contextual embedding like word2vec (Mikolov et al., 2013) and pretrained contextualized embeddings like ELMo (Peters et al., 2018) and Flair (Akbik et al., 2018). With the emergence of Transformers, the performance of large pretrained contextualized models (Devlin et al., 2019)have sweeped the leaderboard in lots of NLP tasks. In terms of language, Multilingual BERT(M-BERT) (Pires et al., 2019) demonstrates excellent representation of multilingual embeddings, which was later surpassed by XLM-R (Conneau et al., 2020), a more powerful and comprehensive multilingual model. To better allocate these embedding methods, many recent researchers have tried different methods like ensemble, weighting and concatenation. Automated concatenation (Wang et al., 2021) is a superior method that automatically generates optimized concentration of stack embeddings with reinforcement learning strategies. It uses result accuracy as reward for the controller to decide which embeddings to drop.

3 Data

As described by Fetahu et al. (2021), the dataset (Malmasi et al., 2022a) of this semeval task (Malmasi et al., 2022b) mainly consists of three sources: Low-Context Wikipedia, MS-MARCO Question (Bajaj et al., 2018) and ORCAS Search Query (Craswell et al., 2020). Sentences from Wikipedia are parsed and linked pages are resolved to their respective Wikidata entities, to create a corpus of 1.4

million low-context sentences with annotated entities. Part of them form the train and dev dataset. By templating questions in MS-MARCO QnA dataset and 10 million Bing user queries from the ORCAS dataset, and slotting with random entities based on frequency, 17, 868 questions and 471, 746 queries are generated to form the test set together with the rest of Low-context sentences.

Several data processing and augmenting is conducted before training to cater for the applied model. Since document-level embeddings have been proved to be effective for performance improvement in NLP tasks, we adopt Yamada et al. (2020)'s method and extract features by sending the adjacent sentences in corpus together as a document to pretrained models. The number of sentences that each document contains is defined by grid search and eventually set to 30. Although the adjacent sentences are not sentimental related as a document, the document level representation still enriches the context and greatly resolves the low-context situation.

Another novelty of the semeval dataset is the unbalance between train and test set, in terms of quantity and content. To solve the quantity unbalancing, we manage to augment the train set by slotting the entities in sentences and altering with another one from the same type. In case of overfitting, we eventually augment the train set to 3 times of its original size.

4 Methodology

After dealing with data, a common approach for better results is to fine-tune the transformer-based embeddings first, where sentences are sent to the model which is connected to a linear layer for tag prediction. Different language embeddings are selected for different tracks of the task. For English models, we fine-tune BERT-base, BERT-large, M-BERT, XLNET (Yang et al., 2019), Roberta (Liu et al., 2019), XLM-R separately and concatenate these embeddings with basic settings of other embeddings like ELMo, Flair and fastText (Bojanowski et al., 2017), for final training. For Dutch, Spanish and German models, we fine-tine M-BERT, XLM-R and BERT for each language respectively. The parameters for the fine-tuning process are 10 max epochs with batch size of 1 and learning rate of 5.0×10^{-06}.

The concatenated embeddings are used as inputs for a sequence tagging model with BiLSTM layers and CRF layer. The accuracy of the model is used as the reward for reinforcement learning to train the controller, which uses the policy gradient method to maximize the expected reward. We refer to Wang's search space algorithm for the design of reward function and gradient update. The parameters for the training process are 25 maximum episodes, 70 maximum epochs with batch size of 32 and learning rate of 5.0×10^{-06}.

	Dutch	Spanish	German
XLM-R+Fine-tune	0.8985	0.8502	0.8983
Final+Fine-tune	0.9030	0.8612	0.9106

Table 1: Dev Results

5 Results

Due to limitations in time and calculation resources, we only present the results on non-English language models. Table 1 shows the comparison between fine-tuning marco-F1 scores and final marco-F1 scores on dev set for each language in our experiment. It clearly shows that the automatic concatenation method is effective in improving the performance of fine-tuned embeddings. We can also find that XLM-R model plays a vital important role in the concatenated embeddings for non-English models.

Table 2 shows detailed final results on the test set for each language. All scores are calculated as F1 scores. As mentioned in the data section, apart from the performance on low-context NER tasks, the dataset also focuses on the zero-shot learning ability of models on QA and search query scenarios. It can be seen that with fine-tune and reinforcement learning training on low-context corpus, the model achieves high performance on the responsive part in test set, but fails to maintain the performance when making predictions on corpus from other sources.

6 Conclusion

We focus on the performance of automatic concatenated embedding model on semeval complex NER task, and draw the conclusion that with proper data processing methods, the model can learn excellent sequence tagging ability from low-context corpus and achieve outstanding performance on corresponsive part in test set, but cannot transfer such ability to QA and search query domains in test set. Meanwhile, document-level feature extraction and data augmenting by slotting and altering entities are

Abstract

This study introduces the system submitted to the SemEval 2022 Task 11: MultiCoNER (Multilingual Complex Named Entity Recognition) by the UC3M-PUCPR team. We proposed an ensemble of transformer-based models for entity recognition in cross-domain texts. Our deep learning method benefits from the transformer architecture, which adopts the attention mechanism to handle the long-range dependencies of the input text. Also, the ensemble approach for named entity recognition (NER) improved the results over baselines based on individual models on two of the three tracks we participated in. The ensemble model for the code-mixed task achieves an overall performance of 76.36% F1-score, a 2.85 percentage point increase upon our individually best model for this task, XLM-RoBERTa-large (73.51%), outperforming the baseline provided for the shared task by 18.26 points. Our preliminary results suggest that contextualized language models ensembles can, even if modestly, improve the results in extracting information from unstructured data.

1 Introduction

Named Entity Recognition (NER) is a Natural Language Processing (NLP) technique to extract relevant information from unstructured natural language data, identifying and categorizing entities in texts and thereby supporting other NLP tasks.

However, processing complex and ambiguous entities is a challenging task that has not received sufficient attention from the research community (Meng et al., 2021). These complex entities can be formed by any linguistic constituent (long noun phrases and sometimes complete sentences), as titles of creative works such as books and movies, different from traditional entities like person names and locations. As the creative work titles can be semantically ambiguous, the challenge is recognizing entities based mainly on their context.

The SemEval 2022 Task 11: MultiCoNER (Multilingual Complex Named Entity Recognition) (Malmasi et al., 2022b) targets the recognition of lowercase complex entities in multilingual and multi-domain texts, encouraging researchers to develop new approaches to extract diversified entity types. The challenge involves the use of human language modeling in the NER task, on cross-domain texts. The semantic structure has six types of entities: person, location, group, corporation, product and creative work. The dataset was provided for 11 languages, and, in addition, this task also provided multi-language and code-mixed [1] features, encouraging the development of more generic and adaptive systems.

As the contextualized pre-trained language models based on the transformer architecture have reached the state-of-the-art in several NLP tasks (Vaswani et al., 2017), in our method, we explore transformer-based models and combined the results into an ensemble, which can make better predictions and have a superior performance than any single contributing model (as demonstrated by Copara et al. (2020), Knafou et al. (2020) and Hernandez et al. (2021)). The models were fine-tuned to NER task on the English, Spanish and code-mixed datasets.

The paper is organised as follows: Section 2 provides a brief explanation of related works, Section 3 provides details about the data used for training our models, Section 4 describes the proposed method with implementation details, Section 5 presents our results with some discussions, and in Section 6 we present the conclusions obtained from the observed results.

2 Related Works

Context-dependent representations models, pre-trained on large-scale unstructured data, particu-

[1]With entities in a different language than the rest of the query, as explained in (Fetahu et al., 2021).

larly those supported by the transformer architecture (Vaswani et al., 2017), have been reached the state-of-the-art performance in NLP problems, including NER task.

These contextual word embedding models use the learned representations over the large data and, in a process called fine-tuning, have their last layers updated to adapt for a downstream task, using task-specific training data.

The Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) is a language representation model designed to pre-train deep bidirectional representations from unlabeled text conditioning on both left and right context in all layers. A Transformer is a encoder-decoder architecture, but in BERT-based models only the encoder is used, with the attention mechanism that learns contextual relationships between words in a text. The BERT-based models are pre-trained using two language generic tasks: masked language modeling (MLM) and next-sentence-prediction (NSP) tasks.

RoBERTa was built on BERT's language masking strategy, where the system learns to predict hidden sections of text within otherwise unannotated language examples. RoBERTa modifies key hyperparameters in BERT, as removing next-sentence pretraining objective. Also, it was trained with much larger mini-batches and learning rates, improving the masked language modeling objective and leading to better downstream task performance (Conneau et al., 2020).

DistilBERT learns a distilled version of BERT, maintaining almost all performance but using only half the number of parameters with a technique called distillation, which approximates the large neural network by a smaller one (Sanh et al., 2019). We also chose DistilBERT on our ensemble because, although it has 40% less parameters than BERT-base and runs 60% faster, can preserve over 95% of BERT's performances (Sanh et al., 2019).

XLM-RoBERTa is a transformer-based masked language model trained on one hundred languages, which outperformed multilingual BERT on a variety of cross-lingual benchmarks (Conneau et al., 2020).

Some researches have focused on the combination of transformer-based models into an ensemble, for NLP tasks. In the work of Copara et al. (2020), the ensemble of contextualized language models resulted in an effective approach for NER in chemical patent documents, outperforming individual transformer models. Knafou et al. (2020) achieved high results with ensemble approach for NER and their study indicates that the more models were used in the ensemble, the more the performances tend to be high and stable. The research of Hernandez et al. (2021) shows that the combination of three BERT-based models obtained superior results than the individual models, in the classification of texts from social media.

Motivated by the success of transformer-based models along with the ensemble approach, we trained several models and combined the results into an ensemble.

3 Data

This shared task encourages NLP researchers to develop complex NER systems for 11 languages, with semantically ambiguous and complex entities in short and low-context settings. Complex entities as creative works are really challenging as they are harder to recognize. An example of entities for English and Spanish can be seen in Figure 1.

According to the organizers (Malmasi et al., 2022a), 15,300 sentences were made available for training and 800 sentences for evaluation in the mono-lingual tracks. The training file has 15,000 sentences for code-mixed and the evaluation dataset has 500 sentences. Test files have varying sizes, with 219,652 sentences for English, 272,887 sentences for Spanish, and 100,000 for code-mixed tracks.

Data enrichment: To improve the performance of our models, we enriched our datasets with other NER annotated corpus containing similar entities. For English, we concatenated to the original MultiCoNER dataset the corpus CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003), emerging entities (Derczynski et al., 2017), and In Media Res (Braşoveanu et al., 2020). CoNLL-2003 is a NER dataset released in CoNLL-2003 shared task for

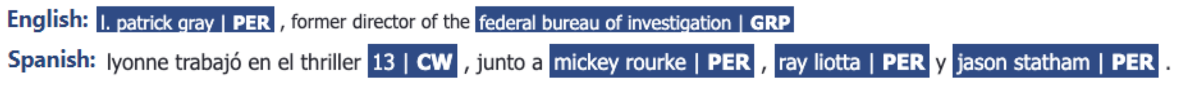

Figure 1: Example of data for English and Spanish (Malmasi et al., 2022a).

language-independent NER. We used the English data (Tjong Kim Sang and De Meulder, 2003), provided from Reuters Corpus containing entities of location, person, organization, and miscellaneous. We converted this data into MultiCoNER format, transforming organization into corporation. The emerging entities (Derczynski et al., 2017) is a corpus released by WNUT2017 Shared Task with focus on rare and emerging entity recognition from noisy user-generated data. This corpus contains the entities person, location, corporation, product, creative-work, and group, the same entity types we have on MultiCoNER. In Media Res is a corpus for evaluating named entity linking with creative works (Braşoveanu et al., 2020), annotated from Wikipedia articles with entities like person, organization, location, (creative) work, event and other. We converted it to MultiCoNER format, excluding events and others and converting work to creative work.

For Spanish, we enriched the dataset with CoNLL-2002 (Tjong Kim Sang, 2002) and Wikiner (Nothman et al., 2012). CoNLL-2002 contains entities of type persons, organizations, locations, times and quantities. We use the Spanish texts, converting organization to corporation, and eliminating entities we do not use. Wikiner (Nothman et al., 2012) is an annotated dataset of Wikipedia texts for 9 languages. It has entities of person, location, organization, and other (misc). We used the texts in Spanish, and we did the conversion from organization to corporation and an analysis of entities of type misc, where could be categorized as products, creative works and others (ignored). Because of this analysis of misc-type entities, we only processed 10% of the corpus.

All the datasets were converted to lowercase format, and concatenated to the original MultiCoNER train dataset.

4 System Description

Our method consists on an ensemble of transformer-based models, trained for NER task and joined by the soft voting method (Figure 2). From the 11 languages, we decided to participate in the English and Spanish tracks, since we already have some related research on them (Rivera and Martinez (2021) and Akhtyamova et al. (2020)), and also in the multilingual and code-mixed tracks to assess our strategy on multilingual texts.

In this section, we detail the development of NER models with its parameters and training setup, the ensemble method, and metrics used in this shared task.

4.1 NER models

We use the transformer-based pre-trained models as checkpoint for fine-tuning on the NER task, with the enriched MultiCoNER datasets. In the fine-tuning step, the existing models were specialized for NER task, where a fully connected layer was added on top of the hidden states of each token to classify tokens according to the named-entities classes. For each track we

Table 1: Pretrained models features.

participated, we performed the fine-tuning for NER on the pre-trained models. Table 1 shows all the models used in the ensembles and their number of parameters.

English track: The following pre-trained models, trained on a large corpus of English text, were fine-tuned on English train dataset: BERT-base-uncased (Devlin et al., 2019), BERT-large-uncased (Devlin et al., 2019), DistilBERT-base-uncased (Sanh et al., 2019), RoBERTa-base (Liu et al., 2019), RoBERTa-large (Liu et al., 2019), Electra-discriminator (Clark et al., 2020), in addition to the multilingual BERT-base-multilingual-uncased (Devlin et al., 2019) and XLM-RoBERTa-base (Conneau et al., 2020).

Spanish track: We fine-tuned on Spanish train dataset the following pre-trained models, trained on a large corpus of Spanish text: Beto uncased (Cañete et al., 2020), RoBERTa-base-bne (Gutiérrez-Fandiño et al., 2022), RoBERTa-large-bne (Gutiérrez-Fandiño et al., 2022), in addition to the multilingual BERT-base-multilingual-uncased (Devlin et al., 2019), XLM-RoBERTa-base (Conneau et al., 2020) and DistilBERT (Sanh et al., 2019).

For English and Spanish, we also pre-trained and fine-tuned a Megatron model (Shoeybi et al., 2019), however, it was not possible to incorporate it in the ensemble on time, and therefore it was separately evaluated as an unofficial result.

Multilingual and code-mixed track: We first fine-tuned models on the multilingual dataset provided by the shared task and then fine-tuned again on the code-mixed dataset, as the code-mixed training dataset is too small and training just with it could have lower performance. We fine-tuned these multilingual models[2]: BERT-base-multilingual-uncased (Devlin et al., 2019), XLM-RoBERTa (Conneau et al., 2020), and DistilBERT (Sanh et al., 2019). Due to time constraints, although we had trained models for the multilingual track, we could not run the predictions on the test dataset on time to submit to the multilingual track (since it was large files), so our results on multilingual track are unofficial.

All language models were fine-tuned on the training dataset explained in the previous section. We fine-tuned for 10 epochs, with a sequence length of a maximum of 128 tokens, a learning rate of 4e-5, warmup proportion of 0.06, and Adam optimizer for the deep learning training. We used the Pytorch implementation of Hugging Face library (Wolf et al., 2020).

Evaluation metrics: The metric returned by the shared task submission system is F1 macro average performance. For a better analysis and discussion, the performance is also examined per class label.

4.2 Ensemble method

Our ensemble method is based on a soft voting strategy (Schwenker, 2013), where each model returns its predicted probabilities and the class label is obtained by an argmax of the sum of all probabilities (in contrast to hard voting, where the system uses predicted class labels for majority rule voting).

In other words, for a given document, all models infer their predictions independently for each entity and return the probabilities of each label, i.e., their logits[3]. For each token, we sum the logits of all models of the ensemble for this given token and

[2]Which attends all languages of the multilingual and code-mixed tracks.

[3]Logits are the model outputs before application of an activation function (e.g. softmax).

then apply an argmax function, to assign a label to this passage.

The final label output for a token *n* is given by:

$$y_n(x_n) = argmax(\sum_{i=1}^{T} w_i h_i(x_n)) \qquad (1)$$

where *T* is the number of models participating in the ensemble, $\mathrm{w_i}$ is the weight of a model *i*, and $\mathrm{h_i(x_n)}$ is a list with the probabilities for all classes of the model *i* for the token *n*.

For each track, we performed three ensemble experiments.

Experiment 1: As explained above, the token label is an argmax of the sum of predicted probabilities of all models. In this experiment, all models have the same weight (w).

Experiment 2: Each model receives a score ranging from 0.1 to 1, which indicates its efficiency in the evaluation dataset (best overall F1-score). To identify the label of each token, we sum the output of all models, i.e., the probabilities of the token belonging to each class, in a weighted way. In other words, the predicted class probabilities for each classifier are multiplied by the classifier weight, summed across all models, and averaged. Thus, the final class label is then derived from the higher average probability (argmax).

Experiment 3: As in experiment 2, we also calculate weights for each model according to its effectiveness in the evaluation set, but on this experiment, we also calculate weights for each class as well (entity type). The model that performed better for that specific class has the highest weight, also values between 0.1 and 1.

5 Results and Discussion

Official results: The share-task proceedings reports the results (macro F1-score) by the participating systems in the SemEval 2022 Task 11 (Malmasi et al., 2022b), where our results are shown as UC3M-PUCPR team. These results, as well as the analysis performed in the discussion section, are exclusively computed on the test set. Our results refer to experiment 2 (where we used weights for each model), which performed better for all tracks. For the English track, our approach was ranked in 21th place from 30 participants, with a F-Score of 69.24, outperforming the baseline provided for

Named entity	English	Spanish	(*) Multilingual	Code-mixed
Location	0.6821	0.5807	0.7312	0.7925
Person	0.8470	0.7522	0.8017	0.8631
Product	0.6695	0.5102	0.6266	0.7692
Group	0.6953	0.5287	0.5945	0.7051
Creative work	0.6171	0.4350	0.6020	0.6937
Corporation	0.6437	0.6003	0.6741	0.7570
All	0.6924	0.5679	0.6641	0.7636

Table 2: Our F1 results for each class. (*) Multilingual results are unofficial.

the shared task by 8.04 points. On the other hand, for the Spanish track, our system had a significant drop, ranking in the last position (18th from 18 teams), with a F1-Score of 56.79, i.e., 33.15 points behind first place and 0.6 points behind baseline. Our Megatron-trained model performed better than the ensemble in this track, with 60.45 of F1 (unofficial result). In the code-mixed track, our approach ranked in 12th place from 22 participants, with an F1-Score of 76.36, outperforming the baseline by 18.26. For the multilingual track, we achieved 66.41 of F1, 12.31 points higher than baseline, but this result are not official since it was obtained after the competition deadline. Table 2 shows the official F1-scores of our submissions separated by classes, which allows the performance analysis of each entity individually, for all tracks. In table 3, we can assess the performance of each model separately, per class, for English track.

Discussion: The ensemble method modestly improved the F1 performance in relation to the use of individual models for English (1.92 of ensemble improve in relation to the best individual model, BERT-large) and code-mixed (2.85 of ensemble improve in relation to the best individual model, XLM-RoBERTa-large). However, for Spanish track, no improvement was seen in the ensemble compared to Beto individually.

For English track, where we work with eight different pre-trained models, the ensemble model outperforms the other models for all classes, as can be seen in table 3, where the F1 seem relatively stable across all the pre-trained models.

To help understand the reason for the low results in Spanish, we present a confusion matrix, in figure 3. In this track, an analysis of the errors indicates that the model had difficulty recognizing the entities products, groups and creative works. By labeling them with "O" instead of the correct class, lowers the recall value for this entities.

When analyzing the performance of the entities

Language Models	Location	Person	Product	Group	Creative work	Corporation	F1
BERT-base	0.6703	0.8268	0.6283	0.6602	0.5777	0.6018	0.6608
BERT-large	0.6706	0.8309	0.6412	0.6766	0.5971	0.6228	0.6732
BERT-base-multilingual	0.6703	0.8268	0.6283	0.6602	0.5777	0.6018	0.6608
DistilBERT-base	0.6531	0.8189	0.5996	0.6445	0.5476	0.5869	0.6418

Ensemble	**0.6821**	**0.847**	**0.6695**	**0.6953**	**0.6171**	**0.6437**	**0.6924**

Table 3: F1-score by model on the English track test set. (*) Megatron model was not part of the ensemble.

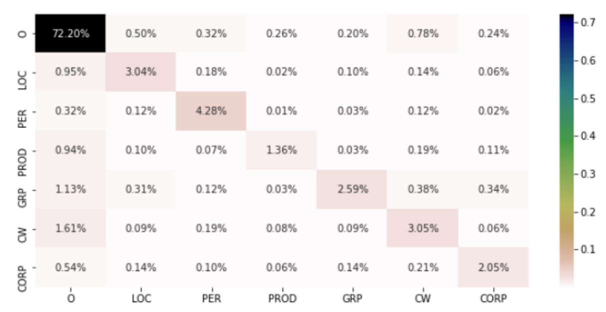

Figure 3: Confusion matrix on Spanish test data.

separately, we noticed that the creative work class had the worst F1 value for English, Spanish and code-mixed tracks, while the person class had the best performance. This is a sign that even in lower case, the trained models could still identify a person's name, i.e., they improved their ability to classify the token based on its context, which is a plus point for transformer-based contextualized models. The creative work entity was already expected to be the most challenging, since movie and book names are not simple noun phrases and are harder to recognize. As noted by Meng et al. (2021), the use of well-formed text with "easy" entities perform better than unseen entities or noisy text. Figure 4 shows how different models detected person and creative work entities, from English evaluation dataset, where we can see correct and incorrect detection in relation to creative work entity. Although some individual models incorrectly predicted the creative work entity, the ensemble achieved the correct answer.

Furthermore, we believe that the prediction of group, corporation, and product entities caused overlap between them because they can be semantically similar, which led to lower than expected results. The datasets we used to enrich the original MultiCoNER datasets do not have these entities so clearly.

For English and code-mixed tracks, we noticed that the large models performed better than the base models, which was already expected, agreeing with the results of previous research. For English, the best-isolated model was BERT-large-uncased, and for code-mixed, XLM-RoBERTa-large, both for evaluation and testing phases. On the other hand, on Spanish track, the uncased version of Beto model performed better than the new RoBERTa models generated from more than 201 million documents (570 Gb) from the Spanish National Library.

Despite improving performance, only the ensemble strategy may not be enough to have competitive results, when analyzing the results of the other teams, especially for the Spanish task, which had poor results.

The enrichment of the train databases may have helped for some entities, but it was not enough to significantly improve performance either, since our best results were precisely in code-mixed track, in which we did not use this technique. The entity types between the external databases may have minor semantic differences, for example, there is a fine line between group and organization. Maybe a closely analyze and even manual re-annotation on these entities could have improved performance.

Also, given such a large amount of test data (files with more than 200,000 sentences), the use of ensemble with transformer-based models may not be the most suitable for processing on regular computers, without much processing GPU power, due to the need to process this large amount of data with several models. In addition to the prediction process, the weighted sum of probabilities also consumes much memory. Our team could not process the test files for the multilingual track before the deadline, and we could not process the Megatron model on time to put into the ensembles (which could improve the results).

We realize that complex entities still represent a great challenge to the NLP community. In addition, lowercase texts, sentences without punc-

tuation or grammatically incomplete, in a cross-domain dataset without any standardization of sentence length, make it even more challenging to extract information from unstructured data, as was the case in this task.

6 Conclusions

We presented our method for recognizing complex entities, which consists in a transformer-based models ensemble. Although our team's results are not among the first, the ensemble method worked for both English and code-mixed tracks, in which we obtained an improvement in the F1 value compared to individual transformer models. Our method outperformed in macro F1 the baseline provided by the organizers in 8.04 points on English track, 18.26 on code-mixed track and 12.31 on multilingual track (unofficial).

As our method is based only on machine learning, without fixed rules, this indicates that the transformer models were able to take advantage of natural language contexts to capture the most relevant features, on lowercase cross-domain texts.

Since extraction of complex entities represents a challenge and these entities are increasingly present, we would like to continue improving our method. Future work intends to train models using a different split (hold out) of the data, training models with more data and for more epochs. Also, since creative works had the worst performance on the three tracks, a hybrid approach that includes a dictionary with creative works can contribute to better results. Furthermore, an analysis of which models should participate in the ensemble can lead to better results and lower processing costs. For example, less robust models like DistilBERT that are faster and lighter, but do not improve performance, possibly do not contribute to the improvement of the results.

Despite having the lowest task evaluation score for the Spanish track, this method exhibited competitive performance at English and code-mixed tracks.

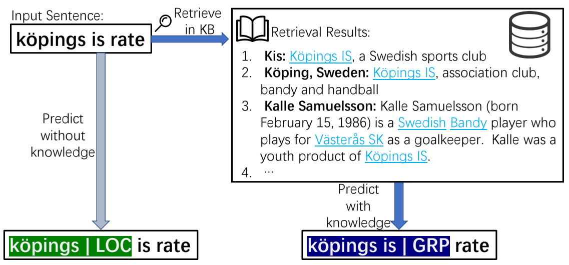
Abstract

The MultiCoNER shared task aims at detecting semantically ambiguous and complex named entities in short and low-context settings for multiple languages. The lack of contexts makes the recognition of ambiguous named entities challenging. To alleviate this issue, our team **DAMO-NLP** proposes a knowledge-based system, where we build a multilingual knowledge base based on Wikipedia to provide related context information to the named entity recognition (NER) model. Given an input sentence, our system effectively retrieves related contexts from the knowledge base. The original input sentences are then augmented with such context information, allowing significantly better contextualized token representations to be captured. Our system wins 10 out of 13 tracks in the MultiCoNER shared task.[1]

1 Introduction

The MultiCoNER shared task (Malmasi et al., 2022b) aims at building Named Entity Recognition (NER) systems for 11 languages, including English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. The task has three kinds of tracks including one multilingual track, 11 monolingual tracks and one code-mixed track. The multilingual track requires training multilingual NER models that are able to handle all languages. The monolingual tracks require training individual monolingual models where each model works for only one language. The code-mixed track requires handling code-mixed samples (sentences that may involve multiple languages). The datasets mainly contain sentences from three domains: Wikipedia, web questions and user queries, which are usually short and low-context sentences. Moreover, these short sentences usually contain semantically ambiguous and complex entities, which makes the problem more difficult. In practice, professional annotators usually use their domain knowledge to disambiguate such kinds of entities. They may retrieve the related documents from a knowledge base (KB) or from a search engine to better guide them the annotation of ambiguous named entities (Wang et al., 2019). Therefore, we believe retrieving related knowledge can help the NER model to disambiguate hard samples in the shared task as well. A motivating example is shown in Figure 1, which shows how the retrieval results could help to improve the prediction in practice.



Input Sentence:
köpings is rate
Retrieve in KB
Retrieval Results:
1. **Kis:** Köpings IS, a Swedish sports club
2. **Köping, Sweden:** Köpings IS, association club, bandy and handball
3. **Kalle Samuelsson:** Kalle Samuelsson (born February 15, 1986) is a Swedish Bandy player who plays for Västerås SK as a goalkeeper. Kalle was a youth product of Köpings IS.
4. ...
Predict without knowledge
Predict with knowledge
köpings | LOC is rate
köpings is | GRP rate

Figure 1: A motivating example from the English test set. In the retrieval results, the bold phrases are the title of the retrieved page and the underlined phrases contain the hyperlinks to other pages. LOC and GRP are entity labels representing location and group respectively.

In this paper, we propose a general knowledge-based system for the MultiCoNER shared task. We propose to retrieve the related documents of the input sentence so that the recognition of difficult entities can be significantly eased. Based on Wikipedia of the 11 languages, we build a multilingual KB to search for the related documents of the input sentence. We then feed the input sentence and the related documents into the NER model. Moreover, we propose an iterative retrieval approach to im-

[*]: project lead. [⋆]: equal contributions.
[1]Our code is publicly available at https://github.com/Alibaba-NLP/KB-NER.

prove the retrieval quality. During training, we propose multi-stage fine-tuning. We first train a multilingual model so that the NER model can learn from all annotations. Next, we train the monolingual models (one for each language) and a code-mixed model by using the fine-tuned XLM-RoBERTa (XLM-R) (Conneau et al., 2020) embeddings in the multilingual model as initialization to further boost model performance on monolingual and code-mixed tracks. For each track, we train multiple models with different random seeds and use majority voting to form the final predictions.

Besides the system description, we make the following observations based on our experiments:

1. Knowledge-based systems can significantly improve both in- and out-of-domain performance compared with system without knowledge inputs.
2. Our multi-stage fine-tuning approach can help improve model performance in all the monolingual and code-mixed tracks. The approach can also reduce the training time to speed up our system building at different stages.
3. Our iterative retrieval strategy can further improve the retrieval quality and result in significant improvement on the performance of code-mixed track.
4. Searching over Wikipedia KB performs better than using online search engines on the MultiCoNER datasets.
5. Comparing with other model variants we have tried, our NER model enjoys a good balance between model performance and speed.

2 Related Work

NER (Sundheim, 1995) is a fundamental task in natural language processing. The task has a lot of applications in various domains such as social media (Derczynski et al., 2017), news (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), E-commerce (Fetahu et al., 2021; Wang et al., 2021b), and medical domains (Doğan et al., 2014; Li et al., 2016). Recently, pretrained contextual embeddings such as BERT (Devlin et al., 2019), XLM-R and LUKE (Yamada et al., 2020) have significantly improved the NER performance. The embeddings are trained on large-scale unlabeled data such as Wikipedia, which can significantly improve the contextual representations of named entities. Recent efforts (Peters et al., 2018; Akbik et al., 2018; Straková et al., 2019) concatenate different kinds of pretrained embeddings to form stronger token representations. Moreover, the embeddings are trained over long documents, which allows the model to easily model long-range dependencies to disambiguate complex named entities in the sentence. Recently, a lot of work shows that utilizing the document-level contexts in the CoNLL NER datasets can significantly improve token representations and achieves state-of-the-art performance (Yu et al., 2020; Luoma and Pyysalo, 2020; Yamada et al., 2020; Wang et al., 2021a). However, the lack of context in the MultiCoNER datasets means the embeddings cannot take advantage of long-range dependencies for entity disambiguation. Recently, Wang et al. (2021b) use Google search to retrieve external contexts of the input sentence and successfully achieve state-of-the-art performance across multiple domains. We adopt this idea so that the embeddings can utilize the related knowledge by taking the advantage of long-range dependencies to form stronger token representations. Comparing with Wang et al. (2021b), we build the local KB based on Wikipedia because the KB matches the in-domain data of the shared task and is fast enough to meet the time requirement in the test phase[2].

Fine-tuning pretrained contextual embeddings is a useful and effective approach to many NLP tasks. Recently, some of the research efforts propose to further train the fine-tuned embeddings with specific training data or in a larger model architecture to improve model performance. Shi and Lee (2021) proposed two-stage fine-tuning, which first trains a general multilingual Enhanced Universal Dependency (Bouma et al., 2021) parser and then fine-tunes on each specific language separately. Wang et al. (2021a) proposed to train models through concatenating fine-tuned embeddings. We extend these ideas as multi-stage fine-tuning, which improves the accuracy of monolingual models that use fine-tuned multilingual embeddings as initialization in training. Moreover, multi-stage fine-tuning can accelerate the training process in system building.

3 Our System

We introduce how our knowledge-based NER system works in this section. Given a sentence of n tokens $\boldsymbol{x} = \{x_1, \cdots, x_n\}$, the sentence is fed into our knowledge retrieval module. The knowledge retrieval module takes the sentence as the query and retrieves top-k related paragraphs in KB.

[2]There are only 7 days for the test phase.

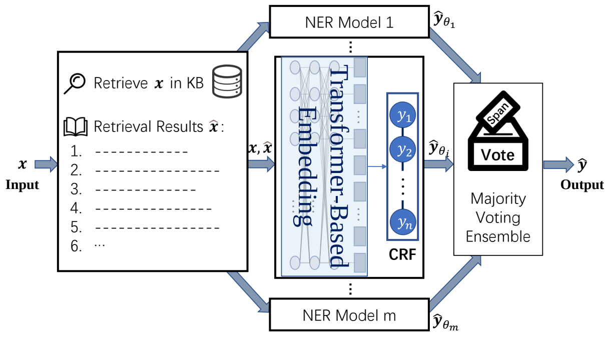


Figure 2: The architecture of our knowledge-based NER system.

The system then concatenates the input sentence and the related paragraphs together and feeds the concatenated sequence into the embeddings. The output token representations of the input sentence are fed into a linear-chain conditional random field (CRF) (Lafferty et al., 2001) layer and the CRF layer produces the label predictions. Given the label predictions of multiple NER models with different random seeds, the ensemble module uses a voting strategy to decide the final predictions $\hat{\boldsymbol{y}} = \{\hat{y}_1, \cdots, \hat{y}_n\}$ of the sentence. The architecture of our framework is shown in Figure 2.

3.1 Knowledge Retrieval Module

Retrieval-augmented context is effective for named entity recognition tasks (Wang et al., 2021b), as external relevant contexts can provide auxiliary information for disambiguating complex named entities. We construct multilingual KBs based on Wikipedia pages of the 11 languages, and then retrieve relevant documents by using the input sentence as a query. These retrieved documents act as contexts and are fed into the NER module. To enhance the retrieval quality, we further designed an iterative retrieval approach, which incorporates predicted entities of NER models into the search query.

Knowledge Base Building Wikipedia is an evolving source of knowledge that can facilitate many NLP tasks (Chen et al., 2017; Verlinden et al., 2021). Wikipedia provides a rich collection of mention hyperlinks (referred to as wiki anchors). For example, in the sentence "*Steve Jobs founded Apple*", entities "*Steve Jobs*" and "*Apple*" are linked to the wiki entries `Steve_Jobs` and `Apple_Inc` respectively. For the NER task, these anchors provide useful clues on where the entities are to the model. Based on Wikipedia we can build local Wikipedia search engines to retrieve the relevant context of the input sentences for each language.

We download the latest (2021-12-20) version of the Wikipedia dump from Wikimedia[3] and convert it to plain texts. Then we use ElasticSearch (ES)[4] to index them. ElasticSearch is document-oriented, and the document is the least searchable unit. We define the document in our local Wikipedia search engines with three fields: sentence, paragraph and title. We create inverted indexes on both the sentence field and the title field. The former is used as a sentence-level full-text retrieval field, while the latter indicates the core entity described by the wiki page and can be used as an entity-level retrieval field. The paragraph field stores the contexts of the sentence. To take advantage of the rich wiki anchors in Wikipedia paragraphs, we marked them with special markers. For example, to incorporate the hyperlinks [*Apple* $\rightarrow$ `Apple Inc`] and [*Steve Jobs* $\rightarrow$ `Steve Jobs`] to the paragraph, we transformed "*Steve Jobs founded Apple*" into "*<e:Steve Jobs>Steve Jobs</e> founded <e:Apple_inc>Apple</e>*"[5].

Sentence Retrieval Retrieval at the sentence level takes the input sentence as a query and retrieves the top-k documents on the sentence field. Given an input sentence, we select the corresponding search engine according to the language of the sentence.

Iterative Entity Retrieval The core of the NER task lies in the entities, while retrieval at the sentence level overlooks the key entities in the sentences. For this reason, we consider the relevance of the entities in the sentence to the title field in the documents during retrieval. We concatenate the entities in the sentences with "|" and then retrieve them on the title field. On the training and development sets, we utilize the ground-truth entities directly. On the test set, we first perform the sentence retrieval and then use the entity mentions[6] predicted by the model for entity retrieval. This bootstrapping manner can be applied for T turns.

Context Processing After top-k results from the KB are retrieved, the system post-processes the retrieved documents into the contexts of the input sentence. There are three options of utilizing

[3]https://dumps.wikimedia.org/
[4]https://www.elastic.co/
[5]<e:XXX>YYY</e>: where XXX is the title of the linked page and YYY is the phrase with hyperlink in the sentence.
[6]Here we define mentions as the named entities ignoring the entity types.

the texts in the documents, which are: 1) use the matched paragraph; 2) use the matched sentence; 3) use the matched sentence but remove the wiki anchors. We compare the performance of each option in section 5.4. In each retrieved document, we concatenate the title and texts together to form the context $\hat{\boldsymbol{x}}_i$. The results are then concatenated into $\{\hat{\boldsymbol{x}}_1, \cdots, \hat{\boldsymbol{x}}_k\}$ based on the retrieval ranking.

3.2 Named Entity Recognition Module

In our system, we use XLM-R large as the embedding for all the tracks. It is a multilingual model and is applicable to all tracks. Given the input sentence $\boldsymbol{x}$ and the retrieved contexts $\{\hat{\boldsymbol{x}}_1, \cdots, \hat{\boldsymbol{x}}_k\}$, we add the separator token (i.e., "</s>" in XLM-R) between them and concatenated them together to form the input $\tilde{\boldsymbol{x}}$ of the NER module. We chunk retrieved texts to avoid the amount of subtoken in the sequence exceeding the maximum subtoken length in XLM-R (i.e., 512 in XLM-R).

Our system regards the NER task as a sequence labeling problem. The embedding layer in the NER module encode the concatenated sequence $\tilde{\boldsymbol{x}}$ and output the corresponding token representations $\{\boldsymbol{v}_1, \cdots, \boldsymbol{v}_n, \cdots\}$. The module then feeds the token representations $\{\boldsymbol{v}_1, \cdots, \boldsymbol{v}_n\}$ of the input sentence into a linear-chain CRF layer to obtain the conditional probability $p_\theta(\boldsymbol{y}|\tilde{\boldsymbol{x}})$:

$$\psi(y', y, \boldsymbol{v}_i) = \exp(\mathbf{W}_y^T \boldsymbol{v}_i + \mathbf{b}_{y',y}) \quad (1)$$

$$p_\theta(\boldsymbol{y}|\tilde{\boldsymbol{x}}) = \frac{\prod_{i=1}^{n} \psi(y_{i-1}, y_i, \boldsymbol{v}_i)}{\sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x})} \prod_{i=1}^{n} \psi(y'_{i-1}, y'_i, \boldsymbol{v}_i)}$$

where θ represents the model parameters and $\mathcal{Y}(\boldsymbol{x})$ denotes the set of all possible label sequences given $\boldsymbol{x}$. In the potential function $\psi(y', y, \boldsymbol{v}_i)$, $\mathbf{W}_y^T \boldsymbol{v}_i$ is the emission score and $\mathbf{b}_{y',y}$ is the transition score, where $\mathbf{W}^T \in \mathbb{R}^{t \times d}$ and $\mathbf{b} \in \mathbb{R}^{t \times t}$ are parameters and the subscripts y' and y are the indices of the matrices. During training, the negative log-likelihood loss $\mathcal{L}_{\text{NLL}}(\theta) = -\log p_\theta(\boldsymbol{y}^*|\tilde{\boldsymbol{x}})$ for the concatenated input sequence with gold labels $\boldsymbol{y}^*$ is used. During inference, the model prediction $\hat{\boldsymbol{y}}_\theta$ is given by Viterbi decoding.

3.3 Ensemble Module

Given predictions $\{\hat{\boldsymbol{y}}_{\theta_1}, \cdots, \hat{\boldsymbol{y}}_{\theta_m}\}$ from m models with different random seeds, we use majority voting to generate the final prediction $\hat{\boldsymbol{y}}$. We convert the label sequences into entity spans to perform majority voting. Following Yamada et al. (2020), the module ranks all spans in the predictions by the number of votes in descending order and selects the spans with more than 50% votes into the final prediction. The spans with more votes are kept if the selected spans have overlaps and the longer spans are kept if the spans have the same votes.

4 Experimental Setup

4.1 Data and Evaluation Methodology

We use the official MultiCoNER dataset (Malmasi et al., 2022a) in all tracks to train our NER models. There are mainly three domains in the dataset: LOWNER (Low-Context Wikipedia NER) contains low-context sentences from Wikipedia; MSQ (MS-MARCO Question NER) is based on MS-MARCO web question corpus (Nguyen et al., 2016) containing a lot of natural language questions; ORCAS (Search Query NER) contains user queries from Microsoft Bing (Craswell et al., 2020). The MSQ and ORCAS samples are taken as out-of-domain data in the shared task. The training and development sets only contain a small collection of samples of these two domains and mainly contain data from the LOWNER domain. The test set, however, contains much more MSQ and ORCAS samples to assess the out-of-domain performance.

The results of the shared task are evaluated with the entity-level macro F1 scores, which treat all the labels equally. In comparison, most of the publicly available NER datasets (e.g., CoNLL 2002, 2003 datasets) are evaluated with the entity-level micro F1 scores, which emphasize common labels.

4.2 Training

NER Model Training Before building the final system, we compare a lot of variants of the system. We train these variant models on the training set for 3 times each with different random seeds and compare the averaged performance of the models. According to the dataset sizes, we train the models for 5 epochs, 10 epochs and 100 epochs for multilingual, monolingual and code-mixed models respectively. Our final NER models are trained on the combined dataset including both the training and development sets on each track to fully utilize the labeled data. For models trained on the training set, we use the best macro F1 on the development set during training to select the best model checkpoint. For models trained on the combined dataset,

Table 1: Part of the official results and the post-evaluation results of our baseline system.

we use the final model checkpoint after training[7].

Multi-stage Fine-tuning Besides our final settings, we have a lot of stages of KB settings during our system building. Multi-stage fine-tuning aims at transferring the parameters of fine-tuned embeddings in a model at an early stage into other models in the next stage. The approach stores the checkpoint of fine-tuned XLM-R embeddings at the early stage and uses it as the initialization of XLM-R embeddings for model training at the next stage. One benefit of multi-stage fine-tuning is the monolingual and code-mixed models, can utilized the annotations of all the tracks to further improve the model performance. XLM-R embedding is a multilingual embedding with strong cross-lingual transferability over all 11 languages. Therefore, we use the checkpoint of fine-tuned multilingual model for continue fine-tuning on the monolingual and code-mixed models. Another benefit of multi-stage fine-tuning is that it accelerates the training speed. As the size of the multilingual dataset is relatively large, it is quite time-consuming to train a multilingual model. When we try different types of KB, we can utilize the checkpoints of multilingual models at the previous stage to train the monolingual and code-mixed models with new types of contexts without training new multilingual models. Moreover, we can reduce the training epochs for faster speed since the XLM-R checkpoints have already learned from all the datasets.

Continue Pretraining To make XLM-R learn the data distribution of the shared task, we combine the training and development sets on the monolingual tracks to build a corpus to continue pretrain XLM-R. Specifically, we collocate all sentences according to their languages, then cut the text into chunks of fixed length, and train the model on these text chunks using the Masked Language Modeling objective. We continue pretrain XLM-R for 5 epochs. We use the continue pretrained XLM-R model as the initialization of the multilingual models during training.

[7]Please refer to Appendix A for detailed settings.

5 Results and Analysis

In this section, we use language codes[8] to represent languages, and use MULTI and MIX to represent multilingual and code-mixed tracks respectively[9].

5.1 Main Results

There are 55 teams that participated in the shared task. Due to limited space, we only compare our system with the systems from teams USTC-NELSLIP, RACAI and Sliced[10]. In the post-evaluation phase, we evaluate a baseline system without using the knowledge retrieval module to further show the effectiveness of our knowledge-based system. The official results and the results of our baseline system are shown in Table 1. Our system performs the best on 10 out of 13 tracks and is competitive on the other 3 tracks. Moreover, our system outperforms our baseline by 14.39 F1 on average, which shows the knowledge retrieval module is extremely helpful for disambiguating complex entities leading to significant improvement on model performance.

5.2 How Significant is the Role of Knowledge-based System on Each Domain?

To further show the effectiveness of our knowledge-based system, we show the relative improvements of our system over our baseline system on each domain in Table 2. We observe that in most of the cases, the two out-of-domain test sets have more relative improvements than the in-domain test set. This observation shows that the knowledge from Wikipedia can not only improve the performance of the LOWNER domain which is the same domain as the KB, but also has very strong cross-domain

transferability to other domains such as web questions and user queries. According to the baseline performance over the three domains, the ORCAS domain has the lowest score, which shows the challenges in recognizing named entities in user queries. However, our retrieved documents in KB can significantly ease the challenges in this domain and results in the highest improvement out of the three domains.

5.3 How Relevant Are the Retrieval Results to the Queries?

To evaluate the relevance of the retrieval results to the query, we define a character-level relevance metric, which calculates the Intersection-over-Union (IoU) between the characters of query and result. Assuming that the character sets[11] of query and retrieval result are A and B respectively, then the character-level IoU is $\frac{A \cap B}{A \cup B}$. We calculate the character-level IoU of the sentence and its top-1 retrieval result on all tracks, and plot its distribution on the training, development and test set in Figure 3. We have the following observations: 1) the IoU values are concentrated around 1.0 on the training and development sets of **EN**, **ES**, **NL**, **RU**, **TR**, **KO**, **FA**, which indicates that most of the samples were derived from Wikipedia. Therefore, by retrieving, we can obtain the original documents for these samples. 2) the distribution of data on the test set is consistent with the training and development sets for most languages, except for **TR**. On **TR**, the character-level IoU values of the samples and query results cluster at around 0.5. We hypothesize that this is because the source of the test set for **TR** is different from the training set. However, the model still performs strongly on this language, suggesting that the model can mitigate the difficulties caused by inconsistent data distribution by retrieving the context from Wikipedia.

[11]The sets take repeat characters as different characters.

5.4 How Important Can the Types of KB be?

We compare several types of KBs and contexts during our system building.

Online Search Engine In the early stage, we tried to use the knowledge retrieved from Google Search, which can retrieve related knowledge from a large scale of webs and is believed to be a strong multilingual search engine.

Three Context Types Retrieved from Wikipedia As we mentioned in Section 3.1, there are three context processing options, which are: 1) use the matched paragraph; 2) use the matched sentence; 3) use the matched sentence but remove the wiki anchors. We denote the three options as PARA, SENT and SENT$_{\text{-LINK}}$ respectively.

Entity Retrieval with Gold Entities We use gold entities on the development set to see whether the model performance can be improved. This can be seen as the most ideal scenario for iterative retrieval. We denote this process as ITER$_G$ and use PARA for the context type.

In Table 3, we can observe that: 1) For the three context options, PARA is the best option for **EN**, **ES**, **NL**, **RU**, **TR**, **KO**, **FA**, **MIX** and **MULTI**. SENT$_{\text{-LINK}}$ is the best option for **HI** and **BN**. For **DE** and **ZH**, SENT and SENT$_{\text{-LINK}}$ are competitive. As a result, we choose SENT for the two languages since we believe the wiki anchors from the Wikipedia can help model performance; 2) Comparing with the baseline, the knowledge from Google Search can improve model performance. Based on the best context option of each track, the knowledge from Wikipedia is better than the online search engine; 3) For ITER$_G$, we can find that the context can further

improve the performance over 8 out of 13 tracks. However, there are only significant improvements for **HI**, **BN** and **MIX**.

Iterative Entity Retrieval with Predicted Entities Based on the results in Table 3, we further analyze how the predicted entity mentions can improve the retrieval quality. We denote the iterative entity retrieval with predicted mentions as ITER$_P$. In the experiment, we set $T = 2$.[12] We extract the predicted mentions of the development sets from the models based on the best context option for each track. We conduct the experiments over **HI**, **BN** and **MIX** which have significant improvement with ITER$_G$. In Table 4, we also list the performance of ITER$_G$ for reference, which can be seen as using the predicted mentions with 100% accuracy. From the results, we observe that only **MIX** can be improved.

Since iterative entity retrieval uses predicted mentions as a part of retrieval query, the performance of mention detection directly affects the retrieval quality. To further analyze the observation in Table 4, we evaluate the mention F1 score of the NER models with sentence retrieval. For comparison with mention detection performance of NER models, we additionally train mention detection models by discarding the entity labels during training. From the results in Table 5, we suspect the low mention F1 introduces noises in the knowledge retrieval module for **BN** and **HI**, which lead to the decline of performance as shown in Table 4. Moreover, the mention F1 of mention detection models (second row of Table 5) only outperform that of the NER models (first row of Table 5) in a moderate scale. Therefore, we train the ITER models only for the code-mixed track and use the NER models with sentence retrieval to predict mentions.

[12]Our preliminary experiments show that there is no significant improvement for $T = 3$.

5.5 Model Efficiency

Table 6 shows the speed of each module in our system. In the table, we also show that the retrieval speed of our local KB is significantly faster than that of Google Search. The bottleneck of the system speed is the NER module rather than the knowledge retrieval module. The main reason for the slow speed of the NER module is that the input length of the knowledge-based system is significantly longer than the original input. Taking the EN test set as an example, there are on average 10 tokens for each input sentence in the original test set while there are 218 tokens for the input of our knowledge-based system. The longer inputs slow down the encoding at XLM-R embeddings.

5.6 Effect of Embedding Concatenation

We compare with some variants of our system that we designed but did not use in the test phase.

CE (Concatenation of Embeddings) CE is one of the usual approaches to NER, which concatenates different kinds of embeddings to improve the token representations. In the early stage of our system building, we compare CE with only using the XLM-R embeddings based on the knowledge retrieved from the Google Search. Results in Table 7 show that CE models are stronger than the models using XLM-R embeddings only in all the cases, which show the effectiveness of CE.

ACE (Automated Concatenation of Embeddings) ACE (Wang et al., 2021a) is an improved version of CE which automatically selects a better concatenation of the embeddings. We use the same embedding types as CE and the knowledge are from our Wikipedia KB. We experiment on EN, ES, NL, RU, TR, KO and FA, which are strong with PARA contexts. In Table 9, we further compare ACE with ensemble XLM-R models. Results show ACE can improve the model performance and even outperform the ensemble models[13].

The results in Table 7 and 9 show the advantage of the embedding concatenation. However, as we have shown in Section 5.5, the prediction speed is quite slow with the single XLM-R embeddings. The CE models further slow down the prediction speed since the models contain more embeddings. The ACE models usually have faster prediction speed than the CE models. However, training the ACE models is quite slow. It takes about four days to train a single ACE model. Moreover, the ACE models cannot use the development set to train the model since they use development score as the reward to select the embedding concatenations. Therefore, due to the time constraints, we did not use these two variants in our submission during the shared task period.

5.7 Effectiveness of Multi-stage Fine-tuning

In Table 8, we show the effectiveness of multi-stage fine-tuning on the development set for our baseline system. The result shows that multi-stage fine-tuning can significantly improve the model performance for all the tracks.

[13]Please refer to Appendix A.3 for detailed settings.

6 Conclusion

In this paper, we describe our knowledge-based system for the MultiCoNER shared task, which wins 10 out of 13 tracks in the shared task. We construct multilingual KBs and retrieve the related documents from KBs to enhance the token representations of input text. We show that the NER models can use the retrieved knowledge to facilitate complex entity prediction, significantly improving both the in-domain and out-of-domain performance. Multi-stage fine-tuning can help the monolingual models learn from the training data of all the languages and improve the model performance and training efficiency. We also show that the system presents a good balance between the model performance and prediction efficiency to meet the time requirement in the test phase. We believe this system can be widely applied to other domains for the task of NER. For future work, we plan to improve the retrieval quality and adopt the system to support other kinds of entity-related tasks.

A.2 System Configurations

For the knowledge retrieval module, we retrieve top-10 related results from the KB. For iterative entity retrieval, we set $T = 2$. In masked language model pretraining, we use a learning rate of 5×10^{-5}. For the NER module, we use a learning rate of 5×10^{-6} for fine-tuning the XLM-R embeddings and use a learning rate of 0.05 to update the parameters in the CRF layer following Wang et al. (2021b). Each NER model built by our system can be trained and evaluated on a single Tesla V100 GPU with 16GB memory. For the ensemble module, we train about 10 models for each track.

A.3 Settings of CE and ACE models

In Section 5.6, we compare our NER model with CE and ACE models. In CE and ACE models, we concatenate monolingual fastText (Bojanowski et al., 2017) word embeddings, monolingual/multilingual Flair embeddings (Akbik et al., 2018), ELMo embeddings (Peters et al., 2018; Che et al., 2018), XLM-R embeddings fine-tuned on the whole training data and XLM-R embeddings fine-tuned on the language data by multi-stage fine-tuning. We only feed the knowledge-based input into XLM-R embeddings and feed the original input into other embeddings because it is hard for the other embeddings (especially for LSTM-based embeddings such as Flair and ELMo) to encode such a long input. We use Bi-LSTM encoder to encode the concatenated embeddings with a hidden state of 1,000 and then feed the output token representations into the CRF layer. Following most of the previous efforts, we use SGD optimizer with a learning rate of 0.01. For ACE, we search the embedding concatenation for 30 episodes.

Voting	**94.65**	**89.18**	**85.51**	**85.22**	**86.57**	**88.23**
CRF	94.04	88.96	85.37	85.12	85.33	87.76

Table 12: A comparison of ensemble approaches on the **development set**.

B More Analysis

B.1 Majority Voting Ensemble and CRF Level Ensemble

As we state in Section 3.3, we use majority voting as the ensemble algorithm in our system. We show an experiment about how the voting threshold affect the ensemble model performance during our system building on the development set. We ensemble the models on **DE**, **ZH**, **HI**, **BN**, **MIX** with PARA since these five tracks have relatively lower performance than the other 7 tracks. In Figure 4, we show how the threshold of the majority voting affects the model performance. From the figure, we can see that the best threshold varies over the language. Therefore, we simply choose 0.5 as there is no best threshold value. Moreover, we compare the majority voting ensemble and CRF level ensemble in Table 12. The CRF level ensemble averages the emission and transition scores in the Eq. 1 predicted by the candidate models and uses the Viterbi algorithm to get the prediction. The results show that CRF level ensemble performs inferior to the majority voting ensemble. The possible reason is that training with different random seeds may lead to different emission transition scores at different

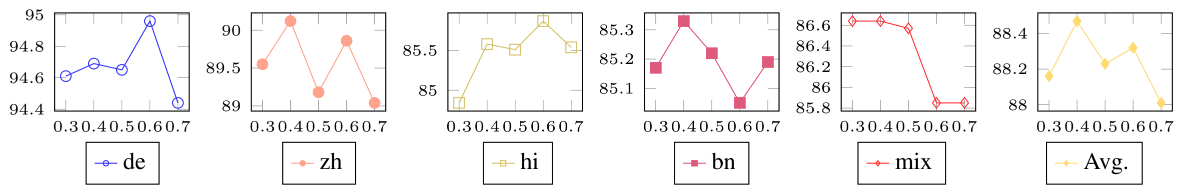

Figure 4: An illustration of majority voting threshold versus the ensemble model performance.

Test Context	PARA		Opt_{Best}	
Search KB	All	Language	All	Language
Wiki-PARA	84.57	84.94	-	-
Wiki+Opt_{Best}	-	84.96	84.38	84.78

Table 13: Test results for multilingual models with different context options and different KB size.

scales. As a result, the models with larger scales have higher weights in the ensemble.

B.2 How the Search Space and the Context Type Affects Multilingual Model Performance?

In the multilingual test set, we can find 304,905 sentences in the other monolingual test sets while there are 167,006 sentences that cannot be found. For these sentences, we can either search on the whole KB of all languages or first detect the language of the input sentence and then search in the specific language KB[14]. Moreover, as we discussed in Section 5.4, using different kinds of retrieved knowledge affects the model performance. As a result, we train two types of multilingual models. One is only using the PARA contexts for all language and another is using the best option for each language based on Table 3. From the results in Table 13, we can observe that: 1) searching over the language specific KB performs better than searching the whole KB, 2) using the language specific context option cannot improve the model performance. Therefore, we ensemble both types of the model for the final submission.

[14]We determine the language of the input sentence using the langdetector (https://pypi.org/project/langdetect/) tool.

Multilinguals at SemEval-2022 Task 11: Complex NER in Semantically Ambiguous Settings for Low Resource Languages

vikram@iiit.ac.in

Abstract

We leverage pre-trained language models to solve the task of complex NER for two low-resource languages: Chinese and Spanish. We use the technique of Whole Word Masking (WWM) to boost the performance of masked language modeling objective on large and unsupervised corpora. We experiment with multiple neural network architectures, incorporating CRF, BiLSTMs, and Linear Classifiers on top of a fine-tuned BERT layer. All our models outperform the baseline by a significant margin and our best performing model obtains a competitive position on the evaluation leaderboard for the blind test set.

1 Introduction

The Named Entity Recognition (NER) task aims to identify the named entities in an input sequence and categorize them into certain predefined categories or class labels. The task of NER can be further broken down into two subtasks: 1) identification of the entity span and 2) classification of the identified entity span into predefined class labels. For example, in the sentence: *New York City is the most densely populated major city in the United States.*, *New York City* is a named entity of type LOCATION with an entity span of 3 tokens.

The most popular NER task in the English language is CoNLL (Baevski et al., 2019), which is widely used as a benchmark for most NER models. Multiple models have been able to obtain sufficiently high performances in this task setting (Wang et al., 2021a; Zhou and Chen, 2021; Luoma and Pyysalo, 2020; Schweter and Akbik, 2020; Ye et al., 2021; Yamada et al., 2020; Wang et al., 2021b). The CoNLL training set consists of 14,987 train sentences, which comprise 203,621 tokens in total for English data. The entity space consists of 4 different types of entity type labels (locations, persons, organizations, and miscellaneous) to classify each named token. The English data was taken from the Reuters Corpus, which comprises of Reuters News Stories for one year. The training data source, and by extension the labeled named entities, comprises of majorly popular entities found in the general English textual content prevalent in the media. Hence, these entities were easier to classify into the correct classes due to the large prevalence of training data. With the use of pre-trained transformer-based language models, which are already trained on a large unlabelled corpus of English text, this task became even less challenging, as the nature of textual structure in these corpora largely overlap with that of CoNLL.

However, this task becomes challenging in practical settings where a multitude of varieties of named entities is possible. Many of these entities, like Creative Works (CW) and Products (PROD) have complex and ambiguous textual structural content. Such complex named entities rarely appear even in the large training data sets, and the length and structure of the named entities keep changing.

We investigate the task of complex, semantically ambiguous, and low-resource NER (Malmasi et al., 2022b). This task is based on the complex NER, search query and code-mixing NER challenges introduced by Meng et al. (2021) and Fetahu et al. (2021). The shared task of MultiCoNER (stands for multilingual complex NER) adds additional challenge by introducing rarer label types (like Creative Work, Product, etc.).

Another way to increase the difficulty of NER task is to perform it for low-resource languages. There is a significant dearth of both labeled and unlabelled data for such languages. The complexity is further enhanced by using rarer entity types in such languages. Therefore, the scarcity of training data, along with the rarity of entity types, makes it difficult for the models to perform better in the low-resource setting. The shared task of MultiCoNER introduces datasets in multiple low-resource lan-

*Equal Contribution

guages.

We leverage large pre-trained language models trained on low-resource language corpora to obtain competitive performances in the low-resource and complex NER setting. We show that simpler architectures successfully outperform other heavier counterparts. We use standard BERT+CRF-based models to obtain high performances in the evaluation set. We experiment on two low-resource datasets: Spanish and Chinese. The code is available at `https://github.com/AmitPandey-Research/Complex_NER`

We compare multiple architectures on the test and validation set of the shared task. The organisers provide a baseline of XLM-RoBERTa model (Conneau et al., 2019) finetuned on the training dataset of the specified language for the given task. In this paper, we treat the finetuned XLM-RoBERTa as baseline (two separate models are trained for Spanish and Chinese language) and compare the performances against our models. All our models beat the baseline by a significant margin. We describe the prior research work done with respect to both general and low-resource NER tasks in Section 2. We provide the formal task description in Section 3, the dataset details in Section 4, the method and the model architecture in Section 5. We provide details about the experimental implementation in Section 6. We discuss the results obtained and error analysis in Sections 7 and 8 respectively, and finally, we conclude the paper in Section 9.

2 Related Work

The task of low-resource NER has been investigated before by multiple researchers. This line of research focuses mainly on leveraging the cross-lingual contextual information obtained from low-resource languages. (Feng et al., 2018) use cross-lingual knowledge transfer to train the NER model for the low-resource target language. (Xie et al., 2018) use bilingual dictionaries to tackle the task of low-resource NER. (Rahimi et al., 2019b) proposes a Bayesian graphical model approach to improve performance on NER tasks.

NER models often use gazetteers (list of named entities) to improve performance in NER tasks. (Rijhwani et al., 2020) creates soft-gazetteers for low-resource languages, leveraging English Knowledge Bases. (Bari et al., 2019) focuses on an unsupervised approach for NER for to circumvent the label scarcity problem in low-resource languages. (Rahimi et al., 2019a) leverages multilingual transfer learning from multiple languages for low-resource NER tasks. (Hedderich et al., 2021) uses distant supervision in the low-resource setting for NER.

There are multiple approaches that have been undertaken in the recent past to improve the state-of-the-art in NER tasks. (Wang et al., 2020) uses concatenation of embeddings to outperform the state-of-the-art in NER tasks, as they infer that concatenation of embeddings leads to a better word representation. Their method automates the process of finding meaningful embeddings to concatenate for improved performance. (Zhou and Chen, 2021) propose a co-regularization framework for entity extraction comprising of multiple models with different architectures but different parameter initializations. This helps to tackle overfitting of large neural network-based models on low-resource training data for NER. (Schweter and Akbik, 2020) use document-level features to improve information extraction on entity-centric tasks.

NER and Relation Extraction are the core information extraction tasks in NLP. (Ye et al., 2021) models this as a span-pair classification problem, and they further improve the pair representations by considering the dependencies between the spans (pairs) by strategically packing the markers in the encoder. (Yamada et al., 2020) proposes a novel entity-aware self-attention framework for transformer based models for NER. (Wang et al., 2021b) extracts document-level context for sentences for which document information is absent. They treat the sentence as a query and use a search engine to extract the document level contextual information. (Luoma and Pyysalo, 2020) uses multiple neighbouring sentences as the contextual information for NER.

Pre-trained Language Models for NER : Ever since the introduction of BERT (Devlin et al., 2019), transformer based pre-trained language models have effectively utilized transfer learning for downstream NLP tasks. NER has been traditionally modeled as a sequence labeling problem. (Huang et al., 2015) proposed a Bidirectional LSTM with a CRF layer on top for classifying tokens as entities. (Jadhav, 2020) use a pretrained BERT model with a CRF layer on top for performing NER on the DailyHunt news dataset. We use a BERT-based model with a CRF layer on top and achieve competitive performance on low-resource

NER tasks on multiple languages, beating the baseline by a significant margin in each case.

3 Task Description

In this task, we attempt complex NER for two low-resource languages: Spanish and Chinese. This task presents additional challenges in the form of test instances consisting of short search queries and low-context sentences. For this task, the systems had to identify the B-I-O format (Ramshaw and Marcus, 1999) (short for beginning, inside, outside) tags for six NER entity type labels: 1) Person, 2) Product, 3) Location, 4) Group, 5) Corporation, and 6) Creative Work. The description of these labels is shown in Table 1.

4 Dataset

The MultiCoNER dataset (Malmasi et al., 2022a) consists of multiple low-resource languages. We consider Chinese and Spanish languages in this paper. For the monolingual track, the participants have to train a model that works for a single language. We fine-tune the language model on the train set to obtain predictions on dev and test set. The labels from the blind test set are not disclosed. The dataset follows a BIO tagging scheme and there are 6 entity types in the label space. The statistics for the Chinese and Spanish datasets in the monolingual track for the train and dev set are provided in Table 2. The total number of test instances for both Spanish and Chinese languages exceed 150,000.

	Train	Dev
# sentences	15300	800

5 System Overview

At first, we pre-train the BERT language model on unlabelled corpora for the target low resource language. For Chinese, we use the strategy outlined by (Cui et al., 2020). BERT uses the WordPiece tokenizer (Wu et al., 2016) to split tokens into smaller fragments. It is easier for the masked language model to predict these masked fragments. However, for the Chinese textual texture, the Chinese characters are not formed by alphabet-like symbols, so the WordPiece tokenizer is unable to split the words into small fragments. Hence, we use the Chinese Word Segmentation (CWS) tool to split the text into separate words and then use Whole Word Masking (WWM) strategy for the masked language model objective. In comparison to masking small fragments, this Whole Word Masking strategy makes it harder for the model to predict whole masked words, leading to more robustness.

For the Spanish variant, we adopt the strategy outlined by Cañete et al. (2020). Similar to (Cui et al., 2020), they use the strategy of whole word masking for pre-training BERT language model on unlabelled Spanish corpus.

We adopt the strategy of finetuning these pre-trained BERT models on the downstream NER task for each language.

5.1 BERT+CRF

Conditional random fields (CRFs) are statistical modeling methods used for pattern recognition. They are better suited for tasks such as Part-of-Speech (POS) tagging and NER compared to classifiers based on softmax normalization. Classifiers based on softmax normalization assume the likelihood of the labels to be conditionally independent, and this causes label bias. CRF alleviates this issue of label bias by capturing inter-token dependencies in a graphical model and learning transition scores in addition to the hidden states. In our model, we use linear-chain CRF. In linear CRFs, prediction for each token is dependent only on its immediate neighbors. As shown in equation 2, CRF tries to maximize the ratio of the probability of an optimal sequence of labels to the probability sum of all the possible sequences of labels. Since CRF focuses on the sequence of labels, it can avoid errors like B-PER followed by an I-PROD. Therefore, based on emission scores provided by BERT layer, we calculate the log-likelihood of a sequence of labels. Now we explain the steps involved BERT+CRF

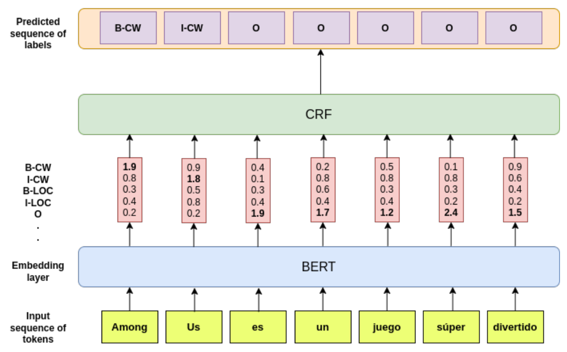

Figure 1: BERT+CRF architecture

architecture that is shown in Figure 1.

Firstly, we obtain token-level dense representations using a fine-tuned BERT-based embedding layer. For an input sequence of tokens $w = (w_1, w_2, w_3, ..., w_n)$, we obtain the ith token representation x_i of dimension d, where d is the dimension of BERT embeddings. The token embedding x_i is passed to a dense linear layer to transform the representation from d to k dimensional space (emission score), where k is the number of labels. We calculate emission scores for all the tokens of the given sequence. We then pass these emission scores to the CRF layer to obtain the probability for a sequence of labels. The emission scores, obtained from the previous layer as $P \in R^{n\times k}$, are passed to the CRF layer whose parameters are $A \in R^{k+2\times k+2}$. Element A_{ij} denotes the transition score from the ith to the jth label. 2 additional states are added to the start and end of the sequence. For a series of tokens $w = (w_1, w_2, w_3, ..., w_n)$ we obtain a series of predictions $y = (y_1, y_2, y_3, ..., y_n)$.

As described in (Lample et al., 2016), the score of the entire sequence is defined as :

$$s(w, y) = \sum_{i=0}^{n} A_{y_i, y_{i+1}} + \sum_{i=1}^{n} P_{i, y_i} \qquad (1)$$

The model is trained to maximise the log probability of the correct label sequence:

$$\log(p(y|w)) = s(w, y) - \log(\sum_{\tilde{y}\in Y_w} e^{s(w,\tilde{y})}) \quad (2)$$

where Y_w are all possible label sequences.

5.2 BERT+BiLSTM+CRF

We obtain token-level contextual dense representations (BERT embeddings) using fine-tuned BERT layer. These embeddings are then passed to a BiLSTM layer which further extracts bidirectional information from the given sequence of vectors. The information is encoded in the hidden-state representations of the BiLSTM. We pass these hidden states to the CRF layer to obtain the likelihood of a sequence of labels. We use the pre-trained language model to map the tokens in each input sentence to a dense embedding representation. The BERT-based dense embeddings are passed to the BiLSTM-CRF layer, which is used to obtain the predicted label for each token in the entire sequence. More formally, for a sequence of tokens $w = (w_1, w_2, w_3, ..., w_n)$, we obtain the ith token representation x_i of dimension d, which is the dimension of the dense vector representations of the BERT-based embeddings obtained from the pre-trained language model. The sequence of token embeddings is taken as an input to the BiLSTM in each time step, and the forward hidden states $\overrightarrow{h_f} = (\overrightarrow{h_1}, \overrightarrow{h_2}, \overrightarrow{h_3}, ..., \overrightarrow{h_n})$ and the backward hidden states $\overleftarrow{h_b} = (\overleftarrow{h_1}, \overleftarrow{h_2}, \overleftarrow{h_3}, ..., \overleftarrow{h_n})$ are concatenated to form the combined hidden state representation $h = [\overrightarrow{h_f}, \overleftarrow{h_b}]$. The combined hidden state representation $h \in R^{n\times m}$, where m is the total dimension of BiLSTM, is transformed to a k dimensional space using a linear layer, where k is the total number of labels. Finally, the CRF layer outputs predicted sequence of labels.

5.3 BERT+Linear

This is the simplest architecture based on fine-tuned BERT layer. The input token sequence is mapped to a vector space of d dimension using a pre-trained BERT layer. These embeddings are then passed to a classifier that consists of two Fully Connected (FC) layers followed by a softmax normalization function. The classifier maps the d dimensional BERT embeddings to k dimensions, where k is the number of labels. These k dimensional vectors generated by the fully connected layers are softmaxed to provide a probability distribution across all labels.

6 Implementation Details

We implement all our transformer based models using Pytorch and Huggingface library. The Chinese language model with the Whole Word Masking (WWM) objective is trained on the Chinese Wikipedia unlabelled text corpus. We use the same training corpus of 3 billion unannotated Spanish tokens as Cañete et al. (2020) to pre-train the BERT

Table 4: Results of our models on validation dataset for Chinese language

language model on Spanish data. We implement 3 models: BERT+CRF, BERT+BiLSTM+CRF, and BERT+Linear, for our low resource NER task setting. We run our experiments between 1-100 epochs. We find that the best results are obtained at 10 epochs of training for each model after which the model starts to overfit. We use a dropout from 0.2 to 0.5 for all models. We employ Adam optimizer with default parameters for all experiments. We also experiment with a cyclic learning rate between $1e^{-4}$ to $1e^{-6}$ to avoid getting stuck in local minima. The size of each of the FC layers in the BERT+Linear model is 512. We validate the results of all models using our validation dataset. The hidden layer size of BiLSTM used in the BERT+BiLSTM+CRF model is 256.

7 Results

We compare the performances of all models in the low-resource setting for both Chinese and Spanish languages. From tables 3 and 4 we observe that the BERT+CRF model performs the best across both languages on validation set. We choose the best performing model to evaluate our results on the blind test set. The baseline model chosen by the organisers of this task is XLM-RoBERTa (Conneau et al., 2019)(base model). It is pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages (Conneau et al., 2019). Our approach beats the baseline by a significant margin and outperforms multiple models in the competition. We present the precision, recall and F1 scores for all 3 models in the Tables 3 and 4 for Spanish and Chinese language respectively. We also compare the results between the baseline and our models for the validation dataset in the Tables 5 and 6.

For the Spanish language, we observe that the BERT+CRF (0.8117 F1 score) beats BERT+Linear (0.8096 F1 score) by a slender margin. This can be attributed to the addition of the CRF layer, which exploits inter-token dependencies. The BERT+BiLSTM+CRF model is much heavier with a larger number of parameters and overfits the training dataset due to the smaller number of training instances.

For the Chinese language, we observe that both the BERT+CRF (0.8564 F1 score) and BERT+BiLSTM+CRF (0.8558 F1 score) beat BERT+Linear (0.846 F1 score).

Our models outperform the baseline for both the languages. Our best performing model BERT+CRF beats the baseline F1 score by around 5% for Spanish and by around 10% for Chinese.

BERT+CRF model in the evaluation phase are shown in Table 7 for the Spanish language and the Table 8 for the Chinese language. We observe a drop in performance on the test dataset compared to the performance on the validation dataset. The model scores 0.6120 F1 for Spanish and 0.6695 F1 for the Chinese language.

8 Error Analysis

We perform error analysis on all 3 different models. We qualitatively analyze the predictions on the validation dataset for both languages. As the final evaluation test set in blind, we are unable to perform analysis on the same. We find that the labels GRP (Group), PROD (Product), and CW (Creative Work) are the most inaccurately predicted labels for the Spanish models. This conforms to our hypothesis that the long-tailed nature of these entities (which means the frequency of occurrence of such entity types in the general literature of the target language is rare). Hence, the model has the most difficulty in recognizing these entities from the contextual sentences. The other label types are more common and were present in the CoNLL dataset as well. We also notice that the BERT+Linear does marginally better than BERT+CRF on predicting such labels (for the Spanish language), despite it not being the best performing model overall. This can be attributed to it being a lighter model, imparting it the capability of generalizing better while training on a relatively lower amount of training instances. BERT+CRF benefits from having CRF along with the lower number of parameters compared to the BERT+BiLSTM+CRF model. This results in it having a better performance compared to both the other models. The drop in the performance of the model on the blind test dataset can be attributed to the model not generalizing well to handle instances of questions and short search queries in the additional test set.

9 Conclusion and Future Work

We have introduced strong improvements over the baseline for the shared task of complex NER for low resource languages. We leverage the Whole Word Masking objective to obtain a better performance in this low-resource setting. We perform extensive experiments and find that simple BERT-CRF based models perform strongly against other heavier models even in such low resource semantically ambiguous setting as evident by the final evaluation rankings. We find this approach to give a higher performance as it is able to utilize the contextual information from a sequence of tokens and learn inter-token dependencies to accurately predict the named entity labels. We also conduct qualitative error analysis and describe our findings. For future work, we aim to leverage these findings to circumvent the label scarcity problem in other low-resource languages and code mixed data.

AaltoNLP at SemEval-2022 Task 11: Ensembling Task-adaptive Pretrained Transformers for Multilingual Complex NER

Aapo Pietiläinen   **Shaoxiong Ji**
Aalto University
{aapo.pietilainen; shaoxiong.ji}@aalto.fi

Abstract

This paper presents the system description of team AaltoNLP for SemEval-2022 shared task 11: MultiCoNER. Transformer-based models have produced high scores on standard Named Entity Recognition (NER) tasks. However, accuracy on complex named entities is still low. Complex and ambiguous named entities have been identified as a major error source in NER tasks. The shared task is about multilingual complex named entity recognition. In this paper, we describe an ensemble approach, which increases accuracy across all tested languages. The system ensembles output from multiple same architecture task-adaptive pretrained transformers trained with different random seeds. We notice a large discrepancy between performance on development and test data. Model selection based on limited development data may not yield optimal results on large test data sets.

1 Introduction

SemEval-2022 shared task 11: MultiCoNER (Malmasi et al., 2022b) was about complex Named Entity Recognition (NER) in the multilingual context. Transformer-based models such as BERT (Devlin et al., 2019) have reached high accuracy in standard NER tasks. However, the models still struggle with complex and code-mixed named entities (Meng et al., 2021; Fetahu et al., 2021). The shared task tries to address the challenges regarding complex NER in a multilingual context. Out of the 13 available tracks, we focus on 5 monolingual tracks. We build models for Bangla, English, Farsi, German, and Korean.

Our strategy is to build an ensemble approach to increase accuracy compared to the baseline model. To tackle multilingualism, we build an approach that starts from the same XLM-RoBERTa (Conneau et al., 2019) encoder and after fine-tuning, achieves good performance across languages. We propose two ensembling approaches: (1) naive ensembling and (2) end-to-end (E2E) ensembling. Naive ensembling is a test-time ensembling where class scores from individually trained models are added together. E2E ensembling trains two encoder models jointly by concatenating their results and passing the concatenated predictions to the final layer. In addition to these strategies, we adapt the encoder model to data context using continued pretraining (Gururangan et al., 2020).

We discover that naive ensembling produces good results with few models and by just using different random seeds for training. We also discover that performance can drastically vary between data sets and model selection based on development data may not yield good results on large test sets. Our final rankings are 11th for Farsi, 12th for Bangla, 13th for German, 15th for Korean, and 25th for English. For each language, our ranking is on the lower half of the participants. The code for our submission has been released [1].

2 Background

In NER, complex and ambiguous entities are hard to classify correctly. Out of the 13 available tracks, we participated in the monolingual tracks for Bangla, English, Farsi, German, and Korean. For training, we used only the competition data sets (Malmasi et al., 2022a) provided by the organizers. The task is to detect named entities in given sentences. Figure 1 contains an example of the task setting. This example can be considered complex, as Madagascar is ambiguous as it could refer to the country or the movie.

Transformer-based models (Vaswani et al., 2017) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) produce state-of-the-art results on variety of natural language processing (NLP) tasks including NER. Transformer models trained

Figure 1: An example of NER task. A sentence from the development data set and the corresponding labels.

on multilingual data, such as XLM (Conneau and Lample, 2019), can be used for cross-lingual tasks. XLM-RoBERTa (XLM-R) (Conneau et al., 2019) combines the XLM and RoBERTa architectures and produces state-of-the-art results across languages. XLM-R is used as the basis in our system, which we built on top of.

Gururangan et al. (2020) showed that continuing pretraining of a transformer model with the domain or task-specific data often increases the performance. We utilize this finding and apply task-adaptive pretraining on multilingual models to increase performance in a specific language.

Ensemble learning is widely used in machine learning, in which, predictions from several different models are combined. The ensemble learning method combines multiple weak learners and provides a strong learner (Mohri, 2012). This works especially well when the weak learners [2] are diverse and make different errors. Speck and Ngonga Ngomo (2014) showed that ensemble methods can significantly increase NER accuracy. Combining transformer-based model predictions has been shown to increase NER accuracy (Li et al., 2020; Zhao et al., 2021; Souza et al., 2020). To keep applicability on languages with limited number of pretrained models, our approach is to form an ensemble model based on training the same model with different random seeds.

3 System overview

The motivation for our system is to produce an approach that can be applied across languages. Initial testing with the baseline system provided by the organizers suggested that XLM-R$_{\text{large}}$ (Conneau et al., 2019) produces comparable or even better performance than tested monolingual pretrained models for targeted languages. Therefore, we resort to building on top of a multilingual encoder model XLM-R$_{\text{LARGE}}$ and the provided baseline system.

Inspired by results using task-adaptive pretraining (Gururangan et al., 2020), we start by training task-adaptive language models. We hypothesize that task-adaptive pretraining could provide two sources of improvement: (1) adapting to the data domain and (2) improving the capability in the specific language. Task-adaptive pretraining is conducted for the XLM-R$_{\text{LARGE}}$ using the provided training data, which we prepare for pretraining by removing labels and constructing line-by-line sentences. The pretraining is applied to each language separately yielding us five encoder models named *koala/xlm-roberta-large-**XX***. The **XX** is replaced with the corresponding language identifier. The pretraining is continued from the XLM-R$_{\text{large}}$ checkpoint with only the preprocessed task data. The pretraining objective remains the same. The models are available at the Huggingface model repository [3]. In this paper, we refer to the models as koala-XLM-R$_{\text{large}}$ interchangeably for all languages.

After obtaining the enhanced encoder models, we propose two ensemble learning approaches, i.e., naive ensemble and E2E ensemble.

3.1 Naive ensemble

As the first ensemble strategy, we combine predictions from multiple independently trained models at test time. Randomness and choosing a random seed can have a significant effect on the model training and final accuracy. Based on that, our hypothesis was to leverage this randomness to increase the accuracy.

To ensure applicability in languages, where a limited number of available models are available, we train the models using the same architecture and only vary the random seed associated with training. The koala-XLM-R$_{\text{large}}$ is used as the encoder model for each language respectively. After the encoder model, we use the linear layer as the prediction head and apply softmax transformation to obtain class probabilities. The models were trained separately and optimized with AdamW optimizer (Loshchilov and Hutter, 2018) and negative log-likelihood loss function (NLLLoss).

The ensembling is conducted during test time. We simply add the class probabilities together from each of the models,

$$y^* = \operatorname{argmax}_j \sum_n p_{nj}, \qquad (1)$$

where p_{nj} is the probability of model n for the class j. The predicted class y^* is the class with the highest sum of probabilities. For the ensemble weights,

[2]also called base models

[3]https://huggingface.co/koala

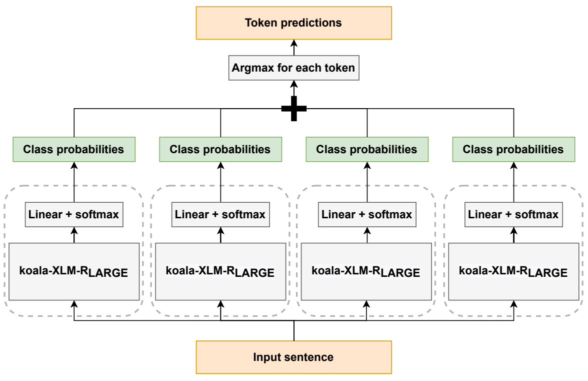

Figure 2: System diagram for the Naive ensemble model. Each of the models are trained separately with different random seeds and ensembling conducted at test time.

we also tried entropy minimized ensemble (Wang et al., 2021), which is based on the intuition that good ensemble weights should decrease entropy (Shannon, 1948; Wang et al., 2020). The algorithm is elaborated in Algorithm 1. This approach did not

Algorithm 1 Entropy minimization for ensembling

```
1: Inputs: scores $\mathbf{p}$, uniform weights $\mathbf{w}^0$
2: for t in $0, 1, \ldots$ steps $= T$ do
3:     Calculate entropy of scores $E \leftarrow \text{Entropy}(\sum_n w_n^t * p_{nj})$
4:     Compute gradient $g^t = \nabla_w E$
5:     Update weights $\mathbf{w}^{t+1} \leftarrow \text{Update}(\mathbf{w}^t, g^t)$
6: end for
7: Output: final prediction $y^* = \sum_n w_n^T * p_{nj}$
```

provide noticeable improvement in our tests and thus, we proceeded with uniform weights.

Our ensemble model consists of four distinct models. The number of four models was chosen as a compromise on the trade-off between accuracy and inference time. The model system is illustrated in Figure 2.

3.2 E2E ensemble

Our second ensemble strategy centered around the idea of jointly training the models. The idea is to include sub-networks (encoder models) in the model, ensemble their predictions, and optimize the loss function jointly. Our system uses koala-XLM-R$_{\text{large}}$ and XLM-R$_{\text{base}}$ as the encoder models.

The input data is passed to both encoder models. After that, we apply linear and softmax layers. For the second encoder model, the linear layer outputs $2 *$ `num classes` scores. We made this decision to add variation between the two sub-networks. The choice to use twice the amount of parameters was arbitrary. We tried a different number of parameters but the performance seemed similar.

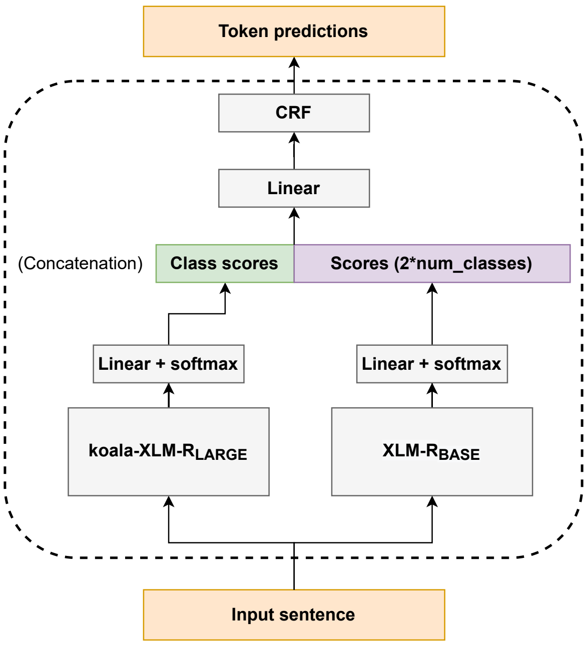

Figure 3: System diagram for the E2E ensemble model.

After outputting the scores from the two sub-networks, the scores are concatenated together. Also, summation was tested when using same-sized outputs, but concatenation seemed to perform better. After that, the concatenated scores are passed to linear and CRF layers. The architecture of E2E ensemble model is illustrated in Figure 3.

The E2E ensemble model consists of two sub-networks. We tried using also three and four sub-networks but adding more models did not improve the performance. Therefore, we settled on using two sub-networks, which also help with the computational burden. We experimented with different sub-network architectures and noticed that using different encoder models provided the best performance despite varying the linear layer size. Also, using koala-XLM-R$_{\text{large}}$ instead of XLM-R$_{\text{base}}$ as the second sub-network did not improve accuracy. Hence, the smaller model was used.

The model was optimized using AdamW optimizer with Viterbi loss as the loss function.

4 Experimental setup

Our experimental setup was based on the provided baseline model (Malmasi et al., 2022b) and the data splits (Malmasi et al., 2022a). Models were trained only using the training data and the best model was selected based on performance on development data. After selecting the best model, we did not do any training with development data. For continued pretraining, we preprocessed the training data. The data were converted from CoNLL format into line-by-line text. Hence, we removed the labels and reconstructed the sentences into a single line of text data.

We selected suitable hyperparameters based on performance on the development data. We selected two learning rates, first for the encoder model and a second one for all subsequent layers (decoder). We set the encoder learning rate to 10^{-6} and the decoder learning rate to 10^{-3}. To prevent overfitting, we used a dropout rate of 0.1. We also used early stopping with development data. The training was stopped when accuracy on development data had not increased in the last three epochs. We selected batch size based on the hardware constraints. For baselines and sub-models in the naive ensemble, we used batch size 64. For E2E ensemble, batch size is 20.

The main Python libraries we used are PyTorch, PyTorch Lightning, AllenNLP, and Transformers. Further details available in the repository [4].

The performance in this shared task is evaluated using prediction accuracy on unseen test data set. The teams are ranked by their macro-averaged F1 classification score.

5 Results

The official metrics were based on the evaluation phase with test data. The participants were ranked by their Macro F1 scores. The performance of built models on test data is shown in Table 1. The best score is bolded and is the model used for ranking. It can be seen that the naive ensemble model performs better than the best individual model across all languages. E2E ensemble model shows mixed results and performance varies run by run. It outperforms naive ensemble on Korean and Farsi test data.

We noticed a rather large discrepancy in accuracies between the development and test data set. The details of model performance on development data are presented in Table 2. Compared to the results on test data, the performance on development data was significantly better. The discrepancies between performance on development and test data suggest that model selection on such limited development data yields sub-optimal results.

Our systems suffer with some of the classes. As can be seen from Figures 4 and 5, PROD and CW classes have significantly lower accuracy than other classes. Performance on GRP, LOC, and PER classes is much higher. Our systems suffer with the no-tag-class O, which has the majority of the misclassifications.

5.1 Task-adaptive pretraining

We hypothesized that task-adaptive pretraining would adapt the multilingual encoder model into the data and language domains. We tested the performance by training the model four times using different random seeds and comparing the average micro F1 score between XLM-R$_{\text{large}}$ and koala-XLM-R$_{\text{large}}$ models. The results of task-adaptive pretraining are elaborated in Table 3. The improvements on this task are small and compared to the original paper, in which, the accuracy increase was considerably larger on some data sets. For German, the accuracy even decreased significantly. The decrease is mainly caused by random variation as one of the four models for koala-XLM-R$_{\text{large}}$ achieved only accuracy of 0.81 when all other models (XLM-R$_{\text{large}}$ and koala-XLM-R$_{\text{large}}$) were in the range of $0.85 - 0.88$.

Model	en	ko	fa	de	bn
XLM-R$_{\text{large}}$	0.836	0.788	0.757	0.873	0.738
koala-XLM-R$_{\text{large}}$	0.837	0.793	0.761	0.850	0.746
Improvement	0.1%	0.6%	0.5%	-2.6%	1.1%

Yes	10	10	3	0.779
Yes	10	100	3	0.776
Yes	10	500	3	0.777
Yes	25	10	1	0.771
Yes	30	15	3	0.775
Yes	100	10	3	0.777

Table 4: EMEA ensemble for Bangla

5.2 EMEA

As discussed earlier, we tried to improve our ensembling strategy using entropy minimization. The results are reported in Table 4. Despite testing different approaches, no sign of improvement is present. The testing was conducted on the Bangla development data set. Our setting differs from the original authors as we are not using off-the-shelf language adapters. We probably have too few models and they are not diverse enough.

6 Conclusion

From our efforts, we conclude that naive ensembling improves accuracy with just four models of the same architecture trained with different random seeds. The ensemble of four models outperforms the best individual model across all the tested languages. The E2E ensemble model can provide good accuracy, but the results vary drastically between runs. Task-adaptive pretraining, which has in some cases improved accuracy significantly, yielded only a slight improvement in this task. We also notice a large difference between performance in development and test data. With such limited development data and a large test set, model selection on solely development data yields sub-optimal results. More attention should be paid to model selection and model's generalizability.

Acknowledgments

We thank the Aalto Science-IT project and CSC - IT Center for Science, Finland, for providing the computational resources, that were necessary to participate in this task. We would like to thank the shared task organizers for the excellent arrangements. We thank Feiyi Wang for the initial discussion.

DANGNT-SGU at SemEval-2022 Task 11: Using Pre-trained Language Model for Complex Named Entity Recognition

Dang Tuan Nguyen, Huy Khac Nguyen Huynh
Saigon University, Ho Chi Minh City, Vietnam
`{dangnt, hnkhuy}@sgu.edu.vn`

Abstract

This paper describes a system that we built to participate in the SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition, specifically the track Mono-lingual in English. To construct this system, we used Pre-trained Language Models (PLMs). Especially, the Pre-trained Model base on BERT is applied for the task of recognizing named entities by fine-tuning method. We performed the evaluation on two test datasets of the shared task: the Practice Phase and the Evaluation Phase of the competition.

1 Introduction

In natural language processing, Named Entity Recognition (NER) is traditionally a fundamental task that aims to recognize groups of words used to identify people, organizations, places, times, etc. in documents. SemEval-2022 Task 11 focuses on detecting semantically complex and ambiguous entities (Malmasi et al., 2022b). This is a challenging NLP task that has not sufficiently received attention from the research community. In practice, available named entity recognition models find it hard to recognize complex named entities, such as titles of works (*movie/book/song/software titles*) that are not simple nouns (Malmasi et al., 2022b).

Type	Description
Complex entities	Not all entities are proper noun -Noun phrases: *Eternal Sunshine of the Spotless Mind* -Gerunds: *Saving private Ryan* -Full clauses: *Mr. Smith goes to Washington…*
Ambiguous entities and Contexts	Not always entities *-Inside out (movie),* *-Bonanza (game)* *-On the Beach (movie)…*
Emerging Entities	New books/songs/movies released daily, weekly…

Table 1: SemEval-2022 Task 11 illustrates some types of complex and ambiguous entities

To enable the recognition of such entities, we believe that it is necessary to make full use of Pre-trained Language Models (PLMs) to increase efficiency as well as reduce training time, which is also the method we applied in this study.

2 Related Work

Nowadays, there are many NER works and different approaches to solving this problem, such as LSTM (Long Short-Term Memory) (Nut Limsopatham and Nigel Collier, 2016), Transformers (Ashish Vaswani et al., 2017). In particular, the BERT model (Jacob Devlin et al., 2019). Many relevant studies also approach the direction of combining deep learning models and adjusting model parameters to improve the efficiency of named entity recognition in the text (Zheng Yuan et al., 2021). However, entities with complex and ambiguous names appear continuously in increasing numbers. This has posed emerging challenges for the natural language processing field. Many research show that clarifies that named substance acknowledgement is particularly troublesome in circumstances with a low context or in scenarios where the named substances are especially complex (Meng et al., 2021). The misrecognition of entities with complex and ambiguous names significantly affects the performance of natural language processing systems (Andreas Hanselowski et al., 2018). In this paper, we will use PLMs to find ways to improve accuracy in such cases.

PLMs are Pre-trained Language Models with large datasets to be utilized in specific tasks. In particular, BERT has drawn great attention and it is the favorite research direction of the NLP community after achieving state-of-the-art on 11 NLP tasks (Jacob Devlin et al., 2019). Based on BERT, there have been many research directions from the NLP research community: distilBERT (Victor Sanh et al., 2019), RoBERTa (Yinhan Liu et al., 2019), and so on.

3 Data

We will use the training and evaluation **English** dataset provided at SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition to conduct the research with 15300 training examples and 800 validation examples (Malmasi et al,. 2022a).

Language	Train	Dev
BN-Bangla	15,300	800
DE-German	15,300	800
EN-English	15,300	800
ES-Spanish	15,300	800
FA-Farsi	15,300	800
HI-Hindi	15,300	800

Table 3: Data Format use in Task 11: Multi-CoNER Multilingual Complex Named Entity Recognition

For the missions of the competition, we will focus on 6 types of entities:

- PER: *Person*
- LOC: *Location*
- GRP: *Group*
- CORP: *Corporation*
- PROD: *Product*
- CW: *Creative Work*

In total, there are 13 tags: B-PER, I-PER, B-LOC, I-LOC, B-GRP, I-GRP, B-CORP, I-CORP, B-PROD, I- PROD, B-CW, I-CW, and O with B is the beginning of a named entity, I is all the words inside an entity and all words outside an entity (Malmasi et al., 2022b)

4 Methodology

In this paper, we use the Transformer library of HuggingFace (Wolf et al.,2020). Currently, the HuggingFace library is considered the most powerful and widely accepted Pytorch interface to deal with BERT. In addition to the support for a wide range of pre-trained language models, the library also includes pre-built modifications of BERT tailored to specific tasks. Then we tested several models based on BERT downloaded from Huggingface as BERT, RoBERTa, and XML-RoBERTa with different versions.

4.1 BASE-BERT

BERT is a transformers model pretrained on a large corpus of English data in a self-supervised fashion (Jacob Devlin et al., 2019). We use the most basic version of BERT and are downloaded from Huggingface with two versions which are **bert-base-uncased** and **bert-large-uncased.**

4.2 RoBERTa

BERT is trained simultaneously with 2 tasks called *Masked LM* (to predict the missing word in a sentence) and *Next Sentence Prediction* (NSP-to predict the next sentence in the current sentence). Meanwhile, to enhance the training process, instead of using the next sentence prediction mechanism from BERT, **RoBERTa** uses a dynamic masking technique, thereby the mask tokens will be changed during the process. The use of a larger batch size shows better performance in training (Yinhan Liu et al., 2019), we applied on **roberta-base** version from Hugging face.

4.3 XML-RoBERTa

XLM-RoBERTa model pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages. It was introduced in (Conneau, Alexis et al., 2019). The **xlm-roberta-large** version we chose to use.

4.4 Experimental Setup

Resources are required to get started; as a large neural network will have to be trained, we use Google Colab Pro to make the best use of the GPU and TPU resources from this environment.

Regarding the hyper-parameter, we have inspected many different values around the "*work well across all tasks*" value recommendations (according to Jacob Devlin et al., 2019) and this is the parameter set that gives the best results: *Batch size: 64, Learning rate: 2e-5, Number of epochs: 10, Maximum sequence length: 128.* Besides, with the desire to increase the recognition efficiency, we try to add a Linear layer and a softmax layer on top to recognize the entity, however, it has no effect on the results.

We import BERT's word tokenizer, which is used to convert text into tokens corresponding to BERT's vocabulary set. BERT requires specifically formatted inputs. For each encoded input sentence, we need to generate *input ids*, *segment mask, attention mask, label*

When the input data is correctly formatted, there comes the fine-tuning stage of the BERT models. For this task, we start with the modification of the pre-trained BERT model to provide outputs for the named entity recognition task, and then we continue to train the model on the dataset until the whole model is correspondent to the task. This is a prominent advantage of using Huggingface Pytorch library which already contains a set of interfaces designed for many NLP tasks.

To evaluate the model, we will use the **Macro Precision, Recall, and F1-score** indexes. The Precision ratio of the number of positive points correctly predicted by the model to the total number of points predicted by the model is Positive. The Recall is the ratio of the number of positive points the model correctly predicted to the total number of points that are actually Positive. F1-score is the harmonic mean of precision and recall (assuming these two quantities are different from 0) (Powers, David, 2008)

$$macro - Precision = \frac{tp}{tp + fp}$$

$$macro - Recall = \frac{tp}{tp + fp}$$

$$macro - F1 = \frac{2 * Precision * Recall}{Precision + Recall}$$

5 Results

This section describes the evaluation results of our system with PLMs based on BERT. These results are calculated using the script provided by SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition (Malmasi et al., 2022b)

Model	PER			LOC			CW			GRP			CORP			PROD		
	P	R	F1	P	R	F1	P	R	F1	P	R	F1	P	R	F1	P	R	F1
base-bert-uncased	0.924	0.959	0.941	0.823	0.893	0.857	0.667	0.761	0.711	0.827	0.879	0.852	0.860	0.798	0.828	0.658	**0.864**	**0.747**
bert-large-uncased	**0.959**	0.966	0.962	0.852	**0.910**	**0.880**	0.743	0.790	0.766	0.848	**0.937**	0.890	**0.904**	**0.829**	**0.865**	**0.706**	0.735	0.720
roberta-large	0.906	0.897	0.901	**0.863**	0.889	0.876	0.674	0.716	0.694	0.793	0.847	0.819	0.875	0.798	0.835	0.687	0.776	0.728

Table 4: Summary of the scores of all the models tested with 6 types of entities in this paper use dataset on the SemEval 2022 Task 11 (Malmasi et al., 2022a)

Based on the results of table 4, the two models bert-large-uncased and xml-roberta-large are slightly better than the other two models in each entity type. In which xml-roberta-large gives the best results in 3 entity types: PER, CW, GRP, while bert-large-uncased is slightly better in two entity types LOC, CORP and interestingly base-bert-uncased gave the best results in the PROD type.

According to the results in the table 5, it can be observed that testing with the XML-RoBERTa model (Conneau, Alexis et al., 2019). with version xml-roberta-large gives good results compared to the rest of the models when it comes to average performance, followed by the bert-large-uncased model (Jacob Devlin et al., 2019).

Model	Precision	Recall	F1-score
base-bert-uncased	0.804	0.869	0.835
bert-large-uncased	**0.849**	0.876	**0.863**
roberta-large	0.812	0.832	0.822
xml-roberta-large	0.845	**0.882**	**0.863**

Table 5: Summary of the scores of all the models tested with the value of macro average performance in this paper on the SemEval 2022 Task 11 (Malmasi et al., 2022a)

However, in general, the results between the models are not much different, so to improve the efficiency of the NER model, in addition to using PLMs, it is necessary to learn more about other improvement methods to achieve positive results. When analyzing each measure, the BERT model with the bert-large-uncased version gave the highest Precision result (0.849), showing that the BERT model has the highest accuracy in entity labeling. Among the tested models, xml-roberta-large gives the best results in 2 measures: recall and F1-score. Therefore, to participate in the Evaluation phase of SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition (Malmasi et al., 2022b) we selected the model with PLM xml-roberta-large performed on the data set of this phase. with data size of 15300 training examples and 217.818 test examples (Malmasi et al., 2022a), the result is F1-score of 0.67, details as below table 6:

	Precision	Recall	F1-score
Type	**0.6651**	**0.677**	**0.6689**
LOC	0.6401	0.7405	0.6866
PER	**0.8233**	**0.8729**	**0.8474**
PROD	0.6092	0.6433	0.6258
GRP	0.6448	0.6449	0.6448
CW	**0.5508**	**0.5781**	**0.5641**
CORP	0.7222	0.5823	0.6448

Table 6: Results of our system evaluation in dataset validation of Evaluation Phase (Malmasi et al., 2022a)

In Evaluation Phase, the test dataset in this phase is 14 times larger in size than the training dataset (217,818 vs 15300 examples), which is a big challenge for this year's competition.

6 Conclusion

In this paper, we proudly introduced our semantically complex and ambiguous entity recognition system. We tested on different PLMs to evaluate the effectiveness of entity recognition. We trained each model with the dataset provided by the contest (Malmasi et al., 2022a): model BERT with two versions bert-base-uncased and bert-large-uncased, model RoBERTa with roberta-large version and model XML-RoBERTa with xml-roberta-large, and we also tried to fine-tune the hyperparameters to increase recognition efficiency, but there were no significant changes. The evaluation results in the Practice Phase are quite positive. Finally, based on the evaluation results, we used the xml-roberta-large model to participate in the Evaluation phase of the competition, but the results were not good.

In future work, we plan to continue testing on other PLMs. In addition, we will also extend the approach by applying deep learning techniques and theories of language to improve the accuracy in the task of recognizing possible entities, especially complex entities

Abstract

This article describes the OPDAI submission to SemEval-2022 Task 11 on Chinese complex NER. First, we explore the performance of model-based approaches and their ensemble, finding that fine-tuning the pre-trained Chinese RoBERTa-wwm model with word semantic representation and contextual gazetteer representation performs best among single models. However, the model-based approach performs poorly on test data because of low-context and unseen-entity cases. Then, we extend our system into two stages: (1) generating entity candidates by using neural model, soft-templates and Wikipedia lexicon. (2) predicting the final entity results within a feature-based rank model. For the evaluation, our best submission achieves an F_1 score of 0.7954 and attains the third-best score in the Chinese sub-track.

1 Introduction

Named Entity Recognition (NER)(Yadav and Bethard, 2019) aims to detecting the boundaries of named entities and recognizing their categories(e.g., person or location). It plays an important role in many downstream tasks, such as information extraction and question answering.

SemEval-2022 Task 11: Multilingual Complex Named Entity Recognition(MultiCoNER) (Malmasi et al., 2022b) is a shared task which encourages participants to develop NER system to detect semantically ambiguous and complex entities in short and low-context settings for 11 languages. Participants can build a NER model that works only for one language or for all the languages. And an additional track with code-mixed data are offered in this task. Different from ordinary NER, this task focuses on complex and unseen entities. Complex entities, like the titles of creative works(movie/book/software names) are harder to recognize. Additional test sets on questions and short search queries are offered in the test phase, which contains large proportion of unseen entities.

Our main interest is to build a NER system which can process complex entities and adapt to other domains in practical scenarios in Chinese language. This paper describes our two-stage hybrid approach for Chinese NER. A description of datasets provided in this shared task and additional datasets adopted in our system is given in Section 3. The implementation details of our system are listed in Section 4. We first experiment with model-based methods and integrate word semantic feature and gazetteer feature with neural model to improve inference performance. Further, we extend our model system to a two-stage prediction system: entity candidates generation and entity confidence ranking. Confidence ranking is used to pick out high-confidence entities from candidates. With the help of Wikipedia lexicon and soft templates for generating entity candidates, our hybrid system shows good performance and great domain adaption capability in the final evaluation phase.

2 Related Work

Our work is mainly related to the pre-trained language models and some specific strategies for Chinese NER task.

2.1 Pre-trained language models

Transformer-based Language Models e.g BERT (Devlin et al., 2018) have demonstrated that rich, unsupervised pre-training is an integral part of many natural language processing system. RoBERTa(Liu et al., 2019) is a BERT-based model with better performance which bring by different training strategies including training the model longer; bigger batches over more data; removing the next sentence prediction objective; training on longer sequences; and dynamically changing the masking pattern applied to the training data. RoBERTa-wwm (Cui et al., 2021) is a pre-trained language model which modifies the masked language model (MLM) task as a language correction manner and mitigates the discrepancy of the pre-training and fine-tuning stage. It could give significant gains in most various Chinese NER task (Yin et al., 2021).

2.2 Chinese NER

Compared with NER in English, Chinese NER is more difficult since there are no explicit word boundaries in sentences. Word-level information cannot be well modeled. Some approaches resort to performing Chinese NER directly at character-level (Sui et al., 2019; Ding et al., 2019) and some others perform word segmentation first (He and Sun, 2017). However, incorrect word segmentation will result in propagation errors in entity detection, and purely char-based approach will miss the word information. Pre-trained language models, such as BERT, can generate contextual embedding which can outperform other character or word-based approaches (Hu et al., 2020). More importantly, BPE subword segmentation method is employed by BERT-based models and word-level information is not explicitly modeled. Consequently, some researches introduce lexicon information into neural models which results in significant improvement (Ma et al., 2019; Liu et al., 2021). In this task, we implement similar strategies to integrate discrete lexicon and neural representation.

3 Data

We experiment using the datasets shared by MultiCoNER(Malmasi et al., 2022a) on Chinese monolingual track, which consist of 15300 training sentences, 800 validation sentences and 151661 test sentences. Entities are labeled using BIO scheme, and six entity types are involved: person(PER), location(LOC), group(GRP), corporation(CORP), product(PROD) and creative work(CW).

In order to make our model better adapt to ambiguous semantics and insufficient context, we built an entity lexicon from Wikipedia data. We parsed a Wikidata dump and mapped all the entities to our NER taxonomy following the rule from Table 1. We extracted about 3.8 million entities for Chinese language which were mapped to the entity types. Wikipedia entities with multiple categories can be mapped to different entity types in MultiCoNER. Moreover, pre-trained static word embeddings (Song et al., 2018), which provides 200-dimension vector representations for over 12 million Chinese words and phrases pre-trained on large-scale high-quality data, are adopted in this work for integrating the word-level information.

MultiCoNER Entity Types	Wikidata Entity Types
PER	human

CW	creative work
LOC	location
PROD	product

Table 1: The entity types mapping between Wikipedia and MultiCoNER

4 Methodology

Our system classifies NER task into two stages: entity candidates generation and entity confidence ranking. Based on BERT-based model ensembles, soft-template methods and Wikipeida lexicon, we can first generate entity candidates. And then, handcrafted features for each entity candidate are extracted. Finally, a machine learning based rank model is used for entity confidence rank, the entities whose confidence score is above the threshold are regarded as the final predictions. Figure 1 gives an overview of our hybrid approach.

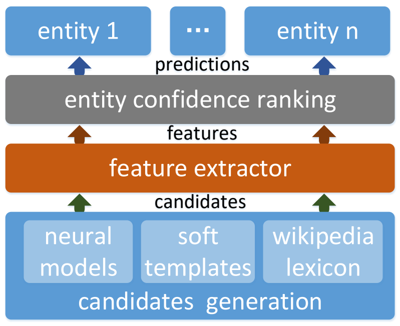

Figure 1: Overview of our hybrid approach

4.1 Entity Candidates Generation

Three approaches are adopted for entity candidates generation: model-based, template-based and lexicon-based. BERT-based model ensembles can achieve named entities recognition, however, its recall performance significantly decreases when dealing with low-context or new-entity cases. To alleviate this effect, soft templates and Wikipedia lexicon is integrated for candidates recall.

4.1.1 Model based approach

Figure 2 gives a glimpse of our model architecture, which consists of three layers: *encoding layer*, *aggregation layer* and *inference layer*. Pre-trained language models are adopted for sentence encoding which can grasp contextual information. However, sentences in Chinese are not naturally segmented, resulting in difficulties in Chinese NER task. Therefore, word semantic representation and contextual gazetteer representation are used in *aggregation* module for incorporating word lexicon information and boundary information into character representations. For further improvement, model ensemble methods are tried for prediction.

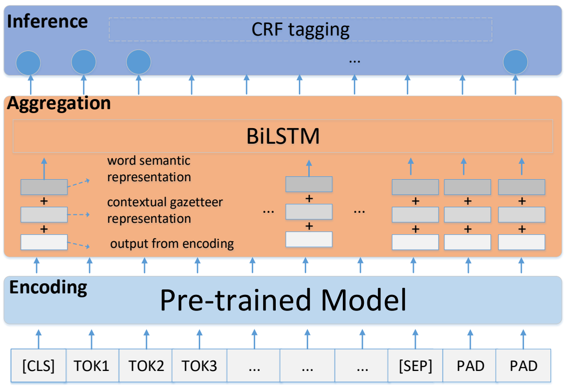

Figure 2: Model Architecture

Encoding: This layer is meant for sequence modeling to capture contextual semantic representation. BERT-based pre-trained models, such as BERT, RoBERTa and RoBERTa-wwm, which have been shown to capture implicit syntactic and semantic knowledge, are tried here.

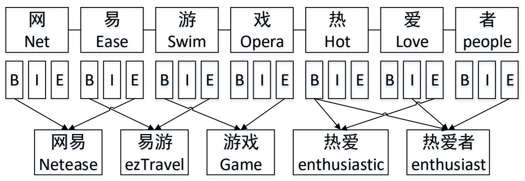
Aggregation: This layer focuses on incorporating word-level information and boundary-dependent features. We use a BiLSTM neural architecture to integrate encoding output with word semantic representation (Ma et al., 2019) and contextual gazetteer representation (Fetahu et al., 2021). An example is presented in Figure 3 for feature constructions. For each character c_i in the input sentence $s = c_1, c_2, ..., c_n$, three word sets(B/I/E) are constructed by:

$$B(c_i) = \{w_{i,k}, \forall w_{i,k} \in eL, i < k \leq n\}$$

$$I(c_i) = \{w_{j,k}, \forall w_{i,k} \in eL, 1 \leq j < i < k \leq n\}$$

$$E(c_i) = \{w_{j,k}, \forall w_{i,k} \in eL, 1 \leq j < i\}$$

Here, eL represents the Wikipedia entity lexicon. $w_{i,k}$ stands for the span that begins with c_i and ends with c_k. The average word embeddings of each word set are concatenated as a 600-dimension vector(200 for each word set) is regarded as the final word semantic representation. Contextual gazetteer representation for each character is a 13-dimension binary vector, which is introduced by Meng et al. (2021) .



(a) word semantic representation

	网 Net	易 Ease	游 Swim	戏 Opera	热 Hot	爱 Love	者 people
B-CORP	1	1	0	0	0	0	0
I-CORP	0	1	1	0	0	0	0
B-PER	0	0	0	0	0	0	0
I-PER	0	0	0	0	0	0	0
...	0	0	0	0	0	0	0
O	0	0	0	0	0	0	0

(b) contextual gazetteer representation

Figure 3: Features introduced in Aggregation Layer

Inference: Sequential conditional random field(CRF), which can capture the dependency between successive labels, is used in the inference layer for final prediction.

Ensemble: Majority voting method is applied to integrate different model results. In detail, for N different models, if more than N/2 models consider a predicted span belongs to the same entity category, the span is used for final prediction.

4.1.2 Lexicon based approach

An entity lexicon is built from wikidata with category mapping rule listed in Table 1. And then Aho-Corasick algorithm [1] is applied for span extraction. When predicting, word span in that Wikipedia lexicon is extracted as an entity candidate, if that word span maps to multiple entity categories, multiple candidates are generated.

4.1.3 Soft-templates based approach

Soft-templates are mined from training data by a simple statistical strategy. More specifically, we first replace entities in sentences with entity category placeholders, and those replaced frequently occurring sentences are regarded as soft-templates without manually labeled. To make improvements, templates differ only in placeholders are removed.

[1]`https://pyahocorasick.readthedocs.io/`

In the evaluation phase, additional soft-templates are mined from test data. Different from the procedures on training data, pseudo entity labels are generated from model prediction results.

4.2 Entity Confidence Ranking

The following paragraphs describe how we select high confident ones from entity candidates for the final predictions. We build a machine learning model with hand-crafted features to calculate the confidence score of each entity candidate. The hand-crafted features consist of 6-dimension lexical features and 16-dimension statistical features. An example of features extracted for an entity candidate in a sentence is given in figure 4.

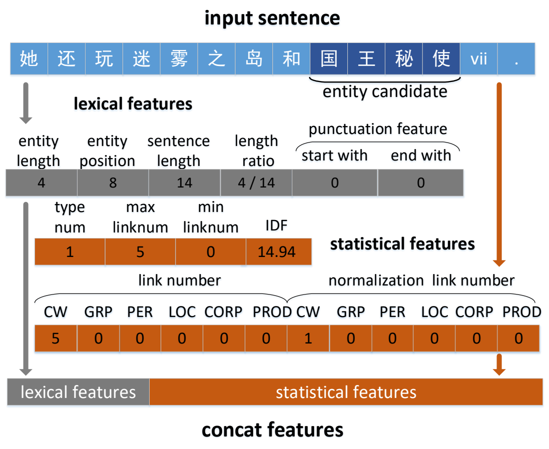


Figure 4: Handcraft Features

A. Lexical Features

- **entity length:** the length of the entity candidate.
- **entity position:** the start position of first character of entity candidate in the input sentence.
- **sentence length:** the length of the input sentence.
- **length ratio:** length ratio between entity candidate and the sentence.
- **punctuation feature:** a two-dimension binary feature indicating whether there is a punctuation at the beginning or end of the entity candidate.

B. Statistical Features

These features are extracted from wiki pages, which can capture entity type information from the link relationships among wiki entities. Two entities are thought to have a link relationship if there is any sitelink in one page which can link to the other. For each entity candidate e_i, the associated wiki pages $P(e_i) = \{p_1, p_2, ..., p_n\}$ are those who have the same label name or alias name to e_i. The number of links which redirect to an entity whose type is $etype_j$ in page p_t is represented as $linknum(p_t, etype_j)$. $etype_j, j = 0, ..., 5$ is one of the six entity types(e.g. PER,LOC,etc.). Therefore, the total number of links for e_i are calculated as $linknum(e_i, etype_j) = \sum_{t=1}^{n} linknum(p_t, etype_j)$.

- **IDF**: inverse document frequency of an entity candidate is calculated from wiki pages.
- **link number**: $\{linknum(e_i, etype_j), j = 0, 1, ..., 5\}$, a six-dimension vector, indicating the number of links in the associated wiki pages of six entity types separately.
- **normalization link number**: normalization value of link number based on entity types, $\{\frac{linknum(e_i,etype_j)}{\sum_j linknum(e_i,etype_j)}, j = 0, 1, ..., 5\}$
- **maximum link number**: maximum value of link number, $\max_{0 \le j \le 5} linknum(e_i, etype_j)$
- **minimum link number**: minimum value of link number, $\min_{0 \le j \le 5} linknum(e_i, etype_j)$
- **number of link types**: the number of entity types where $linknum(e_i, etype_j) > 0$

Then, we adopt LightGBM (Ke et al., 2017) as the multi-label classifier, which is a gradient boosting tree model and performs well on unbalanced classification tasks. For an entity candidate, the confidence on its entity type is calculated by this classifier. If the confidence score is greater than the threshold, e_i is used for the final prediction.

5 Experiments and Results

5.1 Experiment Setup

Our implementation is based on a powerful NLP framework Flair(Akbik et al., 2019), and the Transformers library by HuggingFace(Wolf et al., 2019) for the pre-trained models and corresponding tokenizers.

We first experiment on development dataset with different encoding and aggregation strategies, and we later do an ensemble of these models. During training, the data is processed by batches of size 32 and the maximum length of each sentence is set to 256. In all experiments, we use AdamW optimizer with learning rate set to 2e-5 and train our models for a maximum of 30 epochs. Then, we implement LightGBM for entity confidence ranking with learning rate set to 5e-2, maximum number of leaves set to 50, max-depth set to 6. For the evaluation phase, we mix train and development data and split it randomly for 10-fold cross validation.

Model	Dev P	Dev R	Dev F1
BERT	0.824	0.840	0.832
RoBERTa	0.850	0.837	0.842
RoBERTa-wwm	0.851	0.846	0.847
RoBERTa-wwm-large (I)	0.856	0.860	0.858
+ WE (II)	0.854	**0.863**	0.859
+ GZ (III)	**0.887**	0.842	0.859
+ WE + GZ(IV)	0.867	0.858	**0.861**
Ensemble (V)	**0.913**	0.853	**0.875**

Table 2: Best results achieved by each model on dev dataset, WE and GZ are the shorthand of word semantic representation and gazetteer representation separately

Methods	Dev P	Dev R	Dev F1
Ensemble(V)	0.913	0.853	0.875
Lexicon + LightGBM	0.842	0.779	0.810
Lexicon + V + LightGBM	**0.904**	**0.881**	**0.890**

Table 3: Hybrid results on dev dataset

5.2 Neural Model Results

Table 2 shows the performance of different models and their ensemble approach. The experimental results show that RoBERTa with whole word mask(RoBERTa-wwm) can outperform others in this Chinese language task. The first four rows show the performance of pre-trained Chinese language models. Model I to IV represent different aggregation strategies: no feature introduced, word semantic feature(WE for short) only, gazetteer feature(GZ for short) only, combination of word semantic representation and gazetteer feature representation. We find that the pre-trained model with WE introduced can achieve higher recall and with GZ introduced can achieve higher precision. The last row gives us the results of an ensemble(V) of model I to IV. Model ensemble results in an improvement of about 0.6% on macro-F1 score, indicating that predictions of model I to IV have good complementarity.

5.3 Hybrid Approach Results

Table 3 shows the results of the hybrid approach on dev dataset. We can find that the recall value of model ensemble(V) is far less than precision from the first row. By integrating lexicon-based and ensemble model-based results for entity candidates generation, and adopting LightGBM for entity confidence ranking, the recall value improves more than 3% and the macro-F1 increases by 1.4%.

The results of hybrid approaches on test dataset are given in Table 4. We can find that with lexicon-based entity candidates generation, the recall improves a lot. By integrating lexicon, model V with a LightGBM confidence ranking model, the F1 score increases more than 10%. To make further improvements, soft templates are used for additional candidates generation, which helps gain an improvement of 0.9% on F1 socre.

Methods	Test P	Test R	Test F1
Ensemble(V)	0.710	0.673	0.678
Lexicon + LightGBM	0.484	0.858	0.359
Lexicon + V + LightGBM	0.786	0.806	0.786
+ soft-template(Hybrid)	**0.805**	**0.794**	**0.795**

Table 4: Results of different approaches on test

Methods	LOWNER F1	Orcas F1	MSQ F1
Ensemble(V)	**0.854**	0.582	0.683
Hybrid	0.852	**0.747**	**0.822**

Table 5: Results of different domains on test

To further analyze the differences and respective advantages of different approaches, detail results of different domains are listed in Table 5. For the ensemble model V, when compared to LOWNER results, the results for MSQ and ORCAS are worse. This large gap shows that the existing model approach cannot generalize well.

6 Conclusion

In this paper, we introduce a hybrid approach for Chinese NER, which contains two stages: entity candidates generation and confidence ranking. We find that integrating word semantic representation and gazetteer representation can improve the performance of neural model-based approach. In particular, our ensemble model of different aggregation strategies performs better. However, due to the limitation of training data, the performance of neural model-based approach drops sharply in other new domains.

Considering that there are new entities and other domain sentences in test sets, we can use Wikipeida lexicon and soft templates to help recall unseen entities, and an entity confidence ranking model is built which results in significant improvement on test sets. For future work, semi-supervised approaches or data augmentation methods could be explored to alleviate the limitation of training data.

Sliced at SemEval-2022 Task 11: Bigger, Better? Massively Multilingual LMs for Multilingual Complex NER on an Academic GPU Budget

Barbara Plank
Center for Information and Language Processing (CIS), LMU Munich, Germany
Department of Computer Science, ITU Copenhagen, Denmark
bplank@itu.dk

Abstract

Massively multilingual language models (MMLMs) have become a widely-used language representation method, and multiple large MMLMs were proposed in recent years. A trend is to train MMLMs on larger text corpora or with more layers. In this paper we set out to evaluate recent popular MMLMs on detecting semantically ambiguous and complex named entities with an academic GPU budget. Our submission of a single model for 11 languages on the SemEval Task 11 MultiCoNER shows that a fine-tuned XLM-R$_{large}$ outperforms the more recent RemBERT, ranking 9th from 26 submissions in the multilingual track. Compared to RemBERT, the XLM-R model has the additional advantage to fit on a slice of a multi-instance GPU. As contrary to expectations and recent findings, we found RemBERT to not be the best MMLM, we further set out to investigate this discrepancy with additional experiments on multilingual Wikipedia NER data. While we expected RemBERT to have an edge on that dataset as it is closer to its pre-training data, surprisingly, our results show that this is not the case.

1 Introduction

Pre-trained language models have revolutionized the field of Natural Language Processing (NLP) in recent years (Peters et al., 2018; Devlin et al., 2019; Zhuang et al., 2021). Especially for cross-lingual transfer learning or creating a single multilingual model, pre-trained massively multilingual language models (MMLMs) have become a de-facto standard (Conneau et al., 2020; Chung et al., 2021).

MMLMs such as BERT and XLM-R share the same underlying idea: multilingual representations are obtained by learning from large text collections in multiple languages and are trained using a language modeling objective. MMLMs, in contrast to alternative cross-lingual transfer strategies, thus do not rely on explicit alignment via parallel data and explicit transfer via translations with e.g. annotation projection. MMLMs, together with the pre-training and fine-tuning paradigm, have enabled impressive results (Conneau et al., 2020; Lauscher et al., 2020; Müller-Eberstein et al., 2021).

This paper describes our submission to Task 11 on Multilingual Complex Named Entity Recognition (MultiCoNER) (Malmasi et al., 2022b,a). We evaluate several recent MMLMs in a fine-tuning regime to answer the following main research question (RQ1): *To what extent are more recent larger LMs outperforming earlier MMLMs for the task of multilingual complex NER?* To do so, we test four MMLMs (mBERT, XLM-R base and large and the most recently proposed RemBERT). As other NER datasets exists, albeit with different labels, we further explore multi-task learning (RQ2): *To what extent can we improve upon MultiCoNER by using cross-lingual cross-domain NER data as auxiliary data?* Finally, as the MMLMs were pre-trained on different kinds of data, we include experiments on a second NER dataset, to answer RQ3: *To what extent does RemBERT outperform XLM-R when the pre-training data is a closer match?*

Our contributions are:

- We train a single multilingual model on MultiCoNER, which to our knowledge, is the largest multilingual NER evaluation campaign to date in terms of manually-annotated multilingual training data availability. We compare four MMLMs for the task and examine task performance and GPU budget (here: 20gb).
- Surprisingly, we find that RemBERT does not work well. To shed more light on this, we run additional experiments on a NER benchmark which is closer to RemBERT's pre-training data and prior work. Overall we find XLM-R$_{large}$ to provide the best performance and a good space/training-time trade-off.

Model	Model Name	Language Variety	Languages	Vocab	H_dim	Layers	Params
mBERT	`bert-base-multilingual-cased`	Wikipedia	104	120k	768	12	110M
XLM-R_{base}	`xlm-roberta-base`	CommonCrawl	100	250k	768	12	270M
XLM-R_{large}	`xlm-roberta-large`	CommonCrawl	100	250k	1024	24	550M
RemBERT	`google/rembert`	CommonCrawl+Wikipedia	110	250k	1152	32	559M

Table 1: Overview of pre-trained massively multilingual language models (MMLMs) used in this work. All 12 languages used in MultiCoNer are part of the pre-training data of all MMLMs.

2 Experimental Setup

This section describes the model, all data sets and the multilingual language models used in this work.

2.1 Transformer-CRF

We use a transformer-CRF model for NER, implemented in the MaChAmp toolkit (van der Goot et al., 2021) (v0.3 beta). The toolkit enables easy exchange of pre-trained LM for fine-tuning as well as multi-task learning. Our model is a single MMLM fine-tuned with a single CRF decoder.

To train MaChAmp, we use the proposed default parameters (van der Goot et al., 2021), which have shown to work well across tasks with a learning rate of $lr = 0.0001$. We train the model for 20 epochs and select the best checkpoint using the provided dev data (`multi_dev`).

2.2 MMLMs

As our main RQ is to test the effect of using different pre-trained massively multilingual language models, we opted for four well-known variants: multilingual BERT (Devlin et al., 2019), XLM-R with both the *base* (XLM-R_b) and *large* (XLM-R_l) version (Conneau et al., 2020), and the more recently introduced RemBERT (Chung et al., 2021).

An overview of the MMLMs is provided in Table 1, and summarized as follows:

- mBERT: trained using both Masked-Language Model (MLM) and next-sentence prediction tasks on Wikipedia data and trained with an exponentially decaying smoothing distribution over languages with $\alpha = 0.7$, i.e., to down-scale high-resource languages and up-scale lower-resource languages; 12 layers.

- XLM-R: trained using only MLM on CommonCrawl data and trained with an exponentially decaying smoothing distribution with $\alpha = 0.3$ (more aggressive smoothing); with 12 (base) or 24 (large) layers.

- RemBERT: trained using only MLM[1] on Wikipedia and CommonCrawl data, with an exponentially decaying smoothing distribution $\alpha = 0.5$; trained with decoupled input and output embeddings and parameters redistributed over 32 layers.

We observe that the MMLMs are trained on 100, 104 and 110 languages, where RemBERT is the MMLM with the largest amount of language coverage (110). We note that for MultiCoNER, all 11 target languages are included in the the pre-training material of all four MMLMs. What differs amongst others is the vocabulary size, the number of layers, the pre-training method, the pre-training data and the number of parameters. XLM$_{large}$ and RemBERT are closest in terms of total number of parameters, with RemBERT having an additional 9M parameters over XLM-R_{large}; mBERT and XLM-R_{base} are a fifth and half of the number of parameters, respectively. What stands out is the type of pre-training data, as the language variety that these MMLMs were trained on differs. While the ones created by researchers at Google opted mainly for Wikipedia data (mBERT, RemBERT), the XLM-R models from FAIR research are trained on a cleaned CommonCrawl dump (Wenzek et al., 2020).

2.3 MultiCoNER Data

The training dataset provided by MultiCoNER organizers is one of the largest and most diverse multilingual NER datasets available to date in terms of training/dev/test sizes and language/domain coverage (presumably manually annotated).[2]

In contrast, the Panx (WikiAnn) dataset (Pan et al., 2017; Rahimi et al., 2019) covers a much larger span of languages (over 200) but its coverage is limited to Wikipedia data, and it contains fewer entity types and semi-automatic annotation. Moreover, MultiCoNER is set up for complex NER,

[1] `shorturl.at/pwyFQ`

[2] At the time of writing this system paper we did not have further information on how the data was annotated.

Multilingual	Train	dev	test
sentences	168.3k	8,800	472k
token	2,752,814	144,641	4,565,160
word types	360,679	47,570	556,102
type/token	0.13	0.33	0.12
entities	237,212	12,513	n/a
PER	43,953	2,342	n/a

CW	38,373	2,015	n/a
LOC	54,030	2,932	n/a
GRP	32,846	1,638	n/a

Table 2: Overview of the MultiCoNER dataset. Every sentence in train and dev contains at least one entity.

Model	**micro F1**	**train h**	**GPU m**	**fits?**
$lr = 0.00001$				
mBERT	81.31	4h20	8gb	✓
RemBERT	83.89	7h40	27gb	✗
$lr = 0.0001$				
RemBERT	85.03	7h30	21gb	✗
XLM-R$_b$	83.89	7h13	10gb	✓
XLM-R$_l$	**86.32**	10h30	**16gb**	✓
RemBERT+aux	85.00	9h30	23gb	✗
XLM$_l$+aux	85.89	11h30	19gb	✓

Table 3: Result of training the transformer-CRF with different MMLMs on the multilingual development set. Training time (in hours), GPU max memory usage (approximate) and whether the training fits a single slice of a A100 GPU (the GPU was partitioned into two 20gb slices using NVIDIA's mig mode). XLM$_l$ takes more time but less memory, which enables parallel training of two XLM$_l$ models on a single sliced GPU.

which include further challenges such as detecting named entities on search queries and code-mixed data (Meng et al., 2021; Fetahu et al., 2021). MultiCoNER contains 6 entity types (person, location, product, corporation, groups but also complex entities) for the following 11 languages: English (en), Spanish (es), Dutch (nl), Russian (ru), Turkish (tr), Korean (ko), Persian/Farsi (fa), German (de), Chinese (zh), Hindi (hi), and Bangla (bn). While we focus on the multilingual track, and the data provided for it (`multi`), the shared task further features monolingual tracks and a code-mixed track containing data of some of these languages.

Table 2 provides an overview of the MultiCoNER multilingual data. It is a very large training set of 168.3k sentences, 2.7M tokens and over 237k entities spanning 11 languages. Table 6 in Table 2 shows the size of the dev and test portions (note the very large test data with 472k sentences) and the distribution over the 6 entity types in the training and dev data. Location (LOC) and person names (PER) constitutes the largest portion of entities, followed by CW, corporate names (CORP) and group names (GRP) and the least frequent entity type is product names (PROD). The appendix lists sizes of individual language test files.

2.4 Auxiliary or Matching Data?

For RQ2, we use a multi-task learning setup, and model the MultiCoNER task as the main task with a CRF output decoder, and add a second CRF-decoder that predicts NER types from the union of three cross-lingual cross-domain datasets. In particular, we use German data (Benikova et al., 2014), and two recently proposed derivatives annotated on top of Danish (Plank et al., 2020) and EWT-NNER on top of the English Web Treebank (Plank, 2021). While all three data sources were annotated for nested NERs (a two-level annotation scheme, which annotates e.g., a location for "Birmingham" inside "University of Birmingham"), we here use only their inner layer entities. In addition, these data contain slightly different entity types with finer-grained subsets: location, person, organization and miscellaneous entities with two additional suffixes that add derivations (e.g., adjectival forms like "Brasilian" and partial NERs like "Nintendo-based"). The total auxiliary training data (we take the union of English, Danish and German data) consists of a total of 21.4k sentences (roughly 8% of the MultiCoNER main task data) with 42.6k entity annotations. We train the multi-task model jointly by full-parameter sharing, no loss weighting and selecting the best checkpoint using the sum over both main and auxiliary task development span-F1.

For RQ3, we compare the two best MMLMs on a NER benchmark derived from Wikipedia (Pan et al., 2017) (WikiAnn/Panx). We follow the setup of Lauscher et al. (2020) and use 12 languages: Indian (in), English (en), Arabic (ar), Finnish (fi), Hindi (hi), Japanese (ja), Russian (ru), Turkish (tr), Basque (eu), Hebrew (he), Italian (it), Korean (ko), Swedish (sv) and Chinese (zh), which use the same splits as RemBERT (Chung et al., 2021), which were provided by Rahimi et al. (2019).

2.5 NER evaluation: macro-F1 vs micro-F1

For evaluation and model selection, we use the CoNLL span-F1 which is a micro-F1 over span-based entity F1 scores. We note that some earlier work report Accuracy, which can be misleading for NER due to the high number of non-entity tokens typical for the task. The MultiCoNER organizers opted for span-based *macro* F1. While both micro and macro F1 consider entities correct only if both the entity boundaries and the labels match, the MultiCoNER macro entity-based F1 is typically lower and hence a more conservative measure, particularly when entity types are unbalanced, which is the case for MultiCoNER. Hence, we adapted a Python-version of the Conlleval scorer to include macro-F1.[3] We report macro-F1 for the aggregated evaluation measures.

3 Results

Table 3 provides the main results of a single model trained on the MultiCoNER `multi_train` data and evaluated on the `multi_dev` portion.

Bigger is not always better From the MMLM comparison in Table 3 we first observe that mBERT is outperformed substantially by more recent MMLMs. As expected, XLM-R$_l$ outperforms XLM-R$_b$. However, regarding RQ1 our results show that bigger is not always better: XLM-R$_l$ outperforms the more recent and even larger RemBERT model. Surprisingly, this is consistently the case over all target languages.

XLM-R$_l$ is more space efficient While XLM-R$_l$ is the best MMLM in terms of F1 on multilingual complex NER, for an academic GPU budget XLM-R$_l$ is also more efficient: it still just fits a single 20gb GPU slice (NVIDIA A100 40GB GPU split into two slices), at a cost of slightly longer training duration. This means we can fine-tune 2 XLM-R large models in parallel, while only one RemBERT. Further details are given in Table 3.

Test set results Table 4 provides the results on the MultiCoNER test set (last column, `multi_test`). The results confirm the findings from dev: XLM-R$_l$ results in the best model, and substantially outperforms RemBERT. This model ranks 9th in the multilingual track out of 26 participating systems. The auxiliary task (RQ2) fails to provide additional signal, which we hypothesize might be due to the high-resource setup (already a high amount of training data exists), but this would need further investigation. While `multi_test` already contains test data from all 11 languages, the shared task provides further monolingual (and code-mixed) test sets, which is not equal to the sum in `multi_test`. We submitted runs of the best models on these individual test sets which confirm that XLM-R$_l$ remains the strongest MMLM for NER on MultiCoNER.

4 Discussion

In this section, we provide a deeper analysis of our results, adding an additional experiment on data outside of the shared task. First, we examine the per-class F1 score on MultiCoNER, to rule out that the strong results of XLM-R$_l$ are purely due to strong results on a few frequent entity types. Second, we compare RemBERT vs XLM-R$_l$ on a Wikipedia NER dataset to answer RQ3. Previous findings suggest that RemBERT is a stronger model for multilingual NER (Chung et al., 2021) by testing it on *on Wikipedia* data, which is also closer to its pre-training data. So we test whether this is the case with our model as well.

Test set results per entity Figure 1 provides a breakdown of the three best models, showing the per-class F1 scores for RemBERT, XLM-R$_l$ and XLM-R$_l$+aux. The results show that XLM-R$_l$ outperforms RemBERT over all six entity classes, and that the multi-task setup consistently hurts over all entity types.

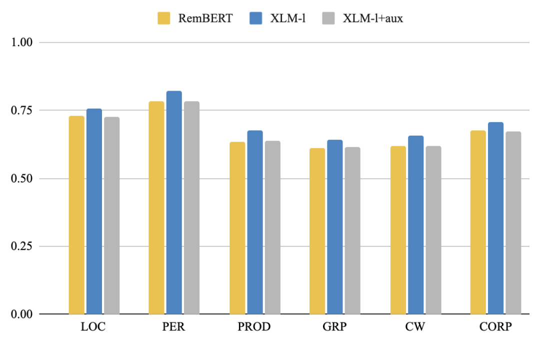

Figure 1: Per-class F1 score on the multilingual test set.

Bigger and better because of better pre-training match? Contrary to our findings, previous work suggests that RemBERT outperforms XLM-R on NER (Chung et al., 2021). We hypothesize that this is not the case on MultiCoNER due to the more

macro-F1	bn	de	en	es	fa	hi	ko	nl	ru	tr	zh	mix	multi
RemBERT	57.14	77.94	73.39	73.62	61.49	60.77	64.59	76.24	70.99	64.97	62.46	70.99	67.61
RemBERT+aux	58.06	77.19	73.27	73.48	62.39	60.09	65.03	75.55	71.10	65.42	62.61	70.79	67.66
XLM-R$_l$	63.05	78.90	74.54	75.11	68.66	67.00	70.66	77.66	73.73	68.77	65.21	72.74	**71.07**

Table 4: Results on the test set. XLM$_l$ is the model that achieved the 9th rank in the multilingual track. Evaluation of this model on all single language and the code-mixed test set included for completeness.

diverse data. A manual inspection reveals that the MulitCoNER data includes both Wikipedia-style data, but also questions without question symbols and short search queries. Therefore, we investigate whether RemBERT instead outperforms XLM-R on a Wikipedia NER benchmark, which matches RemBERT's pre-training data better, cf. Table 1.

	EN	ZH	TR	RU	AR	HI	EU
RB	86.2	82.4	94.1	90.9	90.7	90.7	92.9
XLM	85.9	83.0	93.9	91.3	91.5	92.2	93.2
	FI	HE	IT	JA	KO	SV	avg
RB	92.0	89.5	93.2	76.6	89.6	95.6	89.5
XLM	92.5	90.3	93.1	77.9	90.9	95.9	**90.1**

Table 5: RemBERT (RB) vs XLM-R$_l$ (XLM) on Wikipedia/Panx. Except for EN, TR and IT, XLM-R outperforms RB. Macro-averaged span micro F1 of 90.1.

Table 5 show the results on 13 languages (averaged over 3 runs). The results show that RemBERT has a slight advantage on 3 out of the 13 languages (EN, TR, IT), but overall and on 9 out of the 13 languages XLM-R$_l$ performs substantially better. This additional experiment surprisingly dis-confirms our hypothesis that RemBERT would have an advantage on this Wikipedia/Panx NER data due to the better pre-training data match. While this is in contrast to previous findings on Panx (Chung et al., 2021), the reason is less clear. We studied the literature and found a study on another task (quality estimation) that similarly reports negative results: replacing the XLM-R decoder with a RemBERT decoder performs better only for 1 language pair out of 4 in quality estimation (Treviso et al., 2021). We conclude that XLM-R$_l$ remains the best MMLM for multlingual NER, as tested across two benchmarks (MultiCoNER and WikiAnn).

5 Limitations

We provided a study on four MMLMs for transformer-based multilingual complex NER to shed lights on MMLMs and GPU usage. Our study is limited in number of MMLMs tested, and the fact that we provide only approximate GPU memory consumption figures.

6 Conclusions

We test four massively multlingual language models as encoders for multilingual complex NER. Our results show that XLM-R$_l$ results in the overall best model, and surprisingly outperforms the more recently proposed RemBERT, also in terms of GPU memory consumption. While auxiliary-task training did not further prove promising, we additionally studied the discrepancy between RemBERT and XLM-R on a second benchmark (PANX/WikiAnn data). While we hypothesized that RemBERT would outperform XLM-R, our results show that this is not the case. Overall, a bigger model might not be the best choice, especially not for an academic GPU budget.

Abstract

In low-resource languages, the amount of training data is limited. Hence, the model has to perform well in unseen sentences and syntax on which the model has not trained. We propose a method that addresses the problem through an encoder and an ensemble of language models. A language-specific language model performed poorly when compared to a multilingual language model. So, the multilingual language model checkpoint is fine-tuned to a specific language. A novel approach of one hot encoder is introduced between the model outputs and the CRF to combine the results in an ensemble format. Our team, **Infrrd.ai**, competed in the MultiCoNER competition. The results are encouraging where the team is positioned within the top 10 positions. There is less than a 4% percent difference from the third position in most of the tracks that we participated in. The proposed method shows that the ensemble of models with a multilingual language model as the base with the help of an encoder performs better than a single language-specific model.

1 Introduction

In conll-2003 (Sang and De Meulder, 2003), a shared task was conducted to identify the named entities such as person (PER), location (LOC), organization (ORG), and miscellaneous (MISC). Over a period of time, there was an improvement in the developed systems (Marrero et al., 2009) which resulted in an improved performance that resulted in an increased number of entities. The named entities which needed to be identified and extracted were now six. They are person (PER), location (LOC), organization (ORG), group (GRP), product (PROD), and creative work (CW). Some of these named entities are created by coining a new word that may be non-existent or a combination of existing words in the entire corpus of words in a language. People are most likely interested in coining a new term from the list of words to have an identity tag of a location, an event, or similar concepts. The newly coined words become novel or emerging entities in the list of entities (Derczynski et al., 2017). These words form a most part of ambiguous words, where the word belongs to a particular entity or not, and is difficult to judge. For example, Microsoft is an organization, Windows is a product, and Microsoft Windows is a software product. Apart from this, creating a non-existent word as an entity is an expression of the creativity of the creator which belongs to the creative word entities. A competition was conducted in WNUT 2017 to identify the novel and emerging entities that look for unseen entities as described earlier (Derczynski et al., 2017). These types of entities are complex enough that even a person may miss the context of the entity and represent them differently.

The MultiCoNER competition brings in the additional dimension of complexity of low resources (Malmasi et al., 2022a,b). In a low resource language, the amount of training data available is limited within which the model has to learn to discriminate between the entities and identify them correctly. The model is exposed in this scenario to understand the unseen word that was not part of the training data and doesn't have annotated information to predict. Hence, the development of a model to examine the competition test data is more challenging than ever.

Our contributions and observations are summarized as follows:

- We explore various word-level data augmentation strategies such as LwTR, SR, MR, SiS, and bert-based token augmentation to improve the dataset size when training the transformer-based sequence labeling models. It is shown that the data augmentation increases the model generalization on the test set.

- Performing transfer learning using a multilingual sequence labeling model as an initializer improves the performance on language-specific tracks.
- Introduced the ensemble learning model, 'EnsembleCRF,' that solves the IOB scheme constraint when using majority voting. By learning to optimally combine the model predictions, EnsembleCRF also learns to avoid mistakes made by single sequence labeling models.

2 Related Work

The transformer-based language models fared better in the identification and extraction of entities from a given text. Since there is a necessity for a large amount of training data which provides a much-needed boost in accuracy. Sometimes, a model trained on a huge data in one or more languages is used in another or different language. These types of models are commonly known as cross-lingual language model (Conneau and Lample, 2019) or multilingual language model (Conneau et al., 2019). A fine-tuned language model has a better performance compared to a multilingual language model. But, the multilingual language model is more adaptable across different languages, which is not available for a fine-tuned language model. The researchers started exploring the amount of data required to train a language model. In some cases, the amount of data available in a language with annotation is very limited. These languages are termed low-resource languages. Due to this limitation, the model may not be aware of the complete set of words in the low-resource languages. Here, we are exploring to understand the performance of a transformer-based language model in low-resource constraints. The challenges involved in recognizing complex entities in low-resource environments (Meng et al., 2021; Fetahu et al., 2021) have led to the creation of the competition data (Malmasi et al., 2022a,b).

In low-resource scenarios, different approaches have been adapted to overcome the constraints. The available fine-tuned transformer-based model such as BERT is bootstrapped to improve the accuracy of NER (Yu et al., 2020). A prompt-guided attention layer is used as part of a transformer model by creating a semantic-aware answer space for tuning the model for further betterment (Chen et al., 2021). Sentence reconstruction approach to enhance low resource sequence tagging by utilizing the knowledge of high resource data (Perl et al., 2020). A common approach used on low resource languages is to use cross-lingual transfer learning, where a model trained on high resource language is used as the reference. An active learning mechanism was used to improve the performance of NER (Chaudhary et al., 2019). A teacher-student knowledge transfer model technique has shown to give effective results on low resource NER tasks (Izsak et al., 2019). An unsupervised cross-language transfer learning method where the encoders trained on the source and target language together using adversarial learning followed by augmented fine-tuning technique (Bari et al., 2020).

3 Methodology

Individual pre-trained models were used to evaluate the training and the dev set. Based on the empirical results, we decided to train a baseline language with multiple languages for 20 epochs and then perform transfer learning to train the monolingual models.

3.1 Main architecture

The training set with the following split, 151470 train + 8800 dev + 16830 test sentences, is tokenized and fed to the model xlm-roberta-large to generate the baseline multilingual checkpoint. The embeddings of the transformer model are then passed through the dropout layers. We have three types of dropouts in the mix as shown in Figure 1. The standard dropout with the probability of 0.3, the word dropout with the probability of 0.05, and finally the locked dropout with the probability of 0.5 were used. These embeddings are then linearly reprojected into a vector of size 1024. The reprojected vector is passed through a BiLSTM layer with 256 nodes, which generates a vector of size 512. This output vector is then passed through a CRF layer to generate the class label with IOB sequence tags.

The model is trained for 20 epochs to obtain the starting checkpoint for all the monolingual models. The performance of the monolingual models got a significant boost with cross-language training. We tried to train the last, the last two, the last three, and the last four layers of the transformer but did not get a significant boost while training more layers, so for the final step of training, we resorted to training the last layer of the transformer.

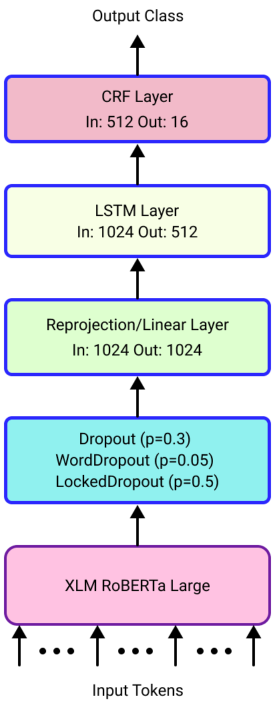

Figure 1: The architecture of the multilingual model was developed to train the training set of the competition data.

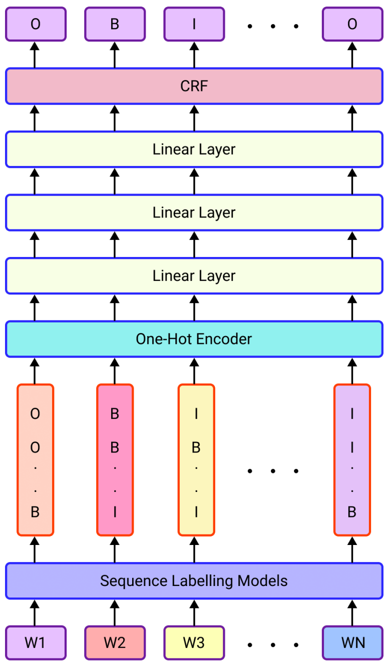

Figure 2: The architecture of EnsembleCRF model. Given a sentence as input, each of the sequence labeling models will output the name entity prediction in IOB format. One hot encoder combines them to generate ensemble output from a Conditional Random Field model.

The generated baseline multilingual checkpoint is loaded and fed with the augmented dataset for each monolingual task to obtain the respective language models. We have used different augmentation techniques described in the Training and Evaluation section. All the sentences provided by the competition organizers were used to generate the augmented data.

3.2 Ensemble architecture

A simple ensemble strategy of *Majority Voting* is developed. Given a set of M sequence labeling models denoted as $C = \{c_1, c_2, ..., c_M\}$ and an input sentence denoted as $S = \{w_1, w_2, ..., w_n\}$, where each w is a word from S. Each model from C will output a sequence of predictions for each word w in sentence S. Let $O^s_{c_i} = \{O^{c_i}_{w_1}, O^{c_i}_{w_2}, ..., O^{c_i}_{w_n}\}$ denote the prediction output of model C_i on sentence S. $O^{c_i}_{w_j}$ denotes the prediction of model C_i on word w_j in IOB format. The set of outputs for all models in C on sentence S will be denoted as

$$O_S = \{O^s_{c_1}, O^s_{c_2}, ..., O^s_{c_M}\} \tag{1}$$

The *Majority Voting* strategy takes all model's predictions of word w_j and outputs the most frequent prediction as to the final prediction for w_j. An obvious issue with *Majority Voting* is the IOB scheme constraint. The final ensemble result is not guaranteed to be passing all the constraints where (I) tag must follow and (B) tag and the entity of neighbor (B) and (I) tag must be the same. We introduce an ensemble learning approach via sequence labeling called 'EnsembleCRF' as shown in Figure 2.

The model outputs are stacked together and passed through a one-hot encoder, three linear layers, and CRF. The CRF layer is trained to optimally combine the model predictions to form a new set of predictions. The addition of the three linear layers helped in the performance improvement. The EnsembleCRF model is of the form

$$C_{en} = EnsembleCRF(C = \{c_1, c_2, ..., c_M\}, \\ D_{en} = \{X, Y\}) \tag{2}$$

D_{en} is the ensemble learning dataset composed of X and Y. $X = \{O_{s_1}, O_{s_2}, ..., O_{s_k}\}$ is created by using model set C and set of input sentences $\{S\} = \{S_1, S_2, ..., S_k\}$ with size K. Each element of X is defined as equation (1). Y is the ground

[a] additionally translated sentences are used

truth entity label in IOB format. During the training phase for some models in set C, we included both provided training and dev datasets. Thus, we choose to perform the ensemble learning using an augmented dev set created using the data augmentation strategies explained in Section 4. Since the second layer classifier is a CRF layer, we solved the problem of breaking the IOB constraints. By learning to optimally combine the model predictions, EnsembleCRF also learns to avoid mistakes made by single sequence labeling models.

We experimented with creating D_{en} with not only the augmented dev dataset but also the augmented training dataset. However, we found that there is no positive correlation between the number of models in C and the macro-averaged F1 score on the test dataset. Treating every possible combination of set C as a hyperparameter to optimize will yield the optimal result.

4 Training and Evaluation

We have used the flair framework (Akbik et al., 2019) which uses pytorch and huggingface transformers to build and experiment with our approaches. The roberta transformer model was used as the base model. However, for some monolingual language training, we stacked a language-specific embedding layer provided by flair. For Dutch, German, and Spanish, flair language-specific embeddings were prepended before transformer embedding for experimentation.

We experimented with two different initial checkpoints loaded to train the transformer model. One checkpoint was from the huggingface library (hug), for both roberta-base and roberta-large. The other was to load the xlm-roberta model trained on the competition dataset as the initial checkpoint for the training of monolingual tasks. However, the models trained with the initial checkpoint from xlm-roberta performed better due to the transfer of knowledge from the multilingual checkpoint to the monolingual checkpoint. The language models used in the experiment for different languages with hyperparameters and macro averaged F1-score on the competition test set are tabulated in Tables 1 and 2.

4.1 Competition Data

The dataset provided by the competition organizers had 15300 train sentences and 800 dev sentences for each language. However, the entity distribution per language varied (Malmasi et al., 2022a,b). The number of sentences used for training is very less when compared to the number of sentences for testing, which provides the low-resource constraint designed by the competition organizers.

Table 2: The language models used for different languages with the strategies adapted and the hyperparameters used for training the model. The last column shows the macro-averaged F1 score on the competition test set (cont.).

4.2 Data Augmentation

Transformer-based language models require huge amounts of data to produce a good performance, but this requires a lot of labeled data. In the real world, such large labeled datasets are not available easily, especially in some specific domains. We need expert knowledge to annotate the data, which is time-consuming. However, we made use of simple data augmentation techniques for token-level (Dai and Adel, 2020). Here, the method concentrates on expanding the training data using smaller training sets and applying transformations to the training instances without changing their labels. We made use of all the techniques (Dai and Adel, 2020) namely Label-wise token replacement (LwTR), Synonym replacement (SR), Mention replacement (MR), Shuffle within segments (SiS), as well as the mixture of all the techniques to augment the training and development datasets. This produced improvement for a few of the languages even over strong baselines, where no augmentation was used. Although there is no clear single winner, applying all augmentation techniques outperformed single augmentation techniques on an average. We have tabulated the results and their explanation in Section 5.

We also made use of other open-source datasets (Samal, 2021) which were related to different domains like history, political parties, and particularly different from the competition training datasets in context. In addition to this, we made use of `nlpaug` (Ma, 2019) to generate the synthetic data without manual effort. A bert-based model was used to augment the original sentences which were later processed to match the number of token labels. These external datasets did not provide improvements to the performance of the baseline model.

5 Discussion and Results

The training strategies for all the tracks fall into these categories namely external dataset, data augmentations, model architecture searching, transfer learning, and ensemble learning as described in Sections 3 and 4. We used a gazetteer as the last option, which didn't improve the performance.

5.1 English

We trained 12 models using a combination of data augmentation, transfer learning, ensemble learning, and model architecture search. Out of the 12 trained models, we observed that using a multilingual model checkpoint for transfer learning on English data gives better performance on the dev set. We also observed that adding BiLSTM and CRF layer gives slightly better performance than using the linear layer as the classifier. Data augmentation didn't show any difference in the performance on the dev set but the model trained using data augmentation performs better in the test set evaluation.

The final model is an EnsembleCRF model trained with 4 Sequence Labeling models. There was a drop in the F1 score when all 12 models were used. So, we eventually kept the 2 models trained with the dev set and for the rest 10 models, we picked the best 2 models on the dev set. For all models in Table 1, we set the maximum epoch to be 100 with a mini-batch size of 50. We used stochastic gradient descent as the optimizer. We skipped the warmup learning rate as it did not show any improvement on the macro-averaged F1 score of the dev dataset. We observed the training to terminate in around the 15th to 20th epoch. For the EnsembleCRF model, we used Adam optimizer with a learning rate of 1e-3 and a weight decay of 0.01. We set the model to train for a maximum of 100 epochs with a mini-batch size of 126. The results of the proposed method for the English language are tabulated in Table 3.

5.2 Spanish

Since Spanish and English languages have a lexical similarity of about 30–50%, we tried translating the English dataset to Spanish and included it in the model training. Unfortunately, the translation experiment did not help in improving the performance of the model. The final model for the Spanish language included all the 4 techniques of token-level augmented data (Dai and Adel, 2020) along with train and dev datasets. We added up augmented datasets to our training pipeline to provide more exposure and to increase the diversity of available data. We used stochastic gradient descent as the optimizer and trained for about 20 epochs after which the performance turned out to be constant. The results on the test set are tabulated in Table 4.

5.3 Dutch

All the strategies with a language-specific embedding layer were used for experimentation namely roberta-base, roberta-large, and xlm-roberta-large models. The final model is an ensemble CRF model trained with 2 sequence labeling models, an xlm-roberta trained on the Dutch dataset and an xlm-roberta trained on the multilingual dataset. We trained the Dutch model on both the train and dev datasets provided by the competition organizers. A test set is created by splitting the (train and dev) dataset internally while training. The model was trained for 20 epochs. The generated predictions on the test set are propagated through an Ensemble-CRF model to ensure consistency in labeling and to improve the labeling accuracy. The results are tabulated in Table 5.

5.4 Korean

We trained 6 models using a combination of strategies as mentioned in Sections 3 and 4. The final model is an xlm-roberta-large followed by a BiLSTM and CRF while using the multilingual model as an initial checkpoint. The Korean model was trained with the training and dev set provided for 30 epochs with a learning rate of 1e-3 and a weight decay of 0.10. Monte Carlo Dropout (MCD) ensemble (Gal and Ghahramani, 2016) was also used for Korean as an ensemble strategy, 15 different inferences were done with varying architecture with a dropout of 0.3 and a majority voting strategy was used for the final submission. Upon analysis, the best performing model and the entire 15 model ensemble had similar performances. We could potentially cherry-pick models from all the 15 possible candidates to improve the scores but time being a limiting factor, it was dropped. The results are tabulated in Table 6.

5.5 German

The German language embedding layer was used with roberta-base, roberta-large, and xlm-roberta models, and all the strategies were evaluated. The submitted model is an ensemble CRF model trained with 2 sequence labeling models, an xlm-roberta trained on the German dataset and an xlm-roberta trained on the multilingual dataset. We trained the German model on both the train and dev datasets provided by the competition organizers. A test set is created by splitting the (train and dev) dataset internally while training. The model was trained for 20 epochs. The generated predictions on the test set are propagated through an EnsembleCRF model to ensure consistency in labeling and to improve the labeling accuracy. The results are tabulated in Table 7.

5.6 Chinese

The amount of work carried out on the Chinese dataset is limited due to time limitations. Most of the experiments were limited to model architecture

searching and transfer learning. We tried various pre-trained Chinese language models that include pre-trained Chinese language models trained on other NER datasets. The best architecture observed is a Chinese BERT model followed by BiLSTM and CRF. Our final model was set to train for a maximum of 50 epochs with a mini-batch size of 24. We use AdamW optimizer (Loshchilov and Hutter, 2017) with a weight decay rate of 0.01. We also used Warmup Learning Rate Scheduler with 10% total training steps as a linear warmup period and rest steps with linear decay. The training terminates at the 24th epoch due to an early stopping mechanism. Our final model with the proposed method was trained for 24 epochs, and the results are tabulated in 8.

5.7 Hindi

We tried various Hindi language-based transformer-word-embeddings to include in the flair framework. Word-embeddings like hindi-bert from monsoon-nlp, multilingual-bert-cased, hindi-bert, and distil-bert of indic transformers were evaluated on the dev set. But none of these outperformed our proposed architecture model. We also tried adding language-specific embeddings which would usually help the model better understand the data. But this did not improve our baseline model performance. Hence, we did not include any additional language-specific embeddings. Our final model is xlm-roberta, which was trained using multilingual train and dev datasets. The model was trained for 30 epochs, and the results are tabulated in Table 9.

5.8 Bangla

It was a challenging task to find good embeddings to represent the Bangla language. We performed a few experiments by including Bangla Indic transformer word embeddings in the flair framework. Similar to the Hindi language, even this embedding did not perform better than our proposed method. We also tried adding language-specific embeddings

which would usually help the model better understand the data. But this did not improve our baseline model performance. Hence, we did not include any additional language-specific embeddings. Our final model is xlm-roberta, which was trained using multilingual train and dev datasets. The model was trained for 40 epochs, and the results are tabulated in Table 10.

5.9 Multilingual

The multilingual task was challenging in itself and our choice of framework made it even harder since we did not have a multi gpu support to conduct all the experiments. The experiments conducted are bucketed mainly into three parts, the architecture search, the data strategy, and the ensemble strategy. After experimenting with various architectures and embeddings, we resorted to xlm-roberta-large for the task. The data strategy was tricky considering all the languages. Open source datasets and translation APIs didn't provide improvements.

We decided to train a stable model and use it as an initial checkpoint for all the other languages. The model was trained for 30 epochs with a learning rate of 1e-3. The final model is xlm-roberta-large followed by a BiLSTM and CRF trained with the entire corpus of train and dev set. Various attempts were made to include the above-mentioned data augmentation techniques but due to the huge model and data along with limited time and resources, we could only do very limited experiments for this model. We tried with the MCD ensemble and took 15 inferences through the varying architectures and used the majority voting strategy to obtain the final submissions. The single best-performing model was at par with the MCD ensemble with majority voting. The results for multiple language sentences are tabulated in Table 11.

6 Conclusion

The recognition of entities from multiple languages with low resources is more complex. The problem lies with the ambiguous entities formed by newly coined words. The syntax of grammar in the sentences was not followed to capture the context between the words. We tried a single multilingual transformer approach, which didn't provide much-expected results. We had used gazetteers for all the languages sourced from the training and wiki data. Both of them didn't produce improvements over the model results.

We trained a multilingual transformer model and performed transfer learning to the individual languages. Since there were multiple languages in the task. We performed unique experiments on one language and then adapted it to the others based on the performance. In the discussion section, the approaches used for experiments are covered and vary for the individual languages. Overall, we created an ensemble of different models which resulted in improvements over the single model. The ensemble architecture covered different types of transformer-based language models. The results reached closer to the top positions with this approach. We also observed that the data augmentation used to improve the performance for a few languages and drop in the performance for the other languages. Our results are above 15% on an average in the participated sub-tasks over the MultiCoNER Baseline results.

We would like to explore the multilingual T5 transformer model, which couldn't be covered during the competition. We would like to explore different augmentation techniques with external data, which couldn't be completed due to time constraints.

Abstract

Building real-world complex Named Entity Recognition (NER) systems is a challenging task. This is due to the complexity and ambiguity of named entities that appear in various contexts such as short input sentences, emerging entities, and complex entities. Besides, real-world queries are mostly malformed, as they can be code-mixed or multilingual, among other scenarios. In this paper, we introduce our submitted system to the Multilingual Complex Named Entity Recognition (MultiCoNER) shared task. We approach the complex NER for multilingual and code-mixed queries, by relying on the contextualized representation provided by the multilingual Transformer XLM-RoBERTa. In addition to the CRF-based token classification layer, we incorporate a span classification loss to recognize named entities spans. Furthermore, we use a self-training mechanism to generate weakly-annotated data from a large unlabeled dataset. Our proposed system is ranked 6th and 8th in the multilingual and code-mixed MultiCoNER's tracks respectively.

1 Introduction

Recent named entity recognition (NER) models have achieved great performance for many languages and using various benchmark datasets such as CoNLL2003 and OntoNotes 5.0 (Devlin et al., 2019). However, it is unclear whether or not these systems can handle ambiguous and complex entities, especially in the case of short and low-context settings (Augenstein et al., 2017). It is also unclear weather these systems can be deployed in real-world scenarios where the input data can be in different languages or code-mixed (Luken et al., 2018; Hanselowski et al., 2018). In fact, to illustrate these issues, if consider the example of complex named entities such as the titles of creative works (movies, songs, books ...), they are hard to be recognized by simple NER systems. This is due to their syntactic ambiguity and the form they can take from one context to another. For instance, they can be as an imperative clause ("Dial M for Murder") or a proposition ("On the beach") which refers to the name of a movie. Thus, it is important to check the performance of NER systems in these scenarios.

The complexity of named entities can be due to three main reasons:

1. **Complex entities:** These entities can be represented as complex infinitives (To Kill a Mockingbird) or full clauses (Mr.Smith Goes to Washington). Additionally, they can be represented as noun phrases or gerunds. State-of-the-art systems (Aguilar et al., 2017) have shown that it is hard to recognize such entities.

2. **Ambiguous entities and contexts:** These types of entities are context-dependent as they can refer to named entities in some contexts, but not in others. “Among Us” which refers to the name of a video game is an example of this challenge. This situation is even more challenging (Mayhew et al., 2019) in the case of short sentences with minimal context such as questions or search queries, which most of the time lack some features such as capitalization or punctuation.

3. **Emerging entities:** This challenge mimics the real-world scenario with many unseen entities, as new named entities are always appearing due to the release of new books, songs, or movies within a short period of time.

It is well known that the state-of-the-art performance reached by current NER systems is mainly due to the presence of easy entities and well-formed input texts (Augenstein et al., 2017). Nevertheless, they yield weak performance when applied in multilingual/code-switched input texts having complex or unseen entities. It is also worth mentioning that the reached state-of-the-art results by current NER systems have been achieved using Transformers-based pre-trained language models (Devlin et al., 2019) that are known to encode the context of input texts and tokens.

In this paper, we introduce our participating system to the MultiCoNER shared task (Malmasi et al., 2022b), in particular, the complex MultiCoNER tracks of multilingual and code-switched queries. Our system relies on a deep learning model based on the multilingual Transformer-based pre-trained language model XLM-RoBERTa (Conneau et al., 2020). To handle the complexity of the two tracks, our model is trained using two optimization objectives, as well as for self-training. The main components of our system can be summarized as follow:

- **Optimization of entities span loss:** We train our model to recognize entities spans as an auxiliary task. The aim is to help the model detect the full entities expressions in an input sentence.

- **Incorporation of Conditional Random Field (CRF) (Lafferty et al., 2001) layer:** We incorporate a CRF layer on top of the Transformer representations to fully exploit the mutual information between tokens in an input sentence.

- **Self-training on unlabeled data:** we create a weakly-supervised data based on the model predictions on unlabeled data.

The rest of this paper is organized as follows. Section 2 presents the related work. Section 3 describes the dataset and the sub-tasks of SemEval-2022 Task 11 (Malmasi et al., 2022b). In section 4, we present our system overview. Section 5 summarizes and discusses the obtained results for both multilingual and code-mixed tracks. Finally, Section 5 concludes the paper.

2 Related Work

During the last years, neural network-based approaches have contributed to improving the performance of NER systems (Panchendrarajan and Amaresan, 2018; Devlin et al., 2019). This was mainly achieved thanks to word embeddings. Static word embeddings are fed to BiLSTM-CRF models and have helped eliminate manual feature engineering while achieving better performance. On the other hand, Transformer-based Language Models (Devlin et al., 2019; Conneau et al., 2020) have greatly improved the NER results thanks to their contextualized word representations.

However, these models may fail when recognizing new or complex entities (Luken et al., 2018; Hanselowski et al., 2018). These challenges are reflecting the real-world setting. Recently, Meng et al. (2021) have proposed an approach to tackle these challenges by using a contextual Gazetteer Representation encoder which can be fused with word-level models. The results have shown that this method enhances the F1-score by +49% in the uncased setting. This work has been mainly applied to the English language. Finally, in another work, Fetahu et al. (2021) have explored the code-mixed NER scenario using multilingual Transformers. They have combined the Mixture-of-Experts model with existing multilingual Transformers models to incorporate the multi-lingual gazetteers. The experiments have demonstrated that their proposed approach enhances the F1-score by +31% in the Code-Mixed NER over the baseline model.

3 Data

The dataset of the MultiCoNER (Multilingual Complex Named Entity Recognition) shared task (Malmasi et al., 2022a) is provided to tackle thirteen different tracks, eleven tracks cover the monolingual cases, while the remaining two tracks cover code-mixed and multilingual data. In this paper, we focus on the last two tracks.

The multilingual track covers eleven languages (English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla), while the code-mixed track covers a subset of these languages. In both tracks, the entities are annotated into six types: PER, LOC, GRP, CORP, PROD, and CW. Table 1 presents the size of the train and test datasets provided for these tracks. We notice that the multilingual track has more data than the code-mixed track, and the test datasets are larger than the train datasets for both tracks.

The provided datasets are labeled using the IOB format which is used for sequence labeling tasks. Table 2 presents the distribution of the entities and the spans in the train datasets for both tracks.

	Multilingual	Code-mixed
Train	168300	1500
Test	471911	100000

Table 1: The size of the train and the test datasets for the multilingual and code-mixed tracks.

4 Methodology

Before discussing the methodology of our proposed system, we assume that we have n labeled sentences with named-entities $D = \{(x_i^t, y_i^t)\}_1^n$ and m unlabeled sentences $U = \{(x_i^u)\}_1^m$, where $x_i = \{x_{i,1}, x_{i,2}, ..., x_{i,l}\}$ represents a sentence containing l tokens, while $y_i = \{y_{i,1}, y_{i,2}, ..., y_{i,l}\}$ are the l labels corresponding to these l tokens.

The proposed system incorporates 4 components used on top of the pre-trained Transformer encoder. In the following, we describe each component of our system.

4.1 Multilingual Transformer encoder

To encode each word in the input sentence, we use the XLM-RoBERTa (XLM-R) (Conneau et al., 2020). It is a multilingual pre-trained transformer encoder network. We choose to use this encoder for the following reasons: 1) XLM-R is the state-of-the-art encoder in the multilingual and code-mixed settings, and 2) It has been trained on 100 languages including the languages covered in the multilingual and code-mixed tracks. This ensures a good contextualized representation for the input sentences despite their language.

This model was mainly trained using the Mask Language Modeling (Devlin et al., 2019). For an input sentence, 15% of the words are randomly masked, then the model tries to predict the masked words. As a result of this training process, the model learns the representations of dimension d for the input words of 100 languages that can be fine-tunned on a downstream tasks such as sequence classification or sequence labeling.

4.2 Span classification module

Span classification is a span-wise classifier, where the aim is to classify whether or not, a sequence of tokens are representing a named entity span based on their semantics. It is a binary classification task as the model predicts **1** if the span is a named entity while it predicts **0** if not.

Given $H = [h_1, h_2, ..., h_k]$, the vector representations of the k sub-tokens contained in a span S, to learn a representation that encodes all the span tokens, we follow the same approach used in (Essefar et al., 2021; El Mekki et al., 2021b; El Mahdaouy et al., 2021), where an attention layer (Bahdanau et al., 2015) learns the span representations SH based on its tokens, as follows:

$$C = tanh(HW^a)$$

$$\alpha = softmax(C^T W^\alpha)$$

$$SH = \alpha \cdot H^T$$

where $W^a \in \mathbb{R}^{d\times1}$, $W^\alpha \in \mathbb{R}^{k\times k}$ are the trainable parameters of the attention layer, $C \in \mathbb{R}^{k\times1}$ and $\alpha \in [0,1]^k$ weights the word representations according to their importance for the task at hand.

The vector representations SH of all the spans in an input sentence are then fed to a feed-forward neural network which classifies whether or not, the input representation refers to a named-entity span.

As illustrated in table 2, we notice that the majority of spans do not represent a named entity. To tackle this imbalanced data issue, we follow (Li et al., 2020) in using the Focal Loss (FL) (Lin et al., 2017). The FL is given by:

$$FL(y, \hat{p}) = -\alpha_y \left(1 - \hat{p}_y\right)^\gamma \log(\hat{p}_y) \qquad (1)$$

where, $y \in \{0,1\}$ denotes the span's label, $\hat{p} = (\hat{p}_0, \hat{p}_1)$ is a vector representing the predicted probability distribution over the labels, α_y is the weight of label y, and γ controls the contribution of high-confidence predictions in the loss. The performed experiments showed that $\gamma = 0.5$ gives the best result.

As the provided dataset in this shared task has been annotated based on named entities, we adjust it for the span classification task. Therefore, we label all the named entities spans as **1** while the rest of spans has been labeled as **0**.

4.3 NER classification using CRF-Layer

Most NER systems using Transformers rely on using the first sub-token of each word as input to the classification layer (Devlin et al., 2019). In our system, we follow the work of (Ács et al., 2021) in using a pooling of the sub-tokens of each word in the input sentence.

Given $H = [h_1, h_2, ..., h_p]$, the vector representations of the all the sub-tokens contained in a word

		Classification tasks							
		Named entity						Entity Span	
	Class	LOC	PER	PROD	GRP	CORP	CW	Entity Span	Not Entity Span
Mutilingual	%	22.02	18.76	15.0	14.0	14.11	16.12	38.82	61.17
Code-Mixed	%	18.27	16.63	17.88	13.9	16.63	16.69	41.71	58.28

Table 2: The distribution of named entities and entities spans in the train dataset for the multilingual and code-mixed tracks

w, an attention layer learns the word pooled representations based on its sub-tokens following the same method explained in section 4.2.

The pooled representations are then fed to the classification layer which is a Conditional Random Field (CRF) layer in our system. We opt for CRF mainly because the Softmax layer does not take into consideration the dependencies between tokens. The self-attention mechanism, performed by the Transformer encoder, encodes these dependencies in the output vectors of the input sentence. While the CRF which is common in sequence labeling tasks ensures output consistency, it transforms the sequence of input word representations to a sequence of probability distributions, therefore, each label prediction depends on the other predictions in the same input sentence.

4.4 Self-training

To take profit from the provided unlabeled dataset in this shared task, we generate a weakly-annotated dataset and re-train the developed model on it. This method has been applied differently in several works (Khalifa et al., 2021; El Mekki et al., 2021a; Huang et al., 2021). In our work, we apply the following pipeline:

1. We train a model M (based on span classification and NER-CRF explained in the previous subsections) using the provided labeled data D.

2. We use the trained model M to predict the labels of the provided unlabeled data. Then we build a weakly-annotated data U

3. We concatenate the datasets T and U and re-train the sequence labeling model.

It is worth mentioning that during the self-training phase, we remove the span classification module.

5 Experiments and results

5.1 Experimental setup

We use the PyTorch framework and the Transformers libraries for the implementation of our proposed system. The training of the model is performed on a server with a single Nvidia Tesla P100 with 16GB of RAM. XLM-RoBERTa Large is used as our multilingual Transformer encoder. Adam optimizer with a learning rate of $1e-5$ is used for all experiments. The system is trained with a batch size of 16 and for 20 epochs.

For the multilingual track, we train our model on the provided labeled multilingual data, then we use the best epoch's model to leverage pseudo-labels from the unlabeled test data, and we re-train the model again from scratch. Besides, for the code-mixed track, we combine the provided data with the training data of the multilingual track and we follow the same training pipeline of the multilingual track.

5.2 Results

Table 3 presents the submitted results for the multilingual and code-mixed tracks using our system. The first row in the table presents the baseline results on the test set published by the shared task organizers. The performance achieved by our best submission largely outperforms the baseline results in both tracks. In fact, the performance using our model boosts the baseline score by 18.39 and 21.11 F1-score points in the multilingual track and the code-mixed track, respectively. The table also reports the performance of our system during the three stages (ablation study):

- The BERT-CRF model that incorporates the named-entity recognition classification layer with CRF,

- The span classification objective, and

- The self-training.

	Multilingual track			Code-mixed track		
	Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**
Baseline	-	-	54.10	-	-	58.10
BERT-CRF	68.59	69.30	68.00	78.47	78.92	78.78
+ Span Classification	70.71	70.56	70.25	78.30	78.77	78.52
+ Self-training	**73.21**	**72.51**	**72.49**	**79.38**	**79.08**	**79.21**

Table 3: Official Complex NER F1-scores on the multilingual and code-mixed tracks using the proposed system.

	Multilingual track			Code-mixed track		
	Precision	**Recall**	**F1**	**Precision**	**Recall**	**F1**
LOC	72.24	81.41	76.01	80.37	83.04	81.68
PER	85.20	81.40	83.13	88.02	88.67	88.35
PROD	70.54	70.24	70.00	82.68	80.51	81.58
GRP	69.78	63.6	66.26	70.85	73.02	71.92
CW	67.58	68.74	67.95	75.00	74.27	74.63
CORP	73.91	69.68	71.60	79.36	74.99	77.11

Table 4: Official Complex NER F1-scores per entity on the multilingual and code-mixed tracks using the proposed system.

The results show that the span classification stage enhances the performance of both tracks: the F1-scores achieved using the span classification are 70.25% for multilingual track and 78.52 % for the code-mixed track. However, we notice that the span classification has significantly boosted the F1-score compared to the BERT-CRF model for the multilingual track, while there is a small performance loss in the case of the code-mixed track. When performing self-training on the predictions extracted from the model using the span classification stage, a large gain has been achieved in both tracks. For the multilingual track, the F1-score obtained using self-training is 72.49% with a gain of 3.18% compared to the system without self-training. For the code-mixed track, our system has achieved the F1-score of 79.21% with a gain of 0.87% compared to the system without self-training.

Finally, Table 4 presents the performance of our best submission for the multilingual and code-mixed tracks. The proposed system fails the most in predicting the **GRP** entities for both tracks, meanwhile, it gives its best performance when predicting the **PER** entities.

6 Conclusion

In this paper, we present our Named Entity Recognition (NER) system for complex scenarios on multilingual and code-mixed queries. Our system relies on 4 components: a multilingual transformer encoder, an entity span classification module, a CRF-layer, and a self-training mechanism that leverages information from unlabeled data. We use our system to submit our predictions in the SemEval-2022 Task 11 within the multilingual and code-mixed tracks. The results show that the use of multilingual Transformer and self-training enhances the results in both multilingual and code-mixed cases. Moreover, the incorporation of the span classification module and the CRF layer allow better recognition of complex named entities.

Abstract

This paper describes our approach to develop a complex named entity recognition system in SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition,Track 9 - Chinese. In this task, we need to identify the entity boundaries and category labels for the six identified categories of CW, LOC, PER, GRP, CORP, and PORD.The task focuses on detecting semantically ambiguous and complex entities in short and low-context settings. We constructed a hybrid system based on Roberta-large model with three training mechanisms and a series of data augmentation. Three training mechanisms include adversarial training, Child-Tuning training, and continued pre-training. The core idea of the hybrid system is to improve the performance of the model in complex environments by introducing more domain knowledge through data augmentation and continuing pre-training domain adaptation of the model. Our proposed method in this paper achieves a macro-F1 of 0.797 on the final test set, ranking second.

1 Introduction

SemEval-2022 Task 11: MultiCoNER Multilingual Complex Named Entities Recognition(Malmasi et al., 2022b). This task aims to address the problem of complex and ambiguous named entities in practical and open domain environments .

The task has 13 tracks, with track 1 being a multilingual track where participants need to train a multilingual model using data from 11 languages. The model should be able to handle monolingual data from any of the languages and code-mixed cases. Tracks 2-12 are monolingual tracks, including English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi and Bengali. Participants are required to train a model for only one language. Track 13 is Code-mixed(Fetahu et al., 2021). This test data contains code-mixed samples. These samples include tokens from any of the 11 mentioned languages in the shared task. We participated in the Chinese monolingual track.

Dealing with complex and ambiguous entities in practical and open domain environments is a challenging NLP task(Meng et al., 2021),however, which has not received sufficient attention from the research community. The challenges of this task are mainly in three facts: 1)The complex entities problem, in which complex noun phrases, verbs, infinitives, or complete sentences, and other entities lack proper nouns, making it difficult to identify them(Ashwini and Choi, 2014).2)The ambiguous entities problem, in which some words are entities in some fields but not in others, especially in search, ASR (Automatic Speech Recognition), and other fields.3)The emerging entities problem, such as books, songs and movies, new works are released every week, and the problem in these fields is that the entities are growing faster, and it is more difficult to identify these newly growing entities.

For the complex entities problem, we use adversarial training and Child-Tuning to increase the representation capability at the parameter level, preventing the model from overfitting due to complex entities, so that the model does not simply remember the complex entities. For the ambiguous entities problem, we use a context-independent data augmentation strategy to replace entities in the data for semantic augmentation, so that the model can reduce the context dependency.For the emerging entities problem, we propose a progressive domain-adaptive pre-training mechanism to improve the performance of the model, so that the preceding methods yielded considerable results, with the F1 value in the Chinese monolingual track reaching 0.797.

2 Related Work

2.1 Named Entity Recognition

Named Entity Recognition is a fundamental problem in natural language processing, and it's a key component of many Natural Language Processing(NLP) activities like information extraction, question-answer systems, syntactic analysis, and machine translation. In general, the aim of named entity identification is to detect three major categories (entity, time, and number) of named entities in the text, as well as seven minor categories (person, institution, location, time, date, currency, and percentage).

NER usually consists of two parts: (1) entity boundary identification and (2) entity category determination. Entity boundaries are easier to identify in English because named entities have more visible indicators (the first letter of each word in the entity should be capitalized), and the work concentrates on establishing entity categories. In contrast to the entity category labeling subtask, the Chinese named entity identification task is more complex, and identifying entity boundaries is more challenging.

2.2 Complex and Ambiguous NER

For complex entities, such as titles of creative works (movie/book/song/software titles), not simple nouns and more difficult to identify. They can be any language component, such as a gerund ("Dial M for Murder"), and they don't appear to be traditional entities (names of people, places, organizations). Because of the syntactic ambiguity, identifying them based on their context is difficult. Finally, these entities increase at a quicker rate than traditional categories.

In datasets like CoNLL03/OntoNots, neural network models (e.g., Transformers) have gotten high scores(Devlin and Ming-Wei Chang, 2019). However these scores are driven by the usage of well-formed news texts, the existence of "easier" entities (e.g., names), and memorization due to entity overlap between training and test sets(Augenstein et al., 2017). These models perform significantly worse on complex/unseen entities. The failure of the NER system to recognize complicated items is responsible for a huge portion of their errors(Hanselowski et al., 2018).

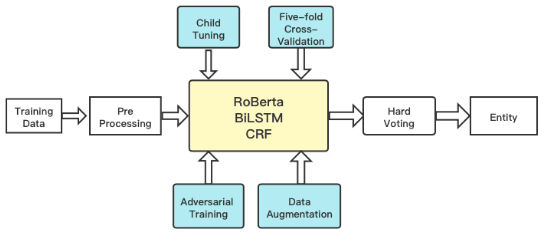

Figure 1: Overall system structure.

3 Our Method

3.1 Overall Approach

The structure of the base model we use is Roberta-wwm-ext-large+BiLSTM+CRF. The sequence samples are pre-trained to obtain their embedding representation, which is then contextually encoded by the BiLSTM(Xu et al., 2017; Ma and Hovy, 2016; Lample et al., 2016) layer, and the contextual encoding is decoded by the CRF(Lafferty et al.; Sutton et al., 2012) to obtain the final annotation result.

In addition, based on the structure of the base model, we first use a back-translation approach to introduce more domain-relevant training data. Related studies have shown that domain-adapted pre-training can improve the performance of the model for the corresponding domain-specific tasks, both with low and high resources. Second, data augmentation is used to extract entities in other languages translated into Chinese and match different contexts to obtain new data, and allow the model to do supervised training using the new data. Finally, we used five-fold cross-training, adversarial training, and child-tuning to improve the performance of the model. Our overall system structure is shown in Figure 1.

3.2 Model Structure

Our basic model structure is shown in Figure 2. The sequence samples get their embedding representation through the pre-training model. Then BiLSTM is connected to the embedding representation for context encoding, and CRF is used to decode the context representation. Finally the annotation result is obtained.

The Bert model, among them, uses Roberta-wwm-ext-large, a joint publication of Harbin Institute of Technology and Pengcheng Lab that uses a full-word Mask scheme in the pre-training phase(Cui et al., 2020). If part of a complete word WordPiece subword is masked, other parts of the

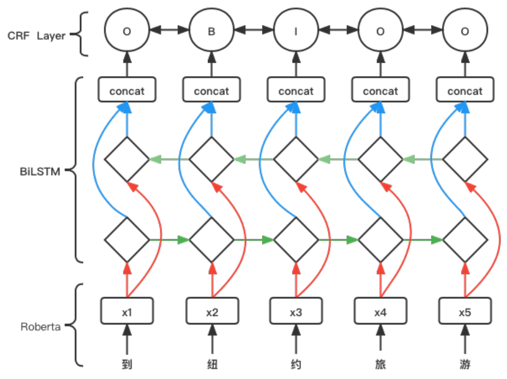

Figure 2: Our basic model structure.

same word will be masked as well, cancels the Next Sentence Prediction, and uses the training model with max len=512.

The underlying model structure is of the form Roberta-wwm-ext-large+BiLSTM+CRF.

3.3 Training Method

Five-fold Cross-voting: We use five-fold cross-validation to divide the training set into five different datasets, and the inconsistencies of entity labeling in each dataset are various. We fix the same model structure, train five models on five training sets, and integrate their prediction results on the same test set by hard voting.

Adversarial Training: To obtain a model with better robustness, we use adversarial training to improve the stability of the model.Referring to the FGM(Miyato et al., 2016) adversarial training mechanism, we directly impose a small disturbance on the embedding representation of the model and assume the embedding representation of the input text sequence $[v_1, v_2, \dots, v_T]$ as x. Then the small disturbance r_{adv} applied each time is:

$$r_{adv} = \epsilon \cdot g/\|g\|_2 \tag{1}$$

$$g = \nabla_x L(\theta, x, y) \tag{2}$$

The meaning of the formulas is to move the input one step further in the direction of rising loss, which will make the model loss rise in the fastest direction, thus forming an attack. In contrast, the model needs to find more robust parameters in the optimization process to deal with attacks against samples.

Among them, applying a small disturbance to the embedding characterization simulates the natural error of the dataset in the labeling to a certain extent. It encourages the model to find more robust parameters during the training process to weaken the impact of aleatoric uncertainty. Then the model's embedding representation will be optimized together with the model. Adversarial training will make the model more tolerant of changes brought about by model parameter fluctuations, thereby decreasing the impact of epistemic uncertainty.

Child-Tuning: In the Fine-tuning process， there is a mismatch between the "high number of parameters" of the large-scale pre-trained model and the "limited number of labeled samples" in the Fine-tuning phase. Child-Tuning proposes, like regular Fine-tuning, using the entire model's parameters to encode the input samples in the forward direction, but without adjusting the huge number of parameters when updating the parameters in the backward direction, i.e. using only a portion of the Child Network. Child-Tuning can be divided into two stages:

- Confirmation of Child Network is found in the pre-trained model, and 0-1Mask of Gradients corresponding to Weights is generated;
- After the gradient is calculated by backward propagation, only the parameters in Child Network are updated, while the other parameters remain unchanged.

Among the above steps,Step 2 is the simplest of the above steps to change the parameters. It's done with a gradient mask, which means that after computing the gradient of each parameter position, it's multiplied by a 0-1 matrix gradient mask, with the positions belonging to the Child Network parameters corresponding to 1 and those not belonging to 0, and the parameters are updated.

The key to this method is to identify the Child Network mentioned in the preceding steps, one of which is the task-independent algorithm Child-Tuning F, whose main advantage is that it is simple and effective; in the Fine-tune process, it only needs to get a Gradients Mask by sampling from the Bernoulli distribution in each update iteration, which is equivalent to randomly discarding part of the gradients when the network parameters are updated.

$$w_{t+1} = w_t - \eta \frac{\partial \zeta(w_t)}{\partial w_t} \odot M_t \tag{3}$$

$$M_t \sim Bernoulli(P_F) \tag{4}$$

Another is the task-related algorithm Child-Tuning-D, which overcomes the disadvantage that Child-Tuning-F treats different downstream tasks with the same policy and treats different model parameters equally.Child-Tuning uses the Fisher Information Matrix (FIM)(Tu et al., 2016) to estimate the importance of each parameter for the downstream task, and, in line with previous work, approximates the diagonal matrix of FIM to calculate the importance score of each parameter relative to the downstream task (i.e., assuming that the parameters are independent of each other), and then selects the parameter with the highest score as the Child-Network.

$$F^(i)(w) = \frac{1}{|D|}\sum_{i=1}^{|D|}(\frac{\partial logp(y_i|x_j;w)}{\partial w^(i))^2} \quad (5)$$

3.4 Data Augmentation

Since the amount of data in the test set is 10 times the amount of data in the training set, the amount of data in the training set is obviously insufficient, so we use data augmentation to get more data. Data augmentation techniques are already standard in the image field, and data augmentation is achieved by techniques such as flipping, rotating, mirroring, and Gaussian white noise on images. However, in the field of NLP, there are four ways of data augmentation: synonym substitution, random insertion, random swapping, and random deletion. In this paper, we use random swapping, i.e., random replacement of entities in a sentence with other entities of the same type. We extract entities in English, German, and Dutch translated into Chinese as replacement entities.

4 Experiment

4.1 Dataset Introduction

SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recog- nition,Track 9 - Chinese provide 15,300 training data, 800 validation sets, and at least 150,000 final test data(Malmasi et al., 2022a). Six types of entities are included: people, places, organizations, products, companies, and creative works.The sentence and character statistics of the training set, development set, and test set are shown in Table 1.

4.2 Evaluation Metrics

This task takes strict macro F1 as the evaluation metric. The macro F1 evaluation metric looks at each entity category equally compared to micro F1, and for the strict F1 evaluation metric, it is considered correct only when both entity boundaries and entity types agree with the standard answer.

Dataset	Type	Train	Dev	Test
Chinese	Sentence	15.3K	0.8K	153K
	Char	382.1K	20K	1835K

Table 1: Statistics of dataset.

4.3 Pre-Processing

Text Expansion: Inevitably there are many combinations of number strings, English and Chinese in Chinese datasets, which are usually done in Chinese ner based on a single character. To maintain uniformity, we expand the English and number strings into a single English letter and a single number.

Labeling Scheme: The annotation scheme is a method for marking character sequences in sequence annotation tasks, by which the type and location of entities in a sentence can be uniquely determined. Moreover, the annotation scheme affects the named entity recognition performance. We use the BIOES annotation scheme which has better performance compared to the BIO annotation scheme.

4.4 Model Parameters

The basic model structure is RoBERTa-wwm-ext-large+BiLSTM-CRF. The batch size is set to 64, the BERT learning rate is set to 1e-5, the BiLSTM+CRF learning rate is set to 1e-3, the training epoch is set to 50, AdamW is used as the optimizer, and a dropout of 0.3 is used.

For the dev set, we used the basic model of RoBERTa-wwm-ext-large+BiLSTM+CRF with two training methods: Child-Tuning and adversarial training.

For the test set, the training data from 10 additional languages were first translated into Chinese using the back-translation approach to do continue pre-training, and then a further pre-training model with 7 epochs and 15 epochs was obtained by changing the training duration.

For the model after continued pre-training, we used data augmentation to extract entities from other languages and translate them into Chinese, and divided the Chinese training set of 15,300 data into five parts, each containing 3,600 training data,

Table 5: Case Study.

and replaced the entities in each part with the translated entities, and added the development set to each data augmentation to get the new five-fold data. Since the total number of entities contained in the other 10 languages is large, we selected three languages with high Baseline scores, English, German and Dutch, to do the data augmentation. Since there are more entities appearing in the three languages, we need to do some filtering by downsampling method.We use the down-sampling method, retaining once for entities that appear once and twice for those that appear twice or more. The final number of entities obtained is shown in Table 2.

4.5 Experimental Results and Analysis

We have conducted a large number of experiments locally and the results are shown in Table 3.

The experimental results of the final test set are shown in Table 4. "+" represents the final results using the fifty-fold cross-validation results of the model to participate in hard voting, and "-" represents not using.

Looking at the results of the local experiments and the test set, we found the following two problems:

- **Why does the use of adversarial training and Child-Tuning in local experiments show a drop in scores?** According to our previous experience, adversarial training and Child-Tuning are effective for improving system performance. We believe this is because local experiments use the development set as the test set for validation, and the number of GRP tags in the Chinese development set is very small, resulting in a strong influence of GRP tags on the results and the score drop phenomenon.
- **Why does the score drop when using data augmentation in a test set?** After using the data augmentation method, the score showed a decreasing trend, which we believe is due to the overfitting phenomenon of adding too many entities, resulting in an imbalance between the number of entities and the number of sentences. Later, we'll experiment with changing the amount of data enhanced entities to see if we can improve the model's performance.

5 Case Study

Our model undergoes the above approach and the above challenges are effectively improved. It is able to identify ambiguous and complex entities in shorter contexts.The case study is shown in Table 5. As you can see, our method can easily predict entities like creative work compared to Baseline and other methods.

6 Conclusion and Future Work

To address the challenges of complex entities, ambiguous entities and emerging entities problem, we propose adversarial training and Child-Tuning training methods, context-independent data augmentation strategies, and a progressive domain-adaptive pre-training mechanism to improve the performance of the named entity recognition system.

In the future, we will focus our efforts on strategies and methods to enhance the use of data and hope to make a good progress.

Abstract

Biological and healthcare domains, artistic works, and organization names can all have nested, overlapping, discontinuous entity mentions that may be syntactically or semantically ambiguous in practice. Traditional sequence tagging algorithms are unable to recognize these complex mentions because they violate the assumptions upon which sequence tagging schemes are founded. In this paper, we describe our contribution to SemEval 2022 Task 11 on identifying such complex named entities. We leveraged an ensemble of ELECTRA-based models exclusively pretrained on the Bangla language with ELECTRA-based monolingual models pretrained on English to achieve competitive performance. Besides providing a system description, we also present the outcomes of our experiments on architectural decisions, dataset augmentations and post-competition findings.

1 Introduction and Related Works

The task of identifying and classifying entities in text is known as named entity recognition (NER). Some named entities are easy to distinguish in English since each of their words is capitalized; e.g. "The capital of Bangladesh is Dhaka". In this sentence, both "Bangladesh" and "Dhaka" are capitalized named entities. But there are other entity mentions that are not simple nouns and are more difficult to recognize. In the SemEval Task 11: MultiCoNER Multilingual Complex Named Entity Recognition (Malmasi et al., 2022b), the organizers concentrated on the more unusual Named Entities, which can be difficult to identify accurately from the text.

NER tasks have received much attention from the research community due to its crucial role in different NLP problems like information retrieval (Etzioni et al., 2005), Question Answering (Banko et al., 2002) (Toral et al., 2005), Relation extraction, Entity linking (Limsopatham and Collier, 2016) and searching (Pasca, 2004). However, there is such a conceptual difference between an ordinary named entity and a complex named entity that traditional tagging strategies cannot be used to recognize these mentions (Brown et al., 1992). Complex NERs can be any language element (single word, abbreviations, imperative clauses, questions) of ambiguous (Multi-type or Overlapping) and non-regular forms (Nested or Discontinuous or Overlapping) (Ashwini and Choi, 2014). What makes the task more challenging is, Complex NER is part of the open-domain with ever expanding and emerging entity sets and categories.

In recent days, Transformer-based models (Devlin et al., 2018) (Liu et al., 2019) (Yang et al., 2019) have been performing as the state-of-the-art (Yamada et al., 2020) (Yan et al., 2019) models in different NER benchmark datasets. Although, Augenstein and colleagues, demonstrate in their paper that these powerful models are only good at picking up the conventional NERs from well formed texts (Augenstein et al., 2017), while for complex NERs we still need to integrate external knowledge sources. A recent paper on integrating external sources or Gazetteer features in combination with contextual information, has shown that this can indeed improve performance on complex NER tasks (Meng et al., 2021). Gazetteer-based solutions also show good performance improvements in extracting NERs from both normal and code-mixed webqueries (Fetahu et al., 2021).

*These authors contributed equally

In tasks like NER, Bangla NLP has not made significant progress. Many linguistic issues arise while training models on Bangla because it is a rich language in terms of both usability and vocabulary (Ekbal and Bandyopadhyay, 2009). In Bangla, there are few markers for tags, such as capitalization (Karim et al., 2019). The same words can have a variety of meanings and types of entities. In addition, because Bangla is a somewhat free word order language, words can exist in any place inside a phrase without changing their meaning (Ekbal et al., 2008). Affixes that are added to the root word to cause complex inflections can modify the meaning and type of the word as well (Ekbal and Bandyopadhyay, 2009). Despite these issues, transfomer models have been used with considerable success for NER tasks in Bangla (Bhattacharjee et al., 2021) (Ashrafi et al., 2020).

In this work, we demonstrate our approaches in tackling the concerns raised in the SemEval Task 11, as well as the obstacles posed by the Bangla language's intrinsic complexity. In our proposed architecture, we used a variety of methodologies, primarily focusing on transfer-learning with state-of-the-art deep learning architectures. In particular, we submitted the results obtained from monolingual ELECTRA models, while we also ran experiments with non-contextual word embeddings and multilingual language models.

2 Dataset Description

According to the organizers, the data were gathered from Wikipedia and Microsoft Orcas, which included both statements and queries (Malmasi et al., 2022a). The train set contains about 100 domain adaption instances, whereas the test set has significantly more out-of-domain data to measure out-of-domain performance. The test dataset is a large file of 130k+ sentences, with a preset training dataset of 15300 Bangla sentences and a development dataset of 800 sentences. Other important statistics about the dataset is presented in ??. The distribution of NER classes in the training set is shown in figure 1.

To perform the experiments, we augmented our datasets in several stages. At first we token-wise translated a portion of our non-Bangla dataset to Bangla using google translate API[1]. In the first stage, we combined translated Hindi and Farsi dataset with our Bangla dataset, as all three languages come from the Indo-Iranian (Wikipedia contributors, 2022) family. Bangla contains borrowed words from Farsi and it has the same sentence structures as Hindi. In the next step, we combined subsets of translated sentences from all the non-Bangla dataset. This process is repeated for English as well. However, for English, we only combined English, Hindi and Bangla datasets. A summary of our augmented datasets is given in table 2.

Type	Frequency
Train	15300
Dev	800
Test	133119
Single Word Tokens	4824
Multi Word Tokens	10481

Table 1: Dataset Statistics

3 System Description

The system we proposed for complex Bangla Named Entity Recognition is an ensemble of ELECTRA based models trained on the augmented datasets mentioned in table 2 and a combination of hyperparameters shown in table 3. The representation of each token is fed into our sequence tagging algorithms, which generate a label for each token. The tag of one token is determined by the attributes of that token in context as well as the tag of the token before it. To execute joint inference, these local decisions are connected together.

The implementation of our mono-lingual ELECTRA-based systems can broadly be categorized based on the decision of using non-contextual embeddings (word2vec) with a contextual pre-trained weight (Bhattacharjee et al., 2021). We defined the vanilla token classification system which is largely based on the huggingface token classifi-

Language	Dataset Version	Dataset Constituents	Train Set (Sentences)
Bangla	D1	Bangla	15300
	D2	Bangla + Hindi(tr.) + Farsi(tr.)	21673

cation scripts [2], as *S1*. The more advanced NER system incorporating non-contextual embedding and optionally, character CNN (Chiu and Nichols, 2016) and CRF (Qin et al., 2008) is defined as *S2*. Finally, we developed a majority voting based ensemble scheme, *S3*, to obtain our final prediction for each token.

3.1 S1 : Vanilla ELECTRA-based token classification

The input to *S1* is first normalized using a specific normalization pipeline developed for Bangla mentioned in the (Hasan et al., 2020) paper. The normalized data is then tokenized and aligned with labels. *S1* has 12 hidden layers, each with 12 attention heads. A standard training loop, with the hyperparameters mentioned in table 3 is used in different combinations. Since the original huggingface script does not include an early stopping mechanism, we wrote a custom callback based on evaluation loss and a patience of 5. High-level overview of *S1* is shown in figure 2.

Table 3: Hyperparameter Settings for *S1 S1.a and S2*

3.1.1 S1.a : Vanilla ELECTRA-based token classification on ENGLISH translated data

As a preprocessing step for this approach, the input dataset was tokenized and translated to english using Google Translate API. The translated input set is then used with the standard huggingface base Electra model with different combination of hyperparameters, as presented in table 3. We experimented with several token-translated language here with early stopping mechanism at patience of 5. The overall architecture is similar to *S1*.

3.2 S2: Advanced NER system

For this system, character and word level features were first extracted and combined with word2vec and ELECTRA embeddings. To generate the final embedding these extracted input features passed through a combination of layers including non-contextual embedding layer, contextual pretrained

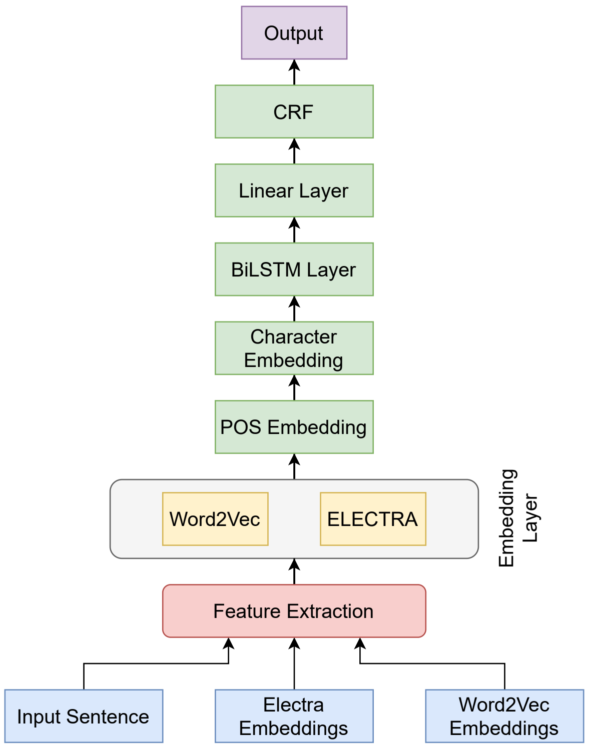

Figure 3: System Overview of *S2*

embedding layer, character embedding layer, parts-of-speech (POS) embedding layer, BiLSTM layer and an additional multi-headed attention(MHA) layer. This is projected through a linear layer and optionally goes through a CRF decoding layer to produce the final predictions. This system also included an early stopping mechanism based on evaluation f1 score. An overview of *S2* is presented in figure 3.

3.3 S3 : Majority Voting Ensemble

The basic concept behind this type of classification is that the final output class is chosen based on the most votes. This ensemble technique has previously been used to overcome the constraints of a single classifier, as presented by the authors in (Siddiqua et al., 2016). Before majority voting, we performed a thresholding on the prediction score for each token from each of the 8 models trained using a variety of augmented datasets, pretrained weights, and hyperparameters. We only considered a token label for majority voting if it had a prediction score over 50%. Then, we counted the number of times the distilled labels appeared in the set. A label was added to the final list of labels if it appeared in the majority of the models. Overview of the *S3* is shown in 4.

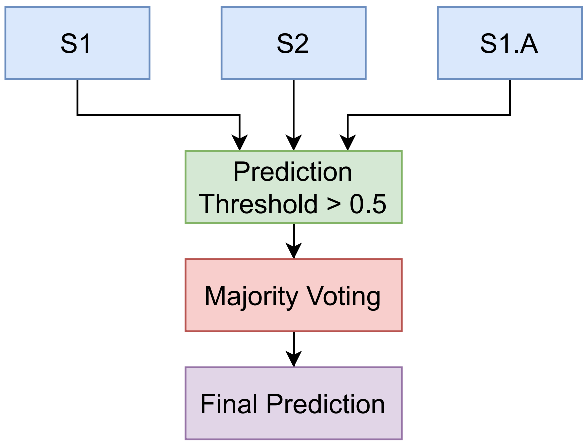

Figure 4: System Overview of *S3*

4 Experimental Setup

As we have previously discussed in section 2, we augmented our training data in multiple steps which extended the dataset several times compared to original. We split each version of these dataset into a 70%-30% ratio during training. The default dev set containing 800 sentences is used for the final validation, in choosing the best performing model during test phase. We employed accuracy, precision, recall, and F1 score as evaluation metrics, with the macro averaged F1 score as the primary and official metric, as per the benchmark of SemEval 2022 Task 11: MultiCoNER (Malmasi et al., 2022b).

We defined each of our best performing model configurations in table 4. While training both *S1* and *S2* we utilized all versions of the Bangla augmented data. Additionally, to train *S1.a* we used all versions of the English translated dataset. In table 3 we have provided the range of hyperparameters used for each of our systems. The performance of these individual models is also demonstrated in table 5. However, in case of the English models, we have only presented the configuration and prediction score for the best performing model. It should be noted that, these models were submitted for evaluation after competition deadline.

5 Results

We made 4 submissions during the test phase, by applying majority voting scheme on various combinations of model predictions. The performance of the final ensemble outputs are presented in 6. As we can observe, the final ensembles of all models performs the highest and it is ranked 8th among all

6 Discussion and Future Directions

From section 5 we see that, there's hardly any difference among the variations of the *S2* models, while major fluctuations can be observed among the variations of *S1* models. Furthermore, separately grouped ensembles of *S1* and *S2* performs almost identically, with the combined ensemble of *S1* and *S2*. However, the performance improves upon including the predictions from *S1.a* models, which are trained on English translated datasets. Despite this, the final best model is clearly overfitting because it had over 80% score on the development dataset, while performing significantly worse (approximately 60%) during the test phase of the competition. This outcome may be attributed to several factors, including the choice of hyperparameters, dataset augmentations and splitting process, early stopping criteria etc. As per the rules of the competition, we only experimented with mono-lingual models to obtain our results. However, we ran the baseline XLM-RoBERTa model which achieves an f1-score of approximately 68% on the development dataset. There are many scopes of expanding this work. For starters, we would like to refine our data augmentation pipeline to generate more well-formed instances. We would explore and compare the performance of cross-lingual and mono-lingual models. We also believe that, the dataset requires further analysis and should receive both quantitative and qualitative error analysis. In addition, we want to do elaborate ablation studies on the components of our systems. In this paper, we have majorly focused on transfer learning and so, in the future, we want to compare the performance of simpler statistical and shallow models with these deep models. Another thing we don't mention empirically in this paper is the class-wise performance of each of our models. From general observation, we find that all the models perform the worst in identifying CW (creative works) tags, while simpler tags like PER (person) and LOC (location) was the easiest to tag. In future, we look forward to investigate more into the reasons behind this behaviors. Finally, we only exploited a simple majority voting based ensemble scheme during this competition. For our future directions, we would also experiment on fusioning the layers of our models to develop a more sophisticated and informed ensembling scheme.

{calebjm288, huichen, bhsu}@ksu.edu

Abstract

In this work, we introduce our system to the SemEval 2022 Task 11: Multilingual Complex Named Entity Recognition (MultiCoNER) competition. Our team (KDDIE) attempted the sub-task of Named Entity Recognition (NER) for the language of English in the challenge and reported our results. For this task, we use transfer learning method: fine-tuning the pre-trained language models (PLMs) on the competition dataset. Our two approaches are the BERT-based PLMs and PLMs with additional layer such as Condition Random Field. We report our finding and results in this report.

1 Introduction

In today's world there is an ever-growing supply of unstructured data, a lot of it in the form of free text. Named Entity Recognition (NER) is a process that seeks to gather information from free text, by extracting and labeling the named entities. SemEval 2022 Task 11 is a competition where NER systems are trained and then they compete against each other for the best scores (Malmasi et al. (2022b)). The task is split into 13 tracks: one for each of 11 different languages, a multi-lingual track, and a mixed language track (Malmasi et al. (2022b)). In this paper we will be focusing on track 1, which is monolingual English NER. For this SemEval Task participants were asked to have their system both identify named entities and then label them with one of the six provided labels. The six labels to be used were person, location, group, corporation, product, and creative work (Malmasi et al. (2022b)). Figure 1 shows an example of these words being tagged with their appropriate labels.

Figure 1: Example of labeling named entities in a sentence using the SemEval 2022 Task 11 tagging scheme. These two sentences are taken directly from the SemEval 2022 Task 11 training set (Malmasi et al. (2022a)).

For this paper our strategy involved trying various transformer models from the HuggingFace library (Wolf et al. (2020)) and training them on the training data provided. We then tried adding a conditional random field layer to some different models to see if that would improve the scores that we received. With all the models we trained we also fine-tuned many different training parameters to obtain the best scores possible. We tried using different number of epochs, different learning rates, different batch sizes, and changing many additional parameters.

In the research we have done leading up to this paper we have learned many things. One is that adding a CRF layer to a BERT model (Devlin et al. (2018)) helps its performance, but adding a CRF layer to a DeBERTa model (He et al. (2021)) doesn't help and actually hurts its performance for NER. We also learned through our testing that a DeBERTa model (He et al. (2021)) is one of the best transformer models for NER, specifically on the SemEval 2022 Task 11 dataset (Malmasi et al. (2022a)).

2 Related Work

There are many challenges that can make NER extremely difficult. In Meng et al. (2021) they explain that named entity recognition is especially difficult in situations with low-context or in scenarios where the named entities are exceptionally complex and unique. Also as stated in Li et al. (2020) NER requires well annotated data and lots of it. This a major obstacle because annotating data can be extremely time consuming and expensive.

Some older approaches to NER include rule-based systems and unsupervised learning systems, however both of these fall short of the performance of modern feature-based supervised methods, which often use transformer models (Li et al. (2020)). According to Li et al. (2020) using pre-trained transformer models with other possible layers and then fine tuning these transformers is becoming the standard for NER. Within this paper we will be using pre-trained transformer models to help us achieve the best results.

Another related work (Souza et al. (2019)) shows the use of a BERT transformer model (Devlin et al. (2018)) for named entity recognition. They also added a conditional random field (CRF) layer on top the BERT model which ended up improving results. This paper (Souza et al. (2019)) shows that both BERT is good for NER and that adding a CRF layer can also help a transformer model perform better.

3 System Overview

For this paper our main strategy will be fine-tuning some large feature-based transformer models on the training data provided. We used the HuggingFace library (Wolf et al. (2020)) to download and train the transformer models. To train our models we used the HuggingFace default optimizer called AdamW. For the most part, we left the AdamW optimizer parameters at the default values. Also, for all of the models we used a linear learning rate scheduler with zero warm up steps.

3.1 BERT

For this competition we experimented with several different systems and methodologies. The first and most basic was to train a BERT model on the data provided (Devlin et al. (2018)). To do this we took a BERT-large-uncased model and trained it for 5 epochs at a learning rate of 2e-5 on the competition training data. With this model we received a precision of 0.870, a recall of 0.811, and a F1-score of 0.839.

3.2 BERT-CRF

Next, we tried improving the score of the BERT model (Devlin et al. (2018)), by adding a conditional random field (CRF) layer after the BERT model. Following the work in (Yang and Hsu (2021)), using the CRF layer should help the model learn the specific parameters of the task, and thus increase the score. We trained this model for 6 epochs at a learning rate of 2e-5 and with a weight decay of 0.01. With this model we received a precision of 0.851, a recall of 0.862, and a F1-score of 0.856.

3.3 DeBERTa-Large

The third model was created using a DeBERTa pre-trained language model. DeBERTa is a BERT (Devlin et al. (2018)) based transformer model that uses disentangled attention and enhanced decoding to improve performance (He et al. (2021)). Within DeBERTa they used a two-vector approach where they split the position encoding and the token encoding into two separate vectors. This allowed the attention layers to be disentangled and learn from each encoding vector separately. They also used enhanced decoding where they give the model both the relative word positions within the sentence and their absolute positions. These improvements allow DeBERTa to outperform BERT in many scenarios (He et al. (2021)). It achieves state of the art scores in many Natural Language Processing tasks including NER (He et al. (2021)).

For this paper we took a DeBERTa model and trained it on the SemEval 2022 Task 11 training data. We got the best results when training the DeBERTa large model for 5 epochs with a learning rate of 2e-5. With this model we received a precision of 0.870, a recall of 0.872, and a F1-score of 0.871.

3.4 DeBERTa-XLarge

This model is similar to the DeBERTa Large except with more parameters. This model has twice the number of layers and parameters. We also got the best results when training the DeBERTa xlarge model for 5 epochs with a learning rate of 2e-5. With this model we received a precision of 0.868, a recall of 0.876, and a F1-score of 0.872.

3.5 DeBERTa-CRF

For this model we decided to follow in the ideas of the BERT-CRF model (Yang and Hsu (2021)) and try to add a CRF layer to our DeBERTa large model (He et al. (2021)). We thought since the CRF layer improved the score of the BERT model that it might do the same for a DeBERTa model. We made a DeBERTa-CRF model and trained it on the task training data for 5 epochs with a starting learning rate of 5e-5 and a weight decay of 0.01. Unfortunately, this model performed quite poorly with a final score precision of 0.820, a recall of

0.830, and a F1-score of 0.825 on the validation dataset (Malmasi et al. (2022a)).

4 Experimental Setup

The data that the organizers provided was in text files in CoNLL format (Malmasi et al. (2022a)). For the English language there was 15300 training examples and 800 validation examples (Malmasi et al. (2022a)). All of the examples provided were in BIO format. BIO is a scheme where all words at the beginning of a named entity are labeled with a B, all the words inside an entity are labeled with a I, and all words outside an entity are labeled with an O. In total that means there are 13 possible tags: O, B/I-PER, B/I-LOC, B/I-GRP, B/I-CORP, B/I-PROD, and B/I-CW (Malmasi et al. (2022b)). The following is the meaning of the abbreviations: PER is person, LOC is location, GRP is group, CORP is corporation, PROD is product, and CW is creative work.

To process that data file first we split the text into each example and then split each example into a list of tokens and labels. Then we mapped each label to a specific number to represent it, 0-12. Finally, from these lists of lists we created a Hugging Face dataset (Wolf et al. (2020)). We left the data sets in the default train/eval splits of 15300 training examples and 800 validation examples.

To evaluate our models, we used the metrics macro precision, recall, and f1-score. Precision deals with how accurate the model is when it does predict a label. Recall corresponds to how good the model is at predicting labels compared to the total number of actual entities. Macro f1-score is the harmonic mean of these two, and gives the best single number representation of how well the model is performing. To calculate these, we used a python library called seqeval (Nakayama (2018)). To use seqeval we simply provide it a list of the predicted values and a list of the ground truth values. The equations seqeval (Nakayama (2018)) uses are shown below with tp being true positives, fp being false positives, and fn being false negatives:

$$Macro\ Precision = \frac{tp}{tp + fp}$$

$$Macro\ Recall = \frac{tp}{tp + fn}$$

$$Macro\ F1 = \frac{2 * Precision * Recall}{Precision + Recall}$$

5 Results

Based on the results shown in Table 1 the DeBERTa-XLarge model (He et al. (2021)) performed the best. The BERT-CRF model was significantly better than the BERT model (Devlin et al. (2018)), but it still wasn't better than the DeBERTa models. As expected, the DeBERTa-XLarge model slightly outperformed the DeBERTa-Large model since it had more parameters. The DeBERTa-CRF model performed much worse than we had hoped and was worse than even the base BERT model.

Model	Precision	Recall	F1
BERT	**0.870**	0.811	0.839
BERT-CRF	0.851	0.862	0.856
DeBERTa-Large	**0.870**	0.872	0.871
DeBERTa-XLarge	0.868	**0.876**	**0.872**
DeBERTa-CRF	0.820	0.830	0.825

Table 1: Summary of the scores of all the models tested in this paper. All the scores are from testing on the SemEval 2022 Task 11 validation data set (Malmasi et al. (2022a)).

Interestingly the BERT base model (Devlin et al. (2018)) was tied for the highest precision score even though its recall and F1 scores were relatively low. This means that when it did make a prediction the BERT model was the most accurate at labeling that entity. Out of all the models tried the DeBERTa-XLarge model (He et al. (2021)) ended up as the best scoring model overall and had the highest recall score.

For the official results we used our best model which was the DeBERTa-XLarge model (He et al. (2021)) and made predictions on the provided test data set (Malmasi et al. (2022a)). According to those official SemEval 2022 Task 11 metrics our model had a macro F1 score of 0.717 on the test data. This score put us in 16th place in the competition results.

5.1 Category Results

Table 2 displays the results of our best model, the DeBERTa-XLarge model, on each tag category. Person and location both have high scores with creative work and product being much lower. This makes sense because person and location had the most instances in the training data. Intuitively it also makes sense because person and location are generally simpler entities to identify.

Model	Precision	Recall	F1
Corporation	0.82	0.84	0.83
Creative Work	0.71	0.74	0.73
Group	0.80	0.88	0.84
Location	0.88	0.93	0.91
Person	**0.94**	**0.96**	**0.95**
Product	0.78	0.81	0.80

Table 2: The results of our best model the DeBERTa-XLarge model on each possible label. These scores are on from evaluating on the SemEval 2022 Task 11 validation data set (Malmasi et al. (2022a)).

5.2 Error Analysis

Figure 2 shows a confusion matrix for out best model, the DeBERTa-XLarge model. It shows a couple of key areas where our model is struggling. The matrix shows that while our model is doing well most of the time, there are a couple of labels it commonly confuses. For example it struggles distinguishing between group and corporation. As seen in the matrix when our model predicts B-CORP it is right 88.1% of the time and its most common error is B-GRP which it mistook for B-CORP 4.1% of the time. Logically this makes sense because those labels are quite semantically similar. Interestingly for the entities the model is the worst at predicting (product and creative work), the most common mistake is labeling them PROD or CW when in reality it isn't an entity and is O.

Another surprising error is the number of I or inside entities the model struggles with. It was expected that the model would figure out that the for example an inside entity like I-PER can not follow a start entity of a different type like B-LOC. In an ideal case the model shouldn't mistake an I entity with another I entity, it should just match the B entity. However there are cases in the output of this happening. This would be a good problem to fix in future work.

6 Conclusion

We tried many different types of models for this SemEval 2022 Task 11 competition. We tried training each of these models on the training data, a BERT model, a BERT-CRF model, a DeBERTa-Large model, a DeBERTa-XLarge model, and lastly a DeBERTa-CRF model. In the end the fine-tuned DeBERTa-XLarge model achieved the highest F1-score. We also found out that adding a CRF layer to a DeBERTa pre-trained model didn't help its performance at all.

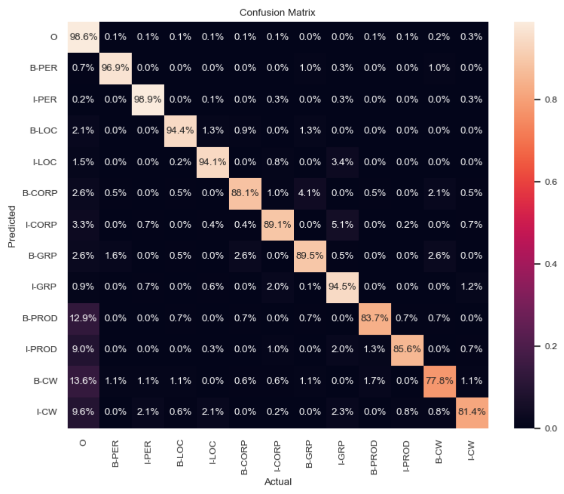

Figure 2: This figure shows a confusion matrix for the different entities that the DeBERTa-XLarge model had to identify. These scores are on from evaluating on the SemEval 2022 Task 11 validation data set (Malmasi et al. (2022a)).

For any future work or improvements on our current work, we would like to try adding some other layers to the DeBERTa model and work on fixing some commmon errors our model has. Since the DeBERTa model seems to be the best at NER, we would like to modify it in some way or modify the data in some way to help it perform better. With further adjustments and experimentation, we believe that the performance of our DeBERTa model could improve.

Abstract

We present Transformer based pretrained models, which are fine-tuned for Named Entity Recognition (NER) task. Our team participated in SemEval-2022 Task 11 MultiCoNER: Multilingual Complex Named Entity Recognition task for Hindi and Bangla. Result comparison of six models (mBERT, IndicBERT, MuRIL (Base), MuRIL (Large), XLM-RoBERTa (Base) and XLM-RoBERTa (Large)) has been performed. It is found that among these models MuRIL (Large) model performs better for both the Hindi and Bangla languages. Its F1-Scores for Hindi and Bangla are 0.69 and 0.59 respectively.

1 Introduction

Named Entity Recognition (NER) is one of the hot topic in natural language processing (NLP). NER is a task of identification of named entities from given sentence and their classification into predefined classes like Person, Location, Organisation, Corporation etc. For below sentence:

राम दिल्ली में गूगल में काम करता है।,
राम is Person, दिल्ली is Location and गूगल is Corporation.

The application of NER can be found in other NLP tasks such as text summarization (Toda and Kataoka, 2005), information retrieval, machine translation (Babych and Hartley, 2003), question-answering (Molla Aliod et al., 2009). The researchers have come up with many approaches for NER task such as Rule-based (Krupka and IsoQuest, 2005), feature-based Supervised approach (Liao and Veeramachaneni, 2009), Unsupervised approach and Deep learning based approach (Li et al., 2020) and Transformer based approach (Vaswani et al., 2017).

The Transformer models are good at capturing features from lengthy sentences compared to recurrent neural networks (Vaswani et al., 2017). RoBERTa model (Liu et al., 2019) performed good for NER task for rich resource languages like English.

For Hindi and Bangla languages, we applied XLM-RoBERTa, which is a multilingual version of RoBERTa pre-trained in 100 languages (including Hindi and Bangla). We also applied IndicBERT (Kakwani et al., 2020) and mBERT (Devlin et al., 2018). At last, we applied MuRIL (Khanuja et al., 2021; Sharma et al., 2022) which is specifically pre-trained in the text of 17 Indic languages and it gave better result than above models for the NER task.

This paper consists of a total of six sections apart from the introduction. Section 2 briefly defines the problem definition and task provided by organizers. Section 3 discusses the work done till now on the NER task. Section 4 mentions the dataset being used in this paper. Section 5 describes the general Transformer architecture for the NER task, along with prepossessing and post-processing. Section 6 discusses the results obtained by used models on both Hindi and Bangla languages and the error analysis. Finally, Section 7 concludes this paperwork.

2 Problem Definition

The organisers (Malmasi et al., 2022b) have arranged 13 tasks according to language. They have provided a separate dataset for each task. Each dataset is comprised of training, development and testing. Respective named entity tags were provided in the training and development dataset. Only tokens were provided in the testing dataset. Participants were required to train the models using the training and development dataset and predict NER tags on the testing dataset. We have worked on Hindi and Bangla tasks.

[*] Authors equally contributed to this work.

3 Related Work

Several works have been done on NER that can be categorized under two broad categories: traditional and deep learning methods.

3.1 Traditional NER approaches

In this approach, feature engineering is carried out by the researchers (Li et al., 2020). Under this category comes the rule-based, feature-based supervised learning, and unsupervised learning approaches.

In the rule-based method, the hand-crafted semantic and syntactic features are provided to recognize the entities (Krupka and IsoQuest, 2005; Aone et al., 1998). These rules-based systems can not be extended to other domains because they depend on domain-specific rules (Appelt et al., 1995).

In the feature-based supervised approach, feature engineering plays a critical role. Features such as word-level features (Liao and Veeramachaneni, 2009; Settles, 2004) and document-level features (Ravin and Wacholder, 1997; Zhu et al., 2005) are used. These features are then passed through supervised models: HMM (Eddy, 1998), Decision trees (Quinlan, 1986), SVM (Hearst et al., 1998) and CRF (Lafferty et al., 2001) for the classification in the labeled corpus.

In the unsupervised approach, the lexical patterns and statistical features are computed, which helps in the clustering (Collins and Singer, 1999). The clustering approach is applied as the data is not labeled in these cases. They extract named entities by making clusters depending on the context similarity (Nadeau et al., 2006).

3.2 Deep Learning NER approaches

As compared to the traditional NER approach, this approach does not explicitly need features. These models automatically extract the hidden features, due to which the accuracies of these models are high compared to the traditional NER approaches. This approach involves the work done using multilevel perceptrons, CNN (Wu et al., 2015), and BiLSTM (Wei et al., 2016; Lin et al., 2017). Recently the Transformer-based models have gained significant advancement in this field (Wolf et al., 2020). The Transformer-based models are good at capturing features in lengthy sentences as compared to recurrent neural networks. The Transformer (Vaswani et al., 2017) is equipped with parallel training and made up of a pair of an encoder and a decoder (to get sequence to sequence prediction). For NER task encoder is used.

In paper (Devlin et al., 2019), the authors have performed NER task on CoNLL-2003 dataset (Tjong Kim Sang and De Meulder, 2003). The authors applied both variants of BERT (Large and Base). The Large variant achieved an F1-score of 92.8 on the test set, whereas the base variant achieved F1-score of 92.4 on the test set. The authors have used BERT as word embedding and fed this to the BiLSTM. XLM-RoBERTa (Conneau et al., 2020) outperform the mBERT (Devlin et al., 2019) and XLM (CONNEAU and Lample, 2019) and show strong improvements over low-resource languages.

4 Data

The dataset (Malmasi et al., 2022a) for Hindi and Bangla contains six different NER entities, namely Location (LOC), Person (PER), Production (PROD), Group (GRP), Corporation (CORP) and Creative Work (CW). The dataset is in standard CONLL format, which uses BIO (Beginning-Inside-Outside) tagging. The dataset provided was of three types, namely training, development and testing. The training and development data contains tokens with tags, whereas testing data contains only tokens. For both Hindi and Bangla tracks, there were 15300 samples in training and 800 samples in development. In the testing dataset, for Hindi and Bangla track there were 141565 (with 933273 total tokens) and 133119

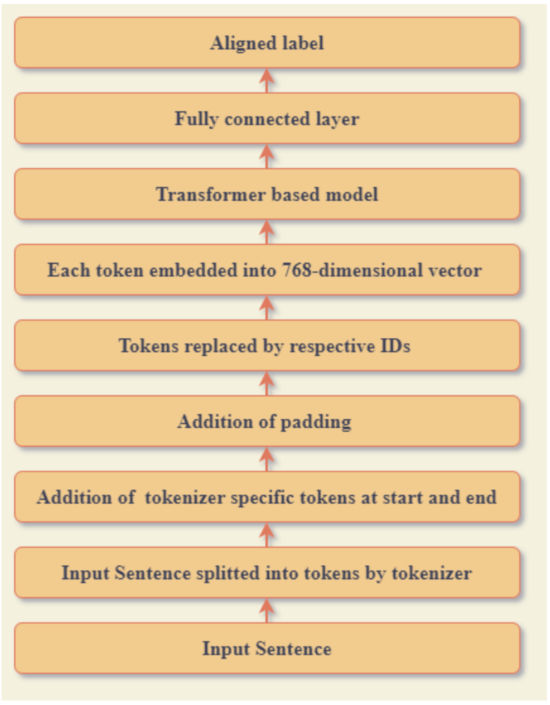
5 Methodology

This work fine tuned 6 Transformer (Vaswani et al., 2017) based pre-trained model for the task. IndicBERT (Kakwani et al., 2020) is Albert based model which is pre-trained on 11 Indic languages, including Hindi and Bangla. We also fine-tuned XLM-RoBERTa (Base) and XLM-RoBERTa (Large) (Conneau et al., 2020), which is pre-trained on text in 100 languages. Other models are mBERT (Devlin et al., 2018) which is pre-trained on text in 104 languages and MuRIL Base and MuRIL Large (Khanuja et al., 2021) which is pre-trained on text in 17 languages with explicitly augmented monolingual text corpora with translated and transliterated document pairs. All the corpora describe above include Hindi and Bangla languages.

Figure 1 shows the architecture of this work, which is divided into 3 sections: Preprocessing, Fine tuning and Post processing.

5.1 Preprocessing

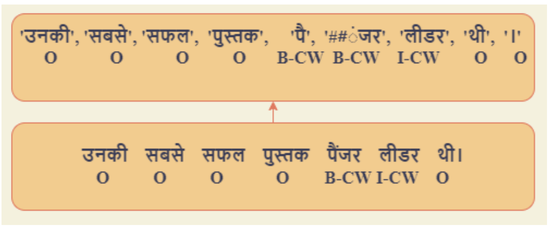
XLM-RoBERTa (Conneau et al., 2020) model and IndicBERT (Kakwani et al., 2020) uses SentencePiece tokeniser (Kudo and Richardson, 2018), which is language independent subword tokeniser and detokeniser. mBERT, MuRIL Base and MuRIL Large model uses WordPiece tokeniser



Aligned label
Fully connected layer
Transformer based model
Each token embedded into 768-dimensional vector
Tokens replaced by respective IDs
Addition of padding
Addition of tokenizer specific tokens at start and end
Input Sentence splitted into tokens by tokenizer
Input Sentence

Figure 1: Generalized transformer-based model

(Wu et al., 2016). As all models use subword tokeniser, any token may get divided into more than one subword. Therefore an alignment of the label is required for that token. Each subword is assigned with the same label as the tokenised word. In figure 2, the token पैंजर is divided by tokeniser into two subwords: 'पै' and 'ंजर', both subwords gets B-CW as their label and the token थी। is divided by tokeniser into two subwords: 'थी' and '।', both subwords gets O as their label. Tokenised sen-



'उनकी', 'सबसे', 'सफल', 'पुस्तक', 'पै', '##ंजर', 'लीडर', 'थी', '।'
O O O O B-CW B-CW I-CW O O
उनकी सबसे सफल पुस्तक पैंजर लीडर थी।
O O O O B-CW I-CW O

Figure 2: Label alignment

tences are added with special tokens along with padding tokens, and thereafter, all the tokens replaced with their ID values for feeding into the models.

5.2 Fine tuning

Architecture in Figure 1 shows that a fully connected layer added on final output hidden vector of the model. This layer takes word embedding corresponding to each token generated by the model (base models generate word embedding of 768 dimension and large models generate word embedding of 1024 dimension) and maps each embedding to the output layer of size (13,), which is the number of unique labels of our task. Further, we calculate loss using the cross-entropy loss function. This model is optimized with Adamw (Loshchilov and Hutter, 2019) and L2 weight decay of 0.01. It is fine-tuned with the dynamic learning rate with linear learning rate scheduler with max learning rate 4e-5, and also, batch size varies from 8 to 64 for different models subject to optimization and a dropout of 0.1 on all layers applied. Maximum token length is taken between 84 to 128 depending on the maximum length of tokenised sentences, which helps in faster training. Number of epochs for training were 30 for all the models in this experiment. We chose best model based on calculated F1-score on valid data. This work predicts the sequence of labels by the argmax of the final layer for each tokens. All models along with the fully-connected layer implemented by XXXForTokenClassification (Wolf et al., 2020), where XXX refers the corresponding model.

5.3 Post processing

After the generation of labels from the model, labels are realigned according to the detokenised sentence. This is reverse of label alignment, discussed in the Preprocessing section. The labels of all the tokens which are first tokens of their original word, are taken as generated labels.

Model	Precision (%)	Recall (%)	F1-Score (%)
M1	47.99	45.77	46.42
M2	51.05	48.08	48.97
M3	62.59	61.49	61.81
M4	**70.06**	**69.07**	**69.08**
M5	47.31	45.98	46.01
M6	51.90	47.90	49.55

Table 3: Results of each model on Hindi test data (M1: mBERT, M2: IndicBERT, M3: MuRIL Base, M4: MuRIL Large, M5: XLM-RoBERTa Base M5: XLM-RoBERTa Large)

6 Results and Analysis

Table 3 and 4 shows the macro average of Precision, Recall and F1-score of each model on testing dataset for Hindi and Bangla respectively.

Model	Precision (%)	Recall (%)	F1-Score (%)
M1	45.28	41.54	42.47
M2	43.40	37.48	38.55
M3	56.98	56.73	56.71
M4	**60.25**	**59.27**	**59.52**
M5	34.75	32.26	33.37
M6	38.74	33.07	35.45

Table 4: Results of each model on Bangla test data (M1: mBERT, M2: IndicBERT, M3: MuRIL Base, M4: MuRIL Large, M5: XLM-RoBERTa Base M5: XLM-RoBERTa Large)

Tables 6 and 7 present the Entity-wise F1 score for Hindi and Bangla testing dataset corresponding to each NER model. It has been found that MuRIL (Large) is showing the highest F1 score for each entity. It has also been observed that the F1 score for CW (Creative work) is the least among all the entities. It indicates that predicting CW is the most difficult for the model.

Sentence	अब तक का सबसे बड़ा बालिका बधू (1976 फ़िल्म)
Gold annotation	[O, O, O, O, O, B-CW, I-CW, I-CW, I-CW]
mBERT	[O, O, O, O, O, O, B-CW, I-CW, I-CW]
IndicBERT	[O, O, O, O, O, O, B-CW, I-CW, I-CW]
MuRIL	[O, O, O, O, O, B-CW, I-CW, I-CW, I-CW]
XLM-RoBERTa Large	[O, O, O, O, O, O, B-CW, I-CW, I-CW]

Table 5: Comparative analysis of a sentence from test corpus

Finally, Table 5 presents the comparative results obtained using different transformer models. Here, the MuRIL output is close to Ground annotation compared to other models.

7 Conclusion

Results show that large models are better than their corresponding base models. MuRIL (Large) model is the best among all six models described above and the second-best model is MuRIL (Base).

Entity	**M1**	**M2**	**M3**	**M4**	**M5**	**M6**

Abstract

In this paper, we describe our proposed method for the SemEval 2022 Task 11: Multilingual Complex Named Entity Recognition (MultiCoNER). The goal of this task is to locate and classify named entities in unstructured short complex texts in 11 different languages. After training a variety of contextual language models on the NER dataset, we used an ensemble strategy based on a majority vote to finalize our model. We evaluated our proposed approach on the multilingual NER dataset at SemEval-2022. The ensemble model provided consistent improvements against the individual models on the multilingual track, achieving a macro F1 performance of 65.2%. However, our results were significantly outperformed by the top ranking systems, achieving thus a baseline performance.

1 Introduction

Named entity recognition (NER) is the process of identifying pre-defined categories of named entities, such as people, places, organizations, from unstructured text. NER usually serves as an important first component in various natural language processing (NLP) tasks, such as question answering (Mollá et al., 2006), information retrieval (Guo et al., 2009) and machine translation (Babych and Hartley, 2003). Thus, the performance of the NER system can influence the quality of many downstream NLP applications. Despite the high performance achieved by the current NER systems, they still face some critical challenges(Augenstein et al., 2017). NER models are typically trained on a well-formed news text containing a variety of entities within a relatively long context. In addition, most of the existing NER datasets usually include a large number of common entities between train set and test set. As a result, the performance of the models drops dramatically in the real world applications as they must deal with unseen entities and noisy texts. Furthermore, previous studies on NER have mostly focused on English and as a result, many other languages specially low-resource ones, such as Turkish, Korean, and Persian, have not been as well studied (Rouhizadeh et al., 2021a,b). In this context, SemEval-2022 proposes the task of Multilingual Complex Named Entity Recognition (MultiCoNER) (Malmasi et al., 2022b), which is concerned with detecting semantically ambiguous and complex entities in short and low-contextual settings for 11 languages (i.e. English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla). In this paper, we present a multilingual NER method based on ensemble of deep neural language models. We first trained multiple NER models on the official training dataset and then utilized an ensemble strategy based on a majority of votes from the top-3 best-performing models. Based on the macro-average F1-score of 65.2, achieved by our model, we placed 20th in the multilingual track of the competition.
The rest of the paper is organized as follows. Section 2 reviews published work related to the NER task. Section 3 and section 4 explain our proposed NER system and the experimental setup respectively. The results and detailed analysis of the model performance are discussed in section 5 and the conclusion and future work are reported in section 6.

2 Related Work

Over the last decade, deep learning approaches have significantly improved the results of different NER tasks (Baevski et al., 2019; Akbik et al., 2018). The most recent works on NER utilize pre-trained language models like BERT in a supervised setting (Yamada et al., 2020; Wang et al., 2020; Schneider et al., 2020; Shaffer, 2021). These models use pre-trained language models that have been trained on a large monolingual or multilingual corpus to fine-tune NER models. Meng et al. (2021) introduced a number of current challenges of developed NER datasets and systems. The challenges include the presence of long-tail entities, i.e., entities with large distribution and millions of values, emerging entities, i.e., domains with growing entities, or complex entities, i.e., linguistically complex entities such as gerunds and full clauses, in the context of the systems' inputs. In addition, as discussed in Jayarao et al. (2018) the context of search queries and questions usually include a short amount of words which could be problematic for NER systems. To overcome the above issues, Meng et al. (2021) created three new NER datasets, including short sentences, questions, and search queries, and a novel NER system which uses a contextual gazetteer representation (CGR) encoder and a mixture of experts (MoE) gating network to feed a CRF layer for final predictions. Fetahu et al. (2021) also tackled the challenge of the code-mixed queries in which entities and non-entity query terms coexist simultaneously. They developed a large-scale NER dataset in six languages with four different scripts as well as a novel multi-lingual NER method for code-mixed queries which integrates external knowledge into the multilingual setting.

3 Method

Our multilingual NER system takes sentences in 11 different languages and automatically identifies and classifies named entities within each sentence. For each sentence, the system utilizes three different BERT-like models (fined-tuned on the multilingual NER dataset) to perform entity prediction independently. Next, for each entity, the label with the majority of votes will be chosen as the final prediction. In the following, we provide details on different NER models we used in our pipeline and our ensemble strategy for label prediction in section 3.1 and section 3.2, respectively.

3.1 Training NER Models

To build our NER model, we first fine-tune a number of pre-trained multilingual transformer-based models, i.e., Multilingual-BERT (Pires et al., 2019), XLM-RoBERTa-base, XLM-RoBERTa-Large (Conneau et al., 2019) and Distilbert-Multilingual (Sanh et al., 2019), on the official training dataset (see section 4.1 for more details about the dataset). We fine-tune each particular model by adding (1): a fully connected neural network (FCNN) layer or (2): a conditional random fields (CRF) layer (Lafferty et al., 2001) on the top of the transformer architecture. Transformer-based models usually use the byte-pair encoding for the tokenization. In other words, each token might be divided into more than one sub-token. To deal with this, during training, among the subtokens labels of a given word, the label of the fisrt sub-token has been considered as the label of the word. We also use the BERT-like models to train a simple BiLSTM model with an additional linear classifier on the dataset [1] Following Reimers and Gurevych (2019), we calculate the vector representation for each context word by taking the average of the layer output embeddings of the pre-trained language model and feed them to a BiLSTM neural network as input[2].

As the next step, we select three of the best-performing NER models and use an ensemble strategy (discussed in section 3.2) to finalize our model.

3.2 Ensemble of the NER Models

Having trained multiple NER models, we use an ensemble strategy based on a majority vote to assign the predictions (Copara et al., 2020b,a; Knafou et al., 2020; Naderi et al., 2021). More in detail, for a given sentence S, three NER models infer their predictions independently. Thus, we will have three labeled instances of S associated with several entity labels. Next, for each identified entity, we choose the label that gets the majority of votes (at least two votes) as the final prediction. Note that as we use three different NER models in our pipeline, three different labels might be assigned to a given entity. In such cases, we choose the predicted label of the best-performing model (evaluated on the dev set) as the final prediction.

4 Experimental Setup

This section discusses the dataset we used to conduct our experiments, followed by the parameters we used to train the models.

4.1 Data

Our experiments were conducted using the multilingual dataset provided by the SemEval-2022 Task 11 organizers (Malmasi et al., 2022a). The dataset consists of entity annotated sentences from eleven dif-

[1]We used the code provided by Adelani et al. (2021) to perform BiLSTM experiments.

[2]We only report the results when we feed the BiLSTM with XLM-RoBERTa-large as it performed best compared to the other models

Table 2: The F1 performance of different multilingual NER models. Each cell include the results when we used a FFCN (the number of the left side) or a CRF layer (the number of the right side) in the model.

ferent languages: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. The six entity types of the dataset are Person, Location, Production, Corporation, Group, and Creative Work. The organizers provided the competitors with NER-tagged training and development sets, and then released an unlabeled test set for the final prediction. To fine-tune our hyper-parameters and evaluate our models in the development phase, we divided the training set into two parts - 0.80% for the train set and 0.20% for the dev set - and used the official dev set (i.e., provided by the organizers) to test the models and analyse our model results as the labels of the official test set are not released. The number and distribution of occurrences of each entity in the training (train and dev) and test (official dev) datasets are reported in Table 1, where we can notice a relatively good class distribution among the training examples.

4.2 Parameters

In our experiments, we fine-tuned different multilingual pre-trained language models including *bert-base-multilingual-uncased*, *XLM-Roberta-base*, *XLM-Roberta-large*, *distilbert-base-multilingual-cased*, and also trained a simple BiLSTM model on the dataset. We trained each particular model for 6 epochs using Adam optimizer (Kingma and Ba, 2014), a batch size of 16, the learning rate of 2e-5, and the maximum sequence length of 256 tokens. We computed the F1 performance of the model on each epoch and finally saved the parameters of the epoch with the best performance to perform NER on the test set.

5 Results and Discussion

5.1 Results

In Table 2, we show the macro-averaged F1 performance of the NER models on the different entities of the unofficial test dataset. We use the three best performing models identified in the dev set, i.e., *XLM-RoBERTa-large + CRF*, *XLM-RoBERTa-base + CRF* and *XLM-RoBERTa-large + FCNN*, to create our ensemble strategy. As shown in Table 2, the ensemble model outperforms the other single transformer-based models, improving the F1-score of the top-performer models by around 1% point. The results also indicate that the models fine-tuned on the XLM-RoBERTa (both large and base) outperform the other models by a wide margin. In addition, a comparison between the results of each particular model with and without CRF on the test set shows that adding a CRF layer to the models could be helpful as it improves the model performance in most cases. The results show that all models perform best in inferring $Person$ and $Location$ entities. This can be due to the large number of instances of both entities in the training set. In Table 1, it is shown that the number of oc-

Sentence Length	$1 \leq N \leq 5$	$6 \leq N \leq 10$	$11 \leq N \leq 15$	$16 \leq N \leq 20$	$N > 20$	All

currences of these entities in the dataset is greater than the other ones. The BiLSTM model also performs significantly worse than the fine-tuned XLM-RoBERTa-large models, despite using the same word vectors.

5.2 Discussion

Effect of the context length One of the most important factors affecting the performance of the NER systems is the context length (Meng et al., 2021). To analyze the effect of the input context on our NER system, we divided the (unofficial) test set into 5 different groups: (1): sentences with five or fewer words, (2): sentences with a context length of at least 6 and less than 11, (3) sentences including at least 10 and less than 15 context words, (4) sentences containing between 15 and 20 words, and (5) sentences containing more than 20 context words. The number and ratio of sentences in each group is reported in Table 3. Figure 1 shows the performance of the ensemble NER model on the different groups of sentences. As it can be seen, the model has the worse performance when the sentences contain 5 or less words. Surprisingly, the model performs best in the second group (sentences containing between 5 and 10 words) showing the strength of the model even in the short the sentences.

6 Conclusion

In this paper, we presented our multilingual NER method that uses an ensemble of different fine-tuned models to identify the named entities in the unstructured texts. Using a variety of multilingual pre-trained language models, we first fine-tuned several NER models and then applied a vote-based ensemble strategy to make the final prediction. Our submission achieved an overall F1 score of 65.2, ranking 20th in the multilingual track of task 11 of SemEval-2022. Our next step would be to examine other possible types of ensemble strategies as it has shown to be effective in the performance of the NER models.

Abstract

Recognizing complex and ambiguous named entities (NEs) is one of the formidable tasks in the NLP domain. However, the diversity of linguistic constituents, syntactic structure, semantic ambiguity as well as differences from traditional NEs make it challenging to identify the complex NEs. To address these challenges, SemEval-2022 Task 11 introduced a shared task MultiCoNER focusing on complex named entity recognition in multilingual settings. This paper presents our participation in this task where we propose two different approaches including a BiLSTM-CRF model with stacked-embedding strategy and a transformer-based approach. Our proposed method achieved competitive performance among the participants' methods in a few languages.

1 Introduction

Named entity recognition (NER) is a popular sequence labeling task in the natural language processing (NLP) arena. It has numerous applications in several computational linguistic tasks including designing efficient search systems, data mining, and document indexing. However, prior studies mostly focused on identifying traditional named entities (NEs) recognition e.g. person names, locations, and organizations names (Murthy et al., 2018).

The ever-growing generation of unstructured social media data contains a huge amount of complex (Meng et al., 2021) and ambiguous(Fetahu et al., 2021) named entities. This is because social media data is severely induced by noise as well as the linguistic constituent, syntactic and semantic ambiguity exists in this data source. Besides, the social media data mostly have multilingual data. Therefore it poses new challenges to the traditional named entity recognizer system (Aguilar et al., 2019; Ashwini and Choi, 2014). To address the challenges of recognizing such complex and ambiguous named entities in multilingual settings, (Malmasi et al., 2022b) introduced a shared task at SemEval-2022 named as MultiCoNER. The task is composed of three category of tracks including multi-lingual, mono-lingual, and code-mixed tracks. A multilingual dataset (Malmasi et al., 2022a) containing data from 11 languages is used to assess the participants' system. To illustrate a clear view of the task definition, we articulate two examples from English languages and corresponding labels in Table 1.

English
Text#1: Adaptation of seinen series by kenichi sonoda. **Tag:** [O, O, B-CW, O, O, B-PER, I-PER, O]
Text#2: It was designed by kohn pedersen fox. **Tag:** [O, O, O, O, B-CORP, I-CORP, I-CORP, O]

Table 1: Data sample.

We articulate the rest of the contents as follows: Section 2 describes our proposed approach whereas, in Section 3, we present our experimental setup and conduct performance analysis against the various settings and participants' methods. Finally, we conclude our work with some future directions in Section 4.

2 Proposed Framework

In this section, we describe our proposed approach for the MultiCoNER shared task. Our goal is to identify the complex and ambiguous named entities in multilingual settings. The task is articulated into multi-lingual, mono-lingual, and code-mixed tracks. To address the task challenges, we employ two different approaches including a BiLSTM-CRF

**The first two authors have equal contributions.

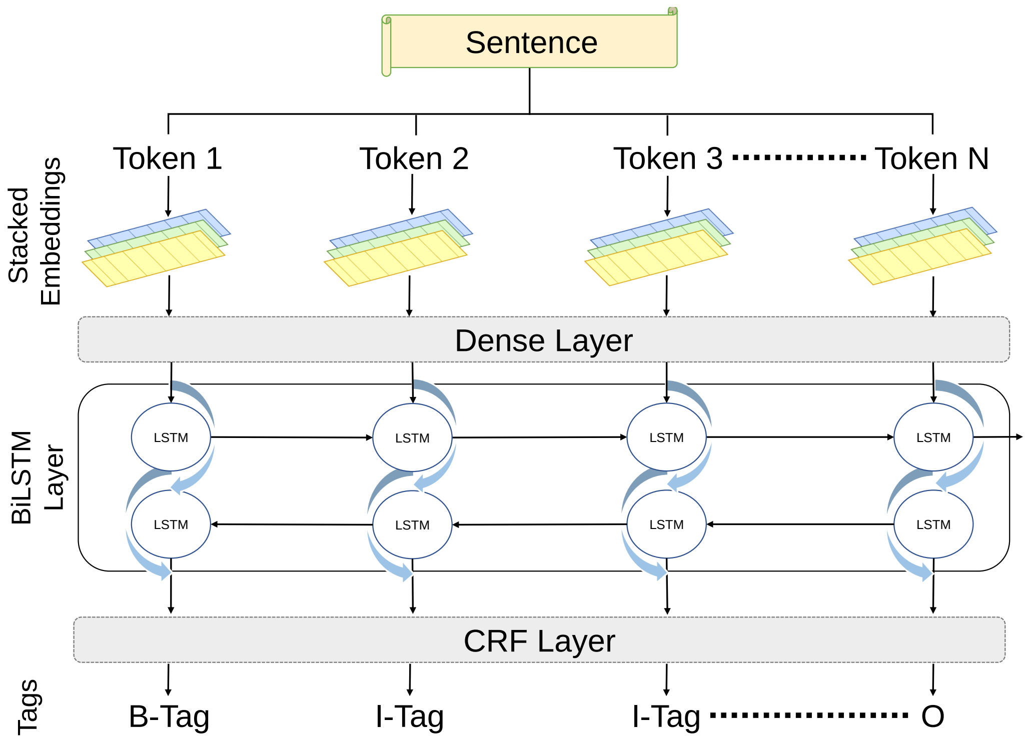

Figure 1: Overview of our proposed BiLSTM-CRF based framework.

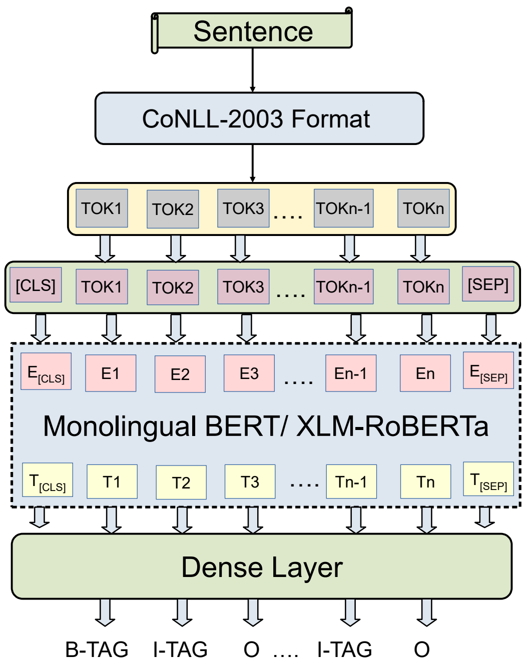

Figure 2: Overview of our proposed transformer-based NER framework.

based approach and a transformer-based approach. The overview diagrams of these approaches are depicted in Figure 1 and Figure 2, respectively. In the BiLSTM-CRF model, we employ the Flair's (Akbik et al., 2019) implementation of stacked embedding technique for effective word representation. Whereas in our transformer-based approach, we employ the available monolingual BERT for each of the languages. However, for some of the languages and for the multilingual and code-mixed settings, we employ the XLM-RoBERTa.

2.1 BiLSTM-CRF with Stacked Embedding

The BiLSTM-CRF model is well-known for the named entity recognition (NER) task. For the training purpose, we use the sentence represented as CoNLL -U format containing BIO tag for each token. A token tagged as O means it is not part of an entity, B-X denotes the first token of an X entity, I-X denotes the token is within the X type entity having multiple tokens. The tokens are then sent to the embedding layer. We employ Flair's (Akbik et al., 2019) implementation of stacked embedding strategy that concatenates embedding vectors of different models together for the effective representation of tokens. To choose the optimal ones in the stacking, we explore various embedding models. The list of embedding models used in our stacked-embedding approach is presented in Table 2. The embedding vectors are concatenated and send to the BiLSTM encoder to distill the contextual dimension of each token. The BiLSTM encoder is followed by a linear-chain conditional random fields (CRF) classifier that generate predictions with the

Track	Word Embeddings Used in Stack Embedding Model (BiLSTM-CRF based System)	Used Transformer Model (Transformer based System)

Table 2: Used word embeddings and transformer models in our CSECU-DSG system.

BIO tagging scheme.

2.2 Transformer based System

In our transformer-based approach, we employ the monolingual BERT model for each of the languages that are available in the Huggingface repository (Wolf et al., 2019). To choose the optimal transformers, we explore various embedding models. However, for some of the languages, XLM-RoBERTa performed better compared to the monolingual BERT. In such cases and also for the code-mixed and multilingual data, we employ the XLM-RoBERTa model.

The Facebook AI launched the XLM-RoBERTa as an upgrade to their initial XLM-100 model (Conneau et al., 2020). It is a scaled cross-lingual sentence encoder. Using self-supervised training approaches, it offers state-of-the-art performances in cross-lingual understanding where a model is taught in one language and then applied to multiple languages with no additional training data. This model showed increased performance on numerous

NLP applications. Utilizing just monolingual data, XLM-RoBERTa was trained with a multilingual masked language model (MLM) objective.

With users publishing content in over 160 languages on Facebook, XLM-RoBERTa is a major leap toward the goal of offering the greatest possible experience on this platform for everybody, regardless of their native language. XLM-RoBERTa creates the possibility for a one-model-for-many-languages approach rather than a single model per language. There are two versions of XLM-RoBERTa. The base version of XLM-RoBERTa contains 250M parameters, whereas the large version has 560M. The vocabulary in both versions is 250K. In our framework, we use the XLM-RoBERTa-base version to extract the effective transfer learning features. The list of transformer models used in our transformer-based approach is presented in Table 2.

3 Experiment and Evaluation

3.1 Dataset Description

The organizers of the SemEval-2022 MultiCoNER shared task 11 (Malmasi et al., 2022b,a) provided a benchmark dataset to evaluate the performance of the participants' systems. The dataset comprises data of 11 languages along with a code-mixed dataset. The dataset statistics are summarized in Table 3.

Track	Training	validation	Test
BN-Bangla	15,300	800	133,119
DE-German	15,300	800	217,824
EN-English	15,300	800	217,818
ES-Spanish	15,300	800	217,887
FA-Farsi	15,300	800	165,702
HI-Hindi	15,300	800	141,565
KO-Korean	15,300	800	178,249
NL-Dutch	15,300	800	217,337
RU-Russian	15,300	800	217,501
TR-Turkish	15,300	800	136,935
ZH-Chinese	15,300	800	151,661
MULTI-Multilingual	168,300	8,800	471,911
MIX-Code_mixed	1500	500	100000
Total	338,100	18,100	2,567,509

Table 3: The statistics of the datasets used in different lingual track.

3.2 Experimental Settings

We now describe the the set of parameters that we have used to design our proposed CSECU-DSG systems for the MultiCoNER task. We employ two different approaches including a BiLSTM-CRF based approach and a transformer-based approach. We employ Flair's (Akbik et al., 2019) implementation of the BiLSTM-CRF approach and Huggingface (Wolf et al., 2019) implementation of the monolingual and multilingual transformer models with fine-tuning. We finetune these models with the provided training data. We also tune several hyper-parameters to obtain the optimal performances. Our hyper-parameters search space is presented in Table 4 and default settings are used for the others.

Hyper-parameters	Search Space
Training batch size	$\{8, 16, 32\}$
Learning rate	$\{0.1, 1e-3, 1e-5, ..., 3e-6\}$
Number of epochs	$\{3, 5, ..., 100\}$
BiLSTM output size	$\{64, 128, 256, 512\}$

Table 4: The hyper-parameters search space.

3.3 Evaluation Measures

To assess the performance of the participants' systems, SemEval-2022 MultiCoNER shared task 11 (Malmasi et al., 2022b) used different strategies and metrics. Since the evaluation file contains instances from all 11 languages and two other language settings including multilingual and code-mixed, the macro averaged F1 score of all these languages is used as the primary evaluation metric to rank the participants' systems. However, the organizers reported the results based on precision and recall evaluation measures too.

3.4 Results and Analysis

In this section, we analyze the performance of our proposed approaches in the MultiCoNER shared task. We have employed two different approaches including a BiLSTM-CRF based approach and a transformer-based approach. The dataset comprises of 11 different languages and two other language settings including multilingual and code-mixed. The overall performance of the system is estimated considering the macro average F1 score obtains in each languages dataset. Considering this,

Table 6: Experimental settings best performing system of all track.

we analyze the performance of our proposed systems, based on each language. The corresponding results are reported in Table 5.

Results showed that the transformer-based approach obtained better performances in most of the languages compared to the BiLSTM-CRF with stacked embedding approach in terms of primary evaluation measure F1-macro. However, in terms of precision BiLSTM-CRF performed better and in terms of recall transformer-based system performed better in most of the languages dataset. Considering the diverse performances in these two approaches the optimal parameter settings of the best-performing ones are articulated in Table 6 and default settings used for the other parameters.

However, comparative performance analysis in most of the languages dataset showed that our proposed system did not perform well to address the task challenges. However, the best performing results of our proposed CSECU-DSG system in the MultiCoNER shared task for the Chinese(ZH) and Hindi (HI) languages along with other top performing and competitive participants systems are articulated in Table 7. Following the benchmark of the MultiCoNER shared task, participants' systems are ranked based on the primary evaluation measures F1-macro. For these two languages, our proposed CSECU-DSG system obtained comparatively better performances.

4 Conclusion and Future Directions

In this paper, we presented our proposed systems to address the challenges of the MultiCoNER shared task. We employed a BiLSTM-CRF with a stacked embedding-based approach and a transformer-based approach. Experimental results demonstrate

Table 7: Comparative results with other selected participants on Chinese and Hindi track.

that transformer-based approach performed better compared to the other approach in most of the languages dataset.

In the future, we have a plan to incorporate the task-specific features and technologies to address the challenges properly. We also have a plan to explore the existing NER technologies and fuse them in a unified architecture to overcome the limitations of the current approaches.

Abstract

Identifying named entities is, in general, a practical and challenging task in the field of Natural Language Processing. Named Entity Recognition on the code-mixed text is further challenging due to the linguistic complexity resulting from the nature of the mixing. This paper addresses the submission of team CMNEROne to the SEMEVAL 2022 shared task 11 MultiCoNER. The Code-mixed NER task aimed to identify named entities on the code-mixed dataset. Our work consists of Named Entity Recognition (NER) on the code-mixed dataset by leveraging the multilingual data. We achieved a weighted average F1 score of 0.7044, i.e., 6% greater than the baseline.

1 Introduction

Named entity recognition (NER) is a fundamental task in NLP. It aims to identify and classify entities in a text into predefined types. It is an essential tool for information retrieval, question answering, (Banerjee et al., 2019) and text summarization tasks (Patil et al., 2016; Li et al., 2020). However, except for some resource-rich monolingual languages, NER annotated data for most other languages are still very limited (Kruengkrai et al., 2020). Moreover, it is usually time-consuming to annotate such data, particularly for low-resource languages such as multilingual and code-mixed (Liu et al., 2021). Therefore, transfer learning and leveraging the other datasets for multilingual and code-mixed NER has attracted growing interest recently, especially with the influx of deep learning methods.

This paper presents the system description for named entity recognition on the code-mixed dataset. Code-mixing is defined as using two or more languages in a single sentence or utterance (Dowlagar and Mamidi, 2021). The use of code-mixed language is prevalent in most multilingual societies. Due to linguistic complexity arising from mixing two languages, the processing of code-mixed sentences is a challenging task (Bali et al., 2014). So, the models that are trained on monolingual and multilingual datasets typically fail to handle code-mixed inputs (Khanuja et al., 2020). Therefore, to encourage research on code-mixing, the speech and NLP communities are organizing several shared tasks. The shared tasks have concentrated on language identification, POS-tagging, sentiment analysis, hate speech detection, and several datasets exist for these as well. Similarly, SEMEVAL 2022's Task 11 sub-task 13 was devoted to identifying named entities in code-mixed languages (Malmasi et al., 2022b). This task aims to classify the given tokens in the code-mixed sentences as persons, corporation, location, and others. An example is shown in Table 1.

Sentence	*hameM*	this	magic	moment
Languge	Hi	En	En	En
NER tags	O	B-CW	I-CW	I-CW

Table 1: An example of the code-mixed NER annotated sentence. The Hindi words are converted from utf to wx format and are italicized

The lack of annotated data is a crucial issue for code-mixed datasets. Lack of data poses a problem of data overfitting and poor entity recognition. The language models trained on such low resource datasets cannot generalize the training data, thus performing low on the test datasets. Several previous studies have used monolingual data as training signals for transfer learning, and these data can also be used in the form of pre-training. Thus, we used a similar approach of including the multilingual data along with the code-mixed dataset.

We used the multilingual pre-trained BERT model as our model for code-mixed NER. The model uses code mixed training data along with the multilingual training and mulilingual validation data.

Table 2: An example of the code-mixed NER annotated sentence. The multilingual words are converted from utf to wx format and are italicized

We have analyzed that Bi-LSTM with CRF models has shown an improved accuracy on the token classification tasks such as POS tagging, language identification, and NER. The ensemble of BERT or XLM-RoBERTa with Bi-LSTM and CRF would have shown a further improvement in the code-mixed NER. Also, using language identification as a downstream task with the current method might have improved the NER's accuracy.

The paper is organized as follows. Section 2 provides related work on Named Entity Recognition on CM social media text. Section 3 provides information on the task and examples of datasets. Section 4 describes the proposed work. Section 5 presents the experimental setup and Section 6 project the performance of the model. Section 7 concludes our work.

2 Related Work

Code-mixed NER has attracted a lot of attention in the NLP community this decade. This section lists the latest works on code-mixed named entity recognition.

Priyadharshini et al. (2020); Winata et al. (2019) generated multilingual meta representations from pre-trained monolingual word embeddings. The model learned to construct the best word representation by mixing multiple sources without explicit language identification.

Aguilar et al. (2019) presented a shared task on named entity recognition in the CALCS workshop. The language pairs used were English-Spanish (ENG-SPA) and Modern Standard Arabic Egyptian (MSA-EGY). They used Twitter data and nine entity types to establish a new dataset for code-switched NER benchmarks. The participating teams used LSTM, CNN, CRF, and word representations to recognize named entities.

Singh et al. (2018) We presented a new Code-Mixed Hinglish corpus for NER. Different machine learning classification algorithms with word, character, and lexical features are used to establish baselines. The algorithms used were Decision tree, Long Short-Term Memory (LSTM), and Conditional Random Field (CRF).

(Meng et al., 2021; Fetahu et al., 2021) presented a novel CM NER model. They proposed a gated architecture that enhances existing multilingual Transformers by dynamically infusing multilingual knowledge bases, a.k.a gazetteers. The evaluation of code-mixed queries shows that this approach efficiently utilizes gazetteers to recognize entities in code-mixed queries with an F1=68%, an absolute improvement of +31% over a non-gazetteer baseline.

(Meng et al., 2021) mentioned that including Gazetteer features could cause models to overuse or underuse them, leading to poor generalization. They proposed a new approach for gazetteer knowledge integration by including Context in Gazetteer Representation using encoder and Mixture-of-Experts gating network models. These models overcome the feature overuse issue by learning to conditionally combine the context and gazetteer features instead of assigning them fixed weights.

3 Task Setup

The shared task detects semantically ambiguous and complex entities in short and low-context settings. Complex NEs, like the titles of creative works (movie/book/song/software names), are not simple nouns. Usually, they take imperative clauses, or they often resemble typical syntactic constituents. Such NEs are harder to recognize (Ashwini and Choi, 2014). Syntactic parsing of such complex noun phrases is hard, and most NER systems fail to identify them. Inside–outside–beginning (IOB) format (Ramshaw and Marcus, 1999) is used for annotating entities. A few examples of complex NEs and ambiguous NEs from the code-mixed dataset are given in Table 2.

So the MultiCoNER shared task encourages the models to handle such complex NEs. A huge dataset (Malmasi et al., 2022a) is released for this task (Malmasi et al., 2022b). The languages focused on in this shared task are: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. The shared task also offered an additional track with code-mixed and multilingual datasets. In this paper, we will be concentrating on the code-mixed dataset.

4 System Overview

We finetuned the pre-trained multilingual BERT model by using the multilingual training and validation datasets for code-mixed named entity recognition. We found that the training data is insufficient for the deep learning language model to identify the named entities in the validation data correctly. The data scarcity of low-resource languages has been a significant challenge for building NLP systems since they require a large amount of data to learn a robust model. We observed that the multilingual NER training data is similar to the code-mixed dataset. Also, it is relatively large when compared to the code-mixed dataset. In our approach, the multilingual training and validation data is combined with the code-mixed training dataset. Using the combined dataset, we finetune the deep neural network model. Our method thus attempts to learn language-agnostic features by using the combined multilingual and code-mixed dataset. This finetuned model can be used to infer named entity information at a token level on a code-mixed low resource language.

We used the pre-trained mBERT (Devlin et al., 2018) model for code-mixed NER. mBERT is a transformer-based self multi-headed attention model that is pre-trained on a massive collection of multilingual data and can be finetuned for our NER task. As the model is pre-trained on a large corpus, the semantic and syntactic information is well modeled and can be directly finetuned for a specific task. BERT is a bi-directional transformer model (Vaswani et al., 2017). It analyzes the meaning of a term depending on its context given on both sides. The transformer part in the BERT works like an attention mechanism capable of learning the contextual relationships between the terms in a sentence.

5 Experimental Setup

The section presents the baselines, hyper-parameter settings, and analysis of observed results.

5.1 Baselines

The baselines used for the proposed work is:

Conditional random field (CRF) (Lafferty et al., 2001) CRF is a statistical model and is a well-known approach for handling NER problems. The CRF model considers the neighboring samples by modeling the prediction as a graphical model. It assumes that the tag for the present word (denoted as y_i) is dependent on the tag of its previous/next word (denoted as y_{i-1} or y_{i+1}).

MultiCoNER baseline (Malmasi et al., 2022b) The XLM-RoBERTa base with CRF model is used as a baseline for NER.

Pre-trained multilingual BERT (mBERT) (Devlin et al., 2018) A pre-trained multilingual BERT model with token classification without leveraging the multilingual data is used as a baseline.

5.2 Hyperparameters and libraries

For developing our model, the neural network library used is PyTorch, and the pre-trained multilingual BERT model (*bert-base-multilingual-cased*) and XLM-ROBERTa base model (*xlm-roberta-base*) is obtained from the hugging face-transformers library and is finetuned for the code-mixed NER task. The model is implemented in Kaggle Notebook with GPU processing.

The batch size of the datasets is kept as 64. The maximum length of the sentence from the training data is considered during the input data encoding/padding. Due to subword tokenization, we used the first token for predicting the tag. The optimizer used is weighted Adam with the learning rate of 2e-5 and epsilon value equal to 1e-5. The dropout is set to 0.1. The loss function used is a cross-entropy loss that is inbuilt into the transformer's BERT model. The number of epochs used for training the model is 30. The training is stopped when there is no change in validation accuracy for more than four epochs.

The CRF is obtained from pytorch-crfsuite library[1]. The previous word and its tag, the next

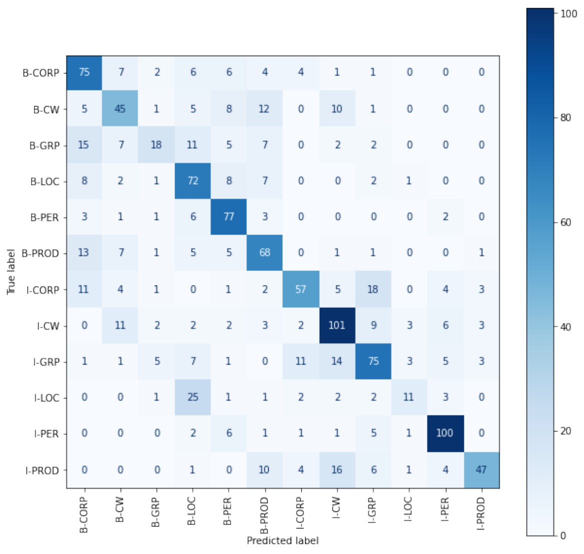

Figure 1: Confusion matrix of CM-NER baseline

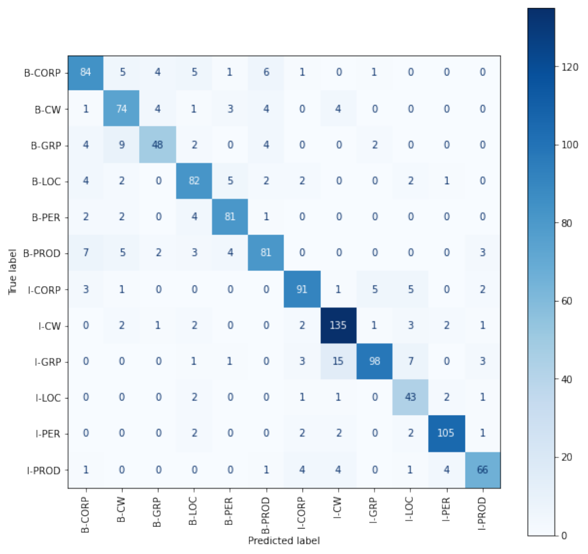

Figure 2: Confusion matrix of CM-NER by leveraging multilingual data

word, and its tag is used as the features to predict the tag of the current word.

6 Results and Analysis

Table 3 presents the f1-score of the models on the Dravidian code-mixed dataset. From the above results, it is clear that our system, i.e., leveraging the multilingual NER data in a low-resource code-mixed setting, improves the NER task compared to the baseline models. The CRF model didn't perform well on the given NER task, as this statistical model does not capture the semantics of the tokens. Even the CRF with multilingual data performed poorly on this task compared to the baseline NN models. It shows the importance of capturing semantical, syntactic, and contextual information while building the NER model on these complex datasets.

Our submission, the pre-trained mBERT by leveraging the multilingual dataset, performed better than the MultiCoNER baseline by 6%. Even the MultiCoNER baseline with the multilingual dataset performed better than our submission.

The confusion matrices with and without multilingual data of our submission on the code-mixed NER validation dataset are shown in the Figures **??** and 2. By using confusion matrices, we observed that the multilingual data given in Figure 2 helped better identify the CW, PROD, CROP, and LOC entities when compared to the baseline model.

7 Conclusion and future work

In this paper, we addressed the shared task on named entity recognition for the code-mixed dataset. As the code-mixed data is a low resource language and there are no pre-trained models, we leveraged the multilingual dataset for training the NER model. The model used for testing our method is the pre-trained multilingual BERT. We finetuned the pre-trained mBERT for the code-mixed NER task by using the code-mixed training data and multilingual training and validation datasets.

The use of meta embeddings for dealing with code-mixed datasets has recently attracted a lot of attention. It might be possible that meta embedding-based NER will work better on this code-mixed dataset. Unlike the social media data where code-mixed sentences/words are written in Roman script, the native script is used for each word, so the language identification will work better on this dataset. Using Language identification or POS tagging as a downstream task for NER on this dataset will help in improving the code-mixed NER.

RACAI at SemEval-2022 Task 11: Complex named entity recognition using a lateral inhibition mechanism

Vasile Păiș
Research Institute for Artificial Intelligence ”Mihai Drăgănescu”, Romanian Academy
Bucharest, Romania
vasile@racai.ro

Abstract

This paper presents RACAI's system used for the shared task of "Multilingual Complex Named Entity Recognition (MultiCoNER)", organized as part of "The 16th International Workshop on Semantic Evaluation (SemEval 2022)". The system employs a novel layer inspired by the biological mechanism of lateral inhibition. This allowed the system to achieve good results without any additional resources apart from the provided training data. In addition to the system's architecture, results are provided as well as observations regarding the provided dataset.

1 Introduction

Named entity recognition (NER) is a well known task in natural language processing. It aims to detect spans of text associated with known entities. Initially, much work focused on detecting persons, organizations, and locations (Grishman and Sundheim, 1996; Tjong Kim Sang and De Meulder, 2003). However, this limited approach is not suitable for every domain, thus leading to research in domain-specific NER. For example, in the biomedical domain, a number of works have addressed entities such as genes, proteins, diseases (Hu and Verberne, 2020), cell types (Settles, 2004), chemicals (Gonzalez-Agirre et al., 2019; Ion et al., 2019). Similarly, in the legal domain additional classes are employed such as money value (Glaser et al., 2018), legal reference (Landthaler et al., 2016; Păiș et al., 2021), judge, and lawyer (Leitner et al., 2019).

In the context of "The 16th International Workshop on Semantic Evaluation (SemEval 2022)"[1], the task number 11 "Multilingual Complex Named Entity Recognition (MultiCoNER)"[2] (Malmasi et al., 2022b) required participants to build a NER system able to recognize complex entities in 11 languages: Bangla, Chinese, Dutch, English, Farsi, German, Hindi, Korean, Russian, Spanish, and Turkish. In addition, a multilingual track and a code-mixed track were available. The task focused on 6 entity types: person, location, group, corporation, product and creative work.

As noted by Ashwini and Choi (2014), non-traditional entities can pose a challenge for NER systems. This happens because datasets are harder to build and certain entities (such as creative works) are updated more frequently than traditional ones (persons, locations). Furthermore, traditional entities tend to occur as noun phrases, while the newly proposed entities (for the purposes of the task) may be linguistically complex (complex noun phrases, gerunds, infinitives or full clauses). An interesting result was provided by Aguilar et al. (2017), where the top system from WNUT 2017 achieved only 8% recall when dealing with creative works.

This paper describes a system for complex NER in a multilingual context, developed at the Research Institute for Artificial Intelligence of the Romanian Academy (RACAI), that participated in the MultiCoNER task. The system employs a new artificial neural network layer trying to mimic the biological process of *lateral inhibition* (Cohen, 2011). In various regions of the brain, excited neurons can reduce the activity of other neighbouring neurons. In the visual cortex this process may account for an increased perception in low-lighting conditions. Thus, intuitively the newly proposed system may better focus on subtle details present in the data and the language model.

The paper is structured as follows: Section 2 presents related work, Section 3 describes the dataset and pre-processing operations used, Section 4 describes the method used with the system architecture in Section 4.1 and performed experiments in Section 4.2. The results are given in Section 5 and finally, conclusions and future work

[1]https://semeval.github.io/SemEval2022/
[2]https://multiconer.github.io/

are available in Section 6.

2 Related work

In a survey regarding NER using deep learning models, Yadav and Bethard (2018) emphasize the importance of pre-trained word embedding representations. Dernoncourt et al. (2017), in the NeuroNER package[3], combine pre-trained word embeddings with character level embeddings passing through a neural network with a final CRF layer achieving high scores on different datasets. Other authors, using similar architectures have shown that combining multiple static word representations can further increase the overall system performance (Păiș and Mitrofan, 2021).

With the introduction of contextual word representation models, such as BERT (Devlin et al., 2019), ELMo (Peters et al., 2018), ROBERTA (Liu et al., 2019), XLNet (Yang et al., 2019), NER systems have been adapted to make use of these new models. For the majority of the contextual models, depending on the size of the artificial neural network being used, we distinguish between a base version and a large version (with a larger number of parameters). Devlin et al. (2019) used the BERT-large model for NER on the CoNLL-2003 English dataset, achieving an F1 score of 92.8%. Nguyen et al. (2020) propose a custom BERT-like model for English tweets, called BERTweet, for improving the NER performance on two datasets: WNUT-16 and WNUT-17.

Contextualized embeddings were also applied with success in domain-specific settings. Considering the ProfNER shared task (Miranda-Escalada et al., 2021), dedicated to identifying mentions of occupations in health-related social media, the best performing system made use of the BETO model (Cañete et al., 2020) trained on a large Spanish corpus.

Wang et al. (2021) propose an algorithm for automatically finding a concatenation of embeddings that improves a system's performance in different tasks, including NER. The authors considered multiple contextual and non-contextual embeddings and the proposed algorithm can identify any of their combinations. Their work builds on previous experiments that showed increased performance when manually concatenating contextual and non-contextual embeddings (Straková et al., 2019; Wang et al., 2020).

Training a contextualized embedding model requires many processing resources. This means that not all flavours are available for all languages. Multilingual models have been proposed, making use of training data in multiple languages. Such models include mBERT and XLM-RoBERTa (XLM-R) (Conneau et al., 2020). These models are known to perform especially well on low resourced languages. Considering NER, Conneau et al. (2020) show that XLM-R large performs better than mBERT, providing an average 2% increase in F1 score for Dutch, Spanish and German. Interestingly, in English the performance of XLM-R is more similar to mBERT (though still offering an improved performance of less than 1%) and less than (Akbik et al., 2018). This seems to support the idea that monolingual models, trained on a specific language or domain, can perform better than multilingual ones.

Meng et al. (2021) recognizes the importance of gazetteer resources, even in the case of state-of-the-art systems making use of contextualized embeddings. The authors propose using an encoder for obtaining Contextual Gazetteer Representations (CGRs) as a way to incorporate any number of gazetteers into a single, span-aware, dense representation. Then, the authors go one step further and propose a gated Mixture-of-Experts (MoE) method to fuse CGRs with contextual word representations from any word-level model.

Fetahu et al. (2021) employ multilingual gazetteers fused with transformer models in a MoE approach to improve the recognition of entities in code-mixed web queries. In this case the entities were written in a different language than the rest of the query, thus posing particular challenges to existing NER systems.

3 Dataset and pre-processing

The dataset (Malmasi et al., 2022a) was provided in a column-based format, with 4 columns in each file. The text was tokenized, with tokens available in the first column. Columns 2 and 3 did not contain useful information (only an underscore symbol was present). Column 4 contains the named entity annotation in BIO format. The first token (or the single token) of an entity contains the "B-" prefix. Other entity tokens (in the case of multi-token entities) start with an "I-" prefix, while non-entity tokens are denoted with "O".

For each language there was a train/dev/test split

[3]http://neuroner.com/

provided by the organizers. In the train set there were 15,300 sentences, in the dev set there were 800 sentences, while the test set was much larger. The actual number of sentences in the test set varies between languages, having as many as 217,818 sentences for English. For the multilingual track, there were 168,300 train sentences, 8,800 dev sentences and 471,911 test sentences. The smallest number of sentences was given in the code-mixed track with only 1,500 training sentences, 500 dev sentences and 100,000 test sentences.

Regardless of the language or additional multilingual and code-mixed tracks the development set is very small while the test set is much larger than the training set. In addition, the number of training sentences in the code-mixed track seems insufficient to build a model by themselves.

Predictions on the test set were required to provide annotations, in the same BIO format, for each token. Furthermore, considering the multilingual nature of the task, with very different languages (such as German and Chinese), no pre-processing was applied, other than converting the provided format to a format suitable for the developed system. For the code-mixed track, a second dataset was generated, based on the original provided dataset augmented with new sentences. These were generated by randomly replacing existing entities in the code-mixed dataset with similar entities extracted from the multilingual dataset. For each sentence containing at least one entity, a new sentence was generated, thus doubling the size of the training dataset for the code-mixed track.

4 Method

4.1 System Architecture

The proposed system employs the XLM-RoBERTa (Conneau et al., 2020) large model. Given an input sequence from the dataset it is first transformed into model-specific tokens. The sequence is also enhanced with the special tokens for sequence start (CLS), sequence end (SEP) and, if needed, padding (PAD). Then it passes through the model to obtain associated contextual embeddings. In existing systems, the word representations usually pass through a linear layer and finally a classification head, giving predictions for each input token. However, in the proposed system, there is a new layer inserted just after the XLM-RoBERTa embeddings calculation and before the linear layer. The resulting system architecture is presented in Figure 1.

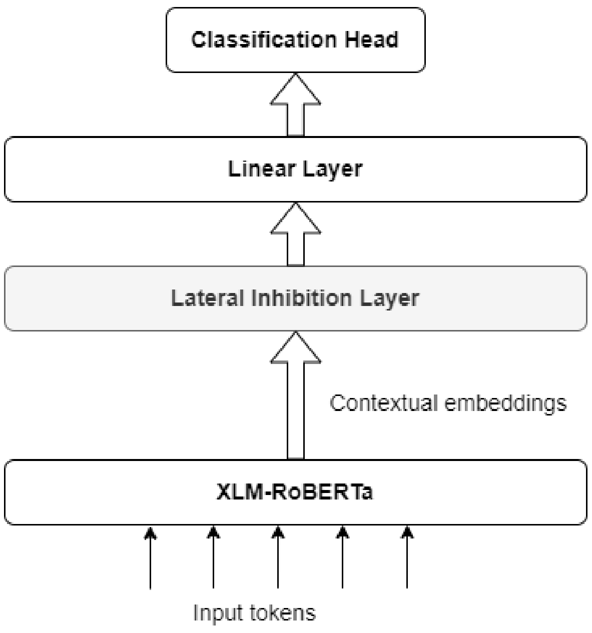

Figure 1: System architecture

The newly introduced layer follows the biological process of lateral inhibition. Thus, an embedding value is either allowed to pass unchanged to the next layer or set to zero, depending on the other values. Similar to a linear layer, a matrix of weights (W) and a bias (B) were kept. However, the diagonal values of the weights matrix were always set to zero to allow only interaction from adjacent neurons. Furthermore, the Heaviside function (see Equation 1) was applied to determine which values pass through the layer or become zero. The equation associated with the forward pass is given in Equation 2, where X is the layer's input vector, associated with a token embedding representation, $Diag$ represents the matrix diagonal, $ZeroDiag$ is the matrix with the value zero on the diagonal, and W and B represent the weights and bias.

$$\Theta(x) = \begin{cases} 1, x > 0 \\ 0, x \leq 0 \end{cases} \tag{1}$$

$$F(X) = X * Diag(\Theta(X * ZeroDiag(W) + B)) \tag{2}$$

To overcome the problem of computing a derivative for the Heaviside function, in the backwards pass the Heaviside function was approximated with the sigmoid function with a scaling parameter (Wunderlich and Pehle, 2021). This is described in Equation 3. The derivative of the sigmoid function is given in Equation 4, where $\sigma(x)$ is the same as in Equation 3. This approximation technique is also

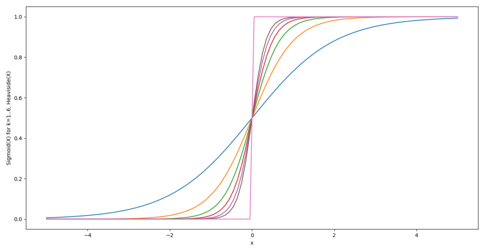

Figure 2: $\sigma(x)$ for k=1..6 and $\Theta(x)$

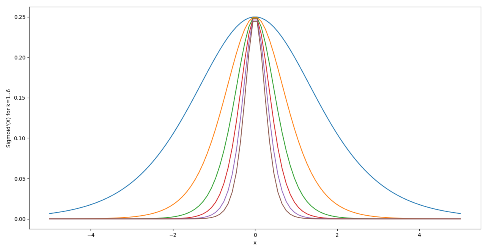

Figure 3: $\sigma'(x)$ for $k = 1..6$

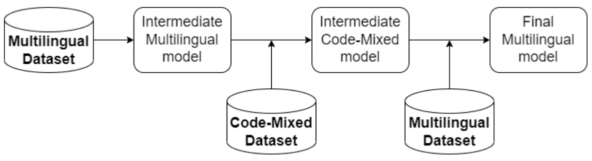

Figure 4: Training flow for creating the multilingual model

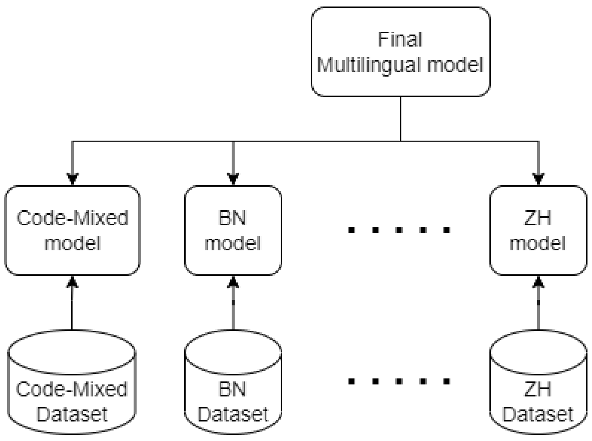

Figure 5: Language-specific training

known as surrogate gradient learning (Neftci et al., 2019). It allows the use of a non-differentiable function in the forward pass (in this case the Heaviside function) and approximates the derivative in the backwards pass by means of a different function.

$$\sigma(x) = \frac{1}{1 + e^{-kx}} \tag{3}$$

$$\sigma'(x) = k\sigma(x)\sigma(-x) \tag{4}$$

Figure 2 shows a plot for the Sigmoid function, for various values of the scaling parameter k, superimposed on a plot of the Heaviside function. Higher values for the scaling parameter give better approximations for the Heaviside function. A plot for the derivative of the Sigmoid function with $k = 1..6$ is given in Figure 3.

The entire system was then implemented in PyTorch following the system diagram given in Figure 1. The embedding vector associated with each token is processed by the lateral inhibition layer, then goes through a linear layer using ReLU as the activation function and finally through the classification head.

4.2 Experiments

Training started with the creation of a multilingual model based on the provided multilingual corpus. Training was performed for 40 epochs, with the best performing model on the dev dataset being stored. The resulting intermediate model was fine-tuned with the code mixed data, for another 40 epochs. Thus, all the available data were now included in the new intermediate model. This model was then used as the basis for further training on the multilingual dataset (another 40 epochs), producing the final multilingual model. The results from this final model were submitted in the multilingual task. This training procedure is described in Figure 4.

The final multilingual model was then used as a starting point for the other models. The architecture was the same and the model parameters were initialized with the multilingual parameters. Fine-tuning was performed for 80 epochs for all languages and in the case of the code-mixed dataset. The best performing model for each task was stored and the results were submitted to the corresponding category. The language-specific training procedure is described in Figure 5.

The models were trained using a single Nvidia Quadro RTX 5000 GPU board. The dataset was first pre-processed, as described in Section 3. Several experiments were performed to determine the best parameters. However, due to limited time and hardware resources, it was not possible to perform an exhaustive search. The participating models employed learning rates of $1e-05$ (the majority of the models) or $2e-05$ (Bangla and code-mixed).

Track	With Lateral Inhibition				Without Lateral Inhibition				Diff
	P	R	F1	Epoch	P	R	F1	Epoch	F1
Bangla	**68.08**	**65.33**	**66.28**	40	65.95	63.99	64.68	68	1.60
Chinese	**68.17**	62.05	62.70	35	67.05	**64.39**	**64.41**	56	-1.71
Dutch	78.82	**78.30**	**78.41**	63	**78.85**	77.27	77.25	37	1.16
English	76.54	75.35	75.78	66	**76.59**	**76.09**	**76.21**	53	-0.43
Farsi	**70.77**	**70.45**	**70.42**	36	70.10	68.84	69.24	21	1.18

Table 1: Results on the test dataset for all tracks.

A dropout value of 0.1 was used for both the lateral inhibition and linear layers. For the backwards pass approximation of the Heaviside function, the sigmoid scaling parameter was set to 10.

5 Results

The models produced by the system described in the previous sections participated in all the MultiCoNER tracks. The official ranking metric was macro-averaged F1. The results are given in Table 1 for all tracks, in alphabetical order of the languages, while the multilingual and code-mixed tracks are shown at the end of the table.

The best best average F1 score was achieved in the German track (79.39%), followed closely by the code-mixed track (79.37%). All these results were obtained by using only the provided dataset, without external resources. For most of the tracks precision and recall are similar (with precision being approximately 1% higher than recall), with the exception of Chinese (precision is 6% higher than recall) and Russian (precision is 2% higher than recall).

In Table 1 is also given a comparison between the results obtained using the new lateral inhibition layer and the results obtained by the same system without the lateral inhibition layer. In 7 tracks (Bangla, Dutch, Farsi, Spanish, Turkish, Multilingual, Code-mixed) the new layer improved the overall F1 score, in 1 track (Russian) the results were roughly the same (a difference of 0.08 %), while in 5 tracks (Chinese, English, German, Hindi, Korean) the new layer actually decreased the system's performance. By looking at the size of the training corpora used in XLM-RoBERTa, as reported by Conneau et al. (2020), it seems the new layer improved the system performance in the case of languages represented by less than 54Gb of data. This seems to confirm the intuition behind the new layer, that the model is able to better focus on details present in the data and potentially filter out the noise. There are two exceptions: Farsi, trained on 111 Gb of data, and Hindi, trained on 20 Gb. In this case additional investigation should probably be performed with regard to the quality of the data used for training the model, possibly taking into account the relative language complexity (Bentz et al., 2016).

Table 1 also presents the training epochs associated with the best model. For some languages, the new layer is able to reduce the number of training epochs, but there is no clear pattern for when this happens. Interestingly however, for Spanish and Korean the new layer is able to reduce the training time to less than 10 epochs.

In the multilingual and code-mixed tracks, the model enhanced with the lateral inhibition layer

Track	LOC	PER	PROD	GRP	CW	CORP
Bangla	69.03	77.41	62.92	73.46	49.57	65.31
Chinese	72.30	64.71	67.93	45.44	58.53	67.27
Dutch	80.85	89.82	76.99	75.14	71.35	76.29
English	77.29	90.11	73.27	72.93	66.76	74.29
Farsi	74.04	79.19	70.71	72.33	58.59	67.67
German	82.19	90.24	78.66	75.28	73.39	76.57
Hindi	70.93	75.14	66.35	68.70	57.13	70.25
Korean	76.54	77.86	72.48	68.02	64.02	71.51
Russian	74.05	80.30	75.04	71.29	70.09	76.84
Spanish	76.95	89.27	70.81	71.61	68.69	76.40
Turkish	72.44	81.80	73.01	64.85	61.91	68.49
Multilingual	76.84	83.85	68.82	64.89	66.72	71.47
Code-mixed	82.29	88.29	81.09	73.13	73.99	77.42

Table 2: F1 scores on the test dataset for all tracks and for all entity types.

was able to improve both precision (by 0.47% for multilingual and 0.65% for code-mixed) and recall (by 0.06% for multilingual and 0.21% for code-mixed), leading to corresponding F1 differences. Nevertheless, the number of epochs is not reduced for these tracks. As described in Section 4.2 and illustrated in Figure 4, there were also two intermediate models (one multilingual and one code-mixed). The results for these models are also provided in Table 1. The proposed approach increased the multilingual F1 score by 0.6% for the lateral inhibition system and by 1.52% without lateral inhibition. Similarly, the code-mixed performance was increased by 0.06% (with lateral inhibition) and by 0.22% (without lateral inhibition). It seems in this case that the presence of the lateral inhibition layer reduced the overall gain obtained from training the model in multiple stages. Nevertheless, the multi-stage approach increased the final F1 score.

Table 2 presents the F1 results obtained with the lateral inhibition layer, for each track and for each entity type. It can be noticed that commonly used named entities (locations and persons) achieve the highest score in all tracks. The hardest to predict (achieving the lowest scores) are group (GRP) and creative work (CW). This observation holds for all tracks, but particularly in Chinese, the group entity obtains the lowest score (45.44%), and in Bangla, the creative works entity obtains 49.57%. It seems that these low values are due to the nature of these entities, their complexity and their evolution over time. Furthermore, by looking at the dataset structure for Chinese, the group entity type was the least represented in the training set. Moreover, by looking at the number of unique entities present in the dataset, there is a high discrepancy between unique training entities, for group and creative works, and the corresponding unique instances in the test set, especially for Chinese and Bangla.

6 Conclusion

The system described in this paper participated in the MultiCoNER shared task. It made use of a new artificial neural network layer inspired by the biological process of lateral inhibition. By means of this mechanism, the system achieved third place in the general ranking associated with 7 languages (Spanish, Dutch, Russian, Korean, Farsi, German, and Hindi). There were no additional resources employed, apart from the provided dataset (no additional text and no gazetteers). A simple data augmentation method (as described in Section 3) was applied only for the code-mixed track, while still using only the provided data.

Experiments performed after the task deadline, showed (as reported in Section 5) that not all tracks benefit from using the new layer. It is likely that languages with an increased number of tokens present when training the multilingual XLM-RoBERTa model will benefit less from employing the new layer. Nevertheless, models with the lateral inhibition layer trained for lower resourced languages, multilingual, and code-mixed datasets seem to achieve higher scores. Furthermore, improvements can be seen in both precision and recall.

The proposed lateral inhibition layer can be applied to other natural language processing tasks as well. In the future more experiments will be conducted with this layer to determine its suitability in other contexts.

Abstract

This paper presents the two submissions of NamedEntityRangers Team to the MultiCoNER Shared Task, hosted at SemEval-2022. We evaluate two state-of-the-art approaches, of which both utilize pre-trained multi-lingual language models differently. The first approach follows the token classification schema, in which each token is assigned with a tag. The second approach follows a recent template-free paradigm (Ma et al., 2021), in which an encoder-decoder model translates the input sequence of words to a special output, encoding named entities with predefined labels. We utilize RemBERT and mT5 as backbone models for these two approaches, respectively. Our results show that the oldie but goodie token classification outperforms the template-free method by a wide margin. Our code is available at: https://github.com/Abiks/MultiCoNER.

1 Introduction

This paper describes two submissions to the Multilingual Complex Named Entity Recognition (MultiCoNER) Shared Task, held by SemEval-2022 (Malmasi et al., 2022b). This shared task aims at recognizing named entities with the ambitious end goal of building systems that support up to 11 languages. Multilingual setups are complicated when the dataset mixes languages from different groups. This way, the MultiCoNER dataset comprises 11 languages from different families, and multiple scripts (Malmasi et al., 2022a). This setup hayj s become increasingly popular recently since it allows to test for transfer learning across languages within a single pre-trained model. The dataset, proposed in the shared task, has several unique features previously neglected in NER evaluation: syntactically complex entities, ambiguous entities, divers, and low-frequency (aka long-tail) entities. This makes the shared task setup closer to real-life settings, where datasets are way noisier and nonuniformly distributed.

Our solution consists of two state-of-the-art approaches adopted to the task. First, we use a mainstream NER technique, token classification. Under this approach, the model is trained to assign a label to each input token. The second approach falls into the group of prompt-based techniques, at the core of which are the capabilities of auto-regressive language models to memorize and reproduce input texts. In this case, we train an encoder-decoder model to replace entities in the input sentence with predefined labels. We utilize RemBERT (Chung et al., 2021) and mT5 (Xue et al., 2021) as backbone models for these two approaches, respectively. These two models provide state-of-the-art results for the common test-beds of cross-lingual experiments (Hu et al., 2020).

In other words, we explore the following questions: 'How do pre-trained transformer-based models perform in the Multilingual Complex Named Entity Recognition task?' and 'Which of the two approaches perform better?'.

Our results show that plain fine-tuning of the above-mentioned state-of-the-art multilingual transformer-based models can give moderate results. Results are within 10% margin of the top solution for the multilingual NER task. We analyzed the errors of both models. As expected, for two novel 'complex' entity types ('Creative Work' and 'Product') error rate is higher than for 'common' types ('Group', 'Location', 'Person'). However, some of the errors might be caused by inconsistencies in the labeling of the MultiCoNER dataset. The performance of the Template-free approach suffers from such inconsistencies more than the performance of the Token classification approach.

2 Related Work

Named Entity Recognition is one of the central tasks in Natural Language Processing, which attracts a lot of research efforts. Yang et al. (2016) encode morphology and context information via character and word embeddings. Recent studies (Ghaddar and Langlais, 2018; Jie and Lu, 2019; Liu et al., 2019; Meng et al., 2021) employ syntactic dependencies, lexical similarity, gazetteers, etc. in the word representations before feeding them to context encoding layers. The authors show that additional information may lead to improvements in NER performance. However, NER still faces multiple challenges (Li et al., 2022) such as detection of fine-grained and nested named entities (Kim and Kim, 2021; Ringland et al., 2019; Loukachevitch et al., 2021), NER in domain-specific areas (Weber et al., 2021), NER from noisy data (Derczynski et al., 2017) and code-mixed data (Fetahu et al., 2021).

Recent research in this area considers not only standard types of entities (*person, location, organization*) but also semantically ambiguous and complex entities (Hanselowski et al., 2018). For example, a system has to recognize the titles of movies, books, or songs, which may contain verbs, adverbs, prepositions, etc. Cui et al. (2021) propose a template-based method, treating NER as a language model ranking problem in a seq2seq manner. Original sentences and statement templates filled by a candidate named entity span are the source sequence and the target sequence, respectively. Ma et al. (2021) induces a language model to predict label words at entity positions during fine-tuning. This method demonstrates the effectiveness under the few-shot setting.

The SemEval-2020 shared task MultiCoNER (Malmasi et al., 2022a) focuses on a more exciting and challenging problem of building a NER system for multiple languages. The results of a recent Multilingual Named Entity Challenge in six Slavic languages (Piskorski et al., 2021) have also confirmed the complexity and significance of the task. Training competitive multilingual NER systems requires either manually labeled text collections or large automatically annotated datasets (Nothman et al., 2013).

3 Experiments

3.1 Token Classification Approach

Our baseline is to treat the NER task as a token classification problem. The base model is a pre-trained RemBERT (Chung et al., 2021) with a linear layer on top of the hidden-states output.

RemBERT is based on a multilingual BERT bidirectional transformer architecture. It uses decoupled embeddings, which allows changing the size of input and output embeddings. The input embeddings are reduced in size, thus making the fine-tuning process faster without performance loss compared to BERT.

In the first experiment on a tokenization step the original label is propagated to all of the word tokens. We fine-tuned the model on multilingual data for three epochs to predict the labels in BIO format. The batch size is 32, Adam optimizer is used with the learning rate of 10^{-5} and the scheduler decreases the learning rate by 0.1 each epoch. The metrics obtained on the development set for this approach are presented in Table 1.

In the following experiment we investigated how the performance changes if we combine the models into an ensemble. The ensemble consists of three models trained with different seeds as described above. The final predictions are made based on a hard or soft voting scheme. The models perform very similarly; the differences in evaluation scores are insignificant.

The confusion matrix in Figure 1 is built for the multilingual model. The largest ratio of erroneously assigned O labels is PROD (Product) or CW (Creative work). Almost for all individual languages, the confusion matrix is very similar to the aggregated one. The picture differs a bit for Farsi and Russian languages: the number of mislabelled entities as O is higher for each entity tag. This might be due to the difference in the language structure. For the Chinese language, 23% of the GRP (Group) entities were classified as CORP (Corporation). This behavior is unique to the Chinese

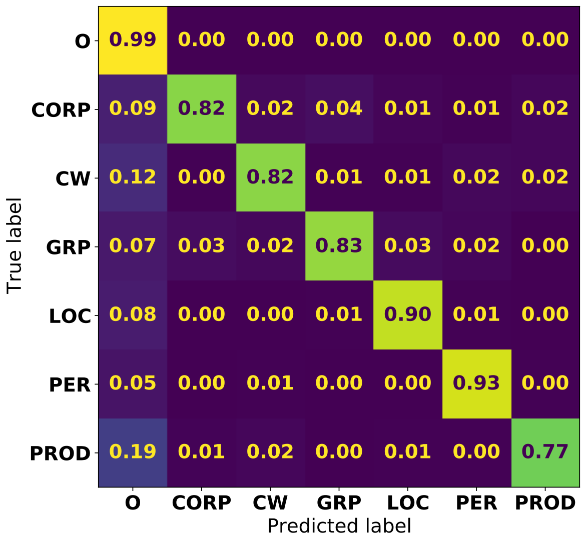

Figure 1: Confusion matrix for fine-tuned RemBERT

language.

The ensemble model does not introduce much improvement. However, training models with different seed values converge almost to the exact predictions. On the dev set, only one model's prediction out of three base models differs in 10% of the cases, and all three models have different predictions in 1% of the cases.

3.2 Template-free Approach

The second approach which we considered was Template-free (Ma et al., 2021). This approach showed decent results on CoNLL03 (Sang and Meulder, 2003) and MIT-Movie (Liu et al., 2013) datasets, so we decided to apply it to the multilingual data. The language model is trained to substitute named entity text spans with several predefined label words. For instance, given the sentence "*its headquarters are in sandy springs, united states of america*" we require the model to replace "*sandy springs*" and "*united states of america*" text spans with a predefined label word "*germany*" since these spans are considered as LOC (location) entities. In this case, the target for this example would be: "*its headquarters are in germany, germany*". After the model has substituted several text spans with the label words, we need to reconstruct these spans based on surrounding tokens to match each initial token with its predicted label. The label word for a specific entity class was chosen as the most frequent token of this class in the training data. Since we were working with multilingual data, we created a unique label words mapping for each language.

As the backbone model for the Template-free approach, we considered the mT5 pre-trained language model (Xue et al., 2021). mT5 is a multilingual variant of the T5 model that is pre-trained on a new Common Crawl-based dataset covering 101 languages. We chose two variants of the mT5 model for our experiments: mT5-Large and mT5-XL; the latter model showed better results. Due to the computational complexity, we could not run similar experiments with the mT5-XXL language model. Both models were trained with batch size equal to 8 and optimizer AdamW with learning rate $5 \cdot 10^{-5}$.

During the experiments with the Template-free approach, we encountered several challenges. Firstly, if the input phrase has two or more consecutive entity spans with a token length of more than one, it was impossible to reconstruct these spans unambiguously based on the sequence of predicted label words. In this case, we assigned the first $k-1$ predicted label words to $k-1$ input tokens, and the last label word was assigned to the rest of the tokens. Secondly, because of the punctuation issues occurring in some languages described in more detail in Section 4, it was difficult to generalize the reconstruction rules for all languages.

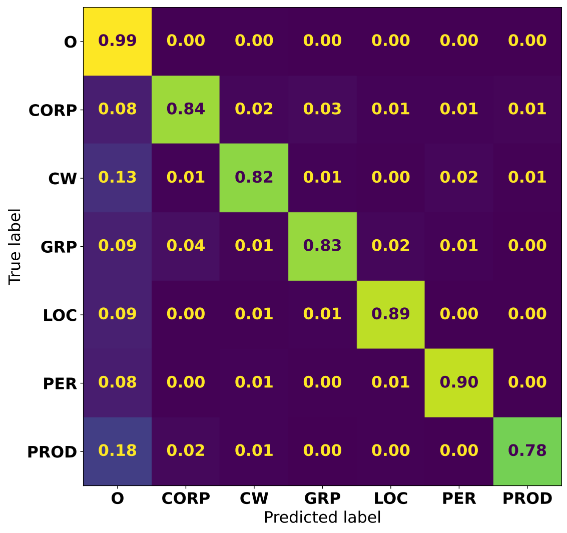

Figure 2: Confusion matrix for Template-free mT5-XL

The token-level confusion matrix for the Template-free approach on the development set is shown on Figure 2. The results for the mT5-XL fine-tuned model on the dev set is presented in Table 1.

Based on Figure 2 we can mention that the most

Table 1: Results for Token Classification and Template-free approaches on dev and test sets

Approach	Dev			Test		
	P	R	F1	P	R	F1
Token Classification	0.81	**0.84**	**0.82**	0.83	0.80	0.81
Template-free	**0.82**	0.77	0.79	0.58	0.51	0.54

common model's error is predicting the O-tag for tokens which are actually considered as parts of the entities. In other words, the model more often fails to recognize a named entity than confuses two different entities. We can also mention that in terms of languages the fine-tuned model shows the best results for English, Dutch and German and the worst results for Farsi and Russian according to F1 score. The dramatic performance downgrade on the test set compared to the dev set for the Template-free model may occur due to the significant distribution shift in the test data. For instance, the average sentence length in terms of tokens in the train and dev data is approximately equal to 16.4. However, the average length in the test data is equal to 9.6, we assume that the Template-free model could not be resistant for such changes.

4 Discussion

We provide the performance analysis of the models that we developed. The confusion matrices for both approaches demonstrate similar commonly occurring errors. Moreover, while working on experiments, we noticed several dataset issues which we suppose are worth mentioning. The problems potentially contribute to the low performance of the Template-free approach.

1. Classification decisions for tokens from PROD and CW entity types are more often confused with the O labeled tokens (Fig. 1, 2). These entities are examples of complex entities, which the competition was focused on. At the same time, the labeling for the two entity types in the provided dataset shows low consistency. For example, in the sentence[1] "*rice - long, medium, or short-grain white; also popcorn rice*" the first occurrence of "*rice*" is labelled as PROD. However, "*popcorn rice*" is not labeled as a named entity. The precise definitions of the complex entities and consistent labeling might be crucial for developing high-performing models for complex entity recognition. Another example is country names. In one sentence a country name can be considered as a named entity, but in another sentence a country name is annotated as O token. For instance, in the sentence[2] "*spain has an embassy ...*" the token "*spain*" has O label, but in the sentence "*in madrid, spain ...*" the same token is considered as a LOC (location) entity despite the fact that in both contexts this token refers to country name. Despite, we call such cases "mislabeled-as-O entities", not all of them can be considered wrong labels. As far as we have noticed, this problem is very common for the Farsi language. To be precise, we calculated the average number of mislabeled-as-O entities for each language (see Table 2). We suppose that this issue can influence the performance of both models.

Language	**Mislabeled-as-O**
BN-Bangla	0.691
DE-German	0.474
EN-English	1.002
ES-Spanish	3.061
FA-Farsi	20.234
HI-Hindi	1.995
KO-Korean	5.489
NL-Dutch	3.269
RU-Russian	1.606
TR-Turkish	3.494
ZH-Chinese	1.094

Table 2: Mean number of mislabeled-as-O entities

2. The second issue is that we noticed while working on the Template-free approach is punctuation labeling. For example, in the sentence[3] "*thomas earnshaw, inventor of ...*" the comma is presented as a separate token. However, in the sentence "*... museum of fine arts, houston ...*" the comma is part of token "*arts,*". This issue was crucial on the reconstruction entity spans step since the tokenizer always considers any punctuation token as a separate one. This issue is common for MultiCoNER data in many languages, especially in German and Bangla.

[1]The example sentence ID: 2e9d398c-a956-4419-a48d-f53790d2d237 (file en_train.conll)

[2]The example sentence IDs are df4360c4-a483-493b-bd93-87814db0104c and 475fb6b2-b9aa-4ec8-8b58-443f5e2774e8 (file en_train.conll)

[3]The example sentence IDs are be16705b-7f6e-4c28-b086-5eabf5950d29 and ea916f1b-b9a5-4959-9537-aeb875c1faf1 (file en_train.conll)

3. For the purposes of more detailed performance analysis we considered the dependence between prediction accuracy and entity length (in number of tokens). The Figure 3 shows this dependence for both Template-free and Token Classification approaches considering the dev dataset. On the one hand, the mT5-XL model, trained according to the Template free approach, performs better on longer entities compared to the RemBert model. On the other hand, the RemBert model, trained that exemplifies the Token Classification approach, shows better results on shorter entities. This could be the reason why the Token Classification method outperforms the Template free approach on the test set since the average sentence length in the test data is dramatically less than the average sentence length in the train and dev datasets.

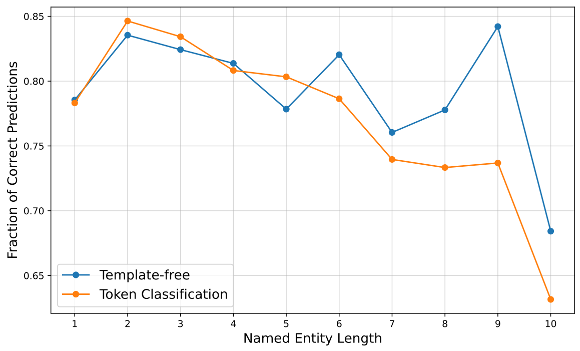

Figure 3: The dependence of prediction accuracy on the entity lengths

5 Conclusion

In the paper, we implemented and evaluated two straightforward yet different approaches to the multilingual NER subtask with complex types of entities (MultiCoNER). The first approach uses a state-of-the-art transformer-based model and fine-tuning for token classification, while the second one applies a template-free information extraction paradigm. Our results are within the 10% margin of the top solution for multilingual NER tasks and much higher than organizers' baseline performance. Therefore, we can conclude that out-of-the-box approaches generalize quite well for complex NER tasks and provide a viable alternative. The performance of the template-free approach can suffer from inconsistent annotation. The second finding is the relatively low performance of an ensemble model, but this issue needs further investigation. Evaluation of systems for multilingual NER with complex entity types is still challenging. Our study analyzed the dataset and found several issues that can be addressed in future versions of MultiCoNER Track or in similar competitions.

Abstract

Named Entity Recognition (NER), an essential subtask in NLP that identifies text belonging to predefined semantics such as a person, location, organization, drug, time, clinical procedure, biological protein, etc. NER plays a vital role in various fields such as information extraction, question answering, and machine translation. This paper describes our participating system run to the Named entity recognition and classification shared task SemEval-2022. The task is motivated towards detecting semantically ambiguous and complex entities in short and low-context settings. Our team focused on improving entity recognition by improving the word embeddings. We concatenated the word representations from State-of-the-art language models and passed them to find the best representation through a reinforcement trainer. Our results highlight the improvements achieved by various embedding concatenations.

1 Introduction

Named entity recognition and classification is an essential subtask in natural language processing (NLP). The task of identifying named entities like a person, location, organization, drug, time, clinical procedure, biological protein, etc. in a text document is key to many applications, including information extraction and retrieval, machine translation(Al-Onaizan and Knight, 2002; Steinberger et al., 2013), topic modeling(Newman et al., 2006), text summarization(Schiffman et al., 2002), and question answering. It can also be used in domain-specific entity types such as disease, symptoms, and treatments. Recently many researchers have identified the name identification issue in a variety of languages and have made efforts to apply named entity recognition.

Complex and ambiguous Named entities, like the title of creative works such as books, songs, and movies, are not simple nouns and are thus harder to recognize(Ashwini and Choi, 2014). Unlike the traditional NEs these works take the form of linguistic constituents such as "Remember me when we are parted," which is an imperative clause and does not look like the traditional NEs (Locations, Person name, organizations). This ambiguity in syntax makes it difficult to identify them based on their context. There can also occur instances where these titles are semantically ambiguous; for example, "the girl on the train" can be a preposition or the name of a book. Such entities are growing at a faster rate as compared to the traditional categories. Therefore, processing these NEs has always been a challenging task in NLP in practical and open-domain settings. However, it has received enough engagement from the research community.

Despite the high score produced by Neural models on benchmark datasets like CoNLL03/OntoNotes, it has been noticed (Augenstein et al., 2017) that these models perform significantly low on complex or unseen data. This happens because the scores were driven by the presence of easy entities, well-formed text, and memorization due to entity overlap between train/test sets. Various researchers have noted that the majority of the errors in their downstream tasks have occurred due to the failure of NER systems to recognize complex entities. Various researchers using NER on downstream tasks have noted that a significant proportion of their errors are due to NER systems failing to recognize complex entities.

This paper presents our system for Shared Task on "MultiCoNER Multilingual Complex Named Entity Recognition @ SemEval 2022" (Malmasi et al., 2022b), (Meng et al., 2021), (Fetahu et al., 2021). The task focused on detecting complex and ambiguous entities in short and low-context settings. Our team focused on improving entity recognition by improving the word representations, following (Wang et al., 2021; Yamada et al., 2020). We concatenated the word embeddings from State-of-the-art language models and passed them to find the best representation through a reinforcement trainer.

2 Related Work

Name entity recognition has always been a challenging task that requires massive prior knowledge resources for good performance (Ratinov and Roth, 2009; Nadeau and Sekine, 2007). Research in various domains using a variety of approaches has been done. Early methods included heuristics and handcrafted rules, lexicons, orthographic features, and ontologies. These systems involved recognizing entities based on pattern matching with input documents(Rau, 1991; Collins and Singer, 1999). A higher degree of accuracy may be achieved using the rule-based system. However, it is time-consuming and challenging to port the developed rules from one domain to another.

Later machine learning methods were used (Borthwick, 1999; McCallum and Li, 2003; Takeuchi and Collier, 2002) . This learning technique involved supervised and unsupervised approaches. The supervised being a dominant technique for named entity recognition (Nadeau and Sekine, 2007). However, this method required massive high-quality annotated data. There also exist some hybrid models that make use of different rule-based and/or learning methods for enhanced performance (Srihari, 2000; Rocktäschel et al., 2012). These systems make the best use of good features and methods for improved performance.

Recently neural network systems (Collobert et al., 2011) have also become a popular method. These systems with minimal feature engineering have become appealing because they do not require sources such as lexicons or ontologies, thus making them domain independent. Most of the neural architectures proposed are based on recurrent neural networks (RNN).

3 Dataset Description

The English dataset provided by SemEval 2022 (Malmasi et al., 2022a) comprises 233,917 instances of data. The training sample included 15300 annotated statements, the dev set comprised 800 annotated sentences, and the test set included 217817 test data (as shown in the table). The sentences in the data are allocated a respective id. Each sentence is further divided into tokens which are separated by a newline. Each token is assigned a label according to the standard BIO tagging followed by the named entity tag in the specified format. *<token>_<BIO_tag>-<NE>*

In the BIO tagging, B and I tags are followed by <NE> tag, while O tags have no following tag. As presented in the fig, an instance of the dataset, statements with the 'O' tag represents a non-named entity. The statements with 'B' tags represent the beginning of the named entity, and 'I' tags represent the continuation of the same-named entity. The tokens are assigned one of the six named entities Person (abbreviated as PER), Location (abbreviated as LOC), Group (abbreviated as GRP), Corporation (abbreviated as CORP), Product (abbreviated as PROD), Creative Work (abbreviated as CW).

4 Methodology

The method used focuses on automating the process of finding better concatenation of embeddings for improved performance. In this approach, a task model and controller module repeatedly interact. To achieve high accuracy, the controller searches for a better embedding concatenation from the given set of pre-trained embeddings. The task model, on the other hand, produces a task output. The architecture works on a reward basis. The controller is rewarded every time the task model is trained over the task data after an embedding is generated. The controller receives a reward for updating its parameter and sampling new embedding concatenations. The general architecture of our approach is shown in Figure 1.

4.1 Design of Task Model

For the task model, a sequence-structure approach is used. Considering the input sentence to be *m* and the structured output to be *n*, the probability distribution *P(n|m)* can be calculated as:

$$P(n|m) = \frac{exp(Score(m,n))}{\sum_{n' \in N(m)} exp(Score(m,n'))} \quad (1)$$

where *N(m)* represents all possible output structures given the input sentence *n*. The BiLSTM-CRF model (Ma and Hovy, 2016; Lample et al., 2016) was used for sequence-structured outputs.

$$P^{seq}(n|m) = BiLSTM - CRF(E, n) \quad (2)$$

where $E = [e_1;\ e_2;\ ...\ e_n], E\ \in \mathbb{R}^{d \times w}$ is matrix of word representation for the input sentence *m* comprising of *w* words, The hidden size of the concatenation of embeddings is represented by *d*.

E_i is the word representation of the i^{th} word, which is a concatenation of L types of word embeddings:

$$e_i^l = embed_i^l(m); \;\; e_i = [e_i^1;\; e_i^2;\; ...\; e_i^L] \qquad (3)$$

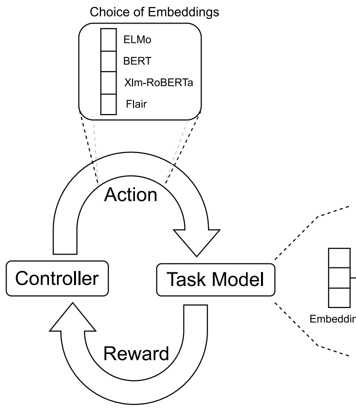

Figure 1: Architecture of our approach. It shows the task model, returning of reward function and the embeddings being concatenated

4.2 Design of Search Space

A set of neural networks can be used to represent neural architecture search space (Elsken et al., 2017). In this method, we have represented the embedding candidates as nodes. The sentence n is passed as the input to the nodes, and the resulting output is the embeddings e^l. Since the embeddings are concatenated as word representations, there is no connection between the nodes in search space, resulting in a significantly reduced search space.

A variety of embeddings are available for the extraction of word representation, for instance, finetuned XLM-RoBERTa-large embeddings.However, due to the restriction on the use of a multilingual model for a single language track, we finetuned the BERT embeddings on the provided training data and concatenated the last four layers as word features applying mean pooling operation over them (Devlin et al., 2019).

Unlike (Kondratyuk and Straka, 2019), applying a weighted sum of all twelve layers did not significantly differ the empirical results. There was no significant difference between the XLM-RoBERTa CONLL-03 English embeddings and the Finetuned BERT-Large embeddings for the submitted predictions. Thus we used regular embeddings to reduce search space. Subsequently, each embedding only has a specific operation resulting in a search space that contains 2^L-1 possible combinations of nodes.

Except for the character embeddings, all the other weights of the pre-trained embedding candidates are fixed. The parameters of task models are shared at each iteration of the search in accordance with Neural Architecture Search (NAS). All the nodes in the graph are kept in the search space. Each node performs an operation to indicate whether the embedding is masked out. This is done to avoid deciding which node is to be kept, making weight sharing difficult. For this binary task.

For this task, a binary vector $o = [o_1, \ldots, o_l, \ldots, o_L]$ is used as a mask for those embeddings which are not selected:

$$e_i = [e_i^1 o_1;\; e_i^2 o_2;\; \ldots\; ; e_i^l o_l; \ldots ; e_i^L o_L] \qquad (4)$$

Where o_l represents a binary variable. Input E is applied to the linear layer in the BiLSTM layer hence the multiplication operation in E, *i.e.* multiplying mask with embedding, is equivalent to directly concatenating the selected embeddings:

$$W^T e_i = \sum W_l^T e_i^l o_l \qquad (5)$$

Also, the unused embedding candidates and the corresponding weights in W are removed for a light task-model after finding the best concatenation.

4.3 Searching in the Space

The controller is responsible for generating the embedding mask using parameters which are generated using $\theta = [\theta_1; \theta_2; ...; \theta_L]$. The probability distribution of selecting a concatenation o is $P^{ctrl}(q;\theta) = \Pi_{l=1}^{L} P_l^{ctrl}(o_l;\theta_l)$. Element o_l of $\mathbf{o}$ is sampled using Bernoulli distribution which is given by:

$$P_l^{ctrl}(o_l;\theta_l) = \begin{cases} \sigma(\theta_l), & o_l = 1. \\ 1 - P_l^{ctrl}(o_l = 1;\theta_l), & o_l = 0. \end{cases} \qquad (6)$$

where σ is the sigmoid function. Given the mask, the task model is trained until convergence and returns an accuracy R on the dev set. The reinforcement algorithm is used for optimization. The accuracy R is used as a reward signal for training the controller, whose aim is to maximize the reward $J(\theta) = \mathbb{E}_{P^{ctrl}(o;\theta)}[R]$ utilizing the policy of gradient method (Williams, 1992). The reward function that we have used:

$$r^t = \sum_{i=1}^{t-1} (R_t - R_i)\gamma^{Hamm(o^t,o^i)-1}|o^t - o^i| \qquad (7)$$

The final gradient comes out as:

$$\nabla_\theta J(\theta) \approx \sum_{l=1}^{L} \nabla_\theta .\, log P_l^{ctrl}(o_l^t;\theta_l)\, r_l^t \qquad (8)$$

This reward function evaluates how each embedding candidate contributes to the accuracy change. The binary vector $|o^t - o^i|$ represents the change in embeddings. o^t represents a binary vector at current iteration t, and o_i represents the previous time step i. The Hamming distance $Hamm(o^t, o^i)$ is used to measure the contribution of embedding candidates in the accuracy. As hamming distance increases, the contribution becomes less significant.

4.4 Training the controller

The corresponding validation scores and concatenations were stored in a dictionary D to train the controller. Firstly the task model was trained with all the embedding candidates concatenated. Then the concatenation o^t was sampled based on Equation (6). The task model was trained using the equation (4) after which the model is evaluated on a development set to return an accuracy R_t. Then the gradient is computed for the controller following Equation (8) using the concatenation o_t, accuracy R_t and D. Based on the computed gradient, the parameters of the controller are updated. Finally, o^t and R_t are added to D. If a concatenation o^t is in dictionary, we compare its accuracy with the value in the dictionary and keep the higher one. Selecting o^{t-1} (i.e., previous concatenation) and zero vector is avoided.

5 Experimental Setup

Data was provided in form of sentences which were broken down into individual words, or tokens, each lying in a newline and their corresponding tags in front of them. All the tokens are first passed through a function to encode them into embeddings, which are initial representations for the tokens. These tokens are pushed through the RNN language model which forms the task model and iteratively returns a reward to the controller.

Table 1: Major Hyperparameters

Parameters	Value
BiLSTM size	800
BiLSTM layer	1
Optimizer	SGD
Learning rate	[0.1, 7.8125e-4]
Epochs	150
Episodes	20

This model first contains a dropout layer, then an encoder layer is added which contains the embedding. The next layer is an LSTM layer with a hidden size of 800. Finally, the representations are fed into a linear-chain CRF layer to predict the final label sequence, where a linear layer is applied for the representations to score each entity label. The above deep learning model has been built using PyTorch[1] along with the transformer embeddings that have been used.

The learning rate was set at 0.1 at the beginning with a patience level set to 5, i.e. the learning rate was halved if there was no improvement in monitored metrics for the patience, that is the validation loss. The batch size was set to 64 and a maximum of 150 epochs were allowed for 20 episodes.

6 Results

The table below shows the micro and macro F1 scores of prediction on the development set. As the tags of the test set are unavailable to us, the model's performance was judged on dev set only and the results of the best 3 models were ensembled in the end, for submission. The best performing model was achieved in a model, where the following embeddings were concatenated: Finetuned BERT-large-uncased, Finetuned RoBERTa-large, ELMo original, FastCharacterEmbeddings, Glove, FastWordEmbeddings-english, Flair news-en embedding. The model was trained on with the following hyperparameters setting 150 epochs, 20 episodes, SGD optimizer, 800 hidden units of BiLSTM-CRF, starting with a learning rate of 0.1 and a batch size of 64.

Table 2: Results with concatenated BERT embeddings

Concatenations	Micro-F1	Macro-F1
TransformerWordEmbedding: BERT-large-uncased ELMoEmbedding: original || FastCharacterEmbeddings FastWordEmbedding-0: glove || FastWordEmbeddings-1: en FlairEmbedding: news-forward	**0.8867**	**0.8745**
TransformerWordEmbedding: BERT-large-cased ELMoEmbedding: original || FastCharacterEmbeddings FastWordEmbedding-0: glove || FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8596	0.8470
TransformerWordEmbedding: BERT-base-cased ELMoEmbedding: original || FastCharacterEmbeddings FastWordEmbedding-0: glove || FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8597	0.847
TransformerWordEmbedding: BERT-base-uncased ELMoEmbedding: original || FastCharacterEmbeddings FastWordEmbedding-0: glove || FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8861	0.8693

Table 3: Results with concatenated Xlm-RoBERTa embeddings

height **Concatenations**	**Micro-F1**	**Macro-F1**
TransformerWordEmbedding: Xlm-RoBERTa-large-finetuned-conll03-english (finetuned on current dataset) ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.868	0.8536
TransformerWordEmbedding: Xlm-RoBERTa-large-finetuned-conll03-english ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8563	0.8423
TransformerWordEmbedding-0: Xlm-RoBERTa-large-finetuned-conll03-english TransformerWordEmbedding-1: RoBERTa-large ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8728	0.8592
TransformerWordEmbedding-0: Xlm-RoBERTa-large-finetuned-conll03-english TransformerWordEmbedding-1: BERT-large-uncased ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	**0.8997**	**0.8881**
TransformerWordEmbedding: Xlm-RoBERTa-base ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8465	0.8332
TransformerWordEmbedding: Xlm-RoBERTa-large ELMoEmbedding: original ‖ FastCharacterEmbeddings FastWordEmbedding-0: glove ‖ FastWordEmbeddings-1: en FlairEmbedding: news-forward	0.8596	0.8456

These results were ensembled with two other models which were developed as follows:

- BERT-base-uncased, BERT-large-uncased, and RoBERTa-large with the rest of the embeddings as it is.
- Finetuned BERT-large-uncased with the rest of the embeddings as it is.

7 Result Analysis

Experiments were conducted to analyze the performance of systems by using different combinations of embeddings. The best concatenation of embeddings can be easily seen in the model containing BERT-large-uncase transformer embedding and ELMo original, FastCharacterEmbeddings, GloVe FastWord: english, and Flair: news-forward with a Macro-F1 score of 0.8745 on the dev set. This model generated the best results after ensembling the results with the models containing BERT-base-uncased embeddings and BERT-large-uncased finetuned on the current dataset, which generated a Macro-F1 score of **0.7418**[2] on the test dataset.

Table 4: Comparison in baseline and our best model

Models	**Micro-F1 Score**[3]
Baseline	0.715
Our Best	0.8867

One clear distinction in the result can be seen among the BERT uncased and cased models. In the BERT-uncased models, the text is set to lowercase before the WordPiece tokenization step, hence case is irrelevant in it, while in BERT-cased models, the case of words is also considered. In our dataset, the tokens were already lowercase.

For comparison's sake, we have experimented with RoBERTa embeddings as well and they have produced slightly better results than BERT embeddings alone. One difference in the functioning of BERT and RoBERTa was noticed during experimenting with their tokenizers. The BERT tokenizer sometimes separated hyphen-separated entities and treated them as individual entities while RoBERTa tokenizer treated them as a combined single entity and generated a representation for it.

For comparison, we have also experimented with XLMR embeddings during result compilation to show the difference (or similarity) between results. After removing a few of the other embeddings like ELMo, Flair, and Glove, we have also collected results from the above model. All the results can be referred to in Table 3.

8 Conclusion and Future work

In this paper, we present our approach to SemEval-2022 Task 11:MultiCoNER Multilingual Complex Named Entity Recognition. Our best submission gave us an F_1 score of **0.7418**, placing us 10^{th} on the Evaluation Phase Leaderboard. Future work includes experimenting with multilingual data and embeddings and different optimizers.

[2]This is the final Macro-F1 score on the test set

[3]Micro-F1 score was the only metric available for baseline

Abstract

In this paper, we present a system for detecting complex named entities in multilingual and code-mix settings. We discuss the results obtained in task 11 (MultiCoNER) of the SemEval 2022 competition. The model is an ensemble of various transformer-based language models combined with a Conditional Random Field (CRF) layer. Our model ranks fourth in track 12 (multilingual track) and fifth in track 13 (code-mixed track). We describe the details of our model implementation and discuss the effect of different aggregation methods. Finally, we conduct additional analyses to understand the performance differences between languages.

1 Introduction

Named Entity Recognition (NER) is the task of identifying proper names in a text and categorizing them into predefined entity types such as person (PER), location (LOC), or creative work (CW). For example, given a sentence *"Michael Jeffrey Jordan was born in Brooklyn, New York"* the goal is to label entities correctly with their corresponding category using the BIO-scheme:

"Michael [B-PER], Jeffrey [I-PER], Jordan [I-PER] was born in Brooklyn [B-LOC], New [I-LOC] York [I-LOC]"

Existing systems are often trained on standard news text and strongly rely on surface form features such as capitalization and punctuation. These approaches do not scale well to user-generated content because of the increased variation in language and context in an ever-expanding domain (Meng et al., 2021; Fetahu et al., 2021; Augenstein et al., 2017).

Examples of challenging scenarios for named entity recognition are: (a) Entities in very short text inputs such as search queries with limited or no context (Meng et al., 2021) (b) Structurally complex entities such as movie or book titles ranging from complex noun phrases to full clauses (c) Recognizing named entities in dynamically evolving contexts in which novel entities emerge (Augenstein et al., 2017; Aguilar et al., 2019).

Although many named entities are shared between languages, named entity recognition systems usually rely on language-specific cues (e.g. capitalization of nouns in German, compounding phenomena in agglutinative languages such as Korean, Japanese and Turkish (Agerri and Rigau, 2016)). Such kind of detection cues do not scale well to other languages. As a consequence, most models need to be fine-tuned for each language separately on manually annotated high-quality training data which is a costly process.

Task 12 of SemEval 2022 provides a test bench for more robust systems which can detect complex named entities in 11 languages (Malmasi et al., 2022b). The dataset intentionally contains semantically ambiguous entities with limited contexts. We focus on the multilingual tracks of the competition which requires the prediction of named entities in all 11 languages by a single model (track 12). As an additional challenge, the model is also evaluated on code-mixed data (track 13).

We summarize the main finding of our analysis as follows:

- In Sec 4.2, we show that the choice of the tagging scheme affects model performance. We observe that BILOU Tagging is more effective than BIO Tagging in our experiment albeit the total number of training is reduced when annotation is changed to BILOU. We hypothesize that this is due to explicit distinction between single and multi-token entities in BILOU which might help model performance.

- In Sec 6.1, we compare the performance differences across languages and find a surprisingly large difference between German and Russian (10-point difference in f1). This is contrary to what is expected since the size of the training data and the label distribution across languages are comparable. We hypothesize that linguistic factors such as script and typology or factors relating to the pre-trained phase contribute to this difference.

- In Sec 6.3, we further expand on this hypothesis and experiment with a zero-shot model to examine patterns of transfer between pairs of languages. We observe higher transfer between English, Dutch and German. These are also the languages for which the model yields the highest scores individually.

In the rest of the paper, we discuss related work, experimental setup and model training, and extensive error analysis.

2 Related Work

Named entity recognition can be modeled as a sequence labeling problem. Deep-learning based approaches learn suitable representations in an end-to-end fashion and outperform rule-based and handcrafted feature-based approaches (Akbik et al., 2018; Wang et al., 2020).

(Huang et al., 2015) proposed a BiLSTM-CRF architecture for sequence tagging which is used by most state-of-the-art models. These models combine long short-term memory layers in a bidirectional fashion to use both past and future input and predict named entity sequences using a conditional random field layer. Significant performance gains have been obtained by initializing the model with pre-trained contextual embedding models such as BERT (Devlin et al., 2019), Flair (Akbik et al., 2018) and LUKE (Yamada et al., 2020).

Subsequent works explore some of the limitation of using a vanilla transformer. (Guo et al., 2019) show that a transformer architecture is less effective for modeling sequence labeling that strongly relies on left and right context and long-range dependencies which is the case for named entity recognition. LUKE (Yamada et al., 2020) is the state of the art in the CoNLL-03 NER dataset. It is pre-trained by contextualized representations based on bi-directional transformers on entity-annotated corpus of words and entities.

The complexity of the task and its multilingual nature are the main factors in choosing our modeling approach. The task complexity entails that our approach should rely on token context and in capturing relationships between labels since the surface form cues (e.g capitalization) are normalized in the training data. The multilingual aspect entails choosing a crosslingual pre-trained model which can handle the target languages. We choose `XLM-RoBERTa-large` (Conneau et al., 2019) and `Microsoft/infoxlm-large` (Chi et al., 2020). `XLM-RoBERTa-large` model is a cross-lingual version of RoBERTa. XLM-RoBERTa has outperformed cross-lingual BERT and it is the state of the art on many cross-lingual tasks including Named Entity Recognition. `Microsoft/infoxlm-large` is similarly a multilingual pre-trained model for over 100 languages with a new cross-lingual pre-training task named cross-lingual contrast (XLCO).

A comparison of the two pre-trained models shows both to be competitive on tasks such as cross-lingual natural language inference (XNLI) and `Microsoft/infoxlm-large` to be significantly better on cross-lingual question answering (MLQA) and cross-lingual sentence retrieval on the Tatoeba dataset. We provide a direct comparison of these two models for named entity recognition (which was previously missing in the literature) and explore an ensemble of the two models.

3 Data analysis

We use the training dataset provided as part of SemEval 2022 Task 11 MultiCoNER: Track 12 (Multilingual) and Track 13 (Code-mixed) (Malmasi et al., 2022a). The dataset consists of training and development data in 11 languages annotated with six named entity types. Table 1 provides statistical characteristics of the dataset. We observe that overall 18% of the tokens are labeled as a named entity which is comparable to other datasets. In terms of entity types, Person (PER), Group (GRP) and Creative Works (CW) occur more frequently across languages. We notice that the absolute number of entity tokens is twice as high for Chinese as for the other languages. This can be explained by the character-level tokenization of the Chinese texts. As a consequence, 98% of all Chinese entities are multi-token entities compared to 55% for Korean and 85% for English. Figure 1 visualizes the entity density across languages showing a large difference for Chinese but only small variations for the other languages. This difference may be smoothed by subtoken representations of the language models. The Chinese characters can not be broken any further, whereas the other language tokens can.

	Multilingual	Code-Mixed

Language (#)	11	N/A
Sentences (#)	168.3 K	1.5 K
Tokens (#)	2750.9 K	17.5 K
Part of Entity (%)	18	30
Outside of Entity (%)	82	70

Table 1: Summary of training data statistics

4 System Description

The system that we proposed for both track 12 and track 13 is based on an ensemble of two pre-trained transformer models (PTMs). The first one is the `XLM-RoBERTa-large` model (Liu et al., 2020; Conneau et al., 2019) which is a cross-lingual version of RoBERTa.The second one is `Microsoft/infoxlm-large` (Chi et al., 2020) which is also multilingual pre-trained model that supports over 100 languages and includes a new cross-lingual pre-training.

4.1 Fine-tuning

Both the selected pre-trained model takes as input a sequence of tokens and encodes them to the embedding space. During fine-tuning. These embeddings are passed to a dense layer that predicts class scores. On top of the class scores, we used a CRF layer.

4.2 Tagging Schemes

Several NER tagging schemes have been used in the literature. However, choosing the ideal scheme is a complex problem (Konkol and Konopík, 2015). The two most popular NER tagging schemes are BIO and BILOU. In BIO, sometimes referred to as IOB (Sang and Buchholz, 2000), a different tag is assigned to each word in the text depending on whether it is the beginning $(B - y)$, inside $(I - y)$, or outside (O) a named entity phrase y. In case of BILOU, in addition to the previous $(B - y)$, $(I - y)$ and (O) tags, words at the end of an entity phrase get an end tag $(E - y)$ and single-token entities get a unit-length tag $(U - y)$. BILOU annotations increase the amount of information related to the boundaries of named entities compared to BIO but reduce the amount of training cases per tag.

4.3 Ensemble

In our experiments on the development set, we get the best performance using an ensemble of seven models. Four of them are based on `XLM-RoBERTa-large`, and the other three are based on `Microsoft/infoxlm-large`. Furthermore, to make the set of models more diverse, we used a different random seed to initialize their weights and while we kept the same set of hyper-parameters as defined in Table 2. Finally, we used two different ensemble techniques, explained in more detail in the following sections. We provide additional information about the ensemble models in Appendix A.

4.4 Voting and Score Fusion

A hard voting ensemble involves summing the votes for crisp (discretized) class labels from our models and predicting the class with the most votes. While *soft voting* is an ensemble that involves summing the predicted probabilities for class labels and predicting the class label with the largest sum probability. To consider the context of the labels, we employed a CRF layer on top of the aggregated scores. See Figure 2.

5 Experiment and Result

All our models were implemented with PyTorch (Paszke et al., 2019), on top of the pre-trained transformer models provided by HuggingFace (Wolf et al., 2019). For the PTMs, the output of the last attention layer was used as input for the classifier layer. The CRF classifier was implemented using the AllenNLP library (Gardner et al., 2017). Adam optimizer (Kingma and Ba, 2014) was used to update model parameters. Finally, cosine annealing decay with $T\_max = 20$ and $eta\_min = 1.0e-8$ was applied for the learning rate after (early_stopping_patience / 2) consecutive epochs without improving (Loshchilov and Hutter, 2016).

5.1 Model Training and Evaluation

We train our model using only the official training data. We used the development data to evaluate the performance of the models. Models were evaluated at the end of every epoch. Early stopping and cosine annealing decay were determined using the macro average span-F1 score. In the evaluation phase, task organizers provided an unlabelled test dataset. We used the pre-trained model to make the predictions without retraining and uploaded it to Codalab. The ensemble of models with score fusion provides the best results on the development and test datasets. See tables 3 and 4.

Hyperparameter selection impact During the training phase, we tested several combinations of the hyperparameters, and we used a greedy approach to select the best individual hyperparameters. Table 2 shows the most important parameters that have a significant impact on the performance

Track →	Track 12 (Multilingual)			Track 13 (Code-Mixed)		
Model ↓	P	R	F1	P	R	F1
Baseline	64.5	65.6	64.2	60.0	61.7	59.0
Best infoxlm-large	86.4	87.1	86.8	76.9	76.5	76.7

Table 3: NER results on the development datasets in span-level precision (P), recall (R) and F1 in %.

of our models.

A crucial first step was the application of curriculum learning which reduced the training time by 50%. That was crucial since training our model on such a big dataset takes about one hour per epoch.

The tagging scheme is one of the most critical parameters that impact the performance of our model. For example, using BILOU scheme improved the performance about 1.5% on span-F1 score compared with the BIO scheme.

Max sequence length and batch size played a primary role in the training speed and performance. At the same time, a small value for the learning rate prevented the model from over-fitting rapidly. Finally, learning rate decay made the model convergence smoother before the early stopping occurrence.

PTM Impact As shown in Table 3, `Microsoft/infoxlm-large` and `XLM-RoBERTa-large` have almost the same performance. To the best of our knowledge, they share the same structure and are pre-trained on the same data. However, their pre-training objective functions differ. On the other hand, model size impact can be clearly seen by comparing the above large models with the `baseline` model which is based on `XLM-RoBERTa-base`.

Ensemble Impact The *score fusion* (Sect. 4.3) ensemble outperforms the individual models and the *vote-based* ensemble on almost all metrics. This improvement was due to the soft score aggregation, which gives the model better control to select the correct class than the crisp *vote-based* class aggregation.

CRF Impact Applying CRF on model scores gives better results than using argmax only. However, it was a bit hard to apply it in the score fusion ensemble model. In this type of ensemble, we aggregated the scores, not the output of the CRF layer. There were two options to solve this problem, i) take the CRF layer of one of the ensemble models and use it directly on top of the aggregated scores without fine-tuning, or ii) fine-tune a new CRF layer on the aggregated scores. We tried both solutions, and our finding was that the second option gives better performance, about 0.1% improvement in span-F1 score compared with the first option. See last row in Table 3.

6 Analysis and Conclusion

In this section, we analyze our model output for the multilingual task and the code-mixed task on the development dataset because the gold labels for the test data were not released. Table 5 shows the performance averaged over six entity types ranked by language.

We see that the model performance varies strongly between languages. The best result is obtained for German and is 10 percentage points higher than the lowest result which is obtained for Russian. When we compare the different entity types, we observe the highest variance for Chinese.

The large differences are surprising as the training data size is equal for all languages and the entity types are roughly evenly distributed (with the exception of Chinese). We therefore analyse these differences further below.

6.1 Variation Across Language

We first clustered languages into three groups based on their model performance: Group-1 has a score of 0.9 or higher and includes German, Dutch and English. Group-2 has a score between 0.85 and 0.9 and includes Turkish, Chinese, Spanish, Korean, Hindi and Bangla. Group-3 has a score lower than 0.85 and includes Farsi and Russian. With a single language model and a comparable

Track → Model ↓	Track 12 (Multilingual) P	R	F1	Track 13 (Code-Mixed) P	R	F1
Ensemble voting	74.64	75.84	74.92	79.72	79.58	79.57
Ensemble fusion	75.96	75.78	75.49	81.10	79.72	80.29

Table 4: NER results on the test datasets in span-level precision (P), recall (R) and F1 in %.

Language	DE	NL	EN	TR	ZH	ES	KO	HI	BN	FA	RU
Macro-F1	92.28	91.43	90.26	88.71	88.11	87.62	86.47	86.19	86.11	84.54	82.92

Table 5: Macro-F1 (in %) averaged over NEs (evaluated on development dataset)

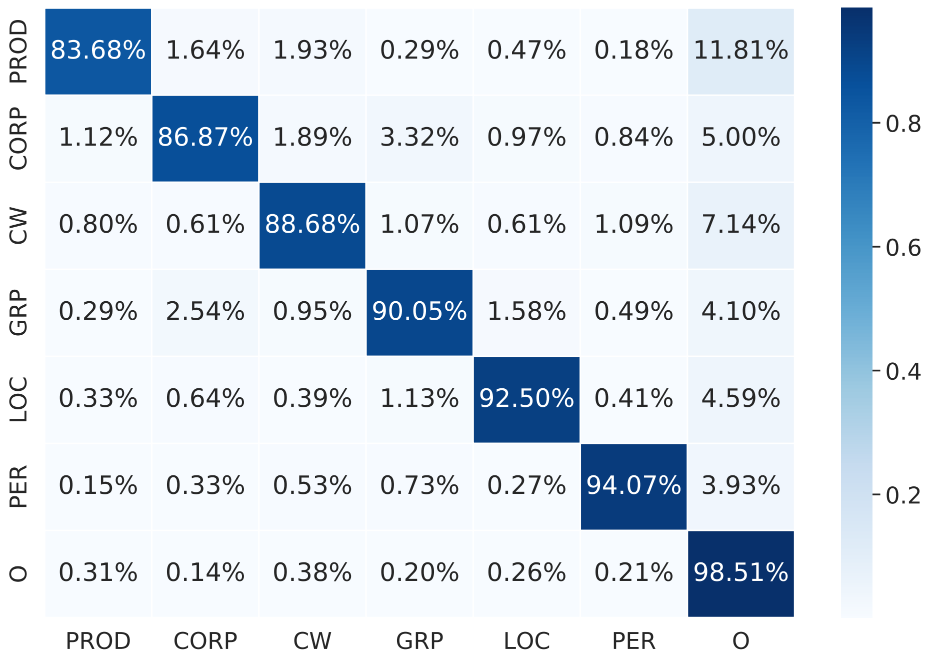

Figure 3: Confusion Matrices on the development datasets (Multilingual + Code-Mixed)

fine-tuning dataset across languages, the disparity in the result could possibly be attributed to
(a) Representational quality: differences in language representations in XLM-R, as some languages are represented better than others
(b) Typological properties: typological difference between languages as languages that are related tend to take advantage of transfer during fine-tuning
(c) Script characteristics: languages with similar scripts tend to take advantage of shared subtokens during fine-tuning.

We observe that all group-1 languages are commonly categorized as high-resource languages for which `XLM-RoBERTa-base` performs well on downstream tasks (Conneau et al., 2019; Joshi et al., 2020). Liu et al. (2020); Hu et al. (2020) give evidence for this effect in downstream tasks.

In terms of typological properties, although group-1 and group-3 languages are members of the same language family, they differ in their scripts which to some extent negatively influence transfer at least during the fine-tuning phase (Muller et al., 2021).

6.2 Confusion Matrix

Figure 3, shows a confusion matrix for coarse-grained entity types. From these results, we observe a stronger ambiguity between the O label and the entity types than across entity types. A possible explanation can be lexical overlap in the training data. The highest confusion can be observed between Creative Work (CW) and the Out Label (O). CW often consists of titles of movies and other creative work that include words that also occur in regular expressions annotated as O.

Frequency Analysis As a follow-up, we carried out a more-detailed frequency analysis of the tokens that are annotated as entity tokens and O. Frequency analysis on the token shows a long tail distribution with more than 90% of the errors occurring only once. Table 6 shows the most frequently misclassified tokens, which are the English and Dutch definite determiner and the Chinese symbol for *Sri Lanka*.

Token	Frequency
De	36
the	22
斯	22

Table 6: Tokens which are misclassified most frequently

From the misclassified tokens, we observed substantial overlap between false negative and false positive tokens. Among these, determiners (articles such as 'a', 'the', 'de') and words that stand for the type of products are common ("movie", "series", "municipal"). These words are typically expected at the border of named entity expressions. There may be two explanations for these cases:

Inconsistent Annotations where a token is sometimes included in the named entity expression and sometimes it is not. This issue most likely occurs on border labels. To show this we take annotation examples from the training data e.g., *the oculus quest* as the name of a product can be annotated as [O, B-PROD, I-PROD] or [B-PROD, I-PROD, I-PROD] where *the* is annotated as outside of entity type in the first case and inside on the second case which creates inconsistency on *the* token.

Variable Contexts where the same token truly occurs both within entity phrases in some context and outside as the context change. For example in *the communist party of great britain* is annotated as [O, B-GRP, I-GRP, I-GRP, I-GRP, I-GRP] where the token *great* is annotated as GRP and in a different context - *the great sum of 1,000 pounds* it is annotated as outside of entity. Both cases are difficult to resolve for a model.

Token	Annotated Labels	Label Distribution
his	I-CW, O, I-PER	[0.01, 0.99, 0.00]
songs	I-CW, O, B-CW	[0.05, 0.83, 0.12]
since	I-CW, O, B-CW	[0.01, 0.99, 0.01]

Table 7: Examples for label variation

We explored the first cause where the issue might arise from an inconsistent annotation in the training data. We first extract tokens from the training data with multiple labels along with their corresponding label proportion. In Table 7 some examples are given, where "songs" also tend to occur at the beginning of a CW. We then use this proportion to create a post processing filter where we "correct" the model output at the borders of entity phrases for tokens with overlapping False Positive and False Negative cases in case the model output deviates from the bias.
We experimented with different thresholds for the bias to apply where the maximum value represents a bias value and the minimum value represents the exception value. Although this approach did not result in a performance gain or loss, we observe that closed class words such as articles but also proper names for locations, product names, proper nouns and symbols are often affected by this filter. A possible explanation for lack of effect could be that the same annotation inconsistency also applies to the test data.

6.3 Transferability

To analyze how transfer plays out between the group-1 languages, we fine-tuned `XLM-RoBERTa-base` on the English dataset and evaluated it in a zero-shot setting on the rest of the languages. Figure 4 shows the result of this experiment. Though other factors might play a role, we can infer from this result that group-1 languages (German and Dutch) have a more positive transfer from English than the other languages, although Spanish also benefits from English.

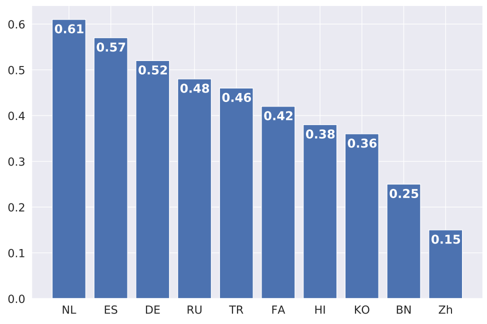

Figure 4: English Zero shot performance across languages

	NL	NL-DE	NL-ZH	NL-Rand ZH	Den-ZH	Den-DE
GRP	0.82	0.8	0.76	0.76	0.02	0.11
CW	0.72	0.68	0.67	0.71	0.14	0.09
PROD	0.69	0.62	0.61	0.69	0.14	0.08
LOC	0.87	0.88	0.84	0.86	0.13	0.09
PER	0.88	0.82	0.86	0.84	0.05	0.12
CORP	0.84	0.78	0.77	0.76	0.12	0.09

Table 8: Bilingual Models evaluated on Dutch Development Dataset (Macro F1)
The last two Column (Den-ZH and Den-DE) shows Named entity density measures

Next to zero-shot transferability, we also experimented with bilingual transfer. We selected one language as the target language, in this case, Dutch, and we measured the contribution of all other languages as training data in addition to half of the Dutch training data. We combine half of the dutch training data with half of German (Column NL-DE), half of Chinese(Column NL-ZH) and randomized Chinese (Column NL-Rand ZH) where we randomize Chinese tokens with a token from XLM vocabulary. The first four column shows bilingual models evaluated on Dutch development set measured in macro-averaged F1. The total set of training sentences was kept the same across all experiments.
We observe that contrary to the zero-shot results, Chinese contributes overall only just a bit lower than German when tested on the Dutch test set. This is remarkable because German and Dutch are typologically very close and use the same script. Apparently, the observed density of entities for Chinese is a factor that may compensate for the difference in script and language typology. We can see in Table 8 that the contributions of Chinese lag behind when the density is lower than German (GRP) but is almost the same when it is higher (CW, PROD, LOC, CORP). The only exception is PER which has the lowest density for Chinese but still a higher contribution. To test the assumption that just the label density plays a role, we even replaced the Chinese tokens with random tokens. The results show that even partially randomized Chinese training data outperforms the German contribution on most entity types.

6.4 Conclusion

In this paper, we proposed a single named entity recognition system that can process multilingual and code-mixed text based on an ensemble of transformer-based models. We have accomplished fourth and fifth positions in the test phase for track 12 (Multilingual) and track 13 (Code-Mixed). Even though the proposed system performs pretty well on the development dataset, there is a considerable performance drop in track 12 on the test dataset. Further study needs to be done to address that performance change.

Summarising the results from the error analysis and the statistics on the training data, we can conclude that there are four factors that play a role in the cross-lingual performance of this task, given that an equal amount of training data is available for fine-tuning in all languages. We provided evidence that transfer from the XLM pre-training, typological relatedness, and shared scripts can be factors that contribute to transfer but on the other hand the density of the entities in the training data is another factor.

Our system does not include external gazetteers or targeted unsupervised learning on difficult entity types such as products and creative works. In future work, we would like to include them, which could help to improve the performance due to the extra information they include.

Abstract

Large scale pre-training models have been widely used in named entity recognition (NER) tasks. However, model ensemble through parameter averaging or voting can not give full play to the differentiation advantages of different models, especially in the open domain. This paper describes our NER system in the SemEval 2022 task11: MultiCoNER. We proposed an effective system to adaptively ensemble pre-trained language models by a Transformer layer. By assigning different weights to each model for different inputs, we adopted the Transformer layer to integrate the advantages of diverse models effectively. Experimental results show that our method achieves superior performances in Farsi and Dutch.

1 Introduction

NER is an essential tool in the application fields of information extraction, question answering system, syntactic analysis, machine translation, etc. It plays a vital role in the process of the practical application of natural language processing technology (Devlin et al., 2018; Meng et al., 2021). However, processing complex and ambiguous Named Entities (NEs) is a challenging NLP task in practical and open-domain settings, but has not received sufficient attention from the research community.

Complex NEs, like the titles of creative works (movie/book/song/software names), are not simple nouns and are harder to recognize (Ashwini and Choi, 2014; Fetahu et al., 2021). They can take the form of any linguistic constituent, like an imperative clause (“Dial M for Murder”), and do not look like traditional NEs (Person names, locations, organizations). This syntactic ambiguity makes it challenging to recognize them based on their context. Such titles can also be semantically ambiguous, e.g., “On the Beach” can be a preposition or refer to a movie. Finally, such entities usually grow faster than traditional categories, and emerging entities pose yet another challenge.

In recent years, the deep learning methods have achieved great success in NLP (Natural Language Processing). However, some limits need to be addressed. Challenges for deep learning in NLP mainly arise from the scarcity of labeled data. One way to alleviate the need for large labeled datasets is to pre-train a model on unlabeled data via self-supervised learning, and then transfer the learned model to downstream tasks (Devlin et al., 2018). These methods have been widely applied and have made a massive breakthroughs, such as BERT (Devlin et al., 2018), XLNET (Yang et al., 2019) and GPT (Radford et al., 2018).

Pre-trained neural models (e.g., Transformers) have produced high scores on benchmark datasets like CoNLL03/OntoNotes (Devlin et al., 2018). However, as noted by Augenstein et al. (Augenstein et al., 2017), these scores are driven by the use of well-formed news text, the presence of “easy” entities (person names), and memorization due to entity overlap between train/test sets; these models perform significantly worse on complex/unseen entities. Researchers using NER on downstream tasks have noted that a significant proportion of their errors are due to NER systems failing to recognize complex entities (Luken et al., 2018; Hanselowski et al., 2018).

2 Related Work

NER. Named entity recognition (NER) is a subtask of information extraction, which aims to locate and classify named entities in text into predefined categories. The traditional NER scheme is rule recognition based on manual induction. Based on domain dictionary and grammar rules. Lample (Lample et al., 2016) explored neural structures for NER, in which the bidirectional LSTMs are combined with CRFs with features based on character-based word representations and unsuper-

vised word representations. Despite BiLSTM's great success in the NER task, it has to compute token representations one by one, which massively hinders full exploitation of GPU's parallelism. Therefore, CNN has been proposed to encode words concurrently. In order to enlarge the receptive field of CNNs, iterative dilated CNNs (IDCNN) (ḞẎu and Koltun, 2016) was used.

Pre-training Language Model. Recent large-scale language model pre-training methods such as BERT (Devlin et al., 2018), XLNET (Yan et al., 2021) and GPT (Radford et al., 2018), further boosted the performance of NER, yielding state-of-the-art performances.

3 Task Descriptions

This task challenges NLP enthusiasts to develop complex Named Entity Recognition systems for 11 languages (In this work, we conducted experiments on Farsi and Dutch). The task focuses on detecting semantically ambiguous and complex entities in short and low-context settings. The task also aims at testing the domain adaption capability of the systems by testing additional test sets on questions and short search queries.

4 Datasets

For the entity recognition task (Malmasi et al., 2022b) on both Farsi and Dutch, there are 15300 pieces of training data. For Farsi, the longest sentence has 46 words, and the shortest sentence has only 1 word, with an average length of 18 words. For Dutch, the longest sentence has 47 words, and the shortest sentence has 2 words, with an average length of 15 words. This means that the length of the current corpus is too short, which means that it is difficult to use a large number of sentence models to cover a large proportion of the length of the current corpus.

In both tasks, there are six types of entities (Malmasi et al., 2022a), CW (Creative Work), PER (Person), LOC (Location), GRP (Group), CORP (Corporation), PROD (Product). The distribution of entity types is relatively average. The lowest proportion is PROD, accounting for 12.9%, and the highest proportion is LOC, accounting for 24.9%. Many types of entities, short sentence length, lack of sufficient context information, and open-domain information extraction all increase the difficulty of these tasks.

5 Systems Description

Overview of our architecture for the NER task was shown in Figure 1. The system mainly includes two parts: data augmentation, pre-trained language model ensemble.

5.1 Data Augmentation

For data augmentation, we expanded the existing training data through text generation and label-wise token replacement. Given a sentence s in the training dataset, we aim to generate a new sentence $s^{'''}$ containing the same type entities. Our augmentation consists of the following steps:

1. Entity Mask: Mask all entities in the sentence with specific symbol $[mask]$. We call this modified text $s^{'}$.

2. Sentence Generation: Generate similar sentences using the GPT model. We call this generated sentence $s^{''}$.

3. Entity Infilling: Fill in $[mask]$ tokens with text that has the same entity type. This final output text is called $s^{'''}$.

Besides, we also delete the non-entity part of the sentence randomly to improve the robustness of the model.

5.2 Model and Benchmarks

As shown in Figure 1, Roberta, XLNET, and GPT are chosen as the base model in out system. We use these large pre-trained models as the basis and then use the training data to fine-tune each one. After the fine-tune is completed, it is worth mentioning that, the outputs from the last fourth to the last second layer are used to average the parameters as the final output for each model. The reason why we did not use the last layer is to avoid over-fitting. There is a huge difference between the training dataset and the test dataset (16,000 training data, but 150,000 test data). In order to avoid overfitting on the training set and maintain the generalization ability, we did not use the output of the last layer.

Second, we take the results of all models as the input of the subsequent attention module, as demos in Figure 1. After obtaining the inputs of base models, we train a transformer layer to assign the corresponding weight to the outputs of different models at the same location, and use the weighted sum of all models as the final output after the model ensemble. Moreover, we add a CRF (Conditional Random Field) layer at the end to limit the final result.

The output of the basic model as shown in below:

$$\begin{bmatrix} r_1^1 & ... & r_i^1 & ... & r_L^1 \\ r_1^2 & ... & r_i^2 & ... & r_L^2 \\ r_1^3 & ... & r_i^3 & ... & r_L^3 \end{bmatrix} \tag{1}$$

where r_i represents the output of the ith model, L means the length of the sentence. Using this matrix as input, we train a transformer layer to learn how to assign different weights to different models. The weight matrix obtained is multiplied by the output results of all models to obtain a matrix with weight, as shown below:

$$\begin{bmatrix} a_1^1r_1^1 & ... & a_i^1r_i^1 & ... & a_L^1r_L^1 \\ a_1^2r_1^2 & ... & a_i^2r_i^2 & ... & a_L^2r_L^2 \\ a_1^3r_1^3 & ... & a_i^3r_i^3 & ... & a_L^3r_L^3 \end{bmatrix} \tag{2}$$

The vector corresponding to the position can be regarded as the influence of the model on the result of this position, so the final result corresponding to each position can be regarded as the weighted sum of the results of the three models, which is $R_i = [a_i^1r_i^1 + a_i^2r_i^2 + a_i^3r_i^3]$. This result is used as the final output of the model to predict labels.

Ensemble model w/o AUG	0.816	0.822	0.819
Ensemble model w/ AUG	**0.823**	**0.834**	**0.828**

Table 2: Benchmarks of Farsi on the dev set. The best performance is highlighted in bold. w/ AUG and w/o AUG denote model with and without data augmentation.

5.3 Experimental Setup

Our implementation is based on PyTorch and we conduct all experiments on one Tesla V100 GPU. Table 1 shows the details of the hyper-parameters for our models. The total training epoch is set to 20 and the batch size is set to 24. The initial learning rate is set to 3×10^{-5}, and the learning rate of CRF layer is set to 1×10^{-3}. Considering the average length of sentences in datesets, the sequence length is 128. Dropout (Srivastava et al., 2014) and early-stop are also used in our method to achieve better performance in the open domain.

Model	ACC	Recall	F1
RoBerta	0.894	0.892	0.893
XLNET	0.892	0.899	0.895
GPT	0.882	0.880	0.881
Ensemble model w/o AUG	0.904	0.909	0.906
Ensemble model w/ AUG	**0.910**	**0.911**	**0.910**

Table 3: Benchmarks of Dutch on the dev set. The best performance is highlighted in bold. w/ AUG and w/o AUG denote model with and without data augmentation.

6 Results and Discussion

The results on both Farsi and Dutch data-sets are shown in Table 2 and Table 3. Notably, our architecture with data augmentation and model ensemble has substantially improved performance. We also conducted the ablation study of different data augmentation ratios. We found that the best results can be obtained when the data is augmented with a ratio 2 + by three times (as shown in Table 4). Moreover, we also carried out experiments on whether post-processing can improve the performances. The post-processing was conducted as follows: based on the dictionary of the training set, we generated entity labels by exact string matching, where conflicted matches were resolved by maximizing the total number of matched tokens. Unfortunately, the final results demonstrated a relatively decreased performance about 0.4 percent. The reason lies in case-sensitive. In many cases, the case of letters plays a vital role in identifying entities. For example, 'Wat is' is a very prevalent query in Dutch, but 'IS' also represents an organization (Islamic State of Iraq and al-Sham).

Augmentation Ratio	ACC	Recall	F1
0 +	0.769	0.811	0.789
1 +	0.772	0.811	0.791
2 +	**0.776**	**0.819**	**0.797**
3 +	0.775	0.816	0.795

Table 4: Ablation study of different data augmentation ratios on the dev set of Farsi using RoBerta.

7 Conclusions

This study describes an effective NER system in the SemEval 2022 task 11: MultiCoNER, the experimental results demonstrated the effectiveness of our ensembled large pre-trained language models on low-resource Named Entity Recognition. In future work, we would further improve the performances by exploiting a more complicated ensemble strategy with more diversified models.

Abstract

This study describes the model design of the NCUEE-NLP system for the Chinese track of the SemEval-2022 MultiCoNER task. We use the BERT embedding for character representation and train the BiLSTM-CRF model to recognize complex named entities. A total of 21 teams participated in this track, with each team allowed a maximum of six submissions. Our best submission, with a macro-averaging F1-score of 0.7418, ranked the seventh position out of 21 teams.

1 Introduction

Named Entity Recognition (NER) is a fundamental task in information extraction that locates the mentions of named entities and classifies them (e.g., person, organization and location) in unstructured texts. The NER is a traditional NLP task that has been solved as a sequence labeling problem, where entity boundaries and category labels are jointly predicted. It is difficult to recognize complex named entities like the titles of creative works (e.g., books, songs, movies) that can take the form of any linguistic constituent (Ashwini and Choi, 2014). Syntactic and semantic ambiguity makes it challenging to recognize such complex named entities based on their context.

The SemEval-2022 Task 11 (MultiCoNER) organized a challenge to develop multilingual complex NER system for 11 human languages (Malmasi et al., 2022b). This task focuses on detecting semantically ambiguous and complex entities in short and low-context settings. The languages include: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. The named entity categories are Person (labeled as PER), Location (LOC), Group (GRP), Corporation (CORP), Product (PROD), and Creative Work (CW). The task evaluation framework is divided in three broad tracks. 1) Multi-lingual (Track 1): participants train a single multi-lingual NER model for all the languages; 2) Mono-lingual (Track 2-12): participants train a model that works for only one language; 3) Code-mixed (Track 13): testing samples include tokens from any of the 11 mentioned languages in the shared task. We only participated the Track 9 for Chinese language.

Chinese NER is more difficult to process than English NER. Chinese language is logographic and provides no conventional features like capitalization. In addition, due to a lack of delimiters between characters, Chinese NER is correlated with word segmentation tasks, and named entity boundaries are also word boundaries. However, incorrectly segmented entity boundaries will cause error propagation in NER. For example, in a short context "這首歌出現在華特迪士尼動畫動物方城市中" (This song appeared in the Walt Disney animation Zootopia), a creative work "動物方城市" (Zootopia) may be incorrectly segmented into three words: "動物" (animal), "方"(square), and "城市" (city). Hence, it has been shown that character-based approaches outperform word-based methods for Chinese NER (He and Wang., 2008; Li et al., 2014; Zhang and Yang., 2018).

Recently, deep learning techniques have been widely used for Chinese NER, mostly with promising results. A character-based LSTM (Long Short-Term Memory)- CRF (Conditional Random Field) model with radical-level features was proposed for Chinese NER (Dong et al., 2016). The ME-CNER model exploited multiple embeddings-based character representation to improve Chinese NER performance (Xu et al., 2019). A joint training objective technique for different types of neural embeddings was adopted for Chinese NER in social media, based on Weibo messages (Peng and Dredze., 2015). The BiLSTM (Bidirectional LSTM)-CRF model was trained based on character-word mixed embeddings to improve the recognition effectiveness of Chinese NER (E and Xiang., 2017). A BiLSTM-CRF model with a self-attention mecha-

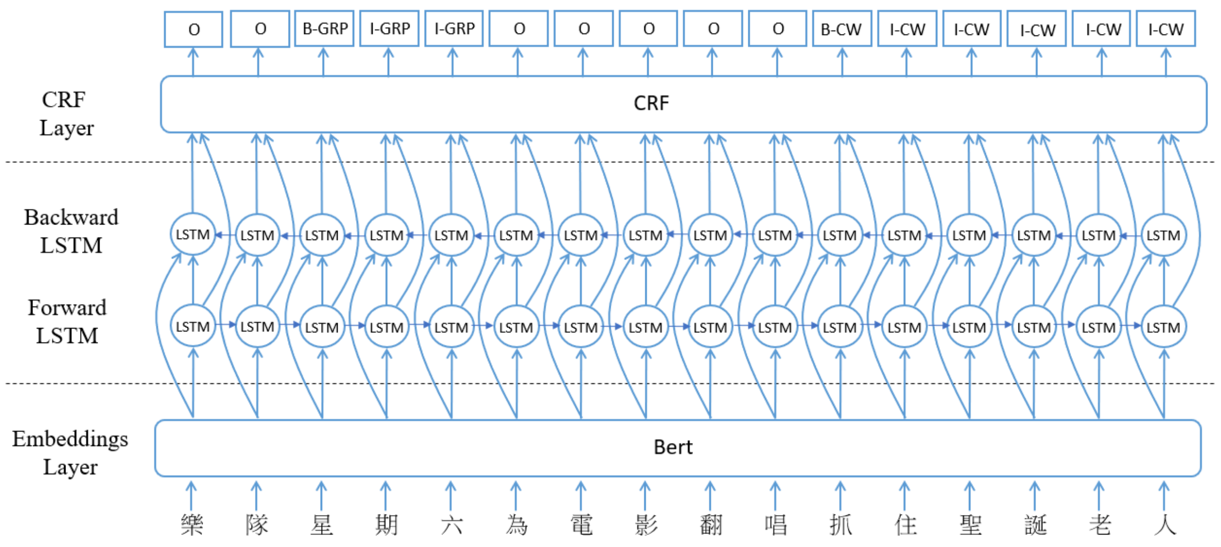

Figure 1: Our NCUEE-NLP system architecture for the Chinese track of SemEval-2022 Task 11.

nism was proposed to integrate part-of-speech labeling information to capture the semantic features of input sequences for Chinese clinical NER (Wu et al., 2019). A residual dilated CNN (Convolution Neural Network) with CRF was also presented to enhance Chinese clinical NER in terms of computational performance and training time (Qiu et al., 2019). An ME-MGNN (Multiple Embeddings enhanced Multi-Graph Neural Network) model was proposed to derive a character representation based on multiple embeddings at different granularities from the radical, character to word levels. Multiple gated graph sequence neural networks, along with standard BiLSTM-CRF, were then used to recognize Chinese named entities in the healthcare domain (Lee and Lu., 2021).

This paper describes the **NCUEE-NLP** (**N**ational **C**entral **U**niversity, Dept. of **E**lectrical **E**ngineering, **N**atural **L**anguage **P**rocessing Lab) system for the Chinese track of SemEval-2022 Task 11. We find that the neural computing approaches based on the BiLSTM-CRF achieved impressive results for Chinese NER. Hence, we follow the investigated results to develop character-based BiLSTM-CRF models.

2 The NCUEE-NLP System

Figure 1 shows our NCUEE-NLP system architecture for the Chinese NER. Our BERT-BiLSTM-CRF model is composed of three main parts: 1) BERT embeddings, 2) Bidirectional LSTM networks, and 3) CRF sequence labeling.

2.1 BERT Embeddings

Word embedding is a type of representation for text analysis that allows words with similar meanings to have similar representations in the form of a real-valued vector (Mikolov et al., 2013). Word embeddings can be obtained using a set of language modeling techniques where words are mapped to a low dimensional vector space of real numbers. Replacing static vectors, such as word2Vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014)), and fastText (Bojanowski et al., 2017), with contextual word representations has led to significant improvements to virtually every NLP task (Ethayarajh., 2019). BERT (Bidirectional Encoder Representations from Transformer) (Devlin et al., 2019), is an encoder-decoder architecture that uses attention mechanisms to incorporate context into word embeddings. Its technical innovation lies in applying the bidirectional training of the transformer with masked language modeling to hide the partial words and infer them using their position information.

Since incorrect Chinese word segmentation may cause error propagation to affect the boundaries of named entities, we only use the last layer of BERT to obtain contextual embedding for each character.

2.2 Bidirectional LSTM Networks

In traditional neural network architectures such as multilayer perceptron, all the inputs and outputs are mutually independent. To address this issue, Recurrent Neural Networks (RNN) create networks with

Data Source		Sent.	All NE	#PER	#LOC	#GRP	#CORP	#PROD	#CW

	Weibo	490	891	648	243	-	-	-	-
	PD	9,281	21,238	6,256	14,982	-	-	-	-
	Boson	566	4,280	2,479	1,801	-	-	-	-
	CLUENER	2,305	3,136	-	-	-	-	-	3,136
	LG	6,135	16,266	-	-	-	-	-	16,266

Table 1: Data statistics of Chinese NER.

loops called Long Short-Term Memory (LSTM) to remember all information over time. Bidirectional LSTM (BiLSTM) (Graves et al., 2013) combines two independent RNNs that allows the networks to obtain both forward (from left to right) and backward (from right to left) information about the character sequence at every time step.

2.3 CRF Sequence Labeling

The learned feature representations of characters in the BiLSTM layer are then fed to a standard Conditional Random Field (CRF) (Lafferty et al., 2001), following the character order in the original sentence to predict the sequence of labels.

During the model training phase, a sentence represented in terms of a character sequence, along with the corresponding named entity labels, are used to train the BERT-BiLSTM-CRF model. We adopt the commonly used BIO (Beginning, Inside, and Outside) format. The B-prefix before a tag indicates that the character is the beginning of a named entity and an I-prefix before a tag indicates that the character is inside a named entity. An O tag indicates a character belongs to no named entity. For example, a sample sentence “樂隊星期六為電影翻唱抓住聖誕老人” (The band The Saturdays covered Christmas Wrapping for the movie.) in Figure 1, “星期六” (The Saturdays) are a British-Irish girl band that belongs to the Group (labeled as GRP) category. The corresponding named entity labels are “B-GRP,” “I-GRP,” and “I-GRP” for individual character “星”, “期”, and “六”. Similarly, “抓住聖誕老人” (Christmas Wrapping) is a song belonging to the Creative Work (CW) category, so we have the named entity labels “B-CW,” “I-CW”, “I-CW”, “I-CW”, “I-CW”, and “I-CW”.

During the testing phase, our trained BERT-BiLSTM-CRF model is used to predict the named entity label of each character for performance evaluation.

3 Experiments and Results

3.1 Data

Table 1 shows detailed statistics for mutually exclusive datasets. The experimental datasets were mainly provided by the task organizers (Malmasi et al., 2022a). The evaluation test set is about 10 times larger than original training dataset. In addition, according to an FAQ on the task website, the training and test data have dissimilar label distributions, though we have yet to obtain the real distribution in the test set. Hence, we also collected external data, including MSRA (Levow., 2006), Weibo (Peng and Dredze., 2015), People Daily (PD)[1] , Boson[2] , CLUENER (Xu et al., 2020), and LG [3] to train our model. The former four datasets consist of sentences annotated with the named entity categories Person (PER) and Location (LOC), while the latter two datasets were converted to contribute instances for the Creative Work (CW) category. We did not find sentences annotated with appropriate labels for the named entity categories Group (GRP), Corporation (CORP), and Product (PROD) as defined in this task.

	Official+ External	0.7553	0.7037	0.7151

Table 3: Results of our NER models on the test set.

3.2 Settings

For character representations, in addition to BERT[4] (Devlin et al., 2019), we also adopted RoBERTa[5] (Liu et al., 2019) and MacBERT [6] (Cui et al., 2020) to compare the performance of different embeddings. We downloaded these pre-trained models from HuggingFace and continuously trained their language models using official data including training, validation and test datasets. The hyper-parameter values for our embedding training were embedding size 768; batch size 64; epoch 20; and learning rate 4e-5.

We trained the BiLSTM-CRF model based on official data provided by task organizers and their variants with our collected external data to confirm performance differences. The hyper-parameter values for our model implementation were optimized as follows: batch size 256; epoch 40; learning rate 0.004; LSTM hidden size 1024; and LSTM dropout rate 0.1.

The evaluation metrics of this shared task are standard precision, recall, and F1-score, which are the most typically used metrics for NER systems at a character level. For each track, the task participants are allowed to have maximum 6 submissions. The final ranking is determined from the best submission based on macro-averaging F1-score.

3.3 Results

Tables 2 and 3 respectively show the results of our submissions on the validation and test sets. We obtained closely consistent results on both datasets. Comparing the embedding effects with RoBERTa and MacBERT, although these two models are modified to improve the BERT model, we did not obtain NER performance improvements when using them as the embedding representation usage. Surprisingly, including external data to train BiLSTM-CRF does not improve the overall F1 performance. The architecture of the BERT-BiLSTM-CRF model using official data training only obtained the best F1-score of 0.7418 on the test set. Table 4 further shows the detailed results per named entity category. The class LOC obtained the best F1-score, followed by PER. In our observations, these two classes are most commonly categories with relatively clear definitions that may not cause recognition confusion. Both combinations of class GRP with CORP and class PROD with CW are usually difficult to distinguish even with manual annotation if insufficient annotation training is provided.

A total of 21 teams participated in the Chinese track of SemEval-2022 MultiCoNER Task, each submitting at least one entry. Our best submission

achieved an F1 score of 0.7418, ranking in the seventh position out of 21 teams.

4 Conclusion

This study describes the NCUEE-NLP system in the Chinese track of SemEval-2022 MultiCoNER task, including system design, implementation and evaluation. We used the BERT embedding to represent each character in the original sentences and trained BiLSTM-CRF using datasets provided by the organizers to predict the named entity categories. Our best submission had a marco-averaging F1-score of 0.7418, ranking in the 7th position among a total of 21 participating teams.

Abstract

This paper presents a solution for the SemEval-2022 Task 11 Multilingual Complex Named Entity Recognition. What is challenging in this task is detecting semantically ambiguous and complex entities in short and low-context settings. Our team (CMB AI Lab) propose a two-stage method to recognize the named entities: first, a model based on biaffine layer is built to predict span boundaries, and then a span classification model based on pooling layer is built to predict semantic tags of the spans. The basic pre-trained models we choose are XLM-RoBERTa and mT5. The evaluation result of our approach achieves an F1 score of 84.62 on sub-task 13, which ranks the third on the learder board.

1 Introduction

Named entity recognition (NER)(Tjong Kim Sang and De Meulder, 2003) is a fundamental task in natural language processing, aiming at identifying the spans of texts that refer to entities. NER is widely applied to information extraction and data mining(Lin et al., 2019)(Cao et al., 2019), which is greatly challenging in practical and open domain settings. However, the previous research has not paid much attention on processing complex and ambiguous named entities.

SemEval 2022 task 11 (Malmasi et al., 2022b) containing a total of 13 sub-tasks is a complex NER task which focuses on detecting semantically ambiguous and complex entities in short and low-context settings (Meng et al., 2021). For the purpose of testing the domain adaption capability of the participating models, the task not only set 11 base sub-tasks: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi and Bangla, but also set two additional testing sets on questions and short queries: Multilingual, and code-mixed (Fetahu et al., 2021). We conduct a two-stage method to deal with the code-mixed sub-task, which achieves an F1 score of 84.62.

This paper is structured as follows. The related work of NER is briefly introduced in Section 2. The data for training and testing the model is presented in Section 3. The details of the two-stage method is described in Section 4. The experimental results of our method are exhibited in Section 5. Section 6 summarizes this paper.

2 Related Work

In the NLP field, the NER task is usually considered as a sequence labeling problem (Liu et al., 2018) (Lin et al., 2019) (Cao et al., 2019). With well-designed features, CRF-based models have achieved the leading performance (Lafferty et al., 2001) (Finkel et al., 2005) (Liu et al., 2011). Recently, neural network models have been exploited for feature representations (Chen and Manning, 2014). Moreover, contextualized word representations such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019) have also achieved great success. As for NER, the end-to-end bidirectional LSTM + CRF model (Lample et al., 2016) (Yang et al., 2018) is one representative architecture. These models are only capable of recognizing regular named entities.

In e-commerce search domain, a common scenario is code-mixed queries, with query terms composed of multiple languages(Bhargava et al., 2016). The application for code-mixed Web queries still remains challenging(Gupta et al., 2014). A recent work proposed an NER hybrid approach for code-mixed queries, consisting of a gazetteer and tree based identifier(Bhargava et al., 2016). Another work leverages linguistic features to train a conditional random field (CRF) model, where the output is further processed using multi-lingual gazetteer lists(Gupta et al., 2016). In Seme Val 2022 task 11 code-mixed sub-task, we use a two-stage NER approach and get the 3rd place in the competition.

3 Data

In this task, we use the official raw data (Malmasi et al., 2022a) to train and test our model. Each line of texts in the data belongs to a sample, the languages involved are: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla, some of which are also provided with code-mixed data as an additional subtask. Entity types include Person, Location, Group, Corporation, Product, and Creative Work. The participants have to use their systems to accurately detect the entities and submit the predictions for the mixed languages task.

In a data file, samples are separated by blank lines. Each data instance is tokenized and each line contains a single token in the first column with the associated label in the last (4th) column. The second and third columns are underscores (_) to separate the tokens and the labels. The entities are labeled with the BIO scheme, which means that the token tagged O is not a part of the entity, the token tagged B-X is the first token of an X type entity, and the remaining tokens of the entity are tagged as I-X.

When the amount of training data is insufficient or unevenly distributed, data augmentation can quickly expand the corpus to avoid overfitting. At the same time, data augmentation can also improve the robustness of the model, preventing the performance of the model from being greatly reduced once the data only changes slightly. We build a dictionary with all entities of the same type to randomly replace the entities in each sample, and translate the replaced entities into other languages to expand the dataset, which is similar is to autoencoders in the computer vision. However, translation between different languages relies on a large number of parallel corpuses, and requires training first.

4 Methodology

The two-stage method we use in this task includes two separated models to recognize the named entities: one for predicting the boundaries of the spans, and the other for predicting the semantic tags of the spans. The processing flow of our approach is depicted in Figure 1.

4.1 Text Encoders

The models we employed are both trained based on XLM-RoBERTa$_{LARGE}$ and mT5$_{LARGE}$.

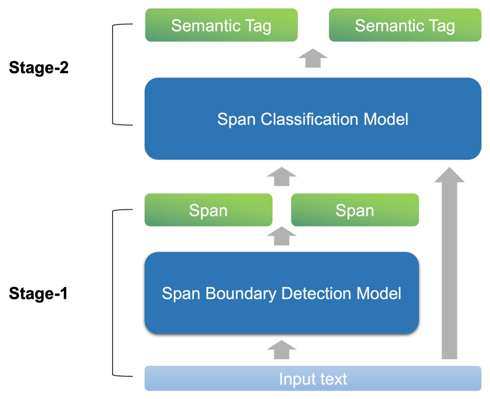

Figure 1: The processing flow of our approach

XLM-RoBERTa (Conneau et al., 2020): XLM-RoBERTa$_{LARGE}$ is pre-trained on 2.5TB of filtered common crawl data containing 100 languages, which consists of 24 transformer layers, 16 self-attention heads per layer, and a hidden size of 1024. In order to deal with a large number of common words in natural language corpus, BPE (byte pair encoding), a coding schema mixed by the character level and the word level representation, is utilized to process the text data.

mT5 (Xue et al., 2021): mT5$_{LARGE}$ is a multilingual pre-trained text-to-text transformer which is pretrained on the common crawl-based dataset corpus, covering 101 languages. We only use the encoder of the mT5$_{LARGE}$ consisting of 24 transformer layers.

4.2 Boundary Detection of Spans

The first stage of our method is to extract the phrase. As shown in Figure 2, we built a boundary detection model by connecting the last hidden states of the pre-trained model to the biaffine layer (Yu et al., 2020) to obtain the span boundaries, which can also be regarded as a named entity recognition (NER) model that only recognize one single category.

The output of the biaffine model is a span boundary matrix as illustrated in Figure 3. All pairs of start-end tokens have corresponding scores indicating whether they are the spans we need. Figure 4 shows an example of a span boundary matrix: the reason why *Jackie Ma* and *the louvre museum* are the entities in this sentence is that they are the two pairs of start-end tokens.

To better detect the span's boundary, we build a dictionary from the training data. Words that appear in training data more than twice are selected and then splice together with the original sentence

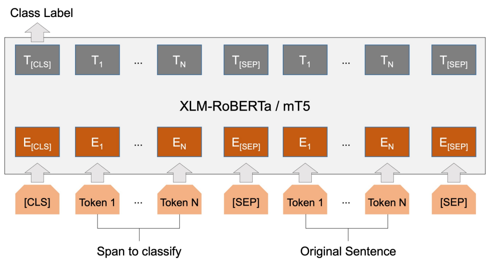

Figure 5: Span classification model

into the input text fragment, as shown below:

[CLS] *word selected 1* [SEP] *word selected 2* [SEP] ... [SEP] *sentence* [SEP].

4.3 Span Classification

The second stage of our method is to classify the spans obtained in the first stage. We built a classification model to determine which semantic tag the span belongs to. As shown in Figure 5, a full connection layer is connected to the pooling layer of the pretrained model to output the score for each category, and then is activated by a softmax function, with the cross entropy set as the loss function of the classification model.

It should be noted that the text fragment to be classified is constructed by the phrase extracted from the first model (boundary detection) and the original sentence. Similar to the sentence pair classification, a sample sentence before BPE applied appears as below:

[CLS] *phrase extracted* [SEP] *sentence* [SEP].

4.4 Training Procedures

In the first stage (span boundary detection), the Adam optimizer with a learning rate of 6×10^{-6} is employed, the batch size is set to 12, and the model is trained for 30 epochs. As for the second stage (span classification), the learning rate of the Adam optimizer is set to 8×10^{-6}, and the batch size and the number of epoch amounts are 16 and 40 respectively. For each stage, we use both the 10-fold cross-validation.

During the training phase of the span classification model, FGM adversarial learning is applied to improve the robustness of model: the samples are mixed with some fairly small disturbances that might lead to misclassification, and the neural network is then adapted to the disturbances to be robust to the adversarial samples.

4.5 Ensemble Model

The ensemble of deep learning models has a great improvement on the test dataset. We ensemble the predictions of span boundary detection models by voting strategy to get the best span boundary. Besides, the predictions of span classification models are also combined to get the final predictions. Each model is trained on different dataset augmented and based on different text encoders (i.e., XLM-RoBERTa and mT5). What is most conspicuous, however, is that the strategy of the two-stage model performs better than the traditional ner model in this task.

5 Results

A two-stage method is employed to complete the code-mixed language sub-task. Based on two pre-trained models (XLM-RoBERTa and mT5), we adopted a variety of optimization schemes, such as: biaffine network structure, two-stage entity prediction, adding distantly supervised dictionary and adversarial training, all of which have achieved a certain improvement, according to the evaluation results shown in Table 1. Lastly, we voted on all prediction results in terms of ensemble learning idea to get the final submission file.

With the XLM-RoBERTa + crf method as the baseline, and an end-to-end structure, we get an F1 score of 79.7. After using the biaffine network structure and two-stage optimization architecture instead, the F1 score improves to 80.9 and 81.3 respectively. In addition, the two-stage optimization architecture introducing supervised dictionary, adversarial training and data augmentation obtains F1 scores of 82.5, 83.1 and 82.7 respectively. Compared to the XLM-RoBERTa, the prediction results acquired based on the mT5 pre-trained model are improved by an average of 0.4 points. As a result, the final evaluation scores gained by voting is 84.62.

6 Conclusion

Aiming at the complex multilingual ambiguity and lack of context in this competition, we adopt a deep learning network model for entity extraction based on the biaffine attention mechanism, and carry out transfer learning based on different pre-trained models such as RoBERTa and mT5.

Through adversarial training, the robustness of the model is enhanced, and the two-stage training also improves the performance of the model in few-shot scenarios. Besides, a remote supervised dictionary is added to revise the results, and the entity dictionary for random replacement and multilingual machine translation is used for data augmentation. Usually for enhanced data, it is necessary to give a weight less than 1, which is different from real data. Data augmentation can also alleviate the problem of data imbalance. Ultimately, the best result (F1 score of 84.62) is achieved via ensemble learning voting strategy.

Comparison of different methods	
Method	F1(%)

UA-KO at SemEval-2022 Task 11: Data Augmentation and Ensembles for Korean Named Entity Recognition

Hyunju Song, Steven Bethard
University of Arizona
{hyunjusong,bethard}@email.arizona.edu

Abstract

This paper presents the approaches and systems of the UA-KO team for the Korean portion of SemEval-2022 Task 11 on Multilingual Complex Named Entity Recognition. We fine-tuned Korean and multilingual BERT and RoBERTA models, conducted experiments on data augmentation, ensembles, and task-adaptive pretraining. Our final system ranked 8th out of 17 teams with an F1 score of 0.6749 F1.

1 Introduction

Named Entity Recognition (NER) is the task of recognizing and classifying named entities in unstructured text. NER is a critical component for NLP tasks such as question answering and relation extraction. Recent advances in neural NER have allowed state-of-the-art systems to perform well in recognizing persons, locations, and organizations in a variety of benchmark datasets. However, these systems still struggle to recognize complex named entities such as titles of creative works. SemEval Task 11 (Malmasi et al., 2022b) asks participants to build systems to identify both classic and complex named entities in multiple languages.

In this paper, we describe the UA-KO team's approach to deal with the challenge of recognizing complex named entities in Korean. We used both monolingual and multilingual transformer-based models. To improve the performance of the models, we conducted experiments on data augmentation, ensembles, and task-adaptive pretraining. Our final performance on the test set ranked 8th out of 17 teams with an F1 score of 0.675. Code to replicate our experiments is available at https://github.com/hyunssong/semeval2022-task11.

2 Related Work

NER in real-world settings is challenging. Identifying entities in short texts, such as search queries on the web, is not easy due to the lack of context. Identifying nontraditional named entities such as titles of creative works (movies, books, or TV shows) is challenging because similar phrases appear as non-named entities and the characteristics of creative work titles change over time (Ashwini and Choi, 2014). Approaches to such real-world named entity types include integrating English Wikipedia as a gazetteer within neural NER models (Meng et al., 2021), though simply relying on the robustness of large pre-trained models like XLM-R is more successful (Ushio and Camacho-Collados, 2021).

SemEval-2022 Task 11 asks participants to build systems that can perform well in real-world settings, providing a dataset with complex named entities in short sentences. The task is divided into three tracks: multi-lingual, monolingual, and code-mixed. We participated in the Korean portion of the monolingual track.

Korean is an agglutinative language, where each word (*eojeol*) is formed by combining a root morpheme with a bound morpheme (*josa*) or postposition (*eomi*) (Choi et al., 2017). More than 60 different forms can thus be created from each root morpheme. A model that is not aware of this morphological richness may end up significantly increasing the vocabulary size to represent all these different forms, at the costs of having only sparse data to learn each form and encountering a high rate of out-of-vocabulary (OOV) forms.

Recent studies have explored different representations to account for the agglutinative characteristics of Korean. Lee et al. (2020) explored both the syllable level and sub-character level representations of the text, achieving similar results to multilingual BERT with 1/10 of the training data. Kwon et al. (2017) proposed a deep learning based NER system that operates over syllables rather than words, resulting in a speedup by removing the need for morphological analysis. Kim et al. (2021) explored morpheme, syllable, and subcharacter rep-

Table 1: The Korean language portion of the SemEval-2022 Task 11 data.

resentations and also found that syllables were the most effective representation for Korean NER.

3 Data

The SemEval-2022 Task 11 dataset follows the CoNLL format. Each token is classified into six entity types: person, location, group, corporation, product, or creative work. The size of the Korean language portion of the dataset is shown in table 1. More details about the dataset can be found in Malmasi et al. (2022a). Systems applied to this dataset are evaluated based on the macro-average F1 score.

Our data augmentation experiments (see section 4.2) utilized additional data. For locations, we used the GeoNames geographical database, which provides countries and place names in many different languages. We selected the 170 country names provided in the Korean language. For person names, we used the Encyclopedia of Korean Culture (of Korean Studies, 1989) , which is a Korean language encyclopedia. We selected their 18,506 names of Korean historical figures.

4 Methodology

We used both monolingual and multilingual pretrained models for the task. For the monolingual models, we used KoBERT[1], KR-BERT (Lee et al., 2020), Ko-ELECTRA[2], and KLUE-RoBERTa-large(Park et al., 2021) , which all have shown successful performance on Korean NLP tasks. For the multilingual model, we used XLM-RoBERTa-large (Conneau et al., 2019), which was provided as the baseline of the shared task.

We fine-tuned these models on the training set. Monolingual models were fine-tuned with a learning rate of 5e-5 for 5 epochs with a weight decay of 0.01. The multilingual model was trained with the same configuration but for 3 epochs. We also experimented with different methodologies to improve performance: task-adaptive pretraining, data augmentation, and ensembles. These approaches are described in the following sections.

[1]`https://github.com/SKTBrain/KoBERT`
[2]`https://github.com/monologg/KoELECTRA`

4.1 Task Adaptive Pretraining

Gururangan et al. (2020) showed that further pretraining models on the unlabeled task data, called task-adaptive pretraining, can improve model performance when the dataset is curated to capture language appropriate to the task. We follow the training environment as Gururangan et al. (2020). To avoid catastrophic forgetting, we additionally reduced the number of epochs following Zhao et al. (2021)'s approach of applying task-adaptive pretraining on small datasets. Specifically, we conduct task-adaptive pretraining with a batch size of 256 for 50 epochs. For the KoELECTRA model, we further train for 7k steps. XLM-R was not included in these experiments due to computing resource limitations.

4.2 Data Augmentation

Data augmentation is a strategy that enhances the amount of training data by modifying existing data or generating new synthetic data, usually by leveraging external resources. Dai and Adel (2020) proposed several data augmentation techniques for NER tasks, including generating sentences by replacing tokens or shuffling within sentence segments. Since the provided training dataset is small relative to the test set, we decided to conduct data augmentation to reduce the overfitting of the model on the training dataset. We specifically focused on person and location named entities as these entities had the highest percentage in the test set.

We generated new sentences by utilizing the external database described in section 3. For each of the sentences that contain location or person named entity, we generated k new sentences where $k = 3$ or 6. New sentences were generated by replacing the location named entity with Korean country names from GeoNames database or replacing the person named entity with historic person names from the Encyclopedia of Korean Culture. We then fine-tuned the language models on the original sentences together with these augmented sentences.

4.3 Ensembles

Ensemble methods are an effective way of combining multiple machine-learning models to make better predictions (Rokach, 2010). We created ensembles over the different monolingual and multilingual models using soft voting, which predicts the class label based on the argmax of the sums of

the predicted probabilities of the various classifiers.

5 Results on Dev

Table 2 shows performance of task adaptive pre-training (TAPT), data augmentation (Augment $k = N$), and ensembles (Ensemble(...)) on the development set. Task adaptive pretraining yielded little benefit over the corresponding unadapted model, and sometimes dramatically worsened performance (e.g., the KoELECTRA model went from 0.827 to 0.767). Data augmentation either led to small gains over the non-augmented model or to roughly the same performance, and $k = 3$ was generally as good or better than $k = 6$. Ensembling led to consistent gains compared to the single models. The best overall model on the development set was an ensemble of KoBERT, KR-BERT, KoELECTRA, KLUE, and XLM combined with data augmentation where $k = 3$.

Given these results, for our official submissions on the test set, we applied data augmentation with $k = 3$, and we included several types of ensembles. We did not apply any task adaptive pre-training because it showed no benefits on the development data.

Model	F1

GRP	0.678	0.595	0.634
CW	0.526	0.563	0.544
CORP	0.688	0.693	0.691

Table 4: Performance by class label for the best performing model, the ensemble of KoBERT, KR-BERT, KoELECTRA, KLUE, and XLM. Results for the other models look qualitatively similar.

6 Results on Test

Table 3 shows the performance of our submitted models on the test set. Unlike our results on the development set, data augmentation significantly reduced performance on the test set. For the runs without data augmentation, ensembles outperformed single models as in our development set results. The failure of data augmentation may imply a low overlap between the names we drew from GeoNames and the Encyclopedia of Korean Culture for data augmentation, and the named entities in the test data. That is, the coverage of these gazetteers may have been insufficient for the unique and nontraditional named entities of the test set, similar to problems mentioned in Meng et al. (2021).

Table 4 shows detailed performance of our best-performing model, the ensemble of KoBERT, KR-BERT, KoELECTRA, KLUE, and XLM. This model performs best in recognizing person names (0.761 F1), but has difficulty recognizing creative works (0.544 F1).

Table 5: Example sentences from the shared task data. Gold annotations are in bold. Model predictions are underlined.

6.1 Error Analysis

We analyze our best-performing system’s predictions on the dev set to understand our system’s strengths and weaknesses. By investigating the errors where the model is highly confident, we identified the following qualities from the errors on the dev set.

Annotation errors: We observed inconsistent labeling in named entities, especially in the creative work named entities. The development data contained many creative works enclosed in《 and 》, such as example A1 in table 5. However the development data also contained creative works marked by the same punctuation that were not labeled as creative works by annotators, such as example A2. This led to a high error rate in predicting creative work named entities on the development data, so we were unsurprised to see similar low performance on the test data creative works. We speculate that the reason data augmentation was not helpful on the test data was these errors in annotation.

Token boundary issues: We see that often tokens are misclassified due to token boundary issues. For instance, in example A3 in table 5, the system found the product named entity but included an extra token before the start of the product name.

Foreign names: The model had difficulty recognizing transliterated named entities, such as names of foreign people or groups as in example sentence A4 of table 5. These names are different from traditional Korean words, likely leading to the system’s difficulty in identifying them.

Grammatical errors: The sentences of the test set differ grammatically from the training and dev set. Table 5 shows some test set inputs that are incomplete (B1) or have grammatical errors (B2). B1 is missing the subject of the sentence, and B2 does not follow the subject-object-verb order of a Korean sentence structure. We found such grammatical problems to be frequent in the test set. As such grammatical problems were not frequently present in the development data, our models were not robust to them.

7 Conclusion

We have presented a description of our different approaches for identifying complex named entities in Korean language data. A monolingual model that considers characteristics of the Korean language performs well, and an ensemble of monolignual models and a multilingual model further improves performance. Though we also explored task-adaptive pretraining and data augmentation, task-adaptive pretraining did not help on the development data, and data augmentation helped on the development data but hurt on the test data. Our results suggest that while ensembles yield reliable gains for Korean named entity recognition, further research is needed to utilize external knowledge when dealing with complex named entity recognition.

Abstract

This paper describes the system developed by the USTC-NELSLIP team for SemEval-2022 Task 11 Multilingual Complex Named Entity Recognition (MultiCoNER). We propose a gazetteer-adapted integration network (GAIN) to improve the performance of language models for recognizing complex named entities. The method first adapts the representations of gazetteer networks to those of language models by minimizing the KL divergence between them. After adaptation, these two networks are then integrated for backend supervised named entity recognition (NER) training. The proposed method is applied to several state-of-the-art Transformer-based NER models with a gazetteer built from Wikidata, and shows great generalization ability across them. The final predictions are derived from an ensemble of these trained models. Experimental results and detailed analysis verify the effectiveness of the proposed method. The official results show that our system ranked **1st** on three tracks (Chinese, Code-mixed and Bangla) and **2nd** on the other ten tracks in this task.

1 Introduction

Named Entity Recognition (NER) is a core natural language processing (NLP) task, which aims at finding entities and recognizing their type in a text sequence. In practical and open-domain settings, it is difficult for machines to process complex and ambiguous named entities (Ashwini and Choi, 2014). For example, "*On the Beach*" is the title of a movie but cannot be recognized easily by present NER systems. This issue may become even more serious in multilingual or code-mixed settings (Fetahu et al., 2021). However, it has not received sufficient attention from the research community. To alleviate the issue, SemEval-2022 Task 11 (Malmasi et al., 2022b) formulates this task which focuses on detecting semantically ambiguous and complex entities in short and low-context settings for 11 languages.

One of the classic approaches to solving this problem is to integrate external entity knowledge or gazetteers into neural architectures (Liu et al., 2019; Rijhwani et al., 2020; Meng et al., 2021). Typically, the two representations respectively from a language model like BERT (Devlin et al., 2019) and a gazetteer network like BiLSTM (Hochreiter and Schmidhuber, 1997) are combined as one merged embedding, which is further fed into a NER classifier such as a conditional random field (CRF) (Lafferty et al., 2001). However, there is a sense of "gap" between the two networks. The gazetteer network has no explicit semantic learning goal itself, which means it is just a more complex but almost isolated embedding layer for gazetteer information and cannot obtain the true meaning of NER tags actively. Almost no semantic information can be gained by the classic gazetteer network.

To effectively connect the two networks, a gazetteer-adapted integration network (GAIN) is proposed. The GAIN adopts a two-stage training strategy to adapt the gazetteer network to the language model. During the first training stage, the parameters of a language model are fixed. Then a sentence and its annotation are fed into the two networks separately. The two outputs are adapted by minimizing the KL divergence between them. This training process helps the gazetteer network truly understand the meaning of NER tags by transferring semantic information from the pre-trained language model to the gazetteer network, as the randomly initialized gazetteer network is gradually adapted to the pre-trained language model during the training. In the second stage, with maintaining the training process above, a gazetteer built from Wikidata is applied to generate pseudo annotations searched by string matching. A sentence and the corresponding pseudo annotation are then fed into the two pre-trained networks separately. Finally, integration methods like the concatenation or weighted summation are utilized

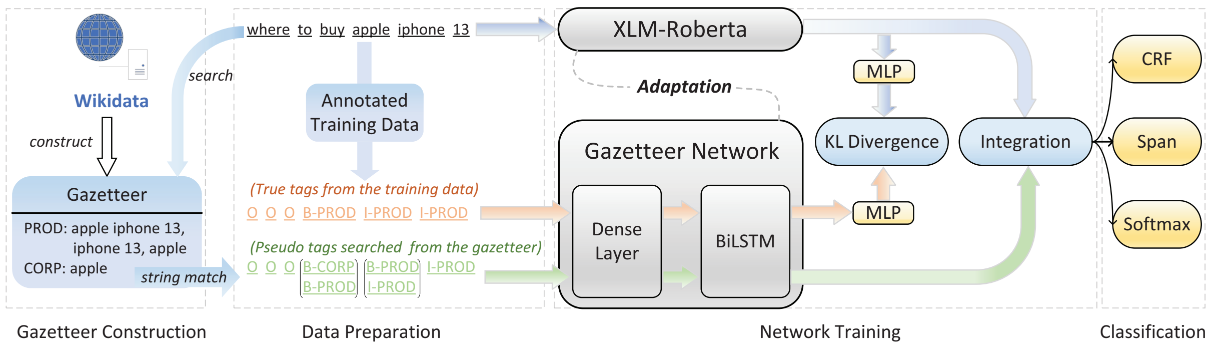

Figure 1: The overall structure of the proposed system.

on the two output representations for classifying.

The proposed method achieves great improvements on the validation set (Malmasi et al., 2022a) of SemEval-2022 Task 11 compared to baseline models and ordinary NER systems with gazetteers. Ensemble models are used for all thirteen tracks in the final test phase, and our system officially ranked **1st** on three tracks (Chinese, Code-mixed and Bangla), and **2nd** on the other ten tracks among nearly 50 teams overall. The outstanding performance demonstrates the effectiveness of our method. Fine-grained results show that our method significantly improves scores of difficult labels like "CREATIVE-WORK" and "PRODUCT", which is the key challenge of this task. To facilitate the reproduction of our results, the code is available at `https://github.com/Mckysse/GAIN`.

2 Task Description

SemEval-2022 Task 11 challenges participants to develop complex NER systems for 11 languages (English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla), focusing on recognizing semantically ambiguous and complex entities in short and low-context settings (Malmasi et al., 2022b). Each language constitutes a single track, while Multilingual and Code-mixed are added as Track 12 and 13. The task adopts the WNUT 2017 (Derczynski et al., 2017) taxonomy entity types: PERSON (PER for short, names of people), LOCATION (LOC, locations/physical facilities), CORPORATION (CORP, corporations and businesses), GROUPS (GRP, all other groups), PRODUCT (PROD, consumer products), and CREATIVE-WORK (CW, movie/song/book/etc. titles). The task also aims at testing the domain adaption capability of the systems by adding additional test sets on questions and short search queries.

For each language, a training set with 15300 samples and a validation set with 800 samples are provided. For the Code-mixed track, 1500 training samples and 500 validation samples are provided. The test data for each track have instances between 150K+ and 500K+ (Malmasi et al., 2022a).

3 System Description

This study focuses on making better use of the external entity knowledge. To describe our system clearly, in this section, we first introduce three basic mainstream NER systems used. Then we show the process of constructing a gazetteer with Wikidata, and how the gazetteer representation is generated and utilized. Finally, we illustrate the gazetteer-adapted integration network (GAIN). The overall structure of the proposed system is shown in Figure 1.

3.1 Basic NER Systems

We mainly use the XLM-RoBERTa large (Conneau et al., 2020) as the pre-trained language model, which is a widely used encoder. Generated by feeding a sentence into the encoder, the representation is then projected to a 13-dimension embedding corresponding to 13 BIO-tags (eg. B-PER, I-PER, O, ...) through a linear transformation. Three mainstream NER backend classifiers are adopted: Softmax (Devlin et al., 2019) and CRF (Huang et al., 2015) are classic sequential labeling methods that predict the tag of each token, and Span (Yu et al., 2020) is a segment-based method that predicts the start and the end of an entity separately.

3.2 The Gazetteer

It's difficult to process complex and ambiguous entities only relying on the language model itself (Ashwini and Choi, 2014). To integrate external entity knowledge, we first need to build a large

		Coverage Rate per Label						
Language	Total Num.	LOC	CW	PER	GRP	PROD	CORP	Average

Average coverage rate		73.12%	69.10%	37.39%	62.82%	34.78%	66.63%	**57.31%**

Table 1: The metrics of our gazetteer in detail. The Total Num. column means the accurate number of entries in the gazetteer for each track. Numbers with % denote the coverage rates to entities in the training and validation set.

gazetteer matching the taxonomy, then we have to consider how to fuse the gazetteer information with the semantic information from the language model.

3.2.1 Construction

Our gazetteer is built based on Wikidata. Wikidata is a free and open knowledge base. Every entity of Wikidata has a page consisting of a label, several aliases, descriptions, and one or more entity types. The entity type annotated by Wikidata is the key to constructing a gazetteer. For example, "*apple*" can be annotated as a kind of fruit or a well-known high-tech corporation in America. Thus, according to WNUT 2017 taxonomy (Derczynski et al., 2017) used in this competition, the word "*apple*" is given both PROD and CORP labels.

To construct a gazetteer fit to the data of this task, firstly every entity of the training set is searched in Wikidata. Then all the entity types returned are mapped to the NER taxonomy with 6 labels. Next, all Wikidata entities stored in these entity types can be added to the 6 labels gazetteer separately. Of course, there is a lot of entities that cannot be searched, especially in some languages such as BN and HI. Also, the elementary gazetteer has plenty of noise. By measuring the number and the coverage rate of each language on each label, the mapping relationships are adjusted manually. In the end, a multilingual gazetteer is obtained that contains entities from 70K to 1M for each language. The gazetteer approximately has a coverage rate of 57 percent on entities in the training and validation set. Basic information about our gazetteer is shown in Table 1. "Coverage Rate" is calculated as the number of entities both appeared in the official data and in our gazetteer divided by the total number of entities in the official data.

Words	O	B-CORP	I-CORP	B-PROD	I-PROD
where	1	0	0	0	0
to	1	0	0	0	0
buy	1	0	0	0	0
apple	0	1	0	1	0
iphone	0	0	0	1	1
13	0	0	0	0	1

Table 2: Example of the one-hot representation for a searched sentence. The rest 8 labels are all zero.

3.2.2 Application

To apply the gazetteer to a sentence, firstly a search tree is constructed for string matching. Once a sentence is fed into the search tree, a maximum length matching algorithm will be conducted, and a 13-dimension one-hot vector for each token will be generated. Take the sentence "*where to buy apple iphone 13*" for example. By string matching with the gazetteer, "*apple iphone 13*", "*iphone 13*" and "*apple*" are found in the PROD gazetteer, while "*apple*" is also found in the CORP gazetteer. Then a 13-dimension one-hot vector will be generated for every word as shown in Table 2.

Denote one sentence as $\mathbf{w} = (w_1, w_2, ...w_N)$ where N is the length of the sentence and w_i is the i^{th} word. By feeding $\mathbf{w}$ into the encoder such as the XLM-RoBERTa large, a semantic representation $\mathbf{e} \in \mathbb{R}^{N \times D}$ is obtained, where D is the hidden size. At the same time, the one-hot vector generated from the search tree is fed into a gazetteer network consisting of a dense layer and a BiLSTM. To match the hidden size of the language model, the output embedding $\mathbf{g}$ has the same size with $\mathbf{e}$.

Two common ways are used to integrate $\mathbf{e}$ and $\mathbf{g}$. One way is to concatenate them on each token, another way is to get the weighted summation of them by setting a trainable parameter $\lambda \in \mathbb{R}^{N \times D}$. The final representation is fed into the backend classifier for supervised NER training.

3.3 Gazetteer-Adapted Integration Network

Through the analysis in Section 6.2, it is found that only conducting the normal training process above is not enough. Since the encoder XLM-RoBERTa large and the gazetteer network BiLSTM are almost isolating each other during the whole training, almost no semantic information can be gained explicitly by the classic gazetteer network.

To address this problem, the GAIN method is proposed as a two-stage training strategy. In the first stage, the adaptation between the two networks is conducted. Take the sentence $\mathbf{w} = \{$*where to buy apple iphone 13*$\}$ for example. Assuming the correct tags are $\mathrm{T} = \{$O,O,O,B-PROD,I-PROD,I-PROD$\}$, an one-hot vector is constructed just based on the true tags. A gazetteer representation $\mathbf{g}_r \in \mathbb{R}^{N \times D}$ is obtained after passing the vector through the gazetteer network. Then the parameters of the language model are fixed, and the sentence $\mathbf{w}$ is fed into it to get a semantic representation $\mathbf{e}$. $\{\mathbf{g}_r, \mathbf{e}\}$ are projected to $\{\mathbf{g}_r^t, \mathbf{e}^t\} \in \mathbb{R}^{N \times 13}$ by two separate linear layers, where the semantic meaning is transferred to the tags meaning as a kind of logits distributions. The adaptation is implemented by the designed loss L_1:

$$L_1(\mathbf{w}) = \mathrm{KL}(sg(\mathbf{g}_r^t)||\mathbf{e}^t) + \mathrm{KL}(sg(\mathbf{e}^t)||\mathbf{g}_r^t) \quad (1)$$

where $\mathrm{KL}(\cdot)$ is the KL divergence calculation and $sg(\cdot)$ operation is used to stop back-propagating gradients, which is also employed in Jiang et al. (2020); Liu et al. (2020). The loss L_1 is the symmetrical Kullback-Leibler divergence, encouraging the distributions $\mathbf{g}_r^t$ and $\mathbf{e}^t$ to agree with each other. Thus, the gazetteer network will understand the real meaning of the NER tags and gain semantic information transferred from the language model.

In the second stage, all the parameters are trained with a gazetteer. As illustrated in Section 3.2.2, a gazetteer representation $\mathbf{g}$ is generated from the search tree and the gazetteer network BiLSTM. Next, an ordinary fusion method is applied to $\mathbf{g}$ and $\mathbf{e}$ to get an integration representation, which is then fed into the backend classifier to compute a conventional loss with true tags T. This supervised training goal is implemented by the loss L_2:

$$L_2(\mathbf{w}) = \mathrm{Classifier}(f(\mathbf{g}, \mathbf{e}), \mathrm{T}) \quad (2)$$

where $f(\cdot)$ denotes ordinary integration methods like concatenation or weighted summation. $\mathrm{Classifier}(\cdot)$ represents one of the three mainstream backend classifiers mentioned in Section 3.1. During the whole second-stage training, a multitask learning goal is conducted shown as:

$$L_3(\mathbf{w}) = \alpha L_1(\mathbf{w}) + L_2(\mathbf{w}) \quad (3)$$

where α is a hyperparameter that is manually set for different fusion and backend methods.

4 Data Preparation

For the basic training set provided officially, an entity replacement strategy is adopted using our own gazetteer to construct a double data-augmented set. This part of data is called “data-wiki”, which mainly consists of rich-context sentences.

In order to improve the performance of our models on low-context instances, a set of annotated sentences are generated from the MS-MARCO QnA corpus (V2.1) (Nguyen et al., 2016) and the ORCAS dataset (Craswell et al., 2020), which are mentioned in Meng et al. (2021). Our trained models and existing NER systems (e.g., spaCy) are applied to identify entities in these corpora, and only templates identically recognized by all models are reserved. Finally, 3753 English templates for MS-MARCO and 13806 English templates for ORCAS are obtained. After slotting the templates by our own gazetteer and translating them to the other 10 languages, we get approximately 16K annotated low-context sentences for each language. This part of data is called “data-query”.

A special operation is conducted for the Code-mixed track, because only 2000 annotated instances are provided officially. The multilingual function

Parameter	Value
Hidden size for language models	1024 for large, 768 for base
Learning rate for language models	2e-5 for large, 1e-5 for base

Table 5: Official rankings of our system. “F1” denotes the macro-F1 on the test set.

5 Experiments

5.1 Encoder Selection

Preliminary experiments show that it’s important to start with advanced pre-trained language models for further improvements. More than a dozen models are evaluated on the development set, and the language models listed in Table 4 are adopted eventually. For some tracks, the XLM-R large and the monolingual model are both used for ensemble. For the other tracks without monolingual models in the corresponding language, just the XLM-R large is used. All the resources can be found on the HuggingFace Page (Wolf et al., 2019).

5.2 Training Details

A lot of models have been trained with the GAIN method using different classifiers, different integration methods, different chosen language models. Hyperparameter settings are shown in Table 3. Sample codes are already available at `https://github.com/Mckysse/GAIN` to help the reproduction.

A 5-fold cross-validation training strategy is also applied in the evaluation. The prepared data “data-wiki” and “data-query” are split into five pieces, each one is used as the validation set, while the other four pieces are used as the training set. After obtaining the five best models by this strategy, the logits of them (for Softmax and Span models) are averaged to integrate them as an aggregated model. CRF models are just voted averagely.

Finally, the predictions of our best models in different methods are token-voted by setting a

Strategy	Classifier	BN	DE	EN	ES	FA	HI	KO	NL	RU	TR	ZH	MIX

Table 6: All macro-F1 scores on the validation set. Only scores of the concatenation integration method are listed due to limited spaces. Strategy A denotes baseline systems mentioned in Section 3.1, B denotes ordinary integration method with the gazetteer mentioned in Section 3.2, and C denotes the GAIN method mentioned in Section 3.3. "weighted token-vote" represents the ensemble of all our models including those with the weighted summation integration method not listed, and achieves the best performance on the validation set.

Table 7: F1 scores of the gradient coverage rate trial. "Coverage Rate" means the number of entities in official data also found in our gazetteer / the number of entities in official data. "avg" denotes the average result of all tracks.

weight for each track. The weight is manually set referring to all scores on the validation set.

5.3 Official Results

Our team participate in all the 13 tracks and the results in the test phase are listed in Table 5. We ranked **1st** on three tracks and **2nd** on ten tracks.

6 Analysis

6.1 Effectiveness of The Gazetteer

To explore the effectiveness of the proposed GAIN methods, a large number of trials are conducted on the official data mentioned in Section 2. All scores under the concatenation integration setting on the validation set are listed in Table 6. Significant improvements are gained by the gazetteer and the GAIN method on all tracks. The results demonstrate that the gazetteer plays a pivotal role in processing complex entities.

6.2 Coverage Rate Trial

Our gazetteer can only reach approximately 57% coverage rate over the entities in the official data. Intuitively, the higher the coverage rate over the entities reaches, the better the performance can achieve. We carry out a toy experiment to explore this conjecture. Since entities from the official training and development set can be extracted, we can control how many of these entities appear in our gazetteer to modulate the coverage rate, as shown in Table 7.

Not as expected, scores on many tracks don't improve in step with the increase of the coverage rate when it does not reach 100%. This situation mostly happens in languages that already have good scores, like DE and EN. To explore the reason why the gazetteers under 100% coverage rate don't work, we check the weight λ mentioned in Section 3.2.2. It's surprising to find the λ is nearly zero when the coverage rate is not 100%, which indicates that our models almost don't use the gazetteer information. Further fine-grained tests find that only when the coverage rate exceeds the basic accuracy of the model, the λ starts to have a non-zero value. An empirical conclusion can be drawn that the gazetteer network and the language model almost process information separately, and the final integration module simply selects the better one for classifying. Thus, this study starts to figure out an explicit way to adapt the two networks, and the GAIN method is designed.

6.3 Detailed Results on the Test Set

As shown in Table 8 and Table 9, we display all the detailed results on all tracks during the test phase for further analyses in-depth.

Multilingual	0.8530	0.8605	0.8489	0.9210	0.8681	0.9076	0.8105	0.8152	0.8786	0.8381

Table 9: Results of the official test set on the Code-mixed and Multilingual tracks.

As shown in the tables, the proposed GAIN method significantly improves the performance of the language model on recognizing entities of hard labels like "CW" and "PROD". Besides, results in the domain of "orcas" and "msq" indicate the effectiveness of the proposed data-augment strategy mentioned in Section 4.

6.4 Average-Logits Experiments

This section explains why we choose to average logits of softmax-based models (for Softmax and Span models) for integrating them as an aggregated model, rather than averagely token-vote. Also, a 5-fold cross-validation training is conducted with the official training data on the basic Softmax method. Without loss of generality, BN, EN, FA, and ZH are chosen to represent different language families. Results on the official validation set are shown in Table 10. It is empirically demonstrated that average-logits for the softmax-based model ensemble is better than average-token-vote in most situations.

Data\Lang	bn	en	fa	zh
1 fold	0.795	0.871	0.814	0.874
2 fold	0.799	0.873	0.8	0.871
3 fold	0.801	0.876	0.795	0.889
4 fold	0.798	0.881	0.791	0.881
5 fold	0.789	0.869	0.8	0.873
avg	0.796	0.874	0.8	0.878
avg-token-vote	0.813	0.887	0.815	0.898
avg-logits	**0.815**	**0.89**	**0.817**	**0.903**

Table 10: Results of the 5-fold cross-validation trial. "avg" denotes the average results of 5 models' scores. "avg-token-vote" represents the averagely token-vote process. "avg-logits" means average logits of 5 models are fed into the backend softmax layer for classifying, which achieves the best performance on all 4 languages.

6.5 About KL

This section illustrates why the GAIN method adopts the KL divergence rather than the MMSE loss. Softmax-based classification usually chooses the position of the maximum in all dimensions to be the predicted tag. Because the softmax module and logits-softmax module exist in the KL calculation, the 13-dimension vector can be considered as a kind of logits distribution with the tags meaning. Thus, the distribution, or the internal relationship between all logits of tokens in a sentence, is the most important thing to pay attention to, rather than the amplitude of all logits. With the KL divergence, two distributions are adapted to each other without considering the amplitude.

A toy trial has been conducted to confirm whether the two 13-dimension vectors from the two networks have the same amplitude. The result shows that they are not always in the same ratio relations for different inputs. Compared to the MMSE loss which also calculates relating to the absolute amplitude difference, the KL divergence is better since it only focuses on the distributions of the two outputs, without being disturbed by the inconsistent relationship of the amplitude.

7 Conclusion

This paper presents the implementation of the USTC-NELSLIP system submitted to the SemEval-2022 Task 11 MultiCoNER. The GAIN method is proposed to adapt the gazetteer network to the language model, and achieves great improvements on the complex NER task. Some construction methods for gazetteers and code-mixed data augmentation are also provided. In future works, we will keep exploring effective ways to integrate gazetteer networks with encoders to make better use of the external entity knowledge.

Abstract

We investigate the task of complex NER for the English language. The task is non-trivial due to the semantic ambiguity of the textual structure and the rarity of occurrence of such entities in the prevalent literature. Using pre-trained language models such as BERT, we obtain a competitive performance on this task. We qualitatively analyze the performance of multiple architectures for this task. All our models are able to outperform the baseline by a significant margin. Our best performing model beats the baseline F1-score by over 9%.

1 Introduction

The Named Entity Recognition (NER) task aims to detect entities from unstructured text and classify them into predefined categories. Although the task of NER has been investigated adequately by previous research work (Mansouri et al., 2008; Nadeau and Sekine, 2007; Lample et al., 2016a; Florian et al., 2003; Ritter et al., 2011), the detection of named entities in open-domain settings is non-trivial. Moreover, the introduction of additional layers of complexity, in the form of semantic ambiguity and a lower amount of contextual availability, poses further challenges. For example, in a low-context and semantically ambiguous sentence such as *Let us play Among Us*, the token sequence *Among Us*, can refer to a common phrase or a popular video game, and hence be categorized as a Creative Work (CW).

Recently, deep learning models have gained popularity for NER (Yadav and Bethard, 2019; Li et al., 2020; Habibi et al., 2017). However, these approaches are data-intensive and become ineffective when there is a lack of labeled data. To foster research in this area, (Malmasi et al., 2022b) has introduced the SemEval MultiCoNER shared task that deals with multilingual complex named entity recognition. This task in based on the complex NER, search query and code-mixing NER challenges introduced by Meng et al. (2021) and Fetahu et al. (2021). The baseline introduced by the organizers for this MultiCoNER challenge is a pre-trained XLM-RoBERTa model (Conneau et al., 2019) that was further fine-tuned on the task-specific training dataset.

This paper describes our approach to tackle complex NER task for the English language using state-of-the-art deep learning models and introduces a simple neural network architecture that builds on top of pre-trained language models. We compare multiple architectures on the validation and test set of the shared task. All our models outperform the baseline by a significant margin. Through our experiments, we discover that leveraging transformer models based on attention mechanism (Vaswani et al., 2017) results in better performance even in low context and ambiguous settings. The code is available at `https://github.com/AmitPandey-Research/Complex_NER`

We describe the prior research work done with respect to both general and low-resource NER tasks in Section 2. We provide the formal task description in Section 3, the dataset details in Section 4, the method and the model architecture in Section 5. We provide details about the experimental implementation in Section 6. We discuss the results obtained and error analysis in Sections 7 and 8 respectively, and finally, we conclude the paper in Section 9.

2 Related Work

A widely used benchmark for NER was the CoNLL 2003 shared task. It contained annotated newswire text from the Reuters RCV1 corpus. Previous researchers (Baevski et al., 2019) had used BiLSTM models with attention to predict named entities on this dataset. (Ma and Hovy, 2016) used a BiLSTM-CNN-CRF to predict the named entities.

*Equal Contribution

Sequence labeling for Named Entity Recognition: Recent approaches have aimed at utilizing deep learning techniques for training NER models. However, these techniques require a large amount of token-level labeled data for NER tasks. Annotation for such kinds of labeled datasets can be expensive, time-consuming, and laborious. The datasets introduced in this task encompass a large number of low-resource and complex NER entities.

Recent work on NER in scientific documents has been concentrated around detecting biomedical named entities (Kocaman and Talby, 2020) or scientific entities like tasks, methods and datasets (Luan et al., 2018; Jain et al., 2020; Mesbah et al., 2018).

NER has been traditonally modelled as a sequence labelling task, using CRF (Lafferty et al., 2001) to classify the labels. Recent approaches have used deep learning based models (Li et al., 2018). These approaches are data intensive in nature. To tackle the label scarcity problem, methods like Distant Supervision (Wang et al., 2020; Liang et al., 2020; Hedderich et al., 2021), Active Learning (Goldberg et al., 2017), Reinforcement Learning-based Distant Supervision (Nooralahzadeh et al., 2019; Yang et al., 2018) have been proposed.

3 Task Description

The objective of this shared task is to build complex Named Entity Recognition systems. The task presents a unique challenge in the form of detecting the entities in semantically ambiguous and low-context settings. Moreover, the shared task also tests the generalization capability and domain adaptability of the proposed systems by testing the system over additional (low-context) datasets containing questions and short search queries, such as Google Search queries.

Label	Description
PER	Person
LOC	Location
GRP	Group
CORP	Corporation
PROD	Product
CW	Creative Work

Table 1: Entity types in the label space

For this task, given an input sentence (an arbitrary sequence of tokens), the systems have to identify the B-I-O format (Ramshaw and Marcus, 1999) (short for beginning, inside, outside) tags for 6 NER entity classes: Person, Product, Location, Group, Corporation, and Creative Work. The description attributed to each class label is described in Table 1.

4 Dataset

The MultiCoNER dataset (Malmasi et al., 2022a) consists of labeled complex Named Entities (NE). For the monolingual track, the participants have to train a model that works for a single language. For training and validation purposes, train and dev sets are provided with labeled entities. The monolingual model trained needs to be used for the prediction of named entities in the test set that consists of more than 150K instances. The labels from the test set are not provided directly. In this system description for the monolingual track, we have considered the English NER dataset for our task. The dataset follows a BIO tagging scheme, and there are six entity types in the label space. The statistics for the English dataset in the monolingual track for the train and dev set are provided in Table 2.

	Train	Dev
# sentences	15300	800

Table 2: Total sentences in English monolingual track

5 System Overview

This section describes our approach to designing a system to solve the problem of classifying the tokens (words) of a given sentence into one of the six NE categories. We also briefly describe features of the BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) model employed in our system.

We designed three architectures based on pre-trained language model BERT: 1) BERT+Linear, 2) BERT+CRF, and 3) BERT+BiLSTM+CRF. A detailed explanation of these architectures is as follows:

5.1 BERT+Linear

We model this task as a multiclass classification problem. The first step to finding labels for the entities is to find dense vector representations of the tokens in the given sentence.

Instead of using static pre-trained word embeddings, such as Word2Vec (Mikolov et al., 2013)

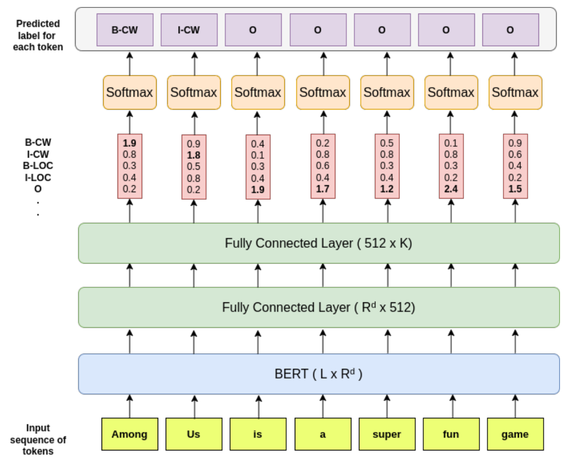

Figure 1: BERT-Linear architecture

and GloVe (Pennington et al., 2014) that rely only on static global representations of word vectors, we employ BERT-based context-aware representations (BERT embeddings) that leverage the full context of the entire sentence.

This helps in extracting more information for the task of NER that is highly dependent on the inter-token relationship. BERT learns the representations for the tokens in the given text by jointly considering both the left and right context of the tokens at each layer (Devlin et al., 2019). To better learn the inter-token dependencies, BERT leverages the attention mechanism with multiple attention heads that focus on different aspects of a token's relation to other tokens. For an ith token x_i among a sequence of tokens $x = (x_1, x_2, x_3, ..., x_m)$, we obtain a low-dimensional BERT embedding, $\tilde{x_i} \in R^d$ where d is the embedding dimension.

We pass this BERT token embedding to a dense classifier that consists of two fully connected layers. This classifier layer maps the BERT embeddings to lower dimension logit vectors $\tilde{x_i} \in R^k$, where k is the total number of labels. The logits are then passed to the softmax normalization function. The softmax generates a probability distribution across all labels for each token, which is then used to predict the most probable label. The system architecture details are shown in Figure 1.

5.2 BERT+CRF

We use a pre-trained BERT model to obtain the token embeddings. These embeddings are passed to a token-level classifier followed by a Linear-Chain CRF. The CRF learns the transfer rules between adjacent entity labels and returns likelihood for a sequence of labels. More formally: 1) For a sequence of tokens $x = (x_1, x_2, x_3, ..., x_m)$, where x_i is the ith token among the sequence of tokens, we obtain a low-dimensional dense embedding, $\tilde{x_i} \in R^d$ where d is the embedding dimension. 2) This embedding is mapped to a lower dimensional space $\tilde{x_i} \in R^k$ where k is the total number of labels. 3) The output emission scores from the linear layer are obtained as $P \in R^{m \times k}$, where m is the number of tokens. These scores are passed to the CRF layer, whose parameters are $A \in R^{k+2 \times k+2}$. Each element A_{ij} signifies the transition score from the ith label to the jth label. The 2 additional states in A are the start and the end state of a sequence. For a series of tokens $x = (x_1, x_2, x_3, ..., x_m)$, we obtain a series of predictions $y = (y_1, y_2, y_3, ..., y_m)$. As described in (Lample et al., 2016b), the score of the entire sequence is defined as :

$$s(x, y) = \sum_{i=0}^{m} A_{y_i, y_{i+1}} + \sum_{i=1}^{m} P_{i, y_i}$$

The model is trained to maximize the log probability of the correct label sequence:

$$\log(p(y|x)) = s(x, y) - \log(\sum_{\tilde{y} \in Y_X} e^{s(x, \tilde{y})})$$

where Y_X are all possible label sequences.

5.3 BERT+BiLSTM+CRF

We use a pre-trained BERT model to obtain the contextual token embeddings for the input sentence. These BERT embeddings are passed to the BiLSTM layer, where the BiLSTM layer captures the information into a hidden state representation. This representation is passed to a CRF layer that obtains the probability distributions across the sequences of labels. Specifically, the fine-tuned BERT language model is used to map the tokens in each sentence to a distributed representation. This is used as the word embedding layer for the BiLSTM+CRF model. The BiLSTM+CRF layer is used to sequence label the sentence, and the predicted labels are obtained. The supervised learning algorithm iterates to improve its predicted label accuracy over every iteration. More formally, the process can be described as follows : 1) The target sentence comprising of m tokens, is represented as $x = (x_1, x_2, x_3, ..., x_m)$, where x_i represents the ith token of the entire target sentence. 2) x_i is mapped to a low dimensional dense vector, $\tilde{x_i} \in R^d$ using the pretrained BERT embeddings, where d is the dimension of dense embedding. 3)

Table 5: Performance of model on test dataset

The sequence of vectors is taken as an input to the BiLSTM in each time step, and the forward hidden states $\overrightarrow{h_f} = (\overrightarrow{h_1}, \overrightarrow{h_2}, \overrightarrow{h_3}, ..., \overrightarrow{h_m})$ and the backward hidden states $\overleftarrow{h_b} = (\overleftarrow{h_1}, \overleftarrow{h_2}, \overleftarrow{h_3}, ..., \overleftarrow{h_m})$ are concatenated to form the combined hidden state representation $h = [\overrightarrow{h_f}, \overleftarrow{h_b}]$. 4) The combined hidden state representation $h \in R^{m \times n}$, where n is the total size of BiLSTM, is reduced to a k dimensions using a linear layer, where k is the number of labels to distribute the probabilities across. 4) Finally, the CRF layer is used to obtain the probability of label sequence.

6 Implementation Details

We implement all our transformer-based models using Pytorch and Huggingface library. We implement 3 models: 1) BERT+Linear, 2) BERT+CRF, and 3) BERT+BiLSTM+CRF. We also experiment with feature engineering by concatenating label encoded Part-of-Speech (POS) tags to the token embeddings. We use a dropout from 0.2 to 0.5 in all models and find that a dropout probability of 0.3 gives the best results throughout.

In the BERT+Linear model, we use two fully connected dense linear layers as a classifier on top of the BERT embedding layer. We add a softmax layer to obtain the probability distribution across all the labels. For the BERT+Linear model, we run our experiments across 1-20 epochs. We find that the model starts to overfit after 10 epochs, and the best results are obtained after 5 epochs of training. We further experiment with BERT-base (12 attention heads) and BERT-large (16 attention heads).

For BERT+CRF and BERT+BiLSTM+CRF, we experiment across 1-100 epochs. We find that the models give the most optimal result at the 20th epoch, after which they start to overfit. We use a learning rate of $1e^{-6}$ for all the models. We validate the results of all models using our dev set and then use the best performing model for final evaluation on the blind test set.

7 Results

We compare the performance of our models in the validation set against the baseline. We use the best performing model for the final submission in the evaluation phase. We provide details of the performance of the best performing model over the blind test dataset provided in the evaluation phase. We provide a detailed comparison of the performance of our models across all the class labels in the validation dataset in Table 3. Table 3 shows that the simple BERT+Linear model (0.8758 F1 score) consistently performs better across all the labels (except for PROD) as compared to other larger models. We attribute this to the limited number of samples in the training dataset. The lack of a sufficient number of training samples limits the ability of larger models to generalize properly over the entire training set.

Also, it can be observed from Table 4 that all the 3 models outperform the baseline by a significant margin. BERT+CRF, BERT+BiLSTM+CRF, BERT+Linear advances the baseline by around 8%, 6%, and 9% respectively. Table 5 shows the performance of our BERT+Linear model on the blind test set. Our best performing model ranks 9th on the validation dataset and 15th on the final blind test set. Moreover, through our experiments, we find that the BERT-large offers a significant boost in performance over BERT-base, due to the larger number of attention heads.

8 Error Analysis

We perform error analysis for all 3 different model performances on the validation dataset. We find that for all 3 models, each model has the greatest difficulty in accurately predicting the *CW (Creative Work)* label. This can be attributed to the higher degree of ambiguity when it comes to *CW* named entities, as these often share a similar type of textual structure as regular non-named entity text tokens. It can be inferred that all 3 models are memorizing entity names from the training data to some extent. It is most prevalent in BERT+BiLSTM+CRF model, as we can see that it has the least amount of prediction accuracy among other models. This is consistent with our reasoning that heavier models tend to overfit the dataset faster. Hence, we deduce that named entity memorization can be attributed to a type of overfitting behavior by the model in question when the training data is scarce. The BERT+Linear model, which is the lightest model with the least amount of trainable parameters among all 3, is found to be significantly less prone to memorize entity names.

Furthermore, upon qualitative analysis, we find that our models often have difficulty in recognizing longer named entities (entities comprising of 5 or more tokens). This can be attributed to the lack of occurrence of such entities in the training dataset. The models are majorly exposed to shorter length entity spans across the training set. Due to the lack of exposure of the models to adequate training instances of longer spans, the models are often unable to predict such longer entity spans.

It is also worth noting that an increase in the number of attention heads in the BERT layer helps in substantial improvement in the accuracy. As discussed, this can be attributed to better learning of the context with the help of attention mechanism. We conclude that the larger number of attention heads are able to classify longer entity spans with greater accuracy.

9 Conclusion and Future Work

We experiment with 3 model architectures for a novel dataset introduced for the shared task of detection of complex NER. Our best performing model comprises of a simple linear classifier on top of fine-tuned BERT-based language model. We find that this simple approach performs competitively as compared to its heavier counterparts. Upon analysis, we attribute this observation to the scarcity of labeled training data. BERT+Linear model is able to optimally avoid overfitting to a larger extent and hence performs better than other heavier models. We find that our simpler model ranks in the top 10 in the validation phase and outperforms numerous teams in the final evaluation phase. For future work, we aim to utilize other data augmentation techniques and distant supervision to create clean silver labels in order to increase our training instances. We believe that this would help us leverage larger models for training purposes.

Abstract

This paper summarizes the participation of the L3i laboratory of the University of La Rochelle in the SemEval-2022 Task 11, *Multilingual Complex Named Entity Recognition* (MultiCoNER). The task focuses on detecting semantically ambiguous and complex entities in short and low-context monolingual and multilingual settings. We argue that using a language-specific and a multilingual language model could improve the performance of multilingual and mixed NER. Also, we consider that using additional contexts from the training set could improve the performance of a NER on short texts. Thus, we propose a straightforward technique for generating additional contexts with and without the presence of entities. Our findings suggest that, in our internal experimental setup, this approach is promising. However, we ranked above average for the high-resource languages and lower than average for low-resource and multilingual models.

1 Introduction

Named entity recognition (NER) is the task of detecting entities and recognizing their type (e.g., person, location, organization) (Grishman and Sundheim, 1996). Standard benchmarks (e.g., CoNLL-2003 (Tjong Kim Sang and De Meulder, 2003)) for NER are either focused on a high-resource language or on a single domain (e.g., news). However, NER is required in different fields, bringing thus several new challenges regarding: the size of the textual content (e.g., short textual snippets like Web queries (Fetahu et al., 2021) or social media posts (Rajoria, 2021)), the characteristics of the entities to be extracted (i.e., capitalization/punctuation features (Mayhew et al., 2019)), unseen and emerging entities (e.g., entities that have a fast growth rate such as new songs and movies are released weekly (Bernier-Colborne and Langlais, 2020)), complex entities (i.e., complex noun phrases such as particularly long nested person names and dates in historical documents (Boros et al., 2020a,c)). Moreover, multilingual documents in which entities of different languages than the rest of the text are present (i.e., code-mixed documents (Winata et al., 2021; Fetahu et al., 2021)) add another level of complexity to the task. Transformer-based (Vaswani et al., 2017) architectures for NER became popular since the release of the BERT model and they hold the state of the art in NER (Akbik et al., 2018; Nie et al., 2020; Yamada et al., 2020; Wang et al., 2020, 2021). However, while most NER systems have been developed to generally address contemporary news data in high resource languages (e.g. English) (Yamada et al., 2020; Wang et al., 2020, 2021), many challenges remain in NER from short texts with complex entities in low-resource scenarios (Meng et al., 2021).

The SemEval-2022 Task 11, *Multilingual Complex Named Entity Recognition* (MultiCoNER) (Malmasi et al., 2022b) aims at developing complex NER systems for 11 languages. The task focuses on detecting semantically ambiguous and complex entities in short, lowercased, low-context monolingual, and multilingual settings. The languages were: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. For some languages, an additional track with code-mixed data was offered. The organizers aim at testing the domain and language adaption capability of a NER system. For this reason, NER systems for monolingual settings are also constrained to avoid multilingual prediction models and vice versa.

Multilingual and code-mixed documents have motivated the development of systems based on multilingual Transformer-based architectures (Winata et al., 2021; Fetahu et al., 2021). Also, recently, Wang et al. (2021) proposed an approach to NER from short texts by finding external contexts of a sentence. The authors retrieved and selected a set of semantically relevant texts through a search engine, with the original sentence as the query, which proved to be efficient in detecting entities.

In this paper, we propose a robust approach for NER and we tackle the following challenges for the language-specific sub-task, including the multilingual and mixed sub-tasks: (1) short texts: by adding multilingual contexts with and without entities, in order to improve and focus more on the context and less on the other surrounding entities, (2) lowercased texts: we prioritize the usage of uncased language models, and (3) code-mixed and low-resource languages: we add a multilingual language model along with a language-specific language model.

2 Data

For each language, organizers provide fixed-sized training and development sets of $15,300$ and 800 sentences respectively, whereas test sets are composed of an average of $181,418$ ($\sigma = 35,181$) sentences. A multilingual dataset consisting of the concatenation of all monolingual sets is also provided (with a selection of $471,911$ sentences for the test set)[1].

In addition, a smaller code-mixed dataset with entities in a foreign language of the rest of the sentence was given. In this case, $1,500$ sentences constitute the training set, 500 the development set, and $100,000$ the test set. We present a sample annotated example from the English training set in Figure 1.

[1]MultiCoNER Dataset can be accessed at https://registry.opendata.aws/multiconer.

To highlight the important difference between the number of phrases in the train and the test sets, we present these numbers in Table 1. The corpus is based on LOWER, MSQ-NER (Bajaj et al., 2016), and ORCAS-NER (Craswell et al., 2020) statements and queries from Wikipedia and Microsoft Bing (Meng et al., 2021). A detailed description and exhaustive statistics of all datasets are presented in Malmasi et al. (2022a,b).

Language	Train	Dev	Test

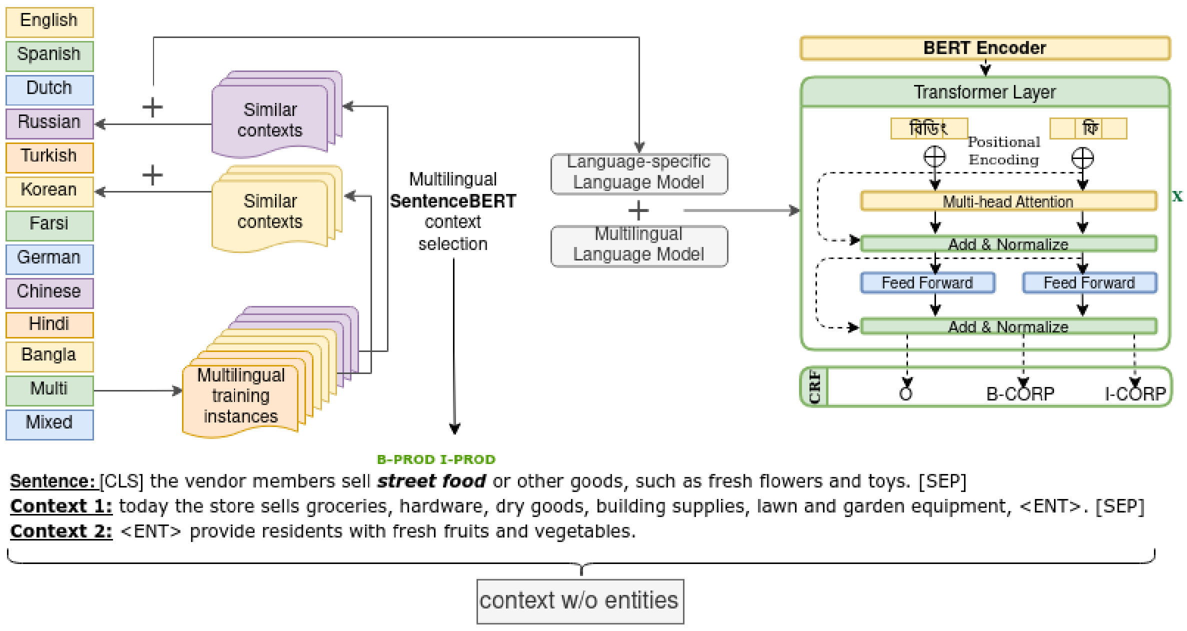
Multilingual	168,300	8,800	471,911
Mixed	1,500	500	100,000

Table 1: Number of sentences in the dataset splits per language.

3 Methodology

Our proposed framework consists in augmenting each input sentence with similar contexts taken from the multilingual train collection and a NER model based on a BERT-based pre-trained and fine-tuned language model as an encoder with several Transformer (Vaswani et al., 2017) layers stacked on top. For each language, we consider a language-specific BERT model, as presented in Table 2. We prioritize the use of uncased models, with some exceptions where there were no such models (Dutch, Polish). Finally, we tackle the multilingualism and lack of resources for all languages by concatenating these representations with those provided by a multilingual language model. The methodology is outlined in Figure 2.

Named Entity Recognition Model Our base model was recently proposed for coarse-grained and fine-grained named entity recognition (Boros et al., 2020a,b). The method consists of a hierarchical approach, with a pre-trained and fine-tuned BERT-based encoder (Devlin et al., 2019a). This model consists of a stack of Transformer blocks



Sentence: [CLS] the vendor members sell ***street food*** or other goods, such as fresh flowers and toys. [SEP]
Context 1: today the store sells groceries, hardware, dry goods, building supplies, lawn and garden equipment, <ENT>. [SEP]
Context 2: <ENT> provide residents with fresh fruits and vegetables.

on top of the BERT encoder, and a conditional random field (CRF) layer to decode the best tag path in all possible tag paths. First, the encoder is already based on a stack of Transformer layers. A Transformer block (encoder) is a deep learning architecture based on multi-head attention mechanisms with sinusoidal position embeddings. It is composed of a stack of identical layers. Each layer has two sub-layers. The first is a multi-head self-attention mechanism, and the second is a simple, position-wise fully connected feed-forward network. A residual connection is around each of the two sub-layers, followed by layer normalization. These language models generally expect the input data in a specific format: a special token, [SEP], to mark the end of a sentence or the separation between two sentences, and [CLS], at the beginning of the text. A Transformer encodes the information contained in a given text in the [CLS] token that flows afterward through the layers. This architecture with additional Transformer layers proved to be efficient when the input is noisy and of varying lengths.

Adding Context First, we encode the collection of training multilingual sentences using a pre-trained multilingual Sentence BERT model (Reimers and Gurevych, 2019, 2020a). We consider that using only sentences from the training set is enough for enriching the contexts, even if they are seen during the training process. The underlying idea behind this is that, since the data is multi-domain, we would expect a very small overlap between the train and the test set, thus the additional contexts could benefit from information from other domains that those existing. Then, for each input sentence (for each dataset split), we rank them using the cosine similarity. From these retrieved texts, we select the first $n \in [1, 10]$ sentences and we consider them as semantically relevant.

Next, as shown in the example in Figure 2 with "street food" as a product (PROD) entity, we concatenate the initial input sentence with the retrieved texts, separated by the special token [SEP]. For this step, we propose two versions of taking advan-

Table 3: MultiCoNER results on the development set.

tage of this additional context. First, we consider that simply concatenating the semantically relevant contexts as they are with the sentence in question are sufficient for bringing an improvement to the detection of entities. These models are referred to as *context w/ entities*.

We also examine the scenario where these additional contexts are added without any entity present, as shown in Figure 2 where the entities from the additional contexts are replaced with a special token <ENT> (Boros et al., 2021, 2022)). The idea behind this choice is that we are trying to improve the contextual information without confusing the detection of entities with the presence of others. We refer to these models as *context w/o entities*.

For finding semantically relevant contexts, we used a multilingual Sentence-BERT (SBERT) (Reimers and Gurevych, 2020b) model[2], a modified pre-trained BERT (Devlin et al., 2019b) that uses a siamese and triplet network structure to derive semantically meaningful sentence embeddings that can be compared using cosine similarity. We keep the top-10 semantically relevant contexts.

Hyperparameters For each language, including the multilingual and the code-mixed cases, we choose a language-specific BERT pre-trained model[3], as presented in Table 2, with the exception for Hindi and Bangla. For the models for which we do not have a language-specific model, we use multilingual BERT. For each language, we additionally use a multilingual model (XLM-RoBERTa-large (Conneau et al., 2020)), approaches referred as BERT$\times$2 in Table 3.

4 Experiments

Next, we perform a detailed error analysis of our approaches[4]. The evaluation is performed in terms of macro precision (P), recall (R), and F1. Our results are presented in Table 3. Each type of approach is detailed with the corresponding pre-trained models.

Table 3 presents the results for our preliminary results on the provided dev set. We, first, observe that all our results considerably outperform the baseline scores provided by the organizers. Also, overall, it is clear that adding a multilingual language model to an already language-specific model brings an increase in performance. Next, we notice that adding *context w/ entities* slightly improved the performance of a limited number of languages (English, Dutch, Korean, German, Bangla) and *context w/o* improved considerably the performance of a larger number of languages (English, Spanish, Dutch, Korean, German, Chinese, Bangla). This allows us to understand that the presence of entities in the additional contexts can influence the detection of the entities of interest by hindering the importance of context with other entities. Thus, adding context brings performance improvements (marginally, with entities, or considerably, without entities). However, the fact that we used the already seen contexts from similar domains or topics (multilingual train data) could also be a factor that contributed to the drop in F1 for some of the languages.

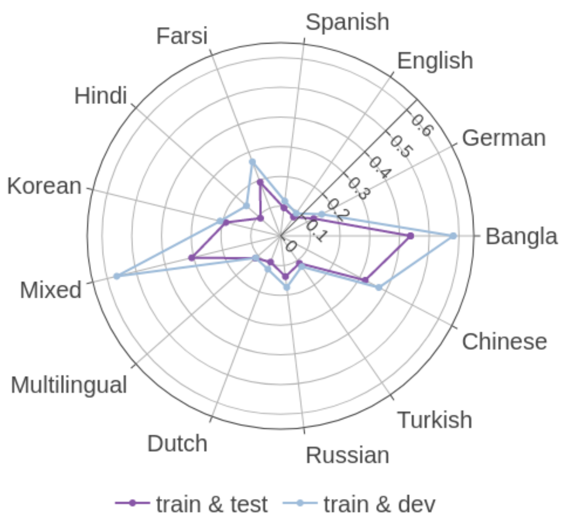

Figure 3: Similarity scores between the topics of the train and test (purple) & train and dev (blue) sets for each language.

Error Analysis Since one of the main challenges and purposes of SemEval-2022 Task 11 is to test not only the language adaption, but also the domain capability of a NER, we analyze the ability of our proposed models to handle multi-domain data. To measure the domain distribution among datasets, we obtain their topic vectors by a joint representation of documents and word semantic embeddings as in Angelov (2020). For this, we first obtain a common embedding of sentences and words with a pre-trained multilingual Sentence-BERT model[5] (Reimers and Gurevych, 2020a). Second, we utilize UMAP (McInnes et al., 2018) to create embeddings of lower dimension for all sentence vectors and find dense areas of sentences with HDBSCAN (Campello et al., 2013). Finally, we calculate the centroid of each dense area that corresponds to the topic vector.

Topic Detection Hyperparameters We set UMAP to a 5-dimensional space with a default

[2]We used the MULTI-QA-MPNET-BASE-DOT-V1 model.

[3]All models can be found at `https://huggingface.co`.

[4]Our code is available at `https://github.com/EMBEDDIA/stacked-ner`

[5]We use the PARAPHRASE-MULTILINGUAL-MINILM-L12-V2 model.

Split	Hyperparameter		
		neigh	dist
	2	5	0.0
Train	Mixed	Bangla	Mixed, Dutch, Chinese, Bangla
Dev	Korean, Mixed, Bangla	Farsi, Dutch	Mixed, Dutch, Chinese, Bangla, Korean
Test	-	-	Mixed, Chinese

Table 4: UMAP hyperparameters.

size of the local neighborhood (`neigh`) of 15, an effective minimum distance between embedded points (`dist`) equal to 0.1, and cosine distance as a similarity metric. We tuned these hyperparameters depending on the language and split when the obtained number of topic vectors was less than 2. These values are summarized in Table 4. Regarding HDBSCAN, we fix the minimum number of samples in a cluster to 15.

Language	**Domains / Topics**		
	Train	**Dev**	**Test**
English	72	12	1,188
Spanish	99	8	1,274
Dutch	112	9	1,404
Russian	95	6	1,330
Turkish	101	8	1,088
Korean	107	10	854
Farsi	126	5	1,097
German	93	6	1,194
Chinese	89	8	607
Hindi	105	5	1,209
Bangla	55	6	142
Multilingual	573	55	1,551
Mixed	32	11	644

Table 5: Number of topics in the dataset splits per language.

As seen in Table 5, the number of topics within the train set for each language is on average 96. The multilingual dataset has roughly six times more topics than the monolingual dataset even though it is the concatenation of all monolingual datasets. This suggests that certain portions of the monolingual datasets were obtained by a translation mechanism. Topic diversity from the development set is clearly smaller than the train set given the limited amount of samples it contains. Monolingual test sets present on average 11 times more topics with respect to the train sets, which is explained by the big amount of out-of-domain data organizers added to test sets with the objective of measuring out-of-domain performance.

To estimate the amount of out-of-domain sentences within data sets, we compute the topic overlap between (train and dev) and (train and test) sets. For each topic vector in the train set, we compute the cosine similarity with the topic vectors of the corresponding test or dev set. Then, we compare the topics by calculating the mean of the cosine similarities between the two sets of topics, as shown in Figure 3. We observe that Bangla and Mixed have very similar topics in the train, test, and dev sets. Our results in Table 3 seem to prove otherwise, thus, we interpret this behavior as the result of the lack of training of the multilingual Sentence-BERT model for this language.

Table 3 shows improvements when adding contexts for English, Spanish, Dutch, Korean, Bangla, and Mixed. With the exception of Bangla and Mixed that we just discussed, we notice that for the other languages, the similarity between the topics is rather small (around 0.2). Table 3 also shows a decrease in performance for Russian, Turkish, Farsi, Chinese, and Hindi. While for Farsi and Chinese, the similarity of topics is slightly higher (between 0.3 and 0.4), for the other languages, it plateaus at 0.2, which could indicate that there is a correlation between the number of overlapping topics between the train, test, and dev sets.

Metric	**Correlation (train, dev)**	**Correlation (train, test)**
P	-0.3812	-0.4995
R	-0.3450	-0.3266
F1	-0.3648	-0.4070

Table 6: Pearson correlation values between the dev and train topic similarity and evaluation metrics.

We, therefore, decide to compute the Pearson correlation between the precision, recall, and F1, and the similarity between topics. We observe weak negative correlation coefficients, allowing us to understand that the higher the topical similarity, the lower the performance scores. These

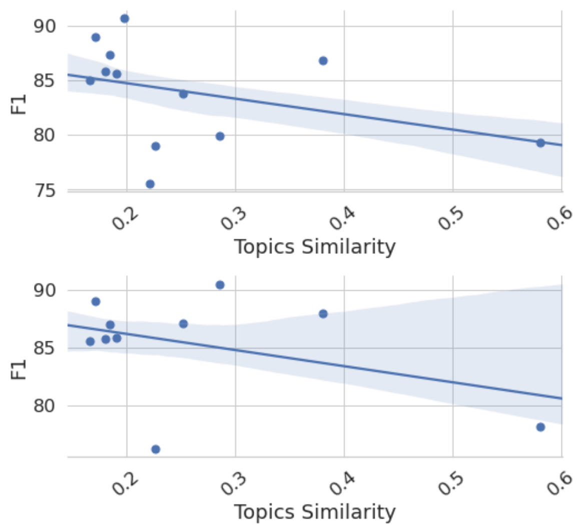

Figure 4: Topics similarity between train and dev set, 2×BERT+2×T-context *w/ entities* (upper figure), train and dev sets, 2×BERT+2×T-context *w/o entities* (lower figure), versus the F1 scores for the context models.

correlation values are shown in Table 6. Moreover, in order to understand if there is a correlation between the number of overlapping topics and the F1 scores for the models that use *context w/* or *w/o entities*, we draw a scatterplot of these two variables, then fit a regression model and plot the resulting regression line and a 95% confidence interval for that regression, in Figure 4. We observe again that, generally, the higher the similarity between topics in test and dev, the lower the F1 scores are.

SemEval-2022 Task 11 In the official SemEval-2022 Task 11, our best results ranked above the average for English, Spanish, and German, close to the average for Dutch, Turkish, Farsi, and Chinese. For the other languages, our approach obtained lower scores (Russian, Korean, Hindi, Bangla, Multilingual, and Mixed). For Hindi and Bangla, we did not have a specialized language model (we used multilingual BERT), which is clearly another reason for which the results were the lowest. Interestingly, we expected higher results for Korean and Spanish, but the size of the test set was most probably another important factor to consider.

5 Conclusions

In this paper, we presented a straightforward approach for adding semantically relevant contexts for NER in the monolingual, multilingual, and code-mixed datasets provided by SemEval-2022 Task 11 *Multilingual Complex Named Entity Recognition* (MultiCoNER). Our findings show that, while adding contexts from the train set, with and without entities, is promising, the topics or domains overlap could influence the performance in both directions. Future work will include the automatic generation of semantically relevant contexts without the presence of entities.

Abstract

The multilingual complex named entity recognition task of SemEval2020 required participants to detect semantically ambiguous and complex entities in 11 languages. In order to participate in this competition, a deep learning model is being used with the T5 text-to-text language model and its multilingual version, MT5, along with the transformer's encoder module. The subtoken check has also been introduced, resulting in a 4% increase in the model F1-score in English. We also examined the use of the BPEmb model for converting input tokens to representation vectors in this research. A performance evaluation of the proposed entity detection model is presented at the end of this paper. Six different scenarios were defined, and the proposed model was evaluated in each scenario within the English development set. Our model is also evaluated in other languages.

1 Introduction

Named Entity Recognition (NER) is a key component of Natural Language Processing (NLP) assigned to identify regions of text that contain references to entities. It is the process of identifying the informative part of data or applicable labels from unstructured data. In NER, data is gathered from unstructured data such as emails, blogs, newspapers, tweets, etc., to extract meaningful information.

To put it another way, the term NER refers to identifying token spans of entities mentioned in the text and classifying them into a set of predetermined categories. The system finds entities from unstructured data and organizes them into multiple categories. As an extension of NLP, the field of NER can be considered as Information Extraction (IE).

For NLP, IEs are among the trending fields and play an essential role in the following tasks: Find and understand limited relevant parts of texts, Gather information from many pieces of text, and Produce the unified representation of all the relevant information. The NER problem falls into a general class of NLP problems called sequence tagging. Part of Speech (POS) tagging and chunking are sequence tagging NLP tasks in addition to NER. It is possible to detect NER in three ways: flat NER, nested NER, and discontinuous NER. Nested NER has overlapping in the span of text Yan et al. (2021). Most approaches only target flat entities, ignoring nested structures common in many scenarios. It is challenging to identify spans as well as types of named entities in text Lample et al. (2016). So to find the best architecture, we implement a transformer-based language model in this research. NLP has significantly benefited from transfer learning in recent years. Transfer learning gains power and effectiveness from pre-training on large, unlabeled text datasets. The model can then be fine-tuned to a smaller labeled dataset, resulting in better performance. Many models have achieved success in this field, including the Text-To-Text Transfer Transformer (T5) Raffel et al. (2019). The T5 is a pre-trained encoder-decoder language model that employs the "text-to-text" format to accomplish all types of NLP work, including generation, translation, and summarization tasks.

In SemEval-2022 task 11 Malmasi et al. (2022b), a multilingual complex NER is provided. Languages presented in Malmasi et al. (2022a) are Bangla, German, English, Spanish, Farsi, Hindi, Korean, Dutch, Russian, Turkish, and Chinese. Since this dataset contains words from different languages, it is challenging to choose an appropriate word representation for converting them into their corresponding vectors. The multilingual nature of this task necessitated the selection of the multilingual variant of Google's T5 model named MT5 Xue et al. (2020) that had already been trained on a database of more than 101 languages and con-

[*] Equal contribution. Listing order is random.

tained up to 13 billion parameters. In this paper, MT5 is used as the main Embedding.

We evaluated the proposed model using the English test set and achieved the F1-score of 71.45% as part of this competition. In our next step, we considered this model in other subtasks, and our rank varied from 9 to 21 depending on which subtask we evaluated. Our code is available at GitHub[1] for researchers.

The contributions of this paper are summarized as follows. Section 2 introduces previous attempts in the NER. In Section 3, information about the task and datasets is presented. We then offer a deep learning framework for recognizing named entities in Section 4. Section 5 details the experimental setup, while Section 6 presents the results of the experiments. Section 7 presents both quantitative and qualitative error analysis. We conclude our paper in Section 8.

2 Background

The NER field has undergone enormous changes in recent years Meng et al. (2021) Fetahu et al. (2021). As mentioned before, NER is the process of identifying relevant objects such as persons, products, genes, place, organization, etc., that are mentioned in the string of the text, sentence, or paragraph. NER typically forms the basis of other tasks such as event detection from news, online shopping customer service, knowledge graph construction, and biological analysis Bokharaeian et al. (2017).

Yu et al. (2020) stated that since NER tags are nested, it uses the graph-based dependency parsing method and examines eight separate corpora to achieve State-of-the-art for all. The embedding layer in this article was composed of BERT, fasttext, and character embedding. There is widespread usage of CRF in the field of NER. CRF is used for the first time in Collobert et al. (2011) for the NER. The representation of the sample in this research was obtained by Convolutional Neural Network(CNN). After that, many articles used CRF in various languages and combined it with other methods, such as Part Of Speech Tagging(POS), Long Short-Term Memory(LSTM), Embeddings from Language Models(ELMo), etc.Lample et al. (2016); Alves-Pinto et al. (2022); Rajan and Salgaonkar (2022); Ma and Hovy (2016); Huang et al. (2015). Peters et al. (2018) which is known as ELMo, extends LSTM-CRF and leverages pre-trained word-level language models for better context-aware representations. Peters et al. (2018) focuses on introducing and defining a Bidirectional language model that is tested on numerous NLP tasks in 2018. The accuracy of this research of NER with the language model and CRF layer was 93.42%.

To resolve ambiguity in NER tags, Straková et al. (2019) encoded nested entities in a sequence (seq2seq) and prepared an LSTM-CRF-based model. By incorporating pre-trained character-level language models into Flair Akbik et al. (2019), researcher presented contextualized representations. The following year, Akbik et al. extended this model to incorporate dataset-level word embeddings, dynamically aggregating embeddings and implementing pooling to extract a global word representation from all instances Akbik et al. (2018).

Word representations and character representations are used in Ma and Hovy (2016), an end-to-end system designed using LSTM, CNN, and CRF. This idea has been implemented on the Penn Treebank WSJ corpus Marcus et al. (1999) for POS and CoNLL 2003 Sang and De Meulder (2003) for NER datasets. A CNN has been used in this research to extract the character-level representation of words, with its output then being input into LSTMs, followed by a CRF layer. There is another extension to CRF known as hybrid semi-Markov conditional random fields (HSCRFs) is explained in Ye and Ling (2018) by contributing word-level labels in the building of SCRFs Lafferty et al. (2001). The purpose of using word-level tags to derive segment scores is to obtain segment scores.

To solve different sequence tagging models with a CRF inference, Yang and Zhang (2018) implemented NCRF++ with three steps: a character sequence layer, a word sequence layer, and an inference layer. RodrigoAgerri et al. presented a multilingual NER system that combines many features to cluster based on local information Agerri and Rigau (2016). Results from standard task evaluation data such as CoNLL for English, Spanish, and Dutch were reposted.

According to Wang et al. (2020), contextualized language models can produce better results when different embeddings are combined. This paper presents a framework for generating and scoring the output of embedded combinations using rein-

[1]`https://github.com/MarSanTeam/Complex_NER_SemEval`

forcement learning, which achieves the best accuracy in 6 different fields and 21 large datasets. According to Wang et al. (2020), contextualized language models can produce better results when different embeddings are combined. By rewarding model scores for better concatenations of embeddings, can propose Automated Concatenation of Embeddings to find better concatenations of embeddings for structured prediction tasks.

Majumder et al. (2022) considers the issue of informal data, whose unstructured and incomplete nature makes the process more challenging. To solve the mentioned challenge, Bi-LSTM based architecture for informal tweets in Hindi and English was implemented. There is more than one way to do it in this field. Finding the part of the text containing entity information, classifying and identifying the right entity, and applying that entity to the appropriate part of the text are just some ways. Generating tags is one other way to implement them. As mentioned in Yan et al. (2021), Hang Yan et al. propose that they use a novel and simple Bidirectional Auto-Regressive Transformer(BART) sequence-to-sequence (Seq2Seq) framework that uses a pointer mechanism Vinyals et al. (2015) to generate the entity sequence directly.

Another approach in NER, which is mentioned in Islam et al. (2022), consists of using an attention mechanism to minimize the problem of detecting redundant and inessential data and ignoring them entirely. Combining semantic, glyph, and phonetic features to improve the expression ability of Chinese character embedding, Li and Meng (2021) proposes an architecture based on Fusion Embedding for the Chinese language.

There is also a paper for the Chinese language entitled Jia et al. (2020) that identifies entities from Chinese social media texts, using uncertain information from word segmentation. Researchers have proposed that interactions between spans of tokens can help determine discontinuous mentions and have developed a transition-based model with a generic neural encoding to be able to detect discontinuous mentions Khan et al. (2020).

A model of bidirectional transformers is presented in Yamada et al. (2020), which produces a contextualized representation of words and tokens. BERT's masked language model is used as pre-trained word embeddings. As a result, Yamada et al. present advancement in attention known as entity-aware self-attention mechanisms and achieve state-of-the-art in five benchmarks that include: Open Entity (entity typing), TACRED (relation classification), CoNLL-2003 (NER), ReCoRD (cloze-style question answering), and SQuAD 1.1 (extractive question answering). Since carelessness or a lack of background knowledge of annotators might lead to model performance errors, some research has been conducted to identify and solve these issues. Wang et al. (2019) provides a framework for finding human errors in NER annotations. Following the correction of labels in the test set, they re-evaluated state models in NER, claiming that the results were more accurate than the original test set. This paper's main idea is cross weighs, which accommodates label mistakes during training and then trains a more robust NER model.

Wang et al. (2021) finds the external context of input sentences by retrieving relevant sentences. The process of selecting the top similar text involves re-ranking retrieved samples according to their semantic relevance to the input sentence. As a result, the inputs are the concatenation of input sentences and external contexts. Both input types are used to implement Cooperative Learning (CL), and different representations are encouraged to produce similar contextual representations or output label distributions. Results on eight other NER datasets achieve state-of-the-art results. But one drawback of this method is that there are no document-level contexts in practice.

3 Task Description

Our investigation aims to comparatively study MultiCoNER-2022 datasets that have been considered individually for complex NER systems in 11 languages. Under short and low-context settings, the task detects semantically ambiguous and complex entities.

Languages presented in MultiCoNER-2022 are: English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, and Bangla. The number of instances for each language varies between 150k to 500k. There are 15300 train data and 800 validation data for each language.

This dataset is labeled with the following tags: PER: Person, LOC: Location, GRP: Group, CORP: Corporation, PROD: Product, CW: Creative Work. There is detailed information of datasets illustrated in Table 1.

The datasets used in this task include sentences labeled with the IOB format. Using this format,

Languages	LOC		PER		PROD		GRP		CW		CORP	
	Span	Token	Span	Token	Span	Token	Span	Token	Span	Token	Span	Token
English	4799	7550	5397	11538	2923	4723	3571	10038	3752	9782	3111	6222

Table 1: Distribution of spans and tokens for each entity

tokens that are not a part of an entity are tagged as ’O’, the first token of an entity is represented by the ’B’ tag, while the rest of the entity’s tokens are represented by an ’I’ tag. The entity category precedes both a hyphen and the "B" and "I" tags. Therefore, NER is a task that labels tokens according to their text, which is multi-class token classification.

4 System overview

In this section, we will introduce our proposed NER framework. The proposed framework consists of three parts:

1. Word Representation Module
2. Feature extraction Module
3. Prediction Module

The proposed architecture takes the token sequence $S = \{s_1, s_2, s_3, ..., s_n\}$, and predicts entity sequence $O = \{o_1, o_2, o_3, ..., o_n\}$ as output. Figure 1 is an illustration of the proposed architecture.

4.1 Word Representation Module

In light of the multilingual nature of the SemEval NER task, the T5 language model was applied to convert tokens into their representation vector. In the word representation module, the last hidden state of the T5-large encoder is chosen to learn the k-dimensional (1024 here) representation for input tokens. The T5 uses SentencePiece encoding and assigns named entity tags to its extracted tokens. Tokens extracted from T5 are always equal to or greater than main tokens. Each token thus becomes one or more subtokens. The label of the first subtoken corresponds to the label of the first token, while the other subtokens have the label X.

Subtoken Check A key consideration is that each token becomes one or more subtokens. To provide better training, a feature called subtoken check is used. This feature checks whether the input token is tokenized into the subtoken or not. After tokenizing the tokens, the first subtoken of each token has a value of 1, and the rest have a value of 0. Hence, the T5 encoder takes two input sequences of the same length; one is the subtoken index, and the other is the subtoken check index. After adding this feature and improving the results, it was found that in token-based tasks such as NER, the existence of this feature is extremely helpful for managing subtokens.

Byte-pair Embeddings The Byte-pair Embeddings(BPEmb) Heinzerling and Strube (2017) consists of pre-trained subword embeddings in 275 languages. BPEmb is a variable-length encoding that views the text as a sequence of symbols, iteratively merging the pair with the highest frequency into a new symbol. It provides a mechanism for properly tokenizing input sequences so that unknown tokens can prepare appropriate representations by using subtokens. To predict the named entity tag for the input sequences, we concatenate the output vector of the BPEmb model with the output vector of the feature extraction layer since fine-tuning of the model is not possible during training.

4.2 Feature Extraction Layer

Since the goal of NER is to predict the entity label of each token, an awareness of the semantic dependencies between tokens can be extremely helpful. The which uses the multi-encoder architecture Vaswani et al. (2017), which uses the multi-head self-attention mechanism, is one of the most suitable deep learning architectures for extracting relation between tokens. There are two sublayers in this encoder module. The first sublayer is a multi-head self-attention mechanism, while the second is

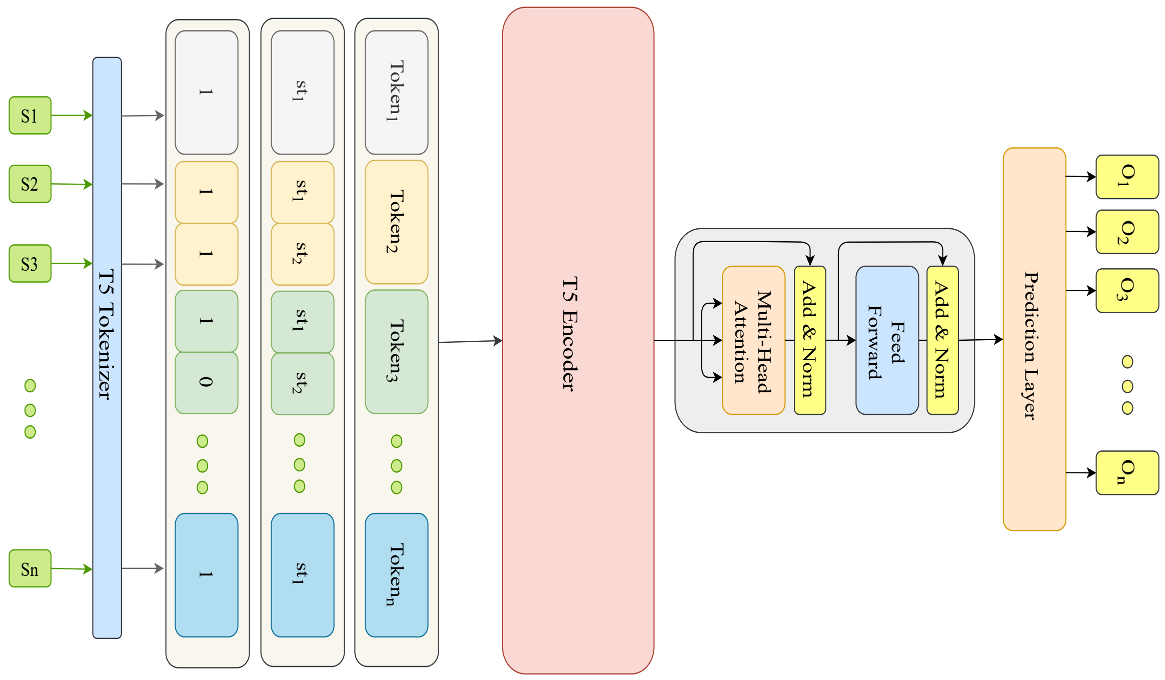

Figure 1: Proposed multilingual NER architecture

a position-wise fully connected feed-forward network. This architecture uses residual connections around each of the two sublayers followed by layer normalization. A multi-head attention module comprises several scaled dot-product attention used in parallel. In scaled dot-product attention, the input consists of three matrices Q, K, and V. The scaled dot-product attention is calculated using the following formula.

$$W_i^Q, W_i^K, W_i^V \in R^{d_{model} \times d_k}$$

$$Q = XW_Q, K = XW_K, V = XW_V \quad (1)$$

$$Attention(Q, K, V) = softmax(\frac{QK^T}{\sqrt{d_k}})V$$

The attention module has three trainable parameters, W_Q, W_K, and W_V. The three matrices Q, K, V are constructed by multiplying the input vector X by the corresponding matrices W_Q, W_K, W_V. Consequently, the dot product between Q and K is divided by $\sqrt{d_k}$ in order to prevent the dot product from becoming too large.

4.3 Prediction Layer

The vector obtained in the feature extraction Layer is given to a fully connected layer to predict the named entity label of the input sequence. For the input sequence $S = s_1, s_2, ..., s_n$ the output sequence $O = o_1, o_2 \ldots, o_n$ is predicted.

5 Experimental setup

We implemented the model in PyTorch and trained it on Nvidia V100 GPUs. The AdamW optimizer with a learning rate of 2e-5 is used to train the network. Our training method includes early stopping, which ensures the validation loss reduction with patience of 10 epochs. The training batch size is set to 32, and the dropout rate is 0.2. Transformer encoders have eight attention heads, and position-wise feed-forward layers have 2048 hidden sizes. In both T5 and MT5 tokenizers, the max length varies between 100 and 250 characters according to the evaluated language. The hyper-parameters of each subtask were tuned with the dev set. All other parameters are initialized randomly.

6 Results

Several experiments have been conducted to develop the most appropriate model for NER. Experiments with the English dataset can be found in Table 2. Due to the success of T5 in this study, this language model has been used to compute the word representation vectors. According to Table 2, using the T5 can improve F1-score by 4% compared to MultiCoNER Baseline that uses XLM-RoBERTa.

We have attempted to improve the language model results by adding deep learning architectures and textual features Tavan et al. (2021). We evaluated LSTM and Transformer architecture on top of the T5 and found that using the transformer improved the F1-score further than LSTM. After various experiments, it was found that the use of BPEmb could not improve the F1-score of the model.

Models	Train	Dev	Test
MultiCoNER Baseline	-	77.60	-
T5	94.40	81.92	65.99
T5 + LSTM	96.40	82.20	67.54
T5 + Transformer	89.09	82.91	67.63
T5 + Transformer + subtoken + bpemb	90.12	82.36	67.22
T5 + subtoken + Transformer (ours)	**97.32**	**86.73**	**71.45**

Table 2: Experiments with English dataset

According to Table 2, the proposed model has achieved the F1-score of 86.73% and 71.45%, on the dev and test dataset for English, respectively, which is the highest F1-score among the other experiments. Figure 2 Compares the F1-score of different deep learning architecture.

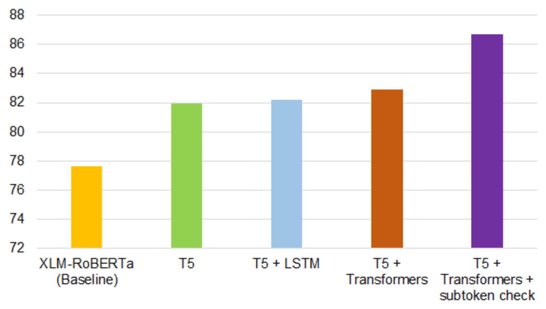

Figure 2: Compares the F1-score of deep learning architectures.

The results of the proposed model on the test dataset, as well as its ranking in the competition, are shown in Table 3. According to these results, Chinese, Hindi, and Bangla have lower F1-scores than other languages like German, Dutch, and English due to their language complexity.

The results of proposed model for the different entities are shown in Table 4. According to Table 4, the "PER" entity has reached the highest F1-score among other entities in all languages. Except for Russian, Turkish and Chinese, "CW" has the lowest F1-score in all other languages. As a result, the proposed model is weaker in identifying the "CW" entity than other entities.

7 Error Analysis

Several scenarios could occur when comparing the golden standard annotation with the output of a NER system Nejadgholi et al. (2020):

Scenario 1, Complete True Positive: An entity is predicted by the NER model correctly.

Scenario 2, Complete False Positive: An entity is predicted by the NER model but is not annotated in the hand-labeled text.

Scenario 3, Complete False Negative: The model does not predict a hand-labeled entity.

Scenario 4, Wrong label, Right Span: A hand-labeled entity and a predicted one have the same span but different tags.

Scenario 5, Right label, overlapping spans: A hand-labeled entity and a predicted one have overlapping spans and the same tags.

Scenario 6, Wrong label, overlapping spans: A hand-labeled entity and a predicted one have overlapping spans but different tags.

The output of the proposed model on the English dev dataset has been evaluated on six scenarios in Table 5. From Table 5, 96.20% of "PER" entities are in Scenario 1, and the most significant proportion of Complete True Positives are related to this entity. Approximately 17% of "PROD" entities are in Scenario 2, higher than other entities. "PROD" actually has the highest Complete False Positive value among all entities. The "CW" has the greatest number of entities in Scenario 3 and the highest proportion of Complete False Negatives among other entities.

Scenario 4 includes 6.21% of "CORP" entities. Scenario 5 has the most significant number of entities compared to other scenarios, having 6.12 percent of the "PROD" entities. The "CORP" also has the highest number of entities in Scenario 6. Table 6 shows examples of the English test samples that are categorized in different scenarios.

Language	Precision	Recall	F1-score

8 Conclusion

This paper proposes a model that uses an encoder module of transformers in the top of the hidden state of the T5 to process the extracted features to obtain the most important feature representations. Many experiments were conducted to evaluate the model's performance and find the best language model. The experiments prove that our architecture is most compatible with the T5 language model and does cover a reasonable range of results. Since this dataset is multilingual, the MT5 embedding module was selected.

The model's accuracy is confirmed by an in-depth analysis of the provided datasets. Accordingly, the same architecture was used in all other sub-tasks. Error analysis enabled us to identify specific NER challenges, creating immediate future tasks. We plan to apply more robust deep architectures to multilingual datasets as part of our future work.

SU-NLP at SemEval-2022 Task 11: Complex Named Entity Recognition with Entity Linking

Buse Çarık[*], **Fatih Beyhan**[*], **Reyyan Yeniterzi**
Sabancı University, İstanbul, Turkey
{busecarik,fatihbeyhan,reyyan}@sabanciuniv.edu

Abstract

This paper describes the system proposed by Sabancı University Natural Language Processing Group in the SemEval-2022 MultiCoNER task. We developed an unsupervised entity linking pipeline that detects potential entity mentions with the help of Wikipedia and also uses the corresponding Wikipedia context to help the classifier in finding the named entity type of that mention. The proposed pipeline significantly improved the performance, especially for complex entities in low-context settings.

1 Introduction

Named Entity Recognition (NER) is a widely studied task of Natural Language Processing. Recent leading architectures achieved impressive performances, especially in formal contexts (like news articles, etc.) and for commonly worked named entity types (like Person, Organization, etc.). In *Multilingual Complex Named Entity Recognition* task (Malmasi et al., 2022b), organizers introduced a dataset which is a large collection of short texts that includes complex entities. As they stated, complex entities can be noun phrases, gerunds, or full clauses (Malmasi et al., 2022a). The participants were challenged to develop NER systems for identifying these complex entities in short and low-context settings.

Recent contextual neural architectures like transformers work quite well on a variety of NLP tasks and datasets. However, they are strongly dependent on the context of the given text. In case of lack of context, these models alone may not gather enough evidence to make a correct prediction. When that is the case, getting help from knowledge bases can be useful. The dataset provided with this task has similar low-context characteristics together with some complex named entity types to be resolved. Therefore, in this work, we investigated whether performing entity linking to provide additional context for a transformer model can be useful for identifying complex named entities. We initially used an unsupervised entity linking approach to identify the possible entity mentions and their corresponding Wikipedia pages. Later on, we used the additional context retrieved from Wikipedia to predict the types of the identified entities. Performing entity linking prior to the classifier seems to be beneficial in the case of complex entities in short and low-context settings. Our code is publicly available[*].

[*]These authors contributed equally to this work.

2 Related Work

NER is an important and also well-studied task in NLP. Similar to other NLP tasks, recent neural architectures provided significant improvements in NER as well. However, since these models are heavily dependent on context information, applying them to short, noisy texts such as very short social media posts or web queries results in significant performance degradation (Meng et al., 2021).

To overcome the lack of context in these short texts, as well as the code-mixed terms, it has been prominent to use external knowledge in neural approaches. Recent studies (Meng et al., 2021; Fetahu et al., 2021) combining multilingual transformer models with gazetteers have shown remarkable improvement in performance. Another study (Yamada et al., 2015) utilized the Entity Linking task to address the issues of Twitter NER by detecting entity mentions from Wikipedia.

In this study, we also focused on external information due to the lack of context. However, instead of using a static auxiliary like gazetteers, we tried to detect entities dynamically from the continuously extending Wikipedia by using a search engine architecture. We integrated the Wikipedia content into the input representation in order to improve the performance of entity type classification.

3 Data

Malmasi et al. (2022a) introduced a new multilingual NER dataset consisting of 6 named entity categories (Person, Location, Group, Corporation, Product, and Creative Work) annotated in short texts for 11 languages. In this paper, even though we propose a language-independent approach, due to the limited resources we only focused on the Turkish part of the dataset. Statistics from this part are shown in Table 1. As seen from Table 1, even though the number of samples is much higher, the length of the samples is significantly lower in the test set compared to train and validation splits. This short length in context may cause state-of-the-art contextual models to perform worse than expected.

	# Samples	Avg. # Tokens
Train	15,300	14.27
Validation	800	14.27
Test	136,935	5.28

Table 1: Distribution of samples and average number of tokens per sample for Turkish part

An issue we found with the dataset is that in some examples, a phrase is labeled as *OTHER* although there are similar phrases that are labeled as a named entity. Consider the following example: *"Nokia 1011, 1994'e kadar, Nokia 2010 ve Nokia 2110'un halefler olarak tanıtılmasıyla üretime devam etti." English: "Nokia 1011 continued in production until 1994, with the introduction of the Nokia 2010 and Nokia 2110 as successors."*

The text includes three different cellphone models produced by Nokia. Two of these models (the blue ones) were annotated as *PRODUCT*; however, *Nokia 1011* was mislabeled as *OTHER*. A more major issue is when the same named entity occurs more than once in a sentence, but their annotations are different. An example is illustrated below: *"Whitney Houston yine bu sene içinde New Jack Swing'e adını yazdırdı, I'm Your Baby Tonight adlı şarkı Whitney Houston'a başarı üstüne başarı getirmiştir." English: "Whitney Houston made her name on New Jack Swing again this year, the song I'm Your Baby Tonight brought Whitney Houston success after success."*

In the example, Whitney Houston in blue was labeled as *PERSON*; but, the red Whitney Houston was labeled as *OTHER*. These types of wrong annotations cause ambiguities and learning problems in supervised approaches.

4 Methodology

In order to overcome the challenges described in previous sections, we propose an unsupervised entity linking pipeline followed by a classifier as our proposed NER architecture. The entity linking pipeline is designed to detect potential entity mentions and retrieve corresponding candidate documents for each mention. Later, these detected mentions and the linked content is used together in a classifier to detect the entity type of the mention. A pre-trained BERT model was also fine-tuned in order to create a strong baseline for comparison.

4.1 BERT

The BERT (Devlin et al., 2018) model was adopted as a baseline approach due to its outstanding performance in many NLP tasks. We fine-tuned the BERTurk (Schweter, 2020) model with a feed-forward layer on top to classify the named entities. The base model with 12 encoder layers and 768 hidden units was used. Since the data provided as part of the task was all lowercase, the uncased version of BERTurk was preferred.

4.2 NER with Entity Linking

BERT like transformer models heavily depend on the context. Therefore having a very short context (like a couple of words, not even a sentence) can be challenging for these models. Especially when the task is to identify complex named entities like creative work or product, it is much more challenging. In a very short context, even human beings may have a hard time resolving entities and their types.

In order to overcome this challenge, additional help from a gazetteer or a knowledge base will be very useful. Therefore in this paper, we propose using Wikipedia in order to both identify entities and also their types. Our proposed architecture which is depicted in Figure 1 consists of three steps. The first two steps work towards identifying possible entities and linking them to their corresponding Wikipedia articles. In this unsupervised entity linking approach as the first step, the original input text is used to retrieve relevant Wikipedia pages which are possible candidate pages for entities. In the second step, content within the retrieved documents (like their titles) is used to identify the entity mentions in the original text. Finally, in the third step, each identified mention and its linked Wikipedia article are used together to predict the type of the

entity.

4.2.1 Candidate Generation

ElasticSearch[*] was used as the underlying search engine architecture. The most recent Wikipedia dump was used to create an index. For each document D_i, the *title*, *referred_by* and *interwikies* were indexed to create the following four fields:

- *title*: This is the title of the document D_i.
- *referred_by*: This is a set of text spans which are parsed from other Wikipedia pages where D_i is being referred with a interwiki link. This set includes all of these text spans sorted from longest to shortest. The title is added to the set as well.
- *interwikies*: This is the list of interwikies[*] in the document D_i.
- *all_text*: Concatenation of all fields (title, text content, interwikies, referred_by, and categories[*]) of the document D_i.

Each sample was queried and the most relevant 200 articles were retrieved. Later on for each query, documents retrieved with different field searches were pooled together. The reason we are pooling these different field results is to make sure we do not miss a possibly relevant article that could have been linked.

For the train and validation tests, around 199 documents were retrieved for each field. After pooling, we ended up with a pool of size 578 documents on average. Since test queries are shorter, the average number of documents returned got as low as 161 with the title field and 465 over the pool. Short queries also affected the empty ones, in other words, no document retrieved samples. After pooling there was not such a case for train and validation, however even pooling could not help the 169

[*] https://www.elastic.co/

[*] Interwikies are the types of hyperlinks which is linking a text span from a Wikipedia page to another Wikipedia page. For instance, Wikipedia pages of Earth, Mercury and Venus are in the interwikies section of the Sun's Wikipedia page, since they are mentioned within its text.

[*] The categories section of a Wikipedia page includes a list of topics which is related to the Wikipedia page.

Field	Train	Validation
title	96.52	97.00
interwikies	57.16	61.26
referred_by	96.46	96.11
all_text	86.50	86.68
After pooling	98.89	98.85

Table 2: Recall Scores over Detected Mentions

queries over 136,935 samples, and no Wikipedia articles were retrieved for those.

4.2.2 Mention Detection and Linking

After generating a set of candidate documents for each input text, the next step is to map these documents to the possible entity mentions in the input. For each input, our proposed algorithm iterated over the retrieved and pooled documents $\{D\}$, and cross-checked each item in the *referred_by* field of the document to see if there was an exact match to any phrase in the input text. In case there was an exact match, then that matched phrase was tagged as a possible entity and linked to the corresponding Wikipedia page. If there were multiple matches for a span of text, then the longest match was considered and shorter ones were ignored. Furthermore, if there was a tie in terms of length, then the relevance score of the Wikipedia document was used. That relevance score was calculated after pooling by doing a summation of the relevance scores from different field retrievals.

In order to see which fields in Wikipedia are more useful for mention detection, recall was calculated over detected entity mentions, without considering the type of entity. The results are summarized in Table 2. Based on the results *title* and *referred_by* are the most useful fields and pooling all retrievals is the best over both train and development sets.

4.2.3 Named Entity Type Detection

After linking the entities, the only thing remaining is to find their NER type. In order to do that we used the original context where the entity was mentioned in the input text and the linked Wikipedia article content. We combined these two as follows:

$$\texttt{[CLS]}\, ctx_l\, \texttt{[SEP]}\, M\, \texttt{[SEP]}\, ctx_r\, \texttt{[SEP]}\, WP\, \texttt{[SEP]}$$

where ctx_l and ctx_r are tokens for left and right context of mention, M is mention itself and WP is the first two paragraphs of a Wikipedia page. `[SEP]` tokens are used to tag the mention. The maximum length of the representation is set to 256. This representation is given to BERT for encoding.

We used two classifier heads following the BERT encoder for classifying the pairs of mentions M and Wikipedia contents WP. The proposed architectural design is presented in Figure 2. The first one is a binary classifier head which aims to solve an auxiliary task of whether the given candidate entity mention is a real entity or not with the help of input context tokens and Wikipedia content. The second classifier head tries to learn the type of the candidate named entity. The loss function for our model is the summation of losses from these two classifier heads. In case the binary classifier head returns O (means mention is not an entity), the second classifier head's decision is ignored, and the given candidate entity mention is directly predicted as O (which stands for Other, not an entity). This multi head model is referred to as *EL_MultiBERT*.

In order to test the effectiveness of multiple heads, we created another model called *EL_BERT*, which has a single classifier head only for identifying named entity types including the Other class.

In our pipeline, the Other class can be assigned to tokens in any of the three steps. Whenever a token is assigned the Other (O) label, then its label does not change during the remaining steps.

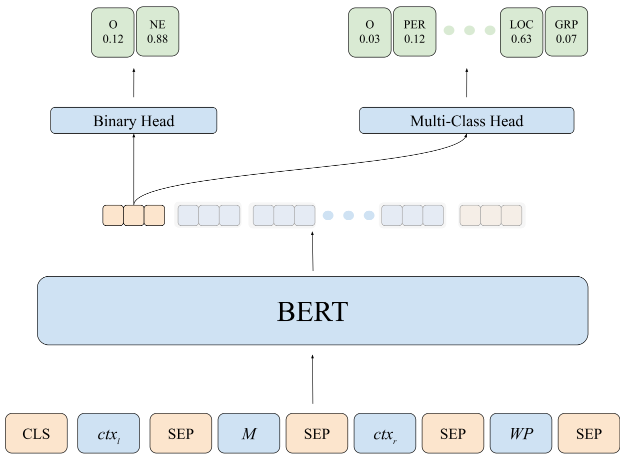

Figure 2: The architecture of the classifier. NE in the binary classifier head's output stands for *Named Entity* and O for *Other*.

5 Experimental Setup

Due to limited resources and time, we only experimented with the Turkish part of the dataset and therefore indexed 749,204 Turkish Wikipedia pages. During retrieval, *OR* operator was used as

Table 3: Results of our proposed methods on development and test data

part of the query and the default BM25 was used for ranking. We fine-tuned the BERTurk model[*]. As the optimizer, we used AdamW (Loshchilov and Hutter, 2019) with a fixed learning rate in all our BERT models as 3 x 10^{-5}. We also applied dropout before the feed-forward layer with 0.3 probability. Our batch size was 32, with a maximum sequence length of 128 for the baseline BERT. We extended the maximum sequence length to 256 for EL_MultiBERT and reduced the batch size to 8. All experiments were conducted with seed 22.

6 Results

The official evaluation metric was chosen as macro-average F1-score by the organizers. In Table 3, we present our results with models described above. Our baseline BERT, the one fine-tuned directly for NER, worked quite well on the validation set but performed badly on the test set. This substantial difference in these two sets shows that contextual models like BERT do not perform well in low-context settings. On the other hand, although our proposed entity linking approaches fell slightly behind the baseline model in the development set, they performed significantly better than the baseline on test set. Among the two entity linking methods, the EL_MultiBERT model with two classification heads performed better. While determining the named entity type, training with this auxiliary task even on the same data seems to be useful.

Table 4 illustrates the performance of BERT and EL_MultiBERT models for each named entity class. As seen from the table, our proposed approach improves the performance, especially in complex entities like *Creative Work*, *Group* and *Product*. Two approaches returned similar results only for *Person* and *Location*. Since we do not have the gold standard labels, we cannot perform any detailed analysis of the reason.

Entity Type	BERT	EL_MultiBERT
Person	70.72	72.43
Location	59.73	57.42
Group	51.49	76.51
Corporation	57.69	73.79
Product	63.13	76.93
Creative Work	44.14	74.40

Table 4: F1-Scores by NER type on Test Set

6.1 Ensemble Approach

Although the majority of the samples in the test set are short texts, there are some longer sentences as well. From the validation set experiments, we already know that when there is enough context, transformer models like BERT perform quite well. Hence, we decided to see if we can use our proposed architecture as a fall back mechanism when there is not enough context available, but otherwise use BERT. We applied an ensemble approach relying on BERT for samples with more than 11 tokens and EL_MultiBERT for shorter ones. So when sentence length is less than 11, we depended on our entity linking architecture and Wikipedia for retrieving and using additional useful context about the input. As shown in Table 3, the ensemble of BERT and EL_MultiBERT achieved 72.02% on the test set, and this system ranked as third in the Turkish track.

7 Conclusion

In this work, we proposed a language-independent method for the Complex NER task in low-context settings. Our results showed that utilizing the use of entity linking for NER provides a significant improvement over state-of-the-art transformer models when there is not enough context. Yet, since our resources are limited, we experimented with only the Turkish part. In future work, we will extend this approach in a multilingual setting.

Abstract

This paper describes our system, which placed third in the Multilingual Track (subtask 11), fourth in the Code-Mixed Track (subtask 12), and seventh in the Chinese Track (subtask 9) in the SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition. Our system's key contributions are as follows: 1) For multilingual NER tasks, we offer an unified framework with which one can easily execute single-language or multilingual NER tasks, 2) for low-resource code-mixed NER task, one can easily enhance his or her dataset through implementing several simple data augmentation methods and 3) for Chinese tasks, we propose a model that can capture Chinese lexical semantic, lexical border, and lexical graph structural information. Finally, our system achieves macro-f1 scores of 77.66, 84.35, and 74.00 on subtasks 11, 12, and 9, respectively, during the testing phase.

1 Introduction

SemEval 2022 Task 11: MultiCoNER Multilingual Complex Named Entity Recognition(Malmasi et al., 2022b) focuses on extracting semantically ambiguous complex named entities(Meng et al., 2021) in short, low-context and code-mixed(Fetahu et al., 2021) scenarios. The domain adaptability capacity of the system is in high demand for this shared task, which contains 13 tracks in English, Spanish, Dutch, Russian, Turkish, Korean, Farsi, German, Chinese, Hindi, Bangla, multi-language, and code-mixed. Among them, multi-language, and code-mixed tracks are in the mixed language, while the other tracks are in the single language. The difference between multi-language track and code-mixed track is that the corpus of multi-language track is multilingual, but the words in each sentence are in a single language, while the corpus of code-mixed track is a corpus in which the words or phrases in each sentence may be from different languages, for example the sentence I Liebe Sie (I love you) consists of English, French and German. Furthermore, the datasets offered by the organizers , which may mainly from Wikipedia, web questions and user queries, comprise data from 11 languages, with each language containing around 15,000 training samples and 800 development (dev) samples(Malmasi et al., 2022a). The corpus contains a total of six entity categories, namely location (LOC), person (PER), product (PROD), group (GRP), corporation (CORP) and creative works (CW). The main contributions of our system are as follows: 1) we propose a unified framework for multilingual NER tasks, using which one can easily perform monolingual or multilingual NER tasks; 2) for low-resource code-mixed NER tasks, we provide several simple and effective data augmentation methods to easily increase the amount of data; 3) for Chinese tasks, we propose a model that captures Chinese lexical semantics, lexical boundaries and lexical graph structure information in a model.

2 Related work

Named Entity Recognition (NER)—a classic and fundamental task that aims to extract named entities from a sentence—plays an important role in a variety of downstream tasks in the field of NLP, including relation extraction (Zhong and Chen, 2021), knowledge graph construction (Bosselut et al., 2019), question answering (Diefenbach et al., 2018) and so on. For a long time, the development of NER was slow, especially before the rise of neural networks, and NER mostly used statistical machine learning methods like HMM(Morwal et al., 2012) and CRF(Konkol and Konopík, 2013). Although these methods were effective at the time, they were still stretched for complex scenarios. After the rise of neural networks, especially structured networks such as RNNs(Sherstinsky, 2020) and CNNs(LeCun et al., 1998), NER has been greatly developed, and the accuracy has been greatly improved compared with traditional statistical learning methods. There are also methods that combine neural networks with traditional statistical learning methods, such as BiLSTM+CRF(Chen et al., 2017). Although these methods take NER to another higher level, they also have certain problems. For example, RNNs cannot model bi-directionally context, and then there is the inability of RNNs to capture long-term dependencies, and though CNNs can model bi-directionally, but due to the size of convolutional kernels, they can only model local contextual information at the same time and cannot capture global contextual information. Recently, self-training pre-training models on large-scale corpus such as BERT(Kenton and Toutanova) and its variant versions have greatly improved the accuracy of NER tasks and effectively solved the problem that RNNs cannot capture long-range dependencies as well as dynamic contexts. From statistical models like HMM and CRF to deep learning models like CNN, RNN, and transformer-based pre-trained models, the accuracy of NER tasks is increasing and has reached commercial levels in many scenarios(Yadav and Bethard, 2018). Despite its remarkable progress, NER still faces some challenges(Ma et al., 2020), such as the problem of discontinued and nested named entities(Yan et al., 2021), the challenge of cross-domain and cross-lingual transfer learning(Mueller et al., 2020), the lack of lexicon information when using sub-character tokenization strategy and word boundary information of Chinese NER tasks(Zhang and Yang, 2018), and the ambiguity of named entities(Meng et al., 2021) under different semantic circumstance.

3 System overview

Figure 1 depicts our system's overall architecture and technological process. As we can see, the unified framework allows us to complete all of the subtasks.

3.1 Backbone encoder

We selected XLM-RoBERT-large (Conneau et al., 2020) as our backbone encoder to establish framework unity and make full use of data from different tracks to realize language transfer. XLM-RoBERTa is a multilingual version of RoBERTa that has been pre-trained on 2.5TB of data in 100 languages. The large version has 24 transformer layers, 16 self-attention heads per layer, and a hidden size of 1024.

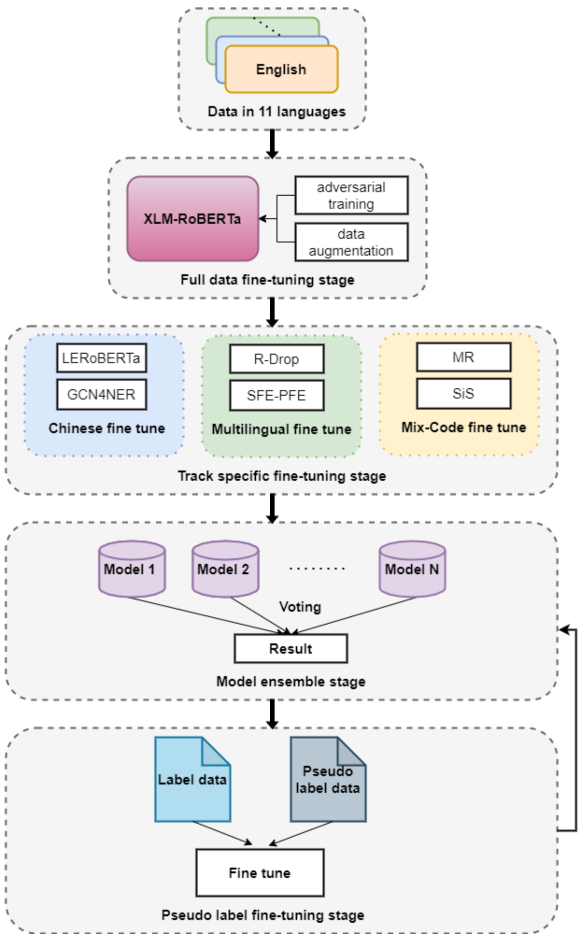

Figure 1: The architecture and procedures of our system

3.2 Training procedures

We take multiple steps to fine tune our system, including full data fine-tuning stage, track specific fine-tuning stage, model ensemble stage and pseudo label fine-tuning stage.

3.2.1 Full data fine-tuning stage

As the first step of our system, we fine tune our model with data from all languages provided by official. At this stage, we hope that the model can learn the distribution of datasets and capture the named entity information from the total data, which will aid our model in transferring to those data on specific tracks. To improve the model's cognitive ability and stability, we implemented the following set of training skills.

Data Augmentation: We did not simply feed the data into our model, but enhanced data firstly in a simple way—concatenating sentences randomly, including **bisent-uni**—concatenating two sentences from the same language randomly into a new sentence, **bisent-mix**—concatenating two sentences from different language randomly into a new sentence, **mulsent-uni**—concatenating several sentences from the same language randomly into a new sentence with a length of no more than 512 and **mulsent-mix**—concatenating several sentences from different language randomly into a new sentence with a length of no more than 512.

Adversarial Training: Considering that the deep neural networks are vulnerable to adversarial examples, we adopt FGM(Miyato et al., 2017), PGD(Mądry et al., 2017) and FreeLB(Zhu et al., 2019) adversarial training techniques to keep our model tolerant of adversarial examples and more robust. These methods create adversarial examples by adding a small perturbation to input that maximizes the loss. The formulation of adversarial training can be drew below,

$$\min_{\theta} \mathbb{E}_{(x,y)\sim D}\left[\max_{\delta\in S} L(\theta, x+\delta, y)\right] \qquad (1)$$

where δ is a small perturbation. The inner maximization can be solved by projected gradient ascent and the outer minimization can be solved by gradient descent. PGD and FreeLB are the improved version of FGM, both of which are devoted to find a more reasonable perturbation.

3.2.2 Track specific fine-tuning stage

At this stage, we use different methods to fine tune according to the specific track.

Track 9 - Chinese (ZH): Track 9 is devoted to the recognition of Chinese named entities. There are significant differences between Chinese and Indo-European languages like English, German, and Spanish. For example, there is no word boundary in the Chinese lexicon, however Chinese word semantic and boundary information is useful for NER. Therefore, after the fine-tuning at the first stage, we utilize some techniques to improve our model's ability to understand Chinese. In particular, we incorporate LEBERT(Liu et al., 2021) and CoGraph4NER(Sui et al., 2019) into our framework to improve our model's understanding of Chinese lexicon boundaries and semantics. It is worth noting that, we did not directly implement these methods; instead, we drew lessons from the ideas presented in these two papers and appropriately transformed the structures mentioned in these two papers to apply to our system.

LERoBERTa: LERoBERTa is our modified version of LEBERT that integrates lexicon information into the specific layers of the pre-training model to obtain word-related information via a structure called Lexicon Adapter. The specific structure of Lexicon Adapter is shown in Figure 2,

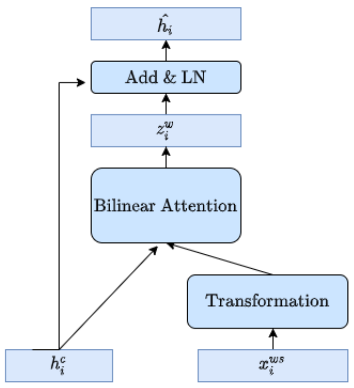

Figure 2: Structure of Lexicon Adapter. This structure pays bilinear attention to characters and vocabulary at the same time, weights vocabulary features into vectors, and then adds them to the input character level vector, and then performs layer normalization.

Because the original LEBERT paper is applied to BERT, it is not consistent with our framework. In order to apply it to our framework, we converted it to LERoBERTa, which differs slightly from LEBERT.

LERoBERTa-GCN4NER: LERoBERTa does not fully utilize the graph relation of containing, transition, and lattice between words and characters because it only integrates information from the bottom encoding layer. An assumption is that the characters in the sentence can capture the boundaries and semantic information of self-matched lexical words using the containing graph (C-graph), the transition graph (T-graph) can assist the character in capturing the semantic information of the nearest contextual lexical words implicitly, and the lattice graph (L-graph) can capture some information of self-matched lexical words explicitly. So, we make some improvements to CoGraph4NER, called GCN4NER, to make full use of the graph relation and thus improve the model's ability to capture Chinese lexicons. GCN4NER is a modified version of CoGraph4NER that replaces the LSTM encoder with LERoBERTa to conform to our algorithm framework and replaces the GAT module with GCN to improve calculation speed. The overall system of LERoBERTa-GCN4NER is shown in Figure 3,

Track 12 - Multilingual: Track 12 focuses on multilingual named entity recognition and the difficulty with this track is that it contains multiple languages, each with its own syntax. So the model

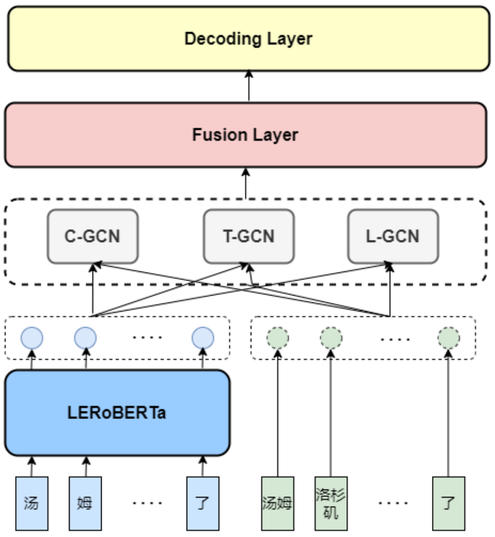

Figure 3: Main architecture of LERoBERTa-GCN4NER. Characters of "Tom left Los Angeles Airport" are encoded by LERoberta and then the hidden vectors and vectors of lexicons are inputted into the GCN module, the outputs of which will then be fused by weighted summation in fusion layer. Finally, the decoding layer assigns a label to each character.

must learn multiple language characteristics concurrently. It is difficult for participants to analyze the model's bad cases because they are not familiar to every language. At this stage, we not only use R-Drop(Wu et al., 2021) but also utilize shared feature extractors and private feature extractors(Chen et al., 2019), considering the fact that there are differences in grammar and common characteristics in semantics of texts in different languages.

R-Drop: Since deep neural networks are very prone to overfitting, the Dropout method randomly discards some neurons in each layer to avoid overfitting during training. Based on this idea, researchers improve dropout method, called R-Drop. Given a training sample $D = \{x_i, y_i\}, i = 1, \cdots, n$, for each sample , it goes through the forward feedback of two different sub-networks to get two predicted probabilities P_1 and P_2. Although the two sub-networks come from the same model, they are not exactly the same because Dropout randomly discards some neurons, and P_1 is not equal to P_2.

Shared Feature Extractor and Private Feature Extractor: We leveraged the ideas of the paper(Chen et al., 2019) and modified the model in combination with datasets offered by the official. With this method, our model can learn general and specific characteristics between different language which may improve model's comprehension.

The shared feature extractor consists of a shared feature learner and a language discriminator. The shared feature learner extracts general features from different languages, and then inputs them into the language discriminator to judge which language these features belongs to. When the language discriminator is unable to determine which language the current text belongs to, it signifies that the shared feature learner has learnt the commonalities between the languages, hence fulfilling the goal of perplexing the language discriminator. There are differences in grammar and meaning of texts in different languages, so the model of this scheme also designs a private feature extractor. The private feature extractor performs feature extraction on the word vector output by backbone encoder, and then outputs it to the multilayer perceptron (MLP) of each language. The MLP of each language extracts the exclusive language features in the text, and then splices the output of each language.

Track 13 - Code-Mixed: Track 13 is a track dedicated to code-mixed data. The prevalence of code-mixed text is fast increasing on social media platforms such as Twitter. The code-mixed task is difficult because it introduces a large number of unseen constructions as a result of merging the lexicon and syntax of two or more languages, and the available data is insufficient in comparison to the other sub-tasks. Therefore, after fine-tuning at the first state, we utilized data augmentation(Dai and Adel, 2020) to supplement the training data in this task. When the labeled datasets are insufficient, data augmentation is a frequently used strategy for enhancing generalization. However, the NER task is concerned with sequence labeling at the token level, and the majority of data augmentation methods at the sentence level may compromise label integrity. We used **Mention replacement (MR)** and **Shuffle within segments (SiS)** techniques to resolve the issue. MR is a data augmentation approach that replaces the position of entities in the original sentence with other entities of the same category while keeping the non-entity part of the sentence unchanged. And SiS is a data enhancement method that keeps the order of words of entities in the original sentence unchanged and disrupts the order of words in the non-entity part.

3.3 Model ensemble stage

Model Ensemble is a method for integrating multiple trained models in order to improve the system's generalization ability in test datasets(Allen-Zhu and Li, 2020). Model ensemble can be achieved in a variety of ways, including voting, averaging, stacking, and confidence blending. Voting is one of them, and it is a simple yet effective method, so we use it in our system. We trained several models for each track based on different hyper parameters and then predicted test datasets to get corresponding results. We then voted for the final result based on these intermediate results.

3.4 Pseudo label fine-tuning stage

Pseudo labelling is a type of semi-supervised learning in which the model trained by labelled data is used to generate pseudo labels for an unlabelled dataset(Lee et al., 2013). We then put both the original labelled dataset and a portion of the unlabelled dataset with pseudo labels into our models for final training during the pseudo label fine-tuning stage. Voting is how we generate pseudo labels. We choose sentences that can be consistently predicted by all models generated in the model ensemble stage as training samples with reasonable pseudo-labels.

4 Experimental setup

In this session, we are going to describe the implementation details of our system.

Dataset and word embeddings: Train and dev datasets we used are provided by official and we don't use test dataset before testing phase because it was not available. Besides, experiments at model ensemble stage and pseudo label fine-tuning stage are carried on test dataset.Since LERoBERTa and GCN4NER techniques require word embedding and considering the lack of embedding of relevant words in the pre-trained model XLM-RoBERTa, we use word embedding sgns.merge.word [†] trained by skip-gram.

Processing and hyper parameters: Limited by the length of the paper, we will only briefly introduce our main processing and part of hyper parameters, with which our system can reach the best result. Learning rate was set to 1×10^{-6}, warming up proportion to 0.06, drop out rate to 0.2, batch size to 32, epoch to 30, random seed to 42 and the number of voting models to 7. Augmentation method for full data fine-tuning stage was **mulsent-uni**, decoder strategy was softmax and adversarial training method was PGD with $\epsilon = 1.0, \alpha = 0.1, K = 3$. For more details, please check the Appendix A. Through out our system we almost only use softmax as our decoder strategy because we have found CRF has no effect on improving the scores compared to softmax but consumes more computing resources and storage space. So, we drop CRF strategy. One plausible explanation for this is that pretrained models have already caught the relations between tokens which may not be well captured by non-pretrained models. We selected the best epoch and the best hyper parameters using performance (measured in terms of macro-f1 score) on corresponding dev dataset.

5 Results

In this section, we will report our main experiment and provide an analysis of the results. Unless otherwise specified, the hyper parameters in our experiments are configured in accordance with Section 3.

Full data fine-tuning stage: Table 1 displays the results of experiments performed with the following parameters: FGM with $\epsilon = 0.8$, PGD with $\epsilon = 1, \alpha = 0.1, K = 3$ and FreeLB with $adv\_lr = 0.3, mag = 0.05, K = 3$. These hyper parameters are the best that we have found.

As we can see from Table 1, three tracks have an improvement in the mulsent-uni data augmentation method where Chinese(ZH) and Multilingual tracks improve nearly 0.5 percent and Mix-Code tack increases 1.2 percent to 77.19. What's more, all adversarial training techniques we employed in our system make a great improvement in Chinese(ZH) and Multilingual track, but nearly have no effect on Mix-Code track. However, when we adopt mulsent-uni and PGD simultaneously, scores are surprisingly high, 88.46 for ZH-Chinese, 86.93 for Multilingual and 78.21 for Mix-Code and this checkpoint is our best checkpoint at full data fine-tuning stage which will continue to be used at track specific fine-tuning stage.

Chinese (ZH) track fine-tuning: As for Chinese (ZH) track, we employ LERoBERTa, GCN4NER and LERoBERTa-GCN4NER for fine-tuning. Table 2 demonstrates that, LEBERT gets the lowest score without our full data fine-tuning stage and our modified version, LERoBERTa,

Table 1: Marco-f1 scores(%) on dev dataset under different methods at full data fine-tuning stage

methods		Chinese(ZH)	Multilingual	Mix-Code
\	\	86.31	85.82	75.93
data augmentation	bisent-uni	86.20	86.02	77.01
	mulsent-uni	86.06	86.06	77.19
	bisent-mix	85.27	86.01	74.67
	mulsent-mix	86.50	85.91	74.43
adversarial training	FGM	86.85	86.85	75.54
	PGD	87.37	86.33	75.96
	FreeLB	86.81	86.14	75.88
methods ensemble	mulsent-uni+PGD	**88.02**	**86.93**	**78.21**

GCN4NER and LERoBERTa-GCN4NER have a positive effect on improving macro-f1 score. We can prove our hypothesis that LERoBERTa only integrates the information of words from the bottom encoding layer, and that it does not make full use of the graph relation of containing, transition, and lattice between words and characters, by observing the differences in results between our modified models. As a result, LERoBERTa just climbs by 0.18 percent. Similar to GCN4NER, it may just consider character graph relationships while ignoring lexical semantic information. So, GCN4NER increases by 0.32 percent. When these two approaches are combined, we discover that LERoBERTa-GCN4NER improves by 1%, giving it the highest score on the dev dataset in our system.

Multilingual track fine-tuning: This experiment continually use the best checkpoint from full data fine-tuning stage . We try R-Drop technique and private feature extractor and shared feature extractor (PFE-SFE) method to improve the performance of our model on this track. In the R-Drop experiment, we use the average method for the KL divergence, and set coefficient parameter α to 0.1 and it obtains a marco-f1 score of 87.15 on the dev dataset which means that this method has a good effect on multilingual tasks. What‘s more, we adopt PFE-SFE method and the marco-f1 score achieve 87.21 in our experiment.

It can be seen from Table 3 that both R-Drop and PFE-SFE have improved macro f1 score compared to the baseline model, R-Drop is 0.22% higher than the baseline, and PFE-SFE is 0.28% higher than the baseline. It can be seen that both methods have certain effects. When we combine R-Drop with PFE-SFE, the macro-f1 value reaches 87.42, which is 0.49% higher than the baseline.

Mix-Code track fine-tuning: As for Mix-Code track, we used mention replacement (MR) and shuffle within segments (SiS) techniques to resolve the insufficiency issue of mix-code data and increase the generalization ability of our model on this track. We not only utilize the parameter setting at full data fine-tuning stage, but also employ the best checkpoint at full data fine-tuning stage.

As shown in Table 4, all of the data augmentation techniques we utilized increase macro-f1 over the baseline value when no augmentation is applied. The MR technique enables the model to get a more accurate representation of entity knowledge and entity boundary information based on external knowledge. Additionally, by changing the order of the sequences, the SiS technique enables the model to learn a more robust position embedding.And the result in bold is our best score on the leaderboard before testing phase.

Model ensemble stage: At this stage, test data is available and we choose the top-7 models based on marco-f1 score under 7 sets of different parameters to vote on the final results. For details, please check the Appendix B. The second row in Table 5 shows the best results predicted singly by our chosen models. As we can see from Table 5, model ensemble has a positive effect. Before the number of models increases to 7, scores increase as the number of models increases but the growth rate slows down which means more models will have little effect even negative effect.

Pseudo labeling fine-tuning stage: After model ensemble stage, we select 7 models with the highest f1 values on the development set to make predictions on the test set, and choose the results that all

Table 2: Marco-f1 scores(%) on dev dataset under different models at Chinese (ZH) track fine-tuning stage

Models	XLM-RoBERTa	LEBERT	LERoBERTa	GCN4NER	LERoBERTa-GCN4NER
Chinese(ZH)	88.46	86.02	88.62	88.78	**89.4**

Table 3: Marco-f1 scores(%) on on dev dataset under different methods at multilingual track fine-tuning stage

methods	\	R-Drop	PFE-SFE	R-Drop+PFE-SFE
Multilingual	86.93	87.15	87.21	**87.42**

Table 4: Marco-F1 scores(%) on dev dataset under different data augmentation strategies at code-mixed fine-tuning stage

Data Augmentation Methods	Mix-Code
\	79.8
Mention replacement (MR)	82.0
Shuffle within segments (SiS)	81.1
MR + SiS	**82.2**

Table 5: Macro-F1 scores(%) on test dataset under different number of models at model ensemble stage(N denotes the number of models)

N	Chinese(ZH)	Multilingual	Mix-Code
1	67.71	73.18	80.32
3	69.42	73.86	82.43
5	**69.73**	**74.32**	**82.75**
7	68.20	73.67	81.53

seven models predict consistently as the pseudo-labeled data and then we put them together with train dataset for fine-tuning at this stage. We continually use the best checkpoint of LERoBERTa-GCN4NER to fine tune on the Chinese(ZH) track and same as the Multilingual track and Code-mixed track. In addition, the hyperparameters remain the same as in the previous phase. The results we obtained are as shown in Table 6. Obvious as the effect is, macro-f1 scores increases 5.22 points on the Chinese(ZH) track, 4.04 points on the Multilingual track and 3.59 points on the Code-mixed track.

Table 6: Macro-F1 scores(%) on test dataset at pseudo labeling fine-tuning stage

pseudo	Chinese(ZH)	Multilingual	Mix-Code
✗	67.71	72.87	80.32
✓	**72.93**	**76.91**	**83.91**

Next, same as model ensemble stage we choose 7 sets of different parameters to train on the pseudo label dataset and get 7 sets of checkpoints. For more details about these models, please check the Appendix A. The results are shown in Table 7. As we can see, the results are similar to those at model ensemble stage. Macro-f1 scores also have an improvement but the increments are less than before.The value in bold is our result in the final ranking.

Table 7: Macro-F1 scores(%) on test dataset under different number of models at pseudo labeling fine-tuning stage (N denotes the number of models)

N	Chinese(ZH)	Multilingual	Mix-Code
1	72.93	76.91	83.91
3	73.60	77.37	84.29
5	**74.00**	**77.66**	**84.35**
7	73.25	77.32	84.02

6 Conclusion

In this paper, we have introduce our system step by step which can be regarded as an universal framework for multilingual NER task. Besides, we proposed a graph-based model to make up for the lack of understanding capacity of Chinese lexicon. Adequate ablation experiments shows that our methods work for this task. In future efforts, we plan to further improve our system to better handle polysemous scenarios.

PAI at SemEval-2022 Task 11: Name Entity Recognition with Contextualized Entity Representations and Robust Loss Functions

Long Ma[*], **Xiaorong Jian**[*],**Xuan Li**
Pingan Life Insurance of China, Ltd
{MALONG633,JIANXIAORONG974,LIXUAN208}@pingan.com.cn

Abstract

This paper describes our system used in the SemEval-2022 Task 11 Multilingual Complex Named Entity Recognition, achieving 3rd for track 1 on the leaderboard. We propose Dictionary-fused BERT, a flexible approach for entity dictionaries integration. The main ideas of our systems are: 1) integrating external knowledge (an entity dictionary) into pre-trained models to obtain contextualized word and entity representations 2) designing a robust loss function leveraging a logit matrix 3) adding an auxiliary task, which is an on-top binary classification to decide whether the token is a mention word or not, makes the main task easier to learn. It is worth noting that our system achieves an F1 of 0.914 in the post-evaluation stage by updating the entity dictionary to the one of Meng et al. (2021), which is higher than the score of 1st on the leaderboard of the evaluation stage.

1 Introduction

Name entity recognition (NER) is a fundamental task in natural language processing. Processing complex and ambiguous Named Entities (NEs) and in low-context situations is a challenging NLP task in practical and open-domain settings, which was recently outlined by Meng et al. (2021). Other work has extended this to multilingual and code-mixed settings (Fetahu et al., 2021) since code-mixed queries, with entities in a different language than the rest of the query, pose a particular challenge in domains like e-commerce (e.g. queries containing movie or product names).

SemEval-2022 task 11 Multilingual Complex Named Entity Recognition (Malmasi et al., 2022b) focuses on dealing with the challenges above: detecting complex entities in short, low-context, and code-mixed settings.

For this task, we propose Dictionary-fused BERT to integrate external dictionaries into the NER model, and it is compatible with emerging entities and user-defined entities, without retraining the model.

2 Related Work

Named Entity Recognition (NER) is a core task in knowledge extraction and is important to various downstream applications such as question answering and dialogue systems. NER is the task of detecting mentions of real-world entities from text and recognizing their types (e.g., locations, persons).

However, the NER task is facing many challenges outlined by Meng et al. (2021), such as short texts like search queries (Wang et al., 2014), emerging entities (Craswell et al., 2020), long-tail entities, complex entities, and entities in code-mixed queries (Fetahu et al., 2021). For example, complex NEs, like the titles of creative works (movie/book/song/software names) are not simple nouns and are harder to recognize. The neural models driven by memorization perform well on "easy" entities (person names) but fail to recognize complex/unseen entities when entities overlap less between train/test sets. A lot of works have been proposed to address the challenges above.

Contextualized Word and Entity Representations There are some works focusing on obtaining good contextual word and entity representations such as KnowBERT (He et al., 2019) and LUKE (Yamada et al., 2020). KnowBERT (He et al., 2019) incorporates knowledge bases into BERT (Devlin et al., 2018) using Knowledge attention and recontextualization, which explores the joint learning of entities and relations. LUKE (Yamada et al., 2020) employs RoBERTa (Delobelle et al., 2020) as the base pre-trained model, trained on a large number of entity-annotated corpora retrieved

[*] The first two authors contributed equally.

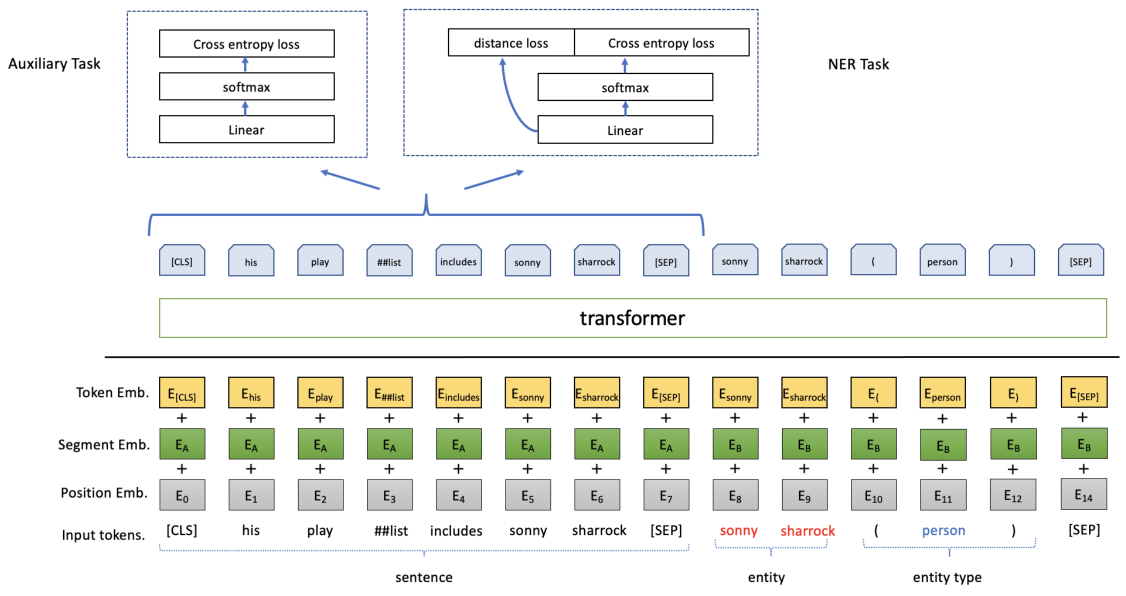

Figure 1: The overall architecture of our proposed system

from Wikipedia. LUKE treats both words and entities as separate tokens and computes the intermediate and output representations of all tokens through the Transformer. Since entities are also used as tokens, LUKE can model the relationship between entities.

Robust Loss Functions Other works like Generalized Cross-Entropy (Zhang and Sabuncu, 2018) and In-trust loss functions (Huang et al., 2021) focus on how to design a robust loss function to solve the NER problem under label noise, which is consistent with complex and ambiguous NER scenarios. Generalized Cross-Entropy (Zhang and Sabuncu, 2018) is actually a new evolutionary form of MAE and CCE, and can be easily applied with the DNN algorithm while yielding good performance in a lot of noisy label scenarios. In-trust loss functions (Huang et al., 2021) combines a CRF loss with a robust Distrust Cross-Entropy term and can effectively alleviate overfitting. What's more, it has been demonstrated that leveraging a logit matrix is an effective way to distinguish noisy samples from difficult samples.

Our proposed model combines the Contextualized-Entity-Representations method and the Robust-Loss-Functions method. Firstly our model incorporates the entity dictionary proposed by LUKE (Yamada et al., 2020) into the BERT-Whole-Word-Masking model and treats entities as separate tokens. Then we design a robust loss function that boosts cross-entropy loss with KL divergence over the logit matrix.

3 Data

We leverage LUKE entity dictionary (Yamada et al., 2020) since our model needs external knowledge. We train and test on MultiCoNER Dataset (Malmasi et al., 2022a).

MultiCoNER.Dataset for the SemEval-2022 Task 11, containing a training set of size 15300, a dev set of size 800, and a test set of size 217818, consisting of 6 entity types: PERSON (PER for short, names of people), LOCATION (LOC, locations/physical facilities), CORPORATION (CORP, corporations and businesses), GROUPS (GRP, all other groups), PRODUCT (PROD, consumer products), and CREATIVE-WORK (CW, movie/song/book/etc. titles). All data are uncased.

LUKE Entity Dictionary consists of 500k entities retrieved from English Wikipedia data.

4 Methodology

We propose Dictionary-fused BERT, which adopts a multi-layer bidirectional transformer (Vaswani et al., 2017) and has the ability to encode not only words of the sentence but also information of matched entities. We experiment with Transformer-

Preained-model	**dev f1**
BERT$_{base}$	0.854
BERT$_{large}$	0.871
RoBERTa$_{base}$	0.836
RoBERTa$_{large}$	0.877
DistilBERT$_{base}$	0.835
BERT-WWM$_{large}$	**0.883**
LUKE$_{base}$	0.856
LUKE$_{large}$	0.878

Table 1: Dev f1 score of different Transformer-based models.

based models which produce contextualized word representations. The overall architecture is shown in Figure 1, the components are detailed below.

4.1 Contextualized Word and Entity Representation

Entity representations are obtained in two steps: entity matching and contextual encoding.

Dictionary Entity Matching We denote the input sentence as $(w_1, w_2..., w_n)$, where w_i is the i-th word and n is the Length. Full string matching is used to match all entities in the input sentence and we choose the longer one while dealing with overlapping matches. $(m_1, m_2, ..., m_L)$ represents the matched entities where $m_j = (w_i, w_{i+1}.., w_{i+k})$ and L is the number of matched entities.

Contextual Encoding The input tokens consist of two segments: words of the sentence and matched entities including the entity itself and entity type. The two parts are separated by a special token [SEP] and different entities are separated by the token $. Then they are fed together into the encoder to get the contextualized representations as LUKE(Yamada et al., 2020) does.

4.2 On-top Binary Classification Task

On-top binary classifier (adding a binary classifier on the top of the encoder) is an auxiliary task to detect entity mention words of the input sentence and helps increase accuracy. For example, the target output of the auxiliary task is represented as $y_{aux} = (0, 0, 0, 1, 0, 0, 1, 1)$ whereas the NER task's is $y_{ner} = (O, O, O, B-CW, O, O, B-PER, I-PER)$ when the input sentence is "adaptation of the manga series by chiho saito".

4.3 Loss Function

As is shown in the Figure 1, the loss is divided into two parts: the cross-entropy loss of the auxiliary task ($L_{CE-auxiliaty-task}$) and the loss of the NER task that consists of the final cross-entropy loss (L_{CE}) and KL divergence loss over the logit matrix (L_{logit}).

4.3.1 Loss over Logit Matrix

The logit matrix is the output of models in the training process, which goes through the softmax layer and then gets into the final loss function. Huang et al. (2021) has demonstrated the use of logit matrix to distinguish noisy samples from difficult samples to prevent overfitting, which we use here to distinguish tag pairs such as (CW, PROD) and (CORP, GRP) pairs that are easily confused with each other by baseline model. These samples are shown below.

* {they have been used experimentally in [gyrobus]{PROD}{CW}}. In this sample, [gyrobus] is a product (PROD) but is mispredicted as a creativework (CW).

* {cockpit concept, developed by [astion martin racing]{GRP}{CORP}}. [astion martin racing] is a group (GRP) but mispredicted as a corporation (CORP).

We denote the logit matrix as $[Z_{ij}]^{N \times M}$ where N is the length of input tokens and M is the number of tags. The loss over logit matrix can be represented as $L_{logit} = -(KLdiv(z_{CW}, z_{PROD}) + KLdiv(z_{GRP}, z_{CORP}))$ where z_{CW}, z_{PROD}, z_{GRP} and z_{CORP} are column vectors corresponding to tag CW, tag PROD, tag GRP and tag CORP in the logit matrix and $KLdiv$ is the Kullback-Leibler divergence loss function. The negative signal $(-)$ indicates that the larger distance between tag pairs the better.

4.3.2 Forming Total Loss

The total loss can be represented as

$$L_{total} = \alpha \cdot L_{CE-auxiliaty-task} + \beta \cdot (L_{CE} + L_{logit})$$

where α and β are two decoupled hyper parameters, α regulates the recall issue while β aims to flexibly explore the robustness of L_{logit}.

	settings	dev f1
baseline	BERT-WWM	0.883
	BERT-WWM$_{entity}$	0.90
ours	BERT-WWM$_{entity}$+auxiliary task	0.904
	BERT-WWM$_{entity}$+auxiliary task+L_{logit}	**0.913**

Table 2: results of ablation experiments

dictionary settings	dev f1	test f1
LUKE (Yamada et al., 2020)'s	0.913	0.784
GEMNET (Meng et al., 2021)'s	0.945	0.914

Table 3: performance of our model with injecting different entity dictionaries

5 Results

In this section, we verify the advantages of our system. On the one hand, we select the pre-trained BERT-Whole-Word-Masking model (BERT-WMM) (Liu et al., 2020) as our baseline model by comparing five different kinds of Transformer-based models. On the other hand, we analyze the effects of the way injecting an entity dictionary, adding an auxiliary task, and the loss function leveraging the logit matrix.

5.1 Baseline Experiments

The baseline performance of BERT (Devlin et al., 2018), BERT-WMM (Liu et al., 2020), DistilBERT (Sanh et al., 2019), RoBERTa (Delobelle et al., 2020) and LUKE(Yamada et al., 2020) is tested by directly fine-tuning the MultiCoNER data(Malmasi et al., 2022a) on the pre-trained LMs. All models are uncased. The results are shown in Table 1. BERT-WWM outperforms the others by 1 to 5 percentage points, so we choose BERT-WWM as our encoder. It may be due to the whole-word-masking mechanism adopted by BERT-WMM. Most hyperparameters are set as before, especially the learning rate is 2e-5, the batch size is 32, max sequence length is 100, max epochs is 20. All the performance data is on the development set.

5.2 Ablation Experiments

Results of ablation experiments are shown in Table 2. Our model Dictionary-fused BERT is represented as BERT-WWM$_{entity}$ + auxiliary task + L_{logit} and achieves an F1 of 0.913 on dev set when integrating LUKE entity dictionary into the model .

Effect of Integrating Entity Dictionaries As Malmasi et al. (2022b) says the MultiCoNER task aims to recognize entities in open-world settings that entities with tag CW and PROD try to mimic, which reminds us of levering external knowledge to deal with such issues. We treat sentence words and matched entities which are obtained by matching the LUKE entity dictionary and the original sentence as separated tokens like Yamada et al. (2020) does. This experiment is called BERT-WWM$_{entity}$ and improves by 1.7% over the no-entity BERT-WWM baseline.

Effect of Auxiliary Task We also explore Multi-Task learning by conducting the experiment of adding a binary classifier on top of the encoder, which predicts whether the token is a mention word or not. The auxiliary task is intended to increase the overall recall of mentions, which indeed brings a tiny improvement by 0.4% over BERT-WWM$_{entity}$.

Effect of L_{logit} As mentioned in the previous chapter, we propose L_{logit} using the logit matrix to distinguish some entities due to they are easily confused with each other. The total loss function boosting with L_{logit} improves by 0.9% . Finally, our model achieves 0.913 F1 on the dev set.

5.3 Evaluation Results

In the stage of evaluation, in order to fully utilize the training and dev sets, we corporate 10-fold cross-validation training trick and ensemble ten results to obtain the final one. Concretely, we divide the origin training and dev sets into 10 mutually exclusive subsets of the same size. Each time the union of 9 subsets is treated as the training set while the remaining subset is treated as the dev set. We do training and predicting 10 times to get 10 models and 10 results of the test set. The final result is a weighted vote of 10 results, where the weight is the F1 score of each label of each model.

We also compare the performance of our model injecting different entity dictionaries on dev and test sets. We incorporate the LUKE entity dictionary into our model in the evaluation stage. In the post-evaluation stage, by updating LUKE(Yamada et al., 2020) entity dictionary to the one of Meng et al. (2021), our system achieves an F1 of 0.914, which is higher than the score of 1st on the leaderboard of the evaluation stage. Results are shown in Table 3.

6 Conclusion

In this paper, we focused on how to integrate external dictionaries into NER models to deal with NER challenges in open-world settings and design a robust loss function to prevent overfitting. We proposed Dictionary-fused BERT, a flexible and simple approach that includes a contextualized entity representation encoder and a robust loss function leveraging a logit matrix. More importantly, our approach can infuse entity dictionaries into any Transformer-based pre-trained models and is compatible with any emerging entities and user-defined entities without retraining the model.

Although we have already succeeded in injecting entity information into Transformer-based models, entity spans are implicitly informed through a special token $. In the future, we will attempt to explore other ways to explicitly encode entity span information.

SemEval 2022 Task 12: Symlink
Linking Mathematical Symbols to their Descriptions

Abstract

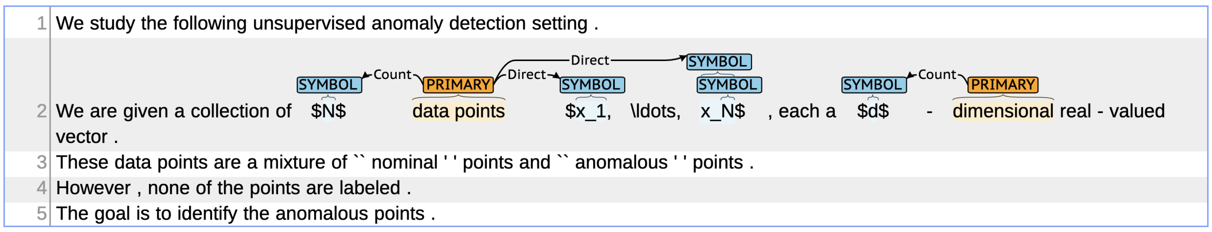
We describe Symlink, a SemEval shared task of extracting mathematical symbols and their descriptions from LaTeX source of scientific documents. This is a new task in SemEval 2022, which attracted 180 individual registrations and 59 final submissions from 7 participant teams. We expect the data developed for this task and the findings reported to be valuable for the scientific knowledge extraction and automated knowledge base construction communities. The data used in this task is publicly accessible at https://github.com/nlp-uoregon/symlink.

1 Introduction

The exponential growth of published articles may exceeds many readers' ability to keep track of the development of their field of interest. Hence, automatic reading comprehension of scientific documents has attracted the attention of researchers across various domains such as Drug Discovery, Knowledge Base Construction, and Natural Language Processing. A crucial aspect of understanding scientific literature is understanding terminologies and formulae because they offer an explicit and precise interface to present the relation between scientific concepts (Schubotz et al., 2018). As such, a reading comprehension machine needs to (i) identify their descriptions and formulae, (ii) segment them into primitive terms and symbols, and (iii) link the associated terms and corresponding symbols.

Working with mathematical formulae is arduous due to two fundamental reasons. First, common text encodings such as ASCII and Unicode do not fully support typing mathematical symbols. As a result, complex mathematical formulae are rarely written using either ASCII or Unicode. Rather, a higher level encoding (or typesetting) is often used to encode the content of scientific documents, in particular LaTeX. Second, most scientific documents are stored in one of two forms: photos or Portable Document Format (PDF). Scientific documents that were published prior to the graphical computer era are printed and now scanned and distributed as photos. Nowadays, scientific documents are often composed in some text editors or word processing software, then exported and shared a PDF file. Unfortunately, analyzing textual information in photo images or PDF files is extremely difficult, and most of the natural language processing tools are not developed to handle this format. As such, to facilitate the understanding of scientific literature, documents should be stored using a universal easy-to-process text-like encoding. In this paper, we use LaTeX as the typesetting to facilitate document analysis. Thanks to recent advances in text processing and image recognition, a LaTeX document can often be restored to some extent from either a photo or a PDF file (Deng et al., 2017).

This paper introduces the Symlink shared task for the extraction of mathematical symbols and their descriptions from English scientific documents using their LaTeX source. Figure 1 visualizes an example of the task. This paper also presents an analysis of the results of participant systems on the task. The rest of the paper is organized as follows. Section 2 presents related work in extracting formulae and their related information from scientific documents. Section 3 describes the subtasks of this Symlink shared task. Section 4 presents the data creation process including data sources, preprocessing, annotation guidelines, annotation, and data format. An analysis of the created data set is provided in Section 5. The evaluation method is presented in Section 6, while the descriptions of the submitted systems are presented in Section 7.



1 We study the following unsupervised anomaly detection setting .
2 We are given a collection of N data points $x_1, \ldots, x_N$, each a d - dimensional real - valued vector .
3 These data points are a mixture of `` nominal ' ' points and `` anomalous ' ' points .
4 However , none of the points are labeled .
5 The goal is to identify the anomalous points .

Figure 1: Example of the Symlink tasks.

2 Related Work

Early studies for scientific literature link formulae to Wikipedia page (Nghiem Quoc et al., 2010; Kristianto et al., 2016). Even though this can provide additional information regarding the mathematical expression, a reader might find it harder to understand the Wikipedia page as it is presented in many unrelated forms. Linking to the description in the same document is more practical (Kristianto et al., 2014; Alexeeva et al., 2020) as the descriptions are dedicated to the symbols and the context presented in the document.

Previous studies on symbol-description extraction rely on pattern matching (Yokoi et al., 2011; Nghiem Quoc et al., 2010) and rule-based algorithms (Alexeeva et al., 2020). These methods might work for observed patterns with an assumption of close proximity between symbol and description. They may fail to capture distant symbol-description pairs and symbols in very complex structures such as algorithms in computer science literature.

Most of the previous studies have attempted to extract and link at formula level (Nghiem Quoc et al., 2010; Kristianto et al., 2014, 2016). In reality, understanding mathematical formulae requires details of atomic symbols e.g. superscript, subscript, function arguments. We believe that addressing the problem at this fine-grain level is crucial to drive future research toward a better understanding of the complex symbol-description extraction task.

Prior to this shared task, some studies have created datasets for similar tasks (Yokoi et al., 2011; Schubotz et al., 2016; Alexeeva et al., 2020). However, one of them is created for publications written in Japanese (Yokoi et al., 2011), making it nearly impossible to transfer to English literature. While two other datasets (Schubotz et al., 2016; Alexeeva et al., 2020) only annotate small-scale golden datasets for evaluation purposes. As the result, no training data is available for training deep neural network models. In this shared task, we provide a large-scale dataset for English literature that we believe will provide enough supervision for the promising deep neural network-based models.

Definition extraction from scientific document is close to the task presented in SemEval Task 12. The Scientific Document Understanding workshop has hosted the Acronym Extraction and Acronym Disambiguation Shared Tasks, namely *Acronym Extraction and Acronym Disambiguation Shared Tasks*(Veyseh et al., 2021a, 2022). The prior studies in this research direction considers extracting definitions from the text (Spala et al., 2019, 2020; Veyseh et al., 2020), or together with acronyms, and acronyms sense disambiguation (Pouran Ben Veyseh et al., 2020, 2021).

3 Task Description

The ultimate goal of Symlink shared task is to extract pairs of mathematical symbols and descriptions from scientific documents. As such, Symlink shared task is a combination of an entity recognition and an entity linking task.

Given a LaTeX source of a paragraph from a scientific document:

- **Named Entity Recognition:** For each paragraph, identify all spans containing mathematical symbols and terminology descriptions.
- **Relation Extraction:** For each pair of entities, identify the relationships between them if it is available among symbols and descriptions using Coref-Description, Coref-Symbol, Direct, Count relation types.

4 Data Annotation

4.1 Data source

We obtain the documents from `arXiv.org`, a repository for preprint scientific articles due to the broad coverage of subjects in scientific articles published in ArXiv. In particular, ArXiv offers articles in physics, mathematics, quantitative biology, computer science, quantitative finance, statistics, electrical engineering, and economics. As such, our obtained papers contain a large number of mathematical symbols and equations, allowing a higher yield of extracted symbol-description relations. Among these subjects, we choose five subjects of mathematics, physics, biology, economics, and computer science for annotation.

4.2 Data preparation

ArXiv open-sources the LaTeX version of their articles, when available. In order to make our Symlink dataset open-access to the whole community, we crawled the metadata of these articles and only selected articles under the CC BY license. Once obtained the LaTeX project, we extracted all the paragraphs from the **.tex** files. We filtered out all short paragraphs with less than 50 words and paragraphs without symbols. Since a formula can be composed in multiple ways such as inline formulae (between \$ \$), displayed formulae (between \$\$ \$\$), or using commands e.g. *array*, to keep the original TeX format of the formulae, all of these math objects are masked before tokenization. Then, we used the SciBERT tokenizer (Beltagy et al., 2019) to tokenize the text. The original math object is then restored. As we observed that many papers have nested math objects, we deleted all the nested objects, hence, having non-nested LaTeX data. This is helpful as it makes the LaTeX documents more similar to the ones generated by the PDF-to-LaTeX tools, which do not contain nested objects.

4.3 Taxonomy

To prepare for the annotation, we designed a taxonomy with 3 general entity types and four relation types. In particular, mathematical symbols are annotated under the tag **SYMBOL**, whereas descriptions are tagged under two labels **PRIMARY**, for single standalone definitions, and **ORDERED**, for the description of multiple terms, whose mentions are not separated without creating non-contiguous mentions. Due to the quadratic numbers of combinations of descriptions and complex math expressions, we only tagged an entity if and only if there is a second entity that pairs with the first entity to form a relationship. For relation, we are particularly interested in two main types of relations: **DIRECT**, linking a symbol with its definition, and **COUNT**, linking a description of a concept with a symbol that is the number of instances of the concept. Due to the sheer number of repetitions and coreferences of both descriptions and symbols, we also annotated **COREF-SYMBOL** relation, linking co-referred symbols, and **COREF-DESCRIPTION** relation, linking co-referred descriptions. Detailed annotation guidelines with examples are presented in Appendix A.

4.4 Annotation

We recruited 10 annotators from the crowdsourcing platform `upwork.com` to annotate scientific papers in the five mentioned domains (each subject was annotated by two annotators). The annotators are explicitly selected based on their demonstrated experiences in reading and writing scientific documents in their expertise field(e.g., holding an M.S. or Ph.D. degree). Detailed annotation guidelines with many examples and explanations are provided to train the annotators. Overall, we annotated 102 papers, accounting for 3,690 paragraphs, and 595K tokens. Our annotators for each domain co-annotate the documents in their domain and achieve Cohen's Kappa scores of (averaged) 0.79. This inter-agreement score thus indicates substantial agreements between our annotators. Eventually, the annotators engage in discussions to resolve any conflict to produce a final consolidated version of our Symlink dataset.

4.5 Data Format

The participants are provided with preprocessed in JSON format. Each paragraph is stored in a JSON object with its id, topic, original LaTeX source, set of entities, and set of relations. An example of the data object is presented in Figure 2.

5 Data Analysis

Table 1 presents the statistics for the dataset including the number of articles, distribution of entities, and distribution of the relations. Overall, our dataset offers more than 31K entities, 20K pairs of relations, which is one order of magnitude larger than existing datasets for a similar task.

Figure 3 presents the distribution of the span lengths of both symbols and descriptions of up to 15 tokens. As can be seen from the figure, the majority of entities have a length of 1-3 tokens. However, overall, the span lengths of both symbols and descriptions vary significantly from 1 up to 47 tokens (note that Figure 3 only illustrates the spans

Figure 2: An example of a paragraph in Symlink dataset.

with up to 15 tokens). This demonstrates a key challenge of the Symbol-Description Linking task in this paper where symbols and descriptions with long spans might introduce confusion for extraction models.

To further understand the dataset, we present the distances between the entities and relations annotated in Symlink by different relation types in Figure 4. The distributions can be grouped into two categories. The first category involves the symbol-description relations while the second group involves the coreference relations. The distributions of symbol-description relations have long tails, indicating that symbols and descriptions tend to appear in close proximity. On the other hand, the distributions of coreference relations are quite flat, suggesting that the coreference relations appear in both short and long distances.

6 Evaluation

The results are evaluated separately for the Named Entity Recognition (NER) task and the Relation Extraction (RE) task. For NER, we use the entity-based partial/type from SemEval 2013 Task 9.1. For RE, we use standard precision, recall, F-score metrics. Relations output by the participating system is correct if the prediction label strictly matches the gold standard.

During the 21-day evaluation period (January 10 through 31, 2022), 7 CodaLab users submitted a total of 59 submissions with 37 submissions passing the validation and being scored. Given the complexity of the task, we allow unlimited submissions

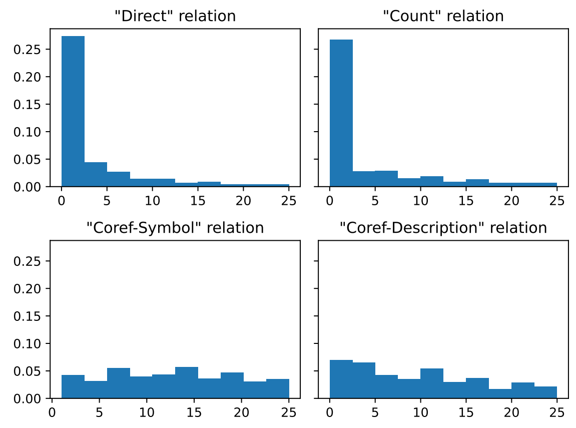

Figure 4: Distribution of distances between entities in Symlink by relation type.

during the evaluation. As such the top submitter tried up to 18 times.

Table 2 shows the performances of the successful submissions. Asterisk denotes teams with system descriptions submitted for review. Among the participated teams, 6 teams performs both Named Entity Recognition and Relation Extraction subtasks while one team tried the Named Entity Recognition subtask only. Figure 5 presents the timelines of submissions and high scores over the evaluation period.

7 Summary of Participating Systems

The Symlink track at SemEval-2022 received 4 system description paper submissions presented in Table 2. Overall, all submitted systems are based on BERT architecture (Devlin et al., 2019). Among those, two out of four systems use SciBERT (Beltagy et al., 2019), while two remaining systems use other variants of BERT such as original BERT (Devlin et al., 2019) and mBERT (Devlin et al., 2019).

7.1 System Specifics

Lee and Na (2022) (JBNU-CCLab) achieved their state-of-the-art performance using SciBERT (Beltagy et al., 2019). Their entity model consists of an MRC-based model (Li et al., 2020), simplifying the tasks as binary classification problems whether span is valid using entity type information as input features. They proposed a simple rule-based Symbol Tokenizer to predict accurately the complex symbols appearing in scientific documents. The relation model exploits entity span information and entity type information as input features using typed entity marker. Additionally, the paper exploited many regularization techniques to improve the model performance such as regularized dropout (Wu et al., 2021) and representational collapse prevention (Aghajanyan et al., 2020) and traditional ensemble techniques.

Popovic and Laurito (2022) (AIFB-WebScience) proposed an end-to-end joint entity and relation extraction approach based on transformer-based language models. Unlike traditional entity and relation extraction methods, which perform the task in sequence, this system incorporates information from relation extraction into entity extraction. As such, the system can be trained even on partially annotated datasets where only a subset of all valid entity spans is annotated.

Ping and Chi (2022) (AN(L)P) participated in the Entity Extraction only. They finetuned a BERT-large model (Devlin et al., 2019) for each domain. For cs.ai domain, they used data from cs.ai only, whereas, for the other domain, they augmented the in-domain data with the data from cs.ai.

der Goot (2022) (MaChAmp) proposed to pretrain a language model and re-finetune after multitask learning for a pre-defined set of semantically focused NLP tasks. They trained a multi-task model for all text-based SemEval tasks that include annotation on the word, sentence, or paragraph level. They compared the performance with models using mBERT (Devlin et al., 2019). The pretrained multi-task embedding showed a consistent improvement across many tasks against the mBERT embedding.

7.2 Symbol tokenizer and detection

In this shared task, the uniqueness of the task is detecting mathematical symbol span. Symbol span in LaTeX source is comprised of both human language and machine language, i.e. LaTeX language. Further, mathematical formulae in LaTeX sources are written in both linear and hierarchical manners. Therefore, a system must consider not only human language modeling but also a highly systematic syntax system of LaTeX source. As such, fundamental tasks such as tokenization is a huge contributor to the robustness of the model.

Among four submitted systems, MaChAmp (der Goot, 2022) and AN(L)P (Ping and Chi, 2022) teams used the default tokenizer from either BERT or mBERT, which are not designed for scientific documents. Consequently, they are unable to correctly segment the mathematic source, hence, they

	Multi RemBERT	25.17	25.25	13.11	5.17	7.42
iyerke	-	6.67	6.46	0.10	0.62	0.17
AN(L)P*	-	-	16.30	-	-	-

achieved the lowest Named Entity Recognition performance. Whereas AIFB-WebScience (Popovic and Laurito, 2022) and JBNU-CCLab (Lee and Na, 2022) achieved much higher performances thanks to SciBERT tokenizer because it is trained on scientific literature. However, the SciBERT tokenizer is far from perfect such that JBNU-CCLab further proposed to tokenize the mathematical formulae using a customized rule-based tokenizer based on capital letters, numbers, and special characters(e.g. %, \$, {, }). Hence, they achieved state-of-the-art performance on both NER and RE subtasks.

8 Conclusion

In this paper, we present the task description, the data annotation, the evaluation, the results, and the descriptions of four submitted systems for Symlink at SemEval 2022. The Symlink shared task is challenging given the complexity of the LaTeX source and partly due to the difference of the domains involved in the data. In this shared task, it is hard to separate the NER and RE subtasks due to their constraints.

The submitted systems employed variants of contextualized embedding BERT for encoding the text. In general, the task can be formatted into similar sequence labeling and relation extraction task. However, special treatments are needed to process LaTeX sources. For instance, a LaTeX-source-trained tokenizer or a customized tokenizer is essential to tokenize the text. Some unique characteristics of the dataset have not been investigated such as the syntax of the LaTeX source, and the hierarchical structure of formulae. These suggest future research directions to improve the robustness of the model.

A Annotation guidelines

This section summarizes some rules that we use to make our annotations more consistent.

Description tagging: A description is usually a noun or a noun phrase that expresses a concept. These are the overall rules for entity annotations:

- We only tag a description if the corresponding symbol presents in the text.
- A description usually is a noun or a noun phrase. Sometimes, a verb, an adverb, or an adjective describes an operation, it is also considered a description.
- Descriptions should be short but it must cover the elements in the corresponding symbol, esp. in case of complex symbols, such as superscript, subscript, arguments, and limits.

Symbol tagging: A mathematical symbol can present an operand, an operator, an expression, or combination of these.

- An atomic symbol in PDF format has to be a character, that means, if we have Y hat, neither Y nor hat is considered an atomic symbol, instead "Y hat" is a symbol. In latex format, \hat{Y} should be annotated.
- A complex symbol is a combination of multiple symbols and brackets, for example: "P(x)", "Wx"
- An annotated symbol has to be a complete symbol e.g. "P(x)" is good, "P(x" is not because of lacking the closing parenthesis.
- A complex formula can be segmented into atomic symbols, we will annotate at all levels of the complex symbol as long as there are appropriate descriptions available.

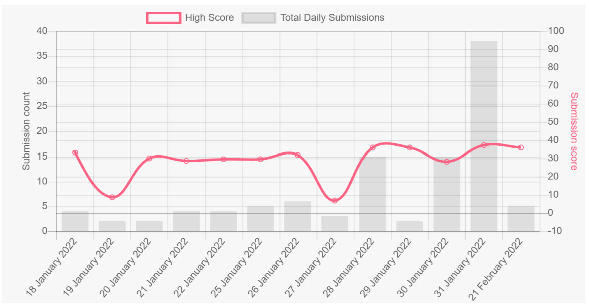

Figure 5: Submission counts and top performances during the evaluation period. The submission score is the F1-score of the RE task.

Relation annotation:

- Every annotated symbol/description has to have at least one relation linking to its description/symbol.
- If there are multiple mentions of a single symbol/description, use coreference relation to link them. A direct relation or a count relation is used to link the closet pair of symbol and description.

B Timeline of submissions

Figure 5 presents the number of submissions over the evaluation of the task.

JBNU-CCLab at SemEval-2022 Task 12: Machine Reading Comprehension and Span Pair Classification for Linking Mathematical Symbols to Their Descriptions

Sung-Min Lee and **Seung-Hoon Na**
Division of Computer Science and Engineering, Jeonbuk National University, South Korea

Abstract

This paper describes our system in the SemEval-2022 Task 12: 'linking mathematical symbols to their descriptions', achieving first on the leaderboard for all the subtasks comprising named entity extraction (NER) and relation extraction (RE). Our system is a two-stage pipeline model based on SciBERT that detects symbols, descriptions, and their relationships in scientific documents. The system consists of 1) machine reading comprehension(MRC)-based NER model, where each entity type is represented as a question and its entity mention span is extracted as an answer using an MRC model, and 2) span pair classification for RE, where two entity mentions and their type markers are encoded into span representations that are then fed to a Softmax classifier. In addition, we deploy a rule-based *symbol tokenizer* to improve the detection of the exact boundary of symbol entities. Regularization and ensemble methods are further explored to improve the RE model. [1]

1 Introduction

Mathematical symbols and descriptions appear in various forms across document section boundaries without explicit markups, and mathematical symbols appear in the form of long texts. Thus, linking mathematical symbols and their descriptions is challenging.

SemEval 2022 task 12: 'linking mathematical symbols to their descriptions (Lai et al., 2022a)', is a relation extraction task targeted at scientific documents divided into two sub-tasks: sub-task A is a **named entity recognition** (**NER**) task that aims to predict the span of symbols and descriptions, and sub-task B is a **relation extraction** (**RE**) task that aims to predict relations between symbols and descriptions.

[1]Our code is publicly available at `https://github.com/ZIZUN/symlink`.

Extracting these entities and relations is done to discover relational facts from unstructured texts. This problem can be decomposed into NER (Tjong Kim Sang and De Meulder, 2003; Ratinov and Roth, 2009) and RE (Zelenko et al., 2002; Bunescu and Mooney, 2005). Early works employed a two-stage relation extraction system, training one model to extract entities (Florian et al., 2004) and another model to classify relations between these entities (Zhou et al., 2005; Chan and Roth, 2011). To reduce the error propagation of NER or better capture the interactions between NER and RE, joint models have been proposed as a promising approach that are based on an end-to-end method or on the setting of multi-task learning using shared representations (Wadden et al., 2019; Lin et al., 2020; Wang and Lu, 2020).

Recently, it has been observed that RE based on the shared encoder is suboptimal, but the use of separated encoders for NER and RE has shown improved performance compared to shared encoders, reexamining the effectiveness of the simple pipelined two-stage approach (Zhong and Chen, 2021; Ye et al., 2021). From these results, we hypothesize that whereas separated encoders for NER and RE can learn customized representations useful for each task, joint models may include irrelevant information in the learned representation for NER or RE tasks, lowering the performance of the model.

These results of using distinct encoders (Zhong and Chen, 2021) encourage us to adopt the aforementioned two-stage approach for NER and RE tasks, consisting of 1) MRC-based NER and 2) span pair classification for RE, as follows:

1. **MRC-based NER using a symbol tokenizer**: Unlike the PURE system of (Zhong and Chen, 2021) that exploits the standard span-based NER of (Lee et al., 2017; Wadden et al., 2019), our NER model is based on an MRC-based model (Li et al., 2020), which treats NER as

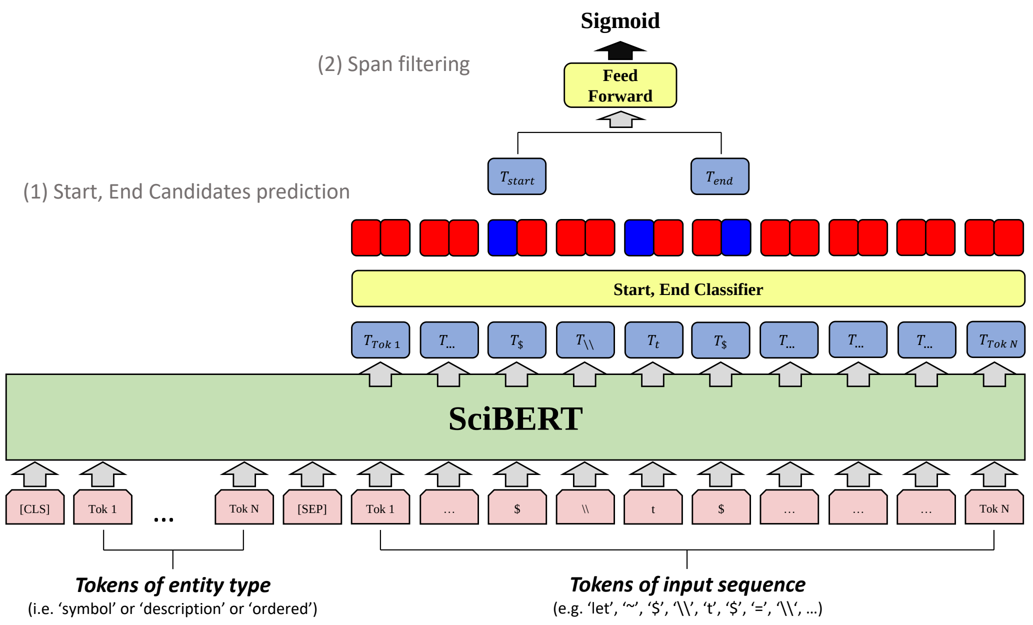

Figure 1: Our NER model architecture based on MRC

an MRC problem by providing an entity type as a question and using an MRC model to extract its entity mentions as answers. As in (Li et al., 2020), an MRC model is based on two binary classification models: first, the position classifier predicts the start and end indexes to create a set of valid answer spans, second, the span classifier determines whether each of the valid spans is an answer. As a pretrained encoder for the NER model, SciBERT of (Beltagy et al., 2019) is used. Before presenting to SciBERT's tokenizer, we apply a rule-based *symbol tokenizer* to precisely predict the span boundary of mathematical symbols that appear in scientific documents,

2. **Span pair classification for RE with solid markers**: Similar to the PURE system of (Zhong and Chen, 2021), a pair of spans resulting from the NER model is given as an input but with *solid markers*, i.e., using a typed entity marker, as in the works of (Wu and He, 2019; Zhou and Chen, 2021). The SciBERT encoder then uses this marked input to generate contextualized representations, which are then transformed to a pair of span representations and fed into a Softmax classifier. To define a set of relation types (or classes), the RE model explicitly adds a *NIL*-type class as a relation type to refer to the case in which a pair of spans has no relationship. It should be noted that the NER model's symbol tokenizer is not used in the RE model. Regularization methods such as *RDrop* (Wu et al., 2021) and *R3F* (Aghajanyan et al., 2020), as well as traditional ensemble techniques, are used to improve the performance of RE models[2].

The remainder of this paper is organized as follows: Section 2 presents our system architecture in detail, Sections 3-5 describe the experimental setting, results, and ablation studies, and Section 6 contains our concluding remarks and future works.

2 System Overview

In this section, we first describe the models of the proposed system for each sub-task.

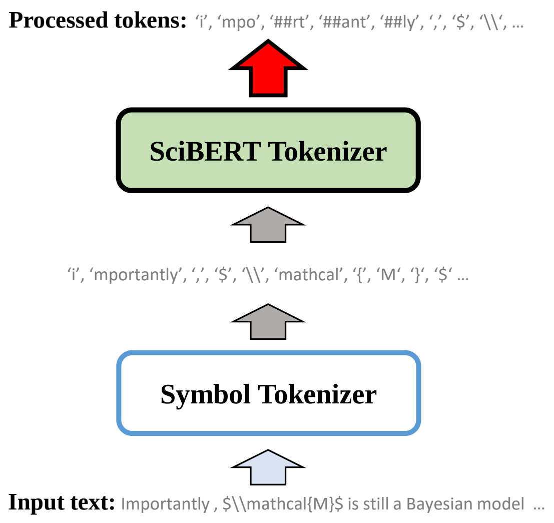
2.1 MRC-based NER with a symbol tokenizer

Figure 1 shows our MRC-based NER model, that extracts mathematical symbols and descriptions from scientific documents.

2.1.1 Symbol tokenizer as a pre-tokenizer

We discovered in our preliminary experiment that SciBERT's tokenizer is not optimal for extracting the boundaries of mathematical symbols, because non-alphanumeric characters are important in the mentions of symbol-type entities. We perform a

[2]Regularization and ensemble methods were not adopted in the NER model.



Processed tokens: ‘i’, ‘mpo’, ‘##rt’, ‘##ant’, ‘##ly’, ‘,’, ‘$’, ‘\\’, ...
SciBERT Tokenizer

Figure 2: Two-step tokenization process for NER model with a symbol tokenizer

rule-based *symbol tokenizer* as a pre-tokenizer before applying SciBERT's tokenizer to precisely detect the boundary of symbol-type entities. Figure 2 presents this two-step tokenization adopted for the NER model.

The symbol tokenizer seperates mathematical symbols based on capital letters, numbers, and special characters (e.g., %, \$, }, {). Our symbol tokenizer's rules are derived heuristically from a training dataset[3].

2.1.2 MRC models for nested NER

Given that the dataset addresses nested entities, we use the MRC model of (Li et al., 2020), that takes a *question-augmented* input. Specifically, suppose that $X = [x_1, \cdots, x_n]$ is a sequence of tokens in a scientific document, where n is the length of the sequence. Given a target entity type t, its natural language form $Q_t = [q_1, \cdots, q_m]$ is provided as a question based on Table 1, where q_i is the i-th token of Q_t and m is the length of the question. The question-augmented input X' is formulated as follows:

$$X' = \text{[CLS]}, q_1, \cdots, q_m, \text{[SEP]}, x_1, \cdots, x_n$$

Type	Text
SYMBOL	symbol
PRIMARY	description
ORDERED	ordered

Table 1: Natural language forms mapped for entity types

[3]This rule-based symbol tokenizer is also included in our codes.

Then, as a pre-trained language model, we apply SciBERT's encoder trained from scientific domain documents to obtain contextualized representations $T \in \mathbb{R}^{n\times d}$ over n tokens in a given document X, where d is the dimensionality of SciBERT's hidden representation.

The NER model predicts the probability of each token being a start or end index as follows:

$$\begin{aligned} P_{start} &= Sigmoid(FFN^{(start)}(T)) \in \mathbb{R}^n \\ P_{end} &= Sigmoid(FFN^{(end)}(T)) \in \mathbb{R}^n \end{aligned} \tag{1}$$

where $FFN^{(start)}$ ($FFN^{(end)}$) is a feed-forward neural network layer for predicting the start position and P_{start} (P_{end}) represents the probability of each index being the start (end) position of an entity, given a question entity type.

Based on Eq. (9), we obtain sets of predicted start and end indices as follows:

$$\begin{aligned} I_{start} &= \left\{ i \middle| \mathbb{1}(P^{(i)}_{start} > 0) \right\} \\ I_{end} &= \left\{ i \middle| \mathbb{1}(P^{(i)}_{end} > 0) \right\} \end{aligned} \tag{2}$$

where $P^{(i)}_{start}$ ($P^{(i)}_{end}$) is the i-th element of P^{start} (P^{end}) and $\mathbb{1}$ is an indicator function that gives 1 if an element is true, and 0 otherwise.

For any start index $i_{start} \in I_{start}$ and $i_{end} \in I_{end}$, a binary classifier is applied to predict whether the span of (i_{start}, i_{end}) becomes an answer, as follows:

$$\begin{aligned} &P_{i_{start}, i_{end}} = \\ &Sigmoid\left(FFN^{(span)}(T_{i_{start}}; T_{i_{end}})\right) \end{aligned} \tag{3}$$

where ; is the concatenation operator and $FFN^{(span)}$ is an additional feed-forward neural network layer for the span prediction.

Training As in (Li et al., 2020), the loss function for predicting the start and end positions is based on the cross-entropy term, which is formulated with probabilities of indexes being the start and end positions, as follows:

$$\begin{aligned} \mathcal{L}_{start} &= CE(P_{start}, Y_{start}) \\ \mathcal{L}_{end} &= CE(P_{end}, Y_{end}) \end{aligned} \tag{4}$$

where $Y_{start} \in \{0, 1\}^n$ and $Y_{end} \in \{0, 1\}^n$ represent the gold start and end positions, respectively of input tokens. The loss function for span probability is formulated as follows:

$$\mathcal{L}_{span} = CE(P_{start,end}, Y_{start,end}) \tag{5}$$

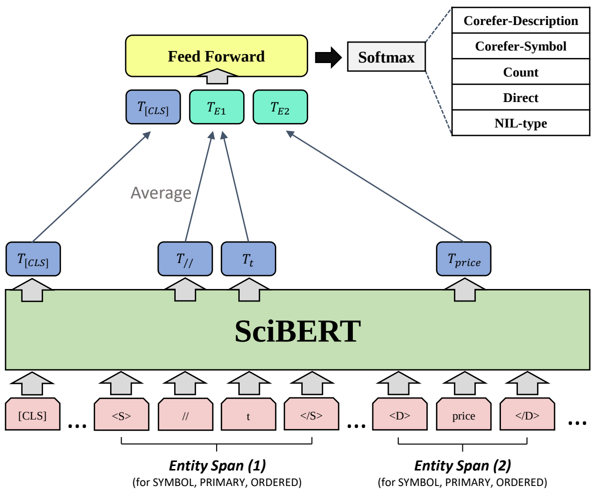

Figure 3: Span pair classification models for RE

where $Y_{start,end}$ represents the gold span of the input tokens. The overall loss is formulated as follows:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{start} + \lambda_2 \mathcal{L}_{end} + \lambda_3 \mathcal{L}_{span} \quad (6)$$

where $\mathcal{L}_{start}$, $\mathcal{L}_{end}$, and $\mathcal{L}_{span}$ are the loss functions for predicting the start, end positions, and for the span prediction task, respectively, and λ_i is the weight for each loss function.

2.2 Span pair classification for RE with solid markers

Figure 3 represents the RE model based on the span pair classification of (Wu and He, 2019; Zhou and Chen, 2021), that classifies a pair of entity spans extracted from the MRC-based NER model in Section 2.1.2.

Like the NER model, we use SciBERT as a pre-trained language model for the RE model, but keep separate parameters that are not shared with the NER's encoder, following the work of (Zhong and Chen, 2021).

In the RE model, a *type-marked* document is provided as input. Specifically, suppose that e_1 and e_2 are a pair of entity spans (i.e., sequences of tokens), and their types are t_1 and t_2, respectively. Then, a type-marked document $\hat{X}$ is defined by prepending and appending *type markers* before and after each entity span, as follows:

$\hat{X}$ =[CLS] $\cdots$ <t_1> e_1 </t_1> $\cdots$ <t_2> e_2 </t_2> $\cdots$ where <t_i> and </t_1> are type markers.

Given $\hat{X}$, we apply SciBERT's encoder to obtain contextualized representations $T^{(rel)}$. We then obtain span representations for e_1 and e_2 by mean-pooling over their contextual representations, as follows:

$$H_{e_i} = \frac{1}{(end_{e_i} - start_{e_i} + 1)} \sum_{j=start_{e_i}}^{end_{e_i}} T_j^{(rel)} \quad (7)$$

where $start_{e_i}$ and end_{e_i} represent the start and end positions of e_i in the type-marked document $\hat{X}$, respectively. Finally, the model predicts the $P_{relation} \in \mathbb{R}^{l+1}$ probabilities over the relation types of e_1 and e_2 as follows:

$$P_{relation} = softmax(FFN^{(rel)}(T_{[CLS]}^{(rel)}; H_{e_1}; H_{e_2})) \quad (8)$$

where l is the number of relation types, NIL-type of relation is presented as $l+1$-th type, $FFN^{(rel)}$ is an additional feed-forward neural network for relation classification, and $T_{[CLS]}^{(rel)}$ (i.e., the contextual representation of the [CLS] token of $\hat{X}$) is concatenated to provide a global context over the entire document.

During training, the loss function for relation classification uses a cross-entropy function, which is formulated as follows:

$$\mathcal{L} = CE(P_{relation}, Y_{relation}) \quad (9)$$

where $Y_{relation} \in \{0,1\}^{l+1}$ represents a one-hot vector for the gold-relation label of a given pair of entities.

Tokenization Unlike the NER model in Section 2.1.2, only SciBERT's WordPiece tokenizer is exploited.

2.2.1 Automatic creation of examples for NIL-type class

Because we do not have explicit training examples for the NIL-type class, we use a simple negative sampling method to train the RE model. When a pair of entities appear in the context within the maximum length of tokens, they are considered *negative* samples (i.e., examples for the NIL-type class) when they do not have any relationship. The number of NIL-type samples collected in this manner, however, was more than 10 times that of normal samples. To correct the data imbalance, we use *oversampling* of (Chawla et al., 2002) on normal positive samples. Oversampling is also used to balance the positive, negative examples in the development set.

Model	NER				RE

+ *R3F*	-	-	-	-	33.77	38.56	36.00
+ *R3F*, Ensemble	-	-	-	-	38.20	36.23	37.19

Table 2: Performances of final submission runs of our NER and RE models on the test dataset

3 Experimental setup

3.1 Dataset

We use the SemEval-2022 Task 12 dataset(Lai et al., 2022b) in our experiments.

The NER dataset contains three entity types: SYMBOL, PRIMARY, ORDERED. SYMBOL is a mathematical symbol, PRIMARY is a primary description, and ORDERED is a description of multiple terms.

The RE dataset contains four relation types: DIRECT, COUNT, COREFER-DESCRIPTION, and COREFER-SYMBOL. The dataset annotation guidelines[4] state that the relations should be directional; however, some of the relations, such as COREFER-SYMBOL, are *unidirectional*. COREFER-SYMBOL($\mathbf{E_1}$, $\mathbf{E_2}$) is the same as COREFER-SYMBOL($\mathbf{E_2}$, $\mathbf{E_1}$),

The directions of the other relations are defined based on the entity types. Such examples include COUNT($\mathbf{E_1}$, $\mathbf{E_2}$) and DIRECT($\mathbf{E_1}$, $\mathbf{E_2}$) where $\mathbf{E_1}$ is a symbol-type entity and $\mathbf{E_2}$ is a description-type entity. In postprocessing, the directions of these relations are automatically determined based on entity types in a post-processing manner. In other words, for the RE model, the order of the two entity spans e_1 and e_2 is determined based on their corresponding entity types.

Our system is evaluated separately for the NER and RE tasks. For NER, we use the entity-based strict/exact/partial/type from SemEval 2013 Task 9.1 (Segura-Bedmar et al., 2013). We use the standard precision, recall, f1-score metrics for RE.

3.2 Regularization and ensemble for RE model[5]

We use two regularization methods to improve the performance of the RE model: *RDrop* (Wu et al., 2021) and *R3F* (Aghajanyan et al., 2020). *Rdrop* is a regularization method that reduces the difference between representations at inference and training time caused by dropout, and *R3F* is a regularization method that maintains more generalizable representations of the pretrained language model during fine-tuning.

We train 10 RE models using different random seeds for the ensemble inference and and then perform maximum voting for each entity pair.

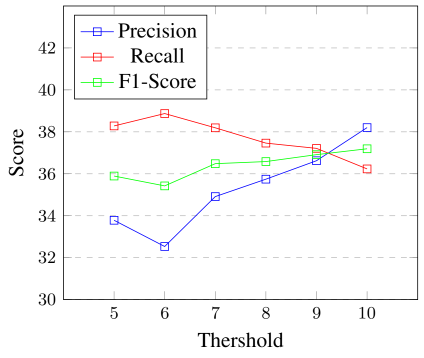

Figure 4: Performance comparison of ensembles of 10 RE models varying thresholds

4 Experimental results

Table 2 presents the final results on the blind test dataset[6].

As shown in Table 2, using the regularization method improves performance over the baseline model. Among the two methods, *R3F* is better than *RDrop*; thus, we use *R3F* for the submission of the RE model.

Overall, the recall is relatively higher than the precision for the RE model. In our preliminary experiments, we observed a similar tendency with high recall for the ensemble method, despite the fact that the ensemble method was shown to be effective in terms of F1 score.

We use a *voting threshold* to increase the pre-

[4]Official annotation guidelines are available at `http://nlp.uoregon.edu/download/symlink/guideline.pdf`

[5]These regularization and ensemble methods were not applied to NER model.

[6]Due to a submission error, we do not report strict/exact scores at the NER task.

cision of the ensemble RE model and adjust the ensemble inference so that a NIL-type class is assigned either when the size of the majority votes from the models does not exceed the voting threshold or when the class from the majority votes is NIL-type.

Figure 4 shows the performance of the ensemble method across different voting threshold values. In this case, we observe that as the voting threshold is raised, the F1 score gradually increases, while precision increases and recall decreases. As a result, when voting threshold is 10, the best performance of the F1 score is obtained. This run was finally submitted.

5 Analysis

In this section, we examine the effects of some of the components of our system as well as additional trials.

5.1 Effect of symbol tokenizer on NER task

Symbol Tokenizer	**Exact**	**Not Exact**	**Recall**
Used	18668	85	99.54
Unused	18412	341	98.18

Table 3: Frequencies and recalls of SYMBOL-type entities whose sequences of tokens are exact gold spans, with and without *symbol tokenizer*.

To examine the effect of the symbol tokenizer, Table 3 compares the frequencies and recalls of SYMBOL-type entities whose exact gold spans are correctly obtained when and without the symbol tokenizer. In this case, recall is defined as the ratio of the number of symbol-type entities whose exact span boundaries are *extractable* using a given tokenizer to the total number of symbol-type entities.

5.2 Effect of removing non-relational entities

Method	NER			
	Strict	**Exact**	**Partial**	**Type**
Not Excluded	-	-	47.61	47.70
Excluded	-	-	47.18	47.31

Table 4: Performances of NER models when including or excluding non-relational entities that have no relationship with other entities.

Assuming that mathematical symbols and descriptions must have one or more relations according to the annotation guideline, our additional trial is to exclude *non-relational* entities that have no relationship with other entities. Table 4 shows the performance of our NER models when those non-relational entities are included or excluded. However, it is observed that removing non-relational entities reduces the performance of the NER model.

5.3 Analysis of RE model

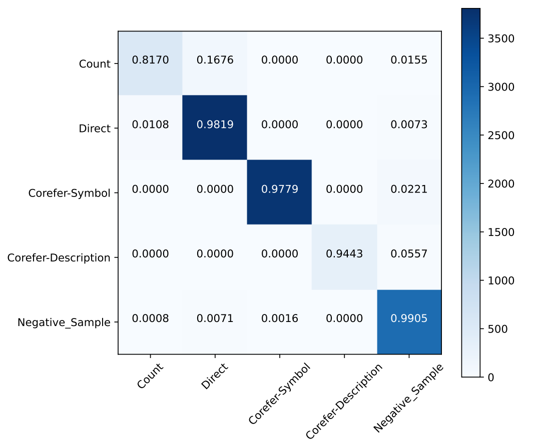

Figure 5: Confusion matrix of RE model on development dataset

Figure 5 shows the confusion matrix of the RE model. It is observed that the discrimination between COUNT and DIRECT is particularly challenging, and the effectiveness of COREFER-DESCRIPTION is relatively low. For this reason, there may be a low number of examples for COUNT and COREFER-DESCRIPTION labels. Given our assumption that these weak performances come from a lack of sufficient number of examples, data augmentation may need to be necessary to improve the performances of these relation labels.

6 Conclusion

Our system shows first for all subtasks of SemEval-2022 Task 12: 'linking mathematical symbols to their descriptions'. MRC-based NER and span pair classification for NER are part of our system that uses SciBERT as a backbone encoder. To improve the performance, the symbol tokenizer for NER model, regularization, and ensemble methods, for RE model are used.

To improve the performance further, future work should look into data augmentation and mathematical symbol and description-aware pretraining.

Abstract

In this paper, we present an end-to-end joint entity and relation extraction approach based on transformer-based language models. We apply the model to the task of linking mathematical symbols to their descriptions in LaTeX documents. In contrast to existing approaches, which perform entity and relation extraction in sequence, our system incorporates information from relation extraction into entity extraction. This means that the system can be trained even on data sets where only a subset of all valid entity spans is annotated. We provide an extensive evaluation of the proposed system and its strengths and weaknesses. Our approach, which can be scaled dynamically in computational complexity at inference time, produces predictions with high precision and reaches 3rd place in the leaderboard of SemEval-2022 Task 12. For inputs in the domain of physics and math, it achieves high relation extraction macro F_1 scores of 95.43% and 79.17%, respectively. The code used for training and evaluating our models is available on GitHub[1].

1 Introduction

Information extraction systems are a key component in making scientific literature more consumable. With the large amount of scientific works which are constantly being published (e.g., more than 60,000 machine learning papers per year (Färber, 2019)), indexing techniques that go beyond keyword searches are becoming more important. While many efforts have focused on the processing of abstracts as a way of building representations of publications (Gábor et al., 2018; Luan et al., 2018), methods processing full text documents will be needed to accurately capture their contents for use cases such as academic search and recommender systems and scientific impact quantification.

The task tackled in this paper (Lai et al., 2022), consisting of linking mathematical symbols to their descriptions in LaTeX documents, is a *joint entity and relation extraction* task. While earlier work tackled both subtasks sequentially via separate models, more recent approaches tend to use a single joint model (Luan et al., 2018; Bekoulis et al., 2018; Nguyen and Verspoor, 2019; Eberts and Ulges, 2021). In contrast to early approaches, which are based on Bi-LSTMs (Luan et al., 2018; Bekoulis et al., 2018; Nguyen and Verspoor, 2019), more recent approaches (Wadden et al., 2019; Eberts and Ulges, 2021) make use of transformer-based language models, such as BERT (Devlin et al., 2019). A key challenge in joint models is the computational complexity stemming from pairwise comparisons between entity spans required for relation extraction. Previous works tackle this using a span scoring mechanism based on a feed forward neural network, which produces a score indicating the likelihood that a span is in a relation (Luan et al., 2018; Wadden et al., 2019). Relation extraction is then performed on only those spans with the highest scores. For data sets which include span annotations even for entities which are not in any relation, such as DocRED (Yao et al., 2019), as examined by Eberts and Ulges (2021), such a scoring mechanism is not necessary, because the entity extraction component of the model can be trained on these annotations. For the task tackled in this paper, complete annotations for entity spans are not provided, making the use of a span scoring mechanism necessary.

In this paper, we propose an end-to-end approach for joint entity and relation extraction. The approach is based on a transformer-based language model, following previous work (Eberts and Ulges, 2020, 2021), but is peculiar in the sense that it incorporates a span scoring mechanism based on dot product similarity which is learned via triplet loss rather than cross entropy loss, making it applicable to datasets which contain annotations only for a subset of all valid entity mention spans.

2 Task Description

The task tackled in this paper is one of joint entity and relation extraction. This means, given an unannotated text as input, a system needs to (1) return annotations of relevant entity mention spans, (2) perform coreference resolution, (3) entity type classification, and finally (4) relation extraction on the identified spans. The specific task at hand has a number of key features that separate it from similar settings.

First, regarding entity extraction, the annotations and, thus, the final scoring are restricted to those entities which participate in relations. This means that a system which correctly identifies all symbols and descriptions in the input will score poorly even on the entity extraction portion of the final benchmark if the relation extraction is incorrect. More importantly from an engineering perspective, the resulting span annotations are incomplete in that they only include a partial set of valid spans for each document. In the entity extraction step we can, therefore, only reliably identify true positives and false negatives, not, however, false positives and true negatives.

Second, while coreference resolution (i.e., the linking of multiple mentions to a single entity) is part of the task, relation extraction is to be performed on a mention-level rather than the entity-level. This means that although a system may correctly identify a text span as being the description of a certain symbol, this classification will only be deemed correct in the evaluation if linked to the correct mention of said symbol. As a result, coreference links are interpreted as relations between mentions and thereby as part of the relation extraction subtask, rather than as part of the entity extraction subtask.

Third, entity types can be reliably inferred from the relations between them, meaning that instances of relations are only found between certain entity types. This feature can be used to inform the design of a system in two ways: Either, the task of relation extraction can be simplified by reducing the choices given to a classifier based on the entity types of two spans (i.e., a symbol cannot be the description to another symbol, therefore any such prediction can be disregarded), or the entity type classification can be informed by the relation extraction (i.e., if we identify a span A as the description of another span B, span A must be a description, while span B must be a symbol).

3 Approach

We propose an end-to-end entity and relation extraction system using a transformer-based language model, as illustrated in figure 1. The system consists of 4 modules: (1) The *input encoding module* tokenizes the input text and produces contextualized embeddings for each token, (2) the *soft mention detection module* ranks possible token spans by the likelihood with which they contain an entity mention, (3) the *relation extraction module* extracts relations on a subset of the highest ranked spans from the previous step, and finally (4) the *entity type classification module* assigns entity types to spans based on the relations detected between them.

3.1 Input Encoding

We examine two separate options of encoding the input: For the first option, we pass the input text to the language model without prior modification, whereas for the second option, we perform preprocessing on the input to remove LaTeX code from the text portions of the input. Any input in LaTeX math mode is passed to the model unchanged.

Since our approach uses a transformer-based language model, the input needs to be tokenized. As a result of the tokenization, there are instances of relations which cannot be matched correctly by our model, due to the annotated span boundaries being contained within a token. For the training and development sets, this occurs in 1.99% and 2.84% of relation instances, respectively, and in these cases we adjust the labels accordingly.

3.2 Soft Mention Detection

Given that we cannot reliably identify false positives and true negatives from our labeled data, a mention detection strategy based on cross-entropy loss cannot be used for this task. Instead of following previous approaches in using feed-forward neural networks (Luan et al., 2018; Wadden et al., 2019), we propose a linear similarity based approach which ranks possible spans based on their similarity to multiple *prototype* embeddings (one prototype per entity type).

We begin by computing the set of all possible continuous spans up to a maximum length n and produce a fixed-size embedding e_s for each span by pooling the contextualized embeddings of all tokens within it. As pooling strategies we use either mean or max pooling. For each span embedding e_s we compute a span score X_s:

$$X_s = \max_{a_i \in A}(sim(e_s, a_i)) \qquad (1)$$

where A is the set of prototype embeddings which contains an embedding for each entity type and $sim(a, b)$ is the dot product similarity of two vectors. We select the k spans with the highest values for X_s as our *candidate mentions* M for relation extraction. We compute the *mention loss* as the mean triplet loss (Schroff et al., 2015) across all prototype embeddings in A and all mentions in M.

3.3 Relation Extraction

For relation extraction, we use the document-level relation extraction model DL-MNAV (Popovic and Färber, 2022). We use the concatenation of two span representations as a representation for the relation between them (Wang et al., 2019). The resulting relation representations are compared to a single relation prototype embedding per relation type, as well as m additional prototypes representing the none-of-the-above class (this follows the MNAV model (Sabo et al., 2021)). The relation type corresponding to the prototype resulting in the highest dot product similarity for a relation representation is used as the predicted type. As loss function for the relation classification we use *adaptive thresholding loss* (Zhou et al., 2021) as it is capable of handling the large imbalance between positive and negative training examples present in document-level relation extraction tasks.

Due to quadratic scaling of the pairwise comparisons it is not feasible to perform relation extraction on all possible continuous spans. We, therefore, perform relation classification on the top k spans[2] with the highest span scores, meaning that we have to classify a maximum of $k(k-1)$ relation representations for a given input text. The computational complexity of the system can, therefore, be adjusted dynamically at inference time by changing k, for example to be run on GPUs with smaller memory capacity or on GPUs with higher memory capacity to improve the quality of predictions.

As a result of the soft mention detection, it is possible that some of the k spans are overlapping and correspond to the same target (see appendix A.2 for examples). This means that the relation classifier may output multiple predictions for the same relation instance with slightly different mention spans. For predictions in which both the head and tail entity overlap, we therefore output only the prediction with the highest classification score.

3.4 Entity Type Classification

Finally, we use a simple mapping to determine the entity type of the spans which participate in the relations predicted by the relation classifier. The mapping used can be found in appendix A.1. For spans classified as "PRIMARY" we additionally change the predicted type to "ORDERED", if they are the head entity of more than one "Direct" relation.

4 Experimental Setup

For our language model we use SciBERT (Beltagy et al., 2019), which is trained on scientific

[2]During training we add annotated spans which are not among the top k spans.

text, via Huggingface's Transformers library (Wolf et al., 2020). For LaTeX preprocessing (see section 3.1) we use Pylatexenc[3]. As our optimizer, we use AdamW (Loshchilov and Hutter, 2019) with learning rates $\in [3\mathrm{e}{-5}, 5\mathrm{e}{-5}, 7\mathrm{e}{-5}]$, a linear warmup of 1 epoch followed by a linear decay to zero, for a total of 60 epochs[4], a batch size of 4, and apply gradient clipping with a max norm of 1. During training, we randomly downsample the amount of candidate spans for soft mention detection to 1000, while ensuring that all labeled spans are included. During training and development set evaluation, we set k, the number of spans to perform relation classification on, to 50, as preliminary experiments showed this value to yield a good compromise between model performance and training time. For test set evaluation we increase k to 400. Training takes approximately 10 hours on a single NVIDIA V100 GPU using mixed precision. We perform early stopping based on the micro F_1 score for relation extraction on the development set. We train each hyperparameter configuration 3 times using different random seeds and report the median and standard deviation for each metric. As a result of the different combinations of preprocessing and mean-/max-pooling, we examine the performance of 4 configurations on the test set. For our evaluation, we report the micro F_1 scores for NER metrics as used in SemEval-2013 Task 9.1 (Segura-Bedmar et al., 2013)[5]. For relation extraction we report *micro* precision, recall and F_1 scores, unless otherwise indicated.

5 Results

5.1 Overview

The results of the 4 model configurations on the test set are reported in table 1. In comparison to the other approaches taking part in SemEval-2022 Task 12, our system ranks in place 3/9 in terms of relation extraction F_1 score.[6]

In general, we find that our model produces predictions with significantly higher precision than recall.

5.2 Impact of Preprocessing

With respect to the preprocessing procedure, we observe no clear performance impact. We conclude that SciBERT appears to cope well with LaTeX code and preprocessing, as described in this paper, is not required.

5.3 Impact of Pooling Procedure

Regarding the pooling procedures we find that mean pooling tends to cause higher variability in the classification performance of the models. For the models trained using mean pooling and preprocessing, 1 of 3 models performed significantly worse than the others, causing the large standard deviation in the results.

5.4 Impact of Domain

In table 2, we show the relation extraction F_1 scores for a model across the 4 different domains covered by the development set paired with the distribution of training data across domains. We observe large performance differences depending on the domain with math and physics showing very high macro

[3]`https://github.com/phfaist/pylatexenc`

[4]The length of one epoch is dictated by the number of training examples, which is 3119.

[5]We use the following implementation: `https://github.com/davidsbatista/NER-Evaluation`

[6]Scores for other metrics are not publicly visible on the leaderboard at the time of writing.

	domain			
	cs	econ	math	physics
% of training corpus	16.63	27.08	12.82	32.08
relation type				
Direct	33.12	21.05	63.82	85.71
Count	-	-	84.62	100.00
Corefer-Symbol	21.05	20.47	91.30	100.00
Corefer-Description	3.51	0.00	76.92	96.00
macro	19.23	13.84	79.17	95.43
micro	25.93	19.49	78.77	88.77

Table 2: F1 scores for relation extraction across different domains and relation types on the development set. cs and econ do not contain any instances of "Count".

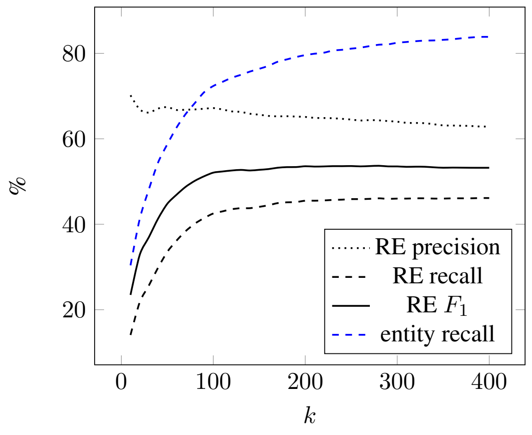

Figure 2: Plot of the impact of increasing values of k on precision, recall, and F1 scores on the development set.

F_1 scores (79.17% / 95.43%) and computer science and economics performing poorly (19.23% / 13.84%). While physics content does represent the majority of training examples, the distribution of domains across training examples does not fully explain the disparity.

5.5 Impact of k

In figure 2, we show the change in relation extraction performance across different values for k. We also include in the plot the percentage of entity spans in the top k ranked spans (entity recall). While the relation extraction performance improves proportional to the entity recall for $k \leq 100$ the improvement slows down for higher k. We hypothesize that this is due to the limiting of $k = 50$ and the candidate span downsampling during training, which prevents the model from seeing some of the more difficult cases. In appendix A.2, we show examples of detected spans.

matching	precision	recall	$F_{1,micro}$
strict	55.85	44.01	49.23
partial	62.87	46.13	53.22

Table 3: Comparison of strict and partial matching requirements with respect to classification scores on the development set.

5.6 Impact of Tokenization

In order to measure the impact of tokenization errors produced by adjusting labels during training, we perform a partial matching of relation labels as follows: For predicted relation triples which are false positives, we accept them as true positives for an annotated instance if the *intersection-over-union* (IOU) scores of both head and tail entities are greater than 67% and the predicted relation type matches the label. In table 3 we show the results of both strict and partial matching for our best model on the development set. We find that the relaxed requirements for span accuracy result in an increase in the F_1 score of 3.99%. We conclude that tokenization errors, while measurable, do not account for the majority of errors of our model.

6 Conclusion

In this paper, we present an end-to-end joint entity and relation extraction approach for linking mathematical symbols to their descriptions in LaTeX documents. Our model appears to be sensitive to the domain of the input documents, achieving high macro F_1 scores of 95.43% and 79.17% for physics and math content, respectively, while achieving macro F_1 scores of only 19.23% and 13.84% for computer science and economics related content. We find that the model's predictions are higher in precision than in recall. We perform a detailed error analysis and identify cross-domain generalization as the most critical problem to tackle in future work.

MaChAmp at SemEval-2022 Tasks 2, 3, 4, 6, 10, 11, and 12: Multi-task Multi-lingual Learning for a Pre-selected Set of Semantic Datasets

Rob van der Goot
IT University of Copenhagen
robv@itu.dk

Abstract

Previous work on multi-task learning in Natural Language Processing (NLP) often incorporated carefully selected tasks as well as carefully tuning of architectures to share information across tasks. Recently, it has shown that for autoregressive language models, a multi-task second pre-training step on a wide variety of NLP tasks leads to a set of parameters that more easily adapt for other NLP tasks. In this paper, we examine whether a similar setup can be used in autoencoder language models using a restricted set of semantically oriented NLP tasks, namely all SemEval 2022 tasks that are annotated at the word, sentence or paragraph level. We first evaluate a multi-task model trained on all SemEval 2022 tasks that contain annotation on the word, sentence or paragraph level (7 tasks, 11 sub-tasks), and then evaluate whether re-finetuning the resulting model for each task specificially leads to further improvements. Our results show that our mono-task baseline, our multi-task model and our re-finetuned multi-task model each outperform the other models for a subset of the tasks. Overall, huge gains can be observed by doing multi-task learning: for three tasks we observe an error reduction of more than 40%.[1]

1 Introduction

Recently, language models have become the de-facto standard in Natural Language Processing (NLP), where we first train a set of parameters on raw data, which are then finetuned on the task at hand. This in itself is a multi-task setup (language-modeling + target task). However, traditionally, multi-task learning was mainly done between multiple NLP tasks with gold annotation. In this setup, many questions arise: not only how to share the information between different tasks, but also when to share and even which tasks to use, as it is non-trivial to decide which auxiliary tasks are beneficial for a certain target task (Ruder, 2017; Crawshaw, 2020). Early work on multi-task learning in NLP often used up to a handful of tasks, carefully curated dataset/task combinations, and carefully tuned how to share the information between these tasks (e.g. Hashimoto et al. (2017); Søgaard and Goldberg (2016)).

A line of recent work has shown that an intermediate step can be used to finetune the language model on a set of NLP tasks, which leads to a model that is more apt for learning other NLP tasks. This is also called Supplementary Training on Intermediate Labeled-data Tasks (STILT), and was introduced by Phang et al. (2018). Phang et al. (2018) train on three classification tasks from the GLUE benchmark (Wang et al., 2018), and then retrain for all GLUE tasks, showing a 1.4 point of improvement over all GLUE tasks. Phang et al. (2020) shows that this positive transfer also holds cross-lingually when using multilingual language models and only doing intermediate training on English tasks. Wang et al. (2019). Similar as with earlier models, it remains an open question for STILT models which tasks transfer well to which tasks (Vu et al., 2020; Pruksachatkun et al., 2020; Chang and Lu, 2021). It should be noted that most work on STILS for autoencoder language models is done on text (i.e. sentence) classification only.

Later work used autoregressive language models, which learn to generate texts (as opposed to the autoencoding models, which learn to predict one token at a time, used by the previously mentioned STILT papers). These language models are commonly used for different types of tasks, namely generation tasks (e.g. question answering, machine translation, summarization), whereas autoencoding models are commonly used for classification and word-level tasks (text classification, pos-tagging, parsing etc.). Recent work has shown that many NLP tasks can be converted to generation tasks, and

Table 1: Overview of all tasks we participate in. Original source of the data of task 10 are Øvrelid et al. (2020); Barnes et al. (2018); Agerri et al. (2013); Wiebe et al. (2005); Toprak et al. (2010).

can then directly be used to (re-)train an autoregressive language model in a multi-task setup (Aribandi et al., 2022; Sanh et al., 2022). In this setup it is easier to exploit a variety of task-types and a much higher amount of datasets (~50-100 datasets) is used compared to previous work.

In this paper, we set out to examine whether we can obtain performance improvements with multi-task learning and re-finetuning after multi-task learning (i.e. STILT) for a pre-defined set of semantically focused NLP tasks. More precisely, we will use the pre-defined set of SemEval 2022 tasks, and train a multi-task model for all text-based SemEval tasks that include annotation on the word, sentence or paragraph level.[2] We compare a strong single task baseline to a default multi-task learning model, where the encoder is shared, each task has its own decoder, and training is done on all tasks simultaneously (shuffled batches). Finally, we use the parameters from the multi-task model to train a task-specific model for each task again. We seek to answer the following research question:

- Can we exploit a pre-selected combination of NLP tasks in a multi-task setup to improve the ability of an autoencoder language model to learn NLP tasks?

To the best of our knowledge, we are the first to participate in more than 2 SemEval tasks simultaneously, by participating in 7 tasks and a total of 11 tasks including sub-tasks. In our multi-task model, we model a total of 19 tasks if we train on the full data from the tasks (some tasks are modeled as multi-task by themselves), and 54 tasks if we separate them by language or dataset. We will release the finetuned multi-task language models on the hugginface hub (Wolf et al., 2020) for future use, which we dub: Sem-mmmBERT (SemEval MaChAmp multi-task multi-lingual BERT)[3] based on mBERT (Devlin et al., 2019) and Sem-RemmmBERT (SemEval Rebalanced MaChAmp multi-task multi-lingual BERT)[4] based on RemBERT (Chung et al., 2021).

2 Datasets

An overview of the datasets for the tasks included in our setup is shown in Table 1. For task 2, the regression task has no gold training data, so it was left out. Furthermore, we did not participate in any constrained tracks, as we are mainly interested in setups where we also trained on other data. The languages used in the tasks have some overlap, but also some unique languages. English is present in all tasks.

[2]document level annotation is excluded, as it is non-trivial to model in current autoencoder language models

Table 2: The task-types used within machamp for each of the (sub-)tasks, and the data size before and after smoothing.

Table 2 reports the sizes of the datasets, we see that there is a large variety. We attempt to overcome this with dataset smoothing, which is described in more detail in Section 3.8.

3 Model

We implemented all of our models in MaChAmp v0.3beta (van der Goot et al., 2021). MaChAmp is a toolkit that focuses on multi-task learning for NLP task-types based on AllenNLP (Gardner et al., 2018) and the transformers library (Wolf et al., 2020). It supports a wide variety of tasks, and a variety of options for multi-task learning (for within as well as cross-dataset multi-task learning). A typical MaChAmp model consists of a shared encoder (i.e. language model), with multiple decoders on top (one for each task), which all share the same encoder. We use all default hyperparameters of MaChAmp for our experiments, except for the dataset smoothing (Section 3.8). Our general setup is shown in Figure 1. As baseline, we take the data of a single SemEval task, and finetune a MaChAmp model with all default hyperparameters (SINGLE). The first multi-task setup, is a MaChAmp model trained on a combination of all SemEval tasks we consider (MULTI), where each task has its own decoder. Finally we take the hyperparameters from the MULTI model, and refinetune them for a single task at a time (MULTI-FINE).

For the relation extraction tasks (task 10 and 12), we first converted the data to a word-level sequence labeling task, and we contributed a regression task-type in MaChAmp, to be able to tackle task 3-2. For all sub-tasks with multiple languages/datasets, we evaluate also whether learning these in separate decoders is useful (so we split the datasets, and learn them as separate tasks). Below, we describe the choices we made for each of the tasks (the MaChAmp task-types can be found in Table 2), after which we describe our two multi-task setups (Section 3.8 and Section 3.9).

Figure 2: Example of conversion of sentiment graph to sequence labeling for task 10, showing a gold annotated sentence (top of line) and the three layers of annotation that the model is supposed to predict (below the line): expression identification, entity identification and relations.

3.1 Task 2

We only participate in the supervised task (one-shot task a), which is a binary task where the goal is to identify whether a sentence contains an idiomatic expression. We use the classification task-type in MaChAmp, and include the multiword expression (MWE) as well as all 3 sentences (target + context) as input. Note that they will automatically be separated by a special separation token in MaChAmp, and their segment ID's will be all 0's for the MWE and third sentence, and 1's for the second and fourth sentence (for language models supporting segment ID's). We use macro-f1 for model picking as well as for the results we report in Section 4.

3.2 Task 3

Subtask 1 is a binary classification task: is a sentence (semantically) acceptable or not. We use the classification task type in MaChAmp and the macro-f1 metric. The data is divided in folds by the organizers, we use fold 1 and 2 as train data, and 3 as dev data. For subtask 1 we use macro-f1 for model picking, and report macro-f1s from the official evaluation script in Section 4.

Subtask 2 is a regression task, where we predict an acceptability score between 1 and 7. We contributed a regression decoder to MaChAmp, which uses a simple linear layer and mean square error loss. We use fold 0 for training and fold 1 as dev data. For subtask 2 we use pearson correlation for model picking.

3.3 Task 4

Subtask 1 concerns a binary classification task: does an utterance contain patronizing or condescending language or not. Subtask 2 identifies one out of 7 sub-categories of patronizing and condescending language. We model both tasks as classification task in MaChAmp, and split the data for both sub-tasks in 80% train and 20% dev data. Following the official metrics, we use accuracy for task 1 and macro-f1 score for task 2 for model picking.

3.4 Task 6

We use an 80:20 split for each of the tasks. Task A is binary sarcasm detection, task B is a multi-class classification task, in which we model each category as a separate task, so that multiple classes can be predicted. Task C is paraphrase detection between sentence-pairs. We follow the official metrics and use macro-f1 for task A and B, and accuracy for C for model picking.

3.5 Task 10

Task 10 is fine-grained sentiment analysis, in which sentiment graphs are predicted. Each opinion is annotated as a tuple consisting of: an expression, which has a polarity (positive/negative) a link to the target, and potentially a link to a holder/source (the person expressing the sentiment). Inspired by Ramponi et al. (2020), we convert this task to three sequence labeling tasks (see also Figure 2). The first task is expression identifiction, which we model as BIO encoded spans. It should be noted that the spans can overlap. The second task is the identification of the source and targets, which are also encoded as BIO spans, which can also overlap. For each token that is the beginning of an expression (B-label), we include a label describing the relations (the third task), which are triples containing of: polarity, link to holder, link to target. The links to targets are simply counts of the directions to the next identified entities (i.e. +1 for the next identified entity), similar to the relative POS strategy of Strzyz et al. (2019), and the relation extraction implementation of Ramponi et al. (2020). There can be multiple relations for a given expression. We concatenate the overlapping labels (which all three sub-tasks have) and model these three tasks in MaChAmp as sequence labeling task. We compared this against using the "multiseq" task type, which can output multiple labels per token. However, performance was better when simply doing sequence labeling, in contrast to Ramponi et al. (2020). Perhaps tuning the threshold of the prediction confidence to include labels could lead to better results (we used the default of 0.5), which we leave for future work. After prediction, we convert the data back to the official json format.

For model picking, we take the average over the accuracies of the concatenated labels, in Section 4 we report the official metric, sentiment graph F1 (Barnes et al., 2022).

3.6 Task 11

Task 11 is multi-lingual named entity recognition. We compared running with and without a CRF-layer, and found that the CRF layer is beneficial. We use span-f1; the implementation of AllenNLP for model picking, and the output of the `conlleval.pl` script for results reported in Section 4, because there is no official evaluation script available

3.7 Task 12

Task 12 is the linking of mathematical symbols, which consists of two steps: 1) detect mathematical symbols 2) identify links between them, which are directed and labeled. We use a similar strategy as we used in task 10, where we convert the task to sequence labeling. In contrast to task 10, the data in task 12 is not pre-tokenized, and some of the spans do not allign with the whitespaces. We tokenize with the `_is_punctuation` function from the transformers library (Wolf et al., 2020) to circumvent this, and save where it splits so that we can undo it after prediction. Similar as for task 10, a token can have multiple labels, we attempt to model this with the "multiseq" task-type in MaChAmp, which can predict multiple labels, but obtain better results by concatenating the labels and predict them as one label per token. We used accuracy for both tasks, as the official metric was not released. The results reported in Section 4 are the average of these two sub-tasks.

3.8 MULTI

We compare the single task baselines to models where we exploit multi-task learning (see also Figure 1). In the first setup, we finetune MaChAmp on all tasks simultaneously, for which we enable the multinomial smoothing in MaChAmp with $\alpha = 0.5$, so that the distribution between tasks becomes more similar (see also Table 2. Note that some SemEval tasks consist of multiple sub-tasks, and some single tasks are modeled as multiple tasks in MaChAmp, we have a total of 19 tasks in the final setting. We evaluate the output of each decoder/task separately for this model.

Task	COMBINED	SEPARATE
task2-a1	**66.00**	61.28
task3-1	**66.77**	66.71
task3-2	**74.07**	72.14

task6-c	90.74	**91.67**
task10	**35.10**	28.90
task11	**79.86**	79.48
task12	96.06	—

Table 3: Scores (dev) of single-task models with mBERT. SEPARATE means that the data from each language (or dataset for task10) has its own decoder. An empty cell (—) means that the task did not consist of multiple datasets/languages, so SEPARATE equals COMBINED.

3.9 MULTI_FINE

After the multi-task model is trained, we save the parameters of the shared encoder, so that they can be re-used for the next step. Finally, we re-finetune the resulting model for each task seperately again, to see whether the multi-task model constitutes a better initialization than the vanilla language model.

4 Results

For all the tasks where the shared task organizers released an evaluation script, we used the official script for the results reported in this section (for the model-picking we used internal equivalent metrics, see Section 3 for the details per task); for task11 we used `conlleval.pl`, and for task12 we used an average of accuracy over our converted data.

task10	**47.70**	45.60
task11	80.45	**82.94**
task12	95.67	**96.33**
avg.	**67.73**	64.27

Table 5: Scores of multi-task settings for RemBERT.

4.1 Single task results

On the single task level, we compared for all datasets consisting of multiple languages or sub-datasets whether it is useful to train them as a single task (with one decoder: COMBINED), or as separate tasks (with N decoders: SEPARATE). For computational efficiency, these tests are only done with mBERT.

Table 3 shows that modeling the languages in separate decoders is only beneficial for task 6 c. We hypothesize that this is because this dataset only contains two languages (English and Arabic), which are relatively distant, so sharing the decoder leads to performance drops. For all further experiments, we will use the COMBINED setup.

4.2 Multi-task results

We first evaluate the results with mBERT, as we also have the single-task results with mBERT (due to computational constraints we do not have them for RemBERT). Table 4 shows the scores for the single-task (SINGLE) baseline, the multi-task model (MULTI), and the intermediate multi-task with finetuning per task setup (MULTI_FINE). Interestingly, each of the three models perform best for 3 or 4 different tasks, and it is thus highly dependent on the task which setup is most beneficial. Differences between scores can be huge though, and when looking at the averages it is clear that the multi-task setups are beneficial over single task models and competetive to each other. The smallest and largest datasets (Table 2) score best with the single task model, as well as task 12, which can be considered an outlier. The multi-task setup without additional finetuning (MULTI) seems to be mostly beneficial for classification tasks. The additional finetuning (MULTI_SEQ) is especially flourishing for task 4-1 and 6c, which are small to medium sized classification tasks, and it is unclear why their trends differ so much compared to task 3-1, 4-2 and 6-a. It should be noted that MULTI is computationally more attractive as well as much smaller to store, as we only need one model for all tasks.

Before the deadline for the SemEval task, we managed to also train the final model with RemBERT (Chung et al., 2021) as language model, however, we do not have the single task baselines. Unfortunately, here only the model with separate decoders for each language/dataset fit on our largest GPU (40gb), so we submitted results with these.

Table 5 shows that also for the RemBERT embeddings, there is no clear single best strategy. The best multi-task strategy sometimes differs compared to the mBERT results (Table 4): task4-2, task11 and task12 differ, where the latter two where the tasks where the single task was the best performing for the mBERT embeddings. On average, the MULTI setup performs more than 3 absolute points higher, but this is mainly due to task 6, which has 3 subtasks (and thus weights heavier in the average).

4.3 Test data

We submitted the results of the mBERT single task baseline and the RemBERT MULTI_FINE setup for the official test evaluations. In Table 6 we show the obtained results and rankings for each task.

Task	Single mBERT	Multi_fine RemBERT	Ranking Ranking
task2-a1	—	66.07	NA
task3-1	78.78	86.42	11/21
task3-2	0.6792	-0.164	17/17 (3/17)
task4-1	0.4172	0.4211	56/78
task4-2	0.0772	0.1546	34/49
task6-a	0.3639	0.3187	31/43 & 12/32
task6-b	0.0919	0.0851	3/22
task6-c	0.2400	0.2250	16/16 & 13/13
task10	0.472	0.501	13/22
task11	0.6027	0.6768	18/26
task12	2.67	7.42	—

Table 6: Official test set results. The — indicate results we could not obtain, and the NA is because we trained on data that was not allowed for that task, so we participated without ranking. For some tasks, multiple rankings are given per sub-track,for task3-2, the single mBERT based model would have ranked 3th.

We note that there are some disrepancies between scores on the test data (Table 6) and the previously reported dev scores (Table 4), these are probably the result of differences in implementation for the metric (when the official code was not released), and could sometimes be the result of uploading the data in the wrong format (e.g. task3-2). Perhaps surprisingly, the single task mBERT model sometimes outperforms RemBERT. This leads to the conclusion that we should not always blindly use the latest, larger language model. Furthermore, we see that for most tasks we rank somewhere in the middle. It should be noted that little to no tuning is done (except for MaChAmp task-type for three of our tasks: 10, 11, 12), as our focus was mostly on comparing our own models to each other and answering our research question. Results can be expected to still increase by selecting the architecture (SINGLE, MULTI, MULTI-FINE), selecting language model per task, tuning the multi-task setup (loss weighing, combination of tasks, smoothing α etc.) or the other hyperparameters (learning rate, scheduler, batch size etc.) of MaChAmp.

5 Conclusion

We have compared three setups in this work: SINGLE: single task finetuning of language models, MULTI: multi-task finetuning of language models, MULTI_FINE: using the output of MULTI and finetuning on single target tasks again. Our setup is both multi-lingual and uses pre-defined set of tasks with a large variety in types of tasks. Our results confirm the findings of recent and concurrent work (Phang et al., 2018; Aghajanyan et al., 2021), showing that for some task combinations, we can benefit from an intermediate task-trained model (MULTI_FINE). However, we also show that all three evaluated setups perform well for certain tasks. We hypothesize that this is an effect of using a pre-defined set of tasks. In our setup the differences between the setups are in some cases extremely large (error reductions larger than 40% compared to the single task baseline have been obtained for three tasks), whereas for some other tasks our single task baseline performed best. This leads to a positive answer to our research question, and the conlusion that intermediate finetuning can be beneficial. However, care should be taken, as our results also show that MULTI_FINE does not outperform MULTI nor SINGLE in all situations, which raises the question: how can we predict whether the intermediate model is better or we need to finetune one more time on the target task?
