Introduction

Welcome to SemEval-2022!

The Semantic Evaluation (SemEval) series of workshops focuses on the evaluation and comparison of systems that can analyze diverse semantic phenomena in text, with the aims of extending the current state of the art in semantic analysis and creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics. SemEval provides an exciting forum for researchers to propose challenging research problems in semantics and to build systems/techniques to address such research problems.

SemEval-2022 is the sixteenth workshop in the series of International Workshops on Semantic Evaluation. The first three workshops, SensEval-1 (1998), SensEval-2 (2001), and SensEval-3 (2004), focused on word sense disambiguation, each time expanding in the number of languages offered, the number of tasks, and also the number of teams participating. In 2007, the workshop was renamed to SemEval, and the subsequent SemEval workshops evolved to include semantic analysis tasks beyond word sense disambiguation. In 2012, SemEval became a yearly event. It currently takes place every year, on a two-year cycle. The tasks for SemEval-2022 were proposed in 2021, and next year's tasks have already been selected and are underway.

SemEval-2022 is co-located (hybrid) with The 2022 Annual Conference of the North American Chapter of the Association for Computational Linguistics (NAACL-2022) on July 14 - 15. This year's SemEval included the following 12 tasks:

- Lexical semantics
  - Task 1: CODWOE - COmparing Dictionaries and WOrd Embeddings
  - Task 2: Multilingual Idiomaticity Detection and Sentence Embedding
  - Task 3: Presupposed Taxonomies - Evaluating Neural-network Semantics (PreTENS)
- Social factors & attitudes
  - Task 4: Patronizing and Condescending Language Detection
  - Task 5: MAMI - Multimedia Automatic Misogyny Identification
  - Task 6: iSarcasmEval - Intended Sarcasm Detection in English and Arabic
- Discourse, documents, and multimodality
  - Task 7: Identifying Plausible Clarifications of Implicit and Underspecified Phrases in Instructional Texts
  - Task 8: Multilingual news article similarity
  - Task 9: R2VQ - Competence-based Multimodal Question Answering
- Information extraction
  - Task 10: Structured Sentiment Analysis
  - Task 11: MultiCoNER - Multilingual Complex Named Entity Recognition
  - Task 12: Symlink - Linking Mathematical Symbols to their Descriptions

This volume contains both task description papers that describe each of the above tasks and system description papers that present the systems that participated in the tasks. A total of 12 task description papers and 221 system description papers are included in this volume.

SemEval-2022 features two awards, one for organizers of a task and one for a team participating in a task. The Best Task award recognizes a task that stands out for making an important intellectual contribution to empirical computational semantics, as demonstrated by a creative, interesting, and scientifically rigorous dataset and evaluation design, and a well-written task overview paper. The Best Paper award recognizes a system description paper (written by a team participating in one of the tasks) that advances our understanding of a problem and available solutions with respect to a task. It need not be the highest-scoring system in the task, but it must have a strong analysis component in the evaluation, as well as a clear and reproducible description of the problem, algorithms, and methodology.

2022 has been another particularly challenging year across the globe. We are immensely grateful to the task organizers for their perseverance through many ups, downs, and uncertainties, as well as to the large number of participants whose enthusiastic participation has made SemEval once again a successful event! Thanks also to the task organizers who served as area chairs for their tasks, and to both task organizers and participants who reviewed paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. Thousands of thanks to our assistant organizers Siddharth Singh and Shyam Ratan for their extensive, detailed, and dedicated work on the production of these proceedings! We also thank the members of the program committee who reviewed the submitted task proposals and helped us to select this exciting set of tasks, and we thank the NAACL 2022 conference organizers for their support. Finally, we most gratefully acknowledge the support of our sponsor: the ACL Special Interest Group on the Lexicon (SIGLEX).

Abstract

Word embeddings have advanced the state of the art in NLP across numerous tasks. Understanding the contents of dense neural representations is of utmost interest to the computational semantics community. We propose to focus on relating these opaque word vectors with human-readable definitions, as found in dictionaries. This problem naturally divides into two subtasks: converting definitions into embeddings, and converting embeddings into definitions. This task was conducted in a multilingual setting, using comparable sets of embeddings trained homogeneously.

1 Introduction

Word embeddings are a success story in NLP. They have been equated to distributional semantics models (Lenci, 2018; Boleda, 2020), a theory of semantics which relates the meaning of words to their distribution in context (Harris, 1954). Recently introduced contextualized word embeddings (e.g. Devlin et al., 2019) have set a new state of the art on a wide variety of tasks. For this reason, they have attracted much research interest. Do they depict consistent semantic spaces and are they theoretically valid (Mickus et al., 2020b; Yenicelik et al., 2020)? What limitations are to be expected in these models (Bender and Koller, 2020)? Can they scale up in performance (Brown et al., 2020)?

Word embeddings are dense vector representations of meaning which are not easily intelligible to a human observer. Many techniques have been employed to make embedding spaces more interpretable. A promising approach consists in *converting these opaque vectors into human readable definitions, as one could find in a dictionary*: accurately translating a dense, opaque vector representation into an equivalent human-readable piece of text would allow us to peer into the black box

of modern neural network architectures. This avenue of research, known as definition modeling, was pioneered by Noraset et al. (2017). One may however question whether the task is at all feasible: there is no guarantee that the information content of a dictionary definition is similar to that which is described by real-valued vectors inferred from word distributions.

The SemEval Shared Task on Comparing Dictionaries and Word Embeddings (CODWOE) sets out to study whether embeddings and dictionaries encode similar information. We present the task and relevant state of the art in Section 2. We describe the data collected and presented to participants in Section 3. In Section 4, we discuss the metrics used to rank participant submissions. Our baseline model is presented in Section 5. We list results from participants' submissions in Section 6 and provide a more in-depth discussion in Section 7.

2 What we are fishing for

What is in a word embedding? Are word embeddings semantic descriptions, in the same sense that dictionary definitions are? If so, embeddings and definitions must be translatable into one another. The CODWOE shared task was set up to test this. The shared task participants investigated whether a word vector—e.g. $\vec{\texttt{cod}}$—contains the same information as the corresponding dictionary definition—viz. "*any of various bottom-dwelling fishes (family Gadidae, the cod family) that usually occur in cold marine waters and often have barbels and three dorsal fins*."[1]

We decompose this research problem into two tracks: the first corresponds to the vector-to-sequence task of Definition Modeling, the second to the sequence-to-vector Reverse Dictionary task. The task of definition modeling consists in using the vector representation of $\vec{\texttt{cod}}$ to produce the associated gloss, "*any of various bottom-dwelling fishes (family Gadidae, the cod family) that usually occur in cold marine waters and often have barbels and three dorsal fins*". The reverse dictionary task is the mathematical inverse: reconstruct an embedding $\vec{\texttt{cod}}$ from the corresponding gloss.

These two tracks display a number of interesting characteristics. These tasks are obviously useful for explainable AI, since they involve converting human-readable data into machine-readable data and back. They also have a theoretical significance: both glosses and word embeddings are representations of meaning, and therefore involve the conversion of distinct non-formal semantic representations. From a practical point of view, the ability to infer word-embeddings from dictionary resources, or dictionaries from large un-annotated corpora, would prove a boon for many under-resourced languages.

2.1 Track 1: Definition Modeling

The first track consists in an application of Definition Modeling. As training material, participants have access to a set of data points, each of which consists of a source word embedding and a corresponding target word definition (see Figure 2). Participants are tasked with generating new definitions for an unseen test set of embeddings.

Definition Modeling is a recent addition in NLG tasks (Noraset et al., 2017) which seeks to do just that. It has since then gained traction (Gadetsky et al., 2018; Mickus et al., 2019; Li et al., 2020; Zhang et al., 2020a, a.o.). Other languages than English have also been studied, including Chinese (Yang et al., 2019), French (Mickus et al., 2020a), Wolastoqey (Bear and Cook, 2021), and more (Kabiri and Cook, 2020). At its very inception, Definition Modeling was suggested as a means of evaluating the content of distributional semantic models (Noraset et al., 2017). In practice however, different researchers rarely use comparable sets of embeddings (Mickus et al., 2020a), effectively making proper comparisons across systems impossible as they use distinct inputs. To fill this gap, we created a dataset of comparable embeddings from different languages and neural architectures, trained as homogeneously as possible on comparable data; see 3.2 below.

2.2 Track 2: Reverse Dictionary

Reverse dictionaries (a.k.a. retrograde dictionaries) are lexical resources that flip the usual structure of dictionaries, allowing users to query words based on the definitions they would expect them to have. One of the major challenges of such resources consists in providing definition glosses that match with users' expectations. As a consequence, a trend of research in NLP has focused on producing dynamic reverse dictionaries, that would interpret input definitions and map them back to the corresponding word. We refer the reader to the comprehensive review of Siddique and Sufyan Beg (2019), and provide here mainly highlights.

An early strand of research focused on augmenting definitions using synonyms or other semantically related words, such as hypernyms or hyponyms. This approach has been applied to multiple languages, from Turkish to English and to Japanese (Shaw et al., 2013; Bila et al., 2004; El Khalout and Oflazer, 2004). Building on this query-augmentation approach, we find works focused on integrating richer lexical resources, such as WordNet, the Oxford dictionary, The Integral Dictionary, or LDA vector spaces (Dutoit and Nugues, 2002; Thorat and Choudhari, 2016; Méndez et al., 2013; Calvo et al., 2016).

A related trend of research is that of Zanzotto et al. (2010) and Hill et al. (2016), who use dictionaries as benchmarks for compositional semantics. Zanzotto et al. (2010) used a shallow neural network to implement a compositional distributional semantics model and use dictionaries as their training data. Hill et al. (2016) instead employ a LSTM to parse the full definition gloss and use the hidden state at the last time-step to predict the word be-

[1]From Merriam-Webster.

ing defined. In both cases, replacing the definition gloss with a user's query would lead to a reverse dictionary system. Since then, a number of works have attempted to implement reverse dictionaries using neural language models. The WantWords system (Zhang et al., 2020b; Qi et al., 2020) is based on a BiLSTM architecture, and incorporates auxiliary tasks such as part-of-speech prediction to boost the performance. Yan et al. (2020) seeks to replace the learned neural language models in Hill et al. (2016) or WantWords with a pre-trained model such as BERT (Devlin et al., 2019) and its multilingual variants, which allows them to use their system in a cross-lingual setting—querying in a language to obtain an answer in another. Most recently, Malekzadeh et al. (2021) used a neural language model based approach to implement a Persian reverse dictionary.

With respect to the CODWOE shared task, our interest lies in reconstructing the word embedding of the word being defined, rather than finding the corresponding word—an approach more closely related to that of Zanzotto et al. (2010) and Hill et al. (2016). Under this slight reformulation, the sequence-to-vector Reverse Dictionary task is strictly the inverse of the vector-to-sequence task of Definition Modeling. Hence we define the Reverse Dictionary task as *computing the components of a target word vector using as input a human-readable definition*. To solve this task, participants have access to a set of data points, each of which consists of a source word definition and a corresponding target word embedding, as training materials.

3 What's in the nets: Data used

The definition modeling and reverse dictionary tasks both require a parallel dataset, where dictionary definitions are aligned with corresponding word embeddings. The task is held in a multilingual setting. We provide data in English, French, Russian, Italian and Spanish. We selected these languages to facilitate the collection of comparable data: all these languages possess comparable large scale resources, including online dictionaries as well as corpora that can be used to train comparable embeddings. Our datasets are made available online at https://codwoe.atilf.fr/.

The aim of both tracks of CODWOE is to compare the semantic contents of definitions and embeddings. As a consequence, we ask participants to refrain from using external data such as pretrained models and lexical resources: including such external data would introduce another source of semantic information, and obfuscate the results from this shared task.

Table 2: Embeddings: corpus statistics

3.1 Dictionary data

As a source of dictionary definitions, we primarily use the DBnary dataset (Sérasset, 2012),[2] an RDF-formatted version of some of the existing Wiktionary projects.[3] DBnary includes data for all of our selected languages. One sub-dataset per language is constructed. Definitions are selected according to corpus frequency and part-of-speech of the word being defined. We solely select nouns, adjectives, verbs and adverbs.

Table 1 presents the number of usable items in DBnary. Not all languages contain examples of usage. A brief regular expression lookup suggests that around 20K examples of usage can be found in the Spanish version of Wiktionary, while English yields at least 200K. We therefore discard the English version of DBnary and replace it by a manual parse, from which we also retrieve examples of usage.

3.2 Embeddings data

We have collected similar amounts of data for each language (Table 2) to use as training corpora. The sources we use to constitute these corpora are selected to be generally comparable: each cor-

[2]http://kaiko.getalp.org/about-dbnary/
[3]See https://www.wiktionary.org/

pus contains 2.5G data parsed and cleaned from Wikipedia,[4] 2.2G from the OpenSubtitles OPUS corpus (Lison and Tiedemann, 2016),[5] as well as 0.3G in books from various genres, drawn from LiberLiber[6] for Italian, Wikisource for Spanish and Russian, and Gutenberg[7] for English and French.

We focus on three embedding architectures: word2vec models (Mikolov et al., 2013) trained with gensim (Řehůřek and Sojka, 2010), the ELECTRA model of Clark et al. (2020), and character-based embeddings. The word2vec and ELECTRA models were selected so as to provide some comparison between static and contextual embeddings; both are trained with default hyperparameters aside from output vector size, which we set to 256. As for the ELECTRA models, given that we need contexts to derive token representations, we train the models only in English, French and Russian. The Spanish and Italian Wiktionary projects contain too few examples of usage. For French and Russian, we derive contextualized embeddings of a word to be defined from usage examples in DBnary datasets. Since the English DBnary dataset does not contain examples of usage, we extracted them from the original Wiktionary dumps.

The character-based embeddings are included to provide baseline expectations for non-semantic representations—as we can expect spelling to be more or less arbitrary with respect to word meaning (Saussure, 1916).[8] In practice, these embeddings are computed through a simple LSTM-based auto-encoder: the word is passed into an LSTM encoder as a sequence of characters, we sum all output hidden states, and use these summed hidden states to initialize an LSTM decoder, whose objective is to reconstruct the input word. As a character-based representation, we can therefore use the summed output hidden states, as they are tailored to contain all the information necessary to reconstruct the spelling of the corresponding word.[9] The datasets used to trained the models correspond to the set of all word types attested in our base corpora described in Table 2. All models achieve a 99% reconstruction accuracy.

[4]See here: https://dumps.wikimedia.org/

[5]See https://opus.nlpl.eu/

[6]Cf. https://www.liberliber.it/online/

[7]See here: https://www.gutenberg.org/

[8]Nonetheless, see Gutiérrez et al. (2016), Kutuzov (2017), Dautriche et al. (2017) or Pimentel et al. (2019), all of which question this assumption.

[9]Given that we implement this module ourselves, we use a Bayesian Optimization algorithm (Snoek et al., 2012) to select hyperparameters for our five character auto-encoder. We use this process to decide learning rate, weight decay, dropout, β_1 and β_2 parameters of the AdamW optimizer, batch size, number of epochs over the full dataset, as well as whether to share a single weight matrix for encoder and decoder character embeddings.

3.3 Datasets

We construct one dataset per language. Each language-specific dataset is split in five: a trial split (200 datapoints per language), a training split (43 608 datapoints), a validation split (6375 datapoints), a definition modeling testing split (6221 datapoints) and a reverse-dictionary testing split (6208 datapoints). Splits are constructed such that there are no overlap in the embeddings. Dataset splits are formatted as JSON files.

Each file consists of a list of JSON dictionary notations. JSON items contain a unique identifier for the data point, the word being defined, definition, part of speech, and all word vectors. A depiction of the sort of items included in our datasets is shown in Figure 2. Sub-figure 2a summarizes the data presented as a JSON item in Sub-figure 2b.

Participants had access to the trial, train and validation splits of all languages. Test splits were made available at the beginning of the evaluation period.

4 The scales we use

We now turn to the metrics of our shared task.

4.1 Reverse Dictionary Metrics

The Reverse Dictionary task, as we have re-framed it here, consists in reconstructing embeddings. To that end, we consider three measures of vector similarity. First is MSE (mean squared error), which measures the difference between the components of the reconstructed and target embeddings. Mean-squared error is however not very easy to interpret on its own. Second is cosine: the reconstructed and target embeddings should have a cosine of 1. It is hard to place specific expectations for what a random output would produce, as this essentially differs from architecture to architecture: for instance, Transformer outputs are known to be anisotropic, so we shouldn't expect two random ELECTRA embeddings to be orthogonal (Ethayarajh, 2019; Timkey and van Schijndel, 2021, a.o.).

As neither MSE nor cosine provides us with a clear diagnosis tool comparable across all targets, we also include a ranking based measure: we compare the cosine of the reconstructed embedding $\vec{p}_i$ and the target embedding $\vec{t}_i$ to the cosine of the reconstruction $\vec{p}_i$ and all other targets $\vec{t}_j$ in the test set, and evaluate the proportion of such targets that would yield a closer association—viz., the number of cosine values greater than $\cos(\vec{p}_i, \vec{t}_i)$. More formally, we can describe this ranking metric as:

$$\text{Ranking}(\vec{p}_i) = \frac{\sum\limits_{\vec{t}_j \in \text{Test set}} \mathbb{1}_{\cos(\vec{p}_i, \vec{t}_j) > \cos(\vec{p}_i, \vec{t}_i)}}{\#\text{Test set}} \tag{1}$$

4.2 Definition Modeling Metrics

A common trope in NLG is to stress the dearth of adequate automatic metrics. Most of the metrics currently existing focus on token overlap, rather than semantic equivalence. The very popular BLEU and ROUGE metrics (Papineni et al., 2002; Lin, 2004) measure the overlap rate in n-grams of various lengths (usually 1-grams to 4-grams).

To alleviate this, researchers have suggested using external resources, such as lists of synonyms and stemmers (Banerjee and Lavie, 2005) or pre-trained language models (Zhao et al., 2019). The reliance of these augmented metrics on external resources is problematic. Different languages will use different resources with varying degrees of quality—and this will necessarily impact scores, introducing a confounding factor for any analysis down the line. In the extreme case, if these resources are not available for a particular language, then the metric will have to be discarded. Even assuming the availability of the required external resources, none of these improved metrics is entirely satisfactory. In the case of synonymy-aware metrics such as METEOR (Banerjee and Lavie, 2005), we can stress that syntactically different sentences can express the same meaning, but would not be captured by such metrics. Embeddings-based metrics such as MoverScore (Zhao et al., 2019) are very recent, and therefore less well understood; moreover concerns can be raised about whether using a method derived from neural networks trained on text will prove of any help in studying the meaning of texts generated by other neural networks.

One alternative frequently used by the NLG community is perplexity, which weighs the probability that the model would generate the target. This last alternative is however not suited to a shared task setup, as it requires us to have access to the actual neural networks trained by participants so we can investigate the probability distributions they model—unlike the other metrics we mentioned thus far, which only require model outputs.

In short, none of the currently available NLG metrics are fully satisfactory. Some are not applicable given the shared task format, some depend on external resources of varying quality, and some merely measure formal similarity, rather than semantic equivalence. Our approach is therefore twofold: on the one hand, we select multiple metrics with the expectation that each might shed light on one specific factor; on the other hand, we encourage participants to go beyond automatic scoring for the evaluation of their model.

As for which metrics we select, we narrow our choice to three. First is a basic BLEU score (Papineni et al., 2002) between a production p_i and the associated target t_i; our reasoning here is that as it is one of the most basic metrics, it is a consistent default choice. Second is the maximum BLEU score between a production p_i and any of the targets $t_i, t_j \dots t_n$ for which the definiendum is the same as that of p_i. This second metric is designed to not penalize models that rely solely on SGNS or char embeddings: as the input would always be the same, deterministic models would always produce the same definition $p_i = p_j = \dots = p_n$.[10] To distinguish between our two BLEU variants, we refer to the former as S-BLEU (or Sense-BLEU),

[10]One way of bypassing this problem would be to include a source of noise, as is done in GAN architectures (Goodfellow et al., 2014). This would still leave open the question of how to optimally align the outputs to the possible targets.

and the latter as L-BLEU (or Lemma-BLEU).

Given that some definitions in our dataset can be very short, we also apply a smoothing to both BLEU-based metrics. In practice, BLEU computes an overlap of n-grams of size m and under; by default, $m = 4$. This overlap is a geometric mean across all n-gram sizes $1 \ldots m$. If a definition d contains less than m tokens, then any associated production for which d is used as a target will contain 0 overlapping n-grams of size m. The use of a geometric mean then entails that the BLEU score for any production associated to d will be 0. To circumvent this limitation of BLEU, it is common to use some form of smoothing. Here, for any n-gram size $\hat{m}$ that would yield an overlap of 0 (i.e., $\hat{m}$ such that $\#d < \hat{m} \leq m$), we replace the overlap count with a pseudocount of $1/\log \#d$.

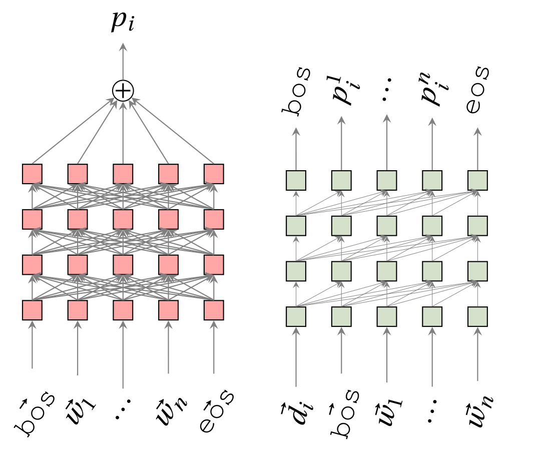
Lastly, we include MoverScore (Zhao et al., 2019), using a multilingual DistilBERT model as the external resource. The fact that this model is multilingual means that we can use it for all five languages of interest. Embedding-based methods have the potential to overcome some of the limitations of purely token-based metrics, which is why we deem them worth including in our setup.

The second part of our approach for evaluating submissions consists in encouraging participants to not rely solely on the automatic scoring system of their outputs. Concretely, we provide participants with a richly annotated trial dataset, which contains frequency and hand-annotated semantic information, and strongly suggest participants to use it for a manual evaluation of their system. We include the presence of a manual evaluation as a criterion to evaluate the quality of a system description paper, and plan to formally recognize the most enlightening evaluations conducted by participants.

Neither our selection of metrics nor our insistence on manual evaluation solves the evaluation issues of NLG systems. We duly note the importance of this question, and plan to conduct a follow-up evaluation campaign on the CoDWoE submissions.

5 Testing the waters: baseline architectures

We implement simple neural network architecture baselines to lower the barrier to entry to this shared task. They are based on the Transformer architecture of Vaswani et al. (2017) and designed to be as simple as possible. Our code is publicly available at `https://github.com/TimotheeMickus/codwoe`.



(a) Reverse dictionary (b) Definition modeling

Figure 3: Baseline architectures for the CoDWoE shared task

We illustrate our Reverse Dictionary baseline architecture in Figure 3a. It consists in feeding the input gloss $\langle \vec{bos}, \vec{w}_1, \ldots, \vec{w}_n, \vec{eos} \rangle$ into a simple Transformer encoder, and then summing all the hidden representations to produce the prediction p_i. In practice, the summed hidden states are passed into a small non-linear feed-forward module to derive the prediction:

$$p_i = W_p \left(\text{ReLU} \left(\sum_t \vec{h}_t \right) \right) \tag{2}$$

Our Definition Modeling baseline is presented in Figure 3b. It consists in a simple Transformer encoder, where earlier time-step representations are prevented from attending to later time-step representations. To provide information about the definiendum to the model, we use the definiendum embedding $\vec{d}_i$ as the input for the first time-step instead of a start-of-sequence token. We train the models with teacher-forcing: i.e., during training we ignore the definientia $p_i^1, \ldots, p_i^n$ that the model produces; instead we feed it the target $w_1, \ldots, w_m$ attested in the training set at each time-step. During inference, we feed the model with its own prediction. This creates a train-test mismatch, which we alleviate by using a beam-search. We stop generation when all beams have produced an end-of-sequence token.

For both tracks, we train one model for each distinct pair of language and embedding architecture. We start by re-tokenizing the datasets using sentence piece with a vocabulary size of 15000. This is done in order to mitigate the effects of different

Table 3: Participants' best scores on the Definition Modeling track. Highest participant scores per metric are displayed in bold font.

vocabulary sizes when training our Transformer baselines, and make the models overall easier to compare across different languages.

We set hyperparameters using a Bayesian Optimization procedure, with 100 hyperparameter configurations tested and 10 initial random samples. For the Reverse dictionary models, we tune the following hyper-parameters: learning rate, weight decay penalty, the β_1 and β_2 hyperparameters of the Adam optimizing algorithm, dropout rate, length of warmup, batch size,[11] number of heads in the multi-head attention layers, and number of stack layers. For the Definition Modeling systems, we also include a label smoothing parameter to tune. Models are trained over up to 100 epochs; training is stopped early if no improvement of at least 0.1% is observed during 5 epochs. In all cases, we decay the learning rate after the warmup following a half cosine wave, such that the learning rate reaches 0 at the end of the 100 epochs.

6 How whale did it go? Shared task results.

Scores attained by participants are shown in Tables 3 and 4. In Table 3, "Mv", "SB" and "LB" refer to Moverscore, Sense-BLEU and Lemma-BLEU respectively; in Table 4, each sub-table corresponds to a different architecure, and "rnk" refers to the cosine ranking metric (cf. Section 4).

In total, we received 159 valid submissions from 15 different users; out of which 11 teams produced a submission paper. 9 of these teams tackled the Definition Modeling, and 10 addressed the reverse dictionary track. Competition rankings are established by ranking each submission received, selecting for each participant the best performance on all metrics, and finally taking the average best rank. Some participants' submissions were faulty and could not be processed by the evaluation website scoring program.

Among the system descriptions we received, two focused solely on definition modeling. Kong et al. (2022, BLCU-ICALL) use a multitasking framework for definition modeling, based on a generation and a reconstruction objectives. Mukans et al. (2022, RIGA) focus on what are the effects of model size and duration of training on GRUs and LSTMs for definition modeling, and whether MoverScore corroborates human judgment.

Five submissions specifically focus on the reverse dictionary task. Bendahman et al. (2022, BL.research) compare the performances of MLP-based to LSTM-based networks for reverse dictionary. Li et al. (2022, LingJing) study pretraining objectives for the reverse dictionary track. Ardoiz et al. (2022, MMG) pay specific attention to how the not-so-satisfactory quality of the Spanish dataset impacts results on Spanish reverse dictionary. Cerniavski and Stymne (2022, Uppsala) study whether foreign language entries can improve the performance of the English reverse dictionary baseline model. Wang et al. (2022, 1cademy) introduce multiple technical tweaks for reverse dictionary, such as a dynamic weight averaging loss, language-specific tags and residual cutting.

[11] In practice, we first manually find the largest batch size that fits on our GPU, and then let the model select the number of batches it should accumulate gradient on.

(c) ELECTRA Reverse Dictionary track results

Table 4: Participants' best scores on the Reverse Dictionary track. Highest participant scores per metric are displayed in bold font.

The last four submissions addressed both tracks. Chen and Zhao (2022, Edinburgh) propose to project embeddings and definitions on a shared representational space. Korenčić and Grubišić (2022, IRB-NLP) take inspiration from Noraset et al. (2017) to address definition modeling, and experiment with pooling strategies over Transformer embeddings for the reverse dictionary track. Tran et al. (2022, JSI) focus on comparing the effects of adding LSTM and BiLSTM layers on top of a Transformer model, as well as zero-shot cross-lingual generalization. Srivastava and Harsha Vardhan (2022, TLDR) propose two Transformer-based architectures for the two tracks, leveraging contrastive learning and unsupervised pretraining.

Looking at Tables 3 and 4, we see that the metrics we chose in section 4 are not always aligned. On the Definition Modeling track (Table 3), while the multitask framework of Kong et al. (2022, BLCU-ICALL) yields generally the most consistent performance, it is often outmatched in specific setups. For instance, BLEU-based metrics favor the shared projection technique of Chen and Zhao (2022, Edinburgh) in Russian and French, while the pooling strategies of Korenčić and Grubišić (2022, IRB-NLP) appear especially effective on the Spanish dataset. As for the Reverse Dictionary track (Table 4), the strongest contender is generally the Edinburgh team, although the IRB-NLP team almost systematically produces the highest cosine ranking score. Interestingly, BLCU-ICALL, IRB-NLP and Edinburgh all rely on multi-task learning. Note however that the SGNS targets seem to depict a rather different picture, where the pretraining objectives of Li et al. (2022, LingJing) bring about some of the best results.

7 A deeper dive into our results

When looking at the competition results, two trends emerge. First, the baseline architectures from Section 5 remain quite competitive with solutions proposed by participants. Second, scores are generally unsatisfactory, especially in the definition modeling track: we do not see a clear divide between char embeddings and distributional semantic representations. The NLG metrics are, in absolute terms, low compared to modern NLP standards and results reported elsewhere on other definition modeling benchmarks. As for the reverse dictionary track, we see that across all submissions, at least a third of the test set is closer (in terms of cosine distance) to the production than the intended target.

Participants have suggested multiple reasons for these hardships. In particular, Ardoiz et al. (2022, MMG) highlight that the automated data compilation in DBnary (Sérasset, 2012) is of an unsatisfactory quality. Similar remarks can be made with respect to the embeddings, which are trained on rather small corpora. Other submissions such as Mukans et al. (2022, RIGA), Chen and Zhao (2022, Edinburgh), Korenčić and Grubišić (2022, IRB-NLP) highlight the limited applicability of mainstream NLG metrics, as we ourselves have discussed in Section 4.[12] One last remark is the limited size of our dataset, discussed by the Edinburgh and RIGA teams. All these remarks suggest avenues for future research: in particular, the release of the full dataset should alleviate some of the concerns with respect to dataset size. The MMG team also suggest some concrete preprocessing steps to handle some of the issues they identify in the proposed definitions.

[12]See also Mickus et al. (2021) for a discussion.

In terms of solutions explored, we can stress that teams have adopted a variety of strategies and architectures: systems used Transformer, RNN and CNN components, often leveraging or exploring multilingualism (Tran et al. 2022, JSI; Cerniavski and Stymne 2022, Uppsala; Wang et al. 2022, 1cademy; Bendahman et al. 2022, BL.research), multitasking, or multiple training objectives (Kong et al. 2022, BLCU-ICALL; 1cadamy; Korenčić and Grubišić 2022, IRB-NLP; Srivastava and Harsha Vardhan 2022, TLDR; Chen and Zhao 2022, Edinburgh). Multi-task training tends to yield varied yet competitive results for our data. No preponderant architecture emerges from the system descriptions; we note that multiple submissions based their work on other contextualized embedding architectures, trained from scratch on the CODWOE dataset (Wang et al. 2022, 1cademy; Li et al. 2022, LingJing). The comprehensive review of architectures by team 1cadamy suggests nonetheless that Transformers might be less suited to this shared task than recurrent models.

7.1 Manual analyses

As for manual evaluations, Kong et al. (2022, BLCU-ICALL) provide a thorough review of the errors produced by their model. Mukans et al. (2022, RIGA) provide some example outputs of their models, while Srivastava and Harsha Vardhan (2022, TLDR) and Wang et al. (2022, 1cademy) include ablation studies. The most thorough analysis, however, is that of Chen and Zhao (2022, Edinburgh), who provide both quantitative and qualitative (PCA-based) analyses across embedding architectures, languages, and trial dataset features. Korenčić and Grubišić (2022, IRB-NLP) provide an extremely well documented review of their systems performances, along multiple analyses of the embeddings proposed for the shared tasks, ranging from 2D down-projection visualizations to descriptive statistics of components. We refer the reader to the respective system papers for a more thorough review and focus here on a few promising approaches to summarize trends that emerge from these manual analyses.

Current metrics are not satisfactory. The IRB-NLP team highlight that the BLEU scores reported on the shared task are dramatically lower than what is generally expected in the literature; the Edinburgh team even shows that the S-BLEU scores obtained by non-sensical glosses such as "`, or .`"

can end up among the highest scores for some languages. The Reverse Dictionary metrics can also be sensitive to different aspects of the embeddings, as shown by the IRB-NLP team: this can lead to very different rankings of model productions, especially when comparing the cosine-based ranking metric to the cosine and MSE metrics. BLEU-based scores are also often sensitive to the length of the production, the target, or both, as shown by both the Edinburgh and the Riga teams.

Erroneous productions abound. Related to the previous remark, many Definition Modeling systems produce irrelevant or under-specified glosses, for which the proposed metrics are not satisfactory. For instance, the BLCU-ICALL report 52% irrelevant glosses and 23.5% under-specified glosses, from a manual evaluation of 200 productions. Other participating teams, such as RIGA or IRB-NLP, also display generated glosses with varying degress of semantic accuracy.

Embeddings contain more than semantics. The Edinburgh team highlights how different linguistic features retrieved from the trial dataset can significantly impact the scores they observe. They also highlight that char embeddings are separable by length, and that the Electra embeddings are clustered according to their frequency.

Not all setups are created equal. The Uppsala team report that Russian seems to be the most effective data source in their multilingual transfer experiments. The IRB-NLP team stresses that vector component distributions across languages and architectures as well as gloss length across languages can take very different values, and they also include 2D visualization suggesting the Electra embeddings tend to form neat cluster not observed for SGNS embeddings. Scores also vary quite a lot across setups (cf. Tables 3 and 4).

8 Conclusions and future perspectives

The CODWOE shared task was constructed so that participants' submissions would be likely to have linguistic significance. Yet, it is not trivial to tease apart the various factors that lead to the overall low results we observed. While the inadequacy of mainstream NLG metrics and the limitations of the dataset certainly play a role, they do not resolve the fundamental issue that we wished to investigate with CODWOE. Whether word embeddings and dictionaries contain the same information is not a solved research problem.

This has two immediate consequences: firstly, one can question the use of definition modeling as an evaluation tool for embeddings, as suggested by the seminal work of Noraset et al. (2017). The CODWOE shared task results indicate that the metrics currently used in the field are rife with caveats; in the controlled setup we have proposed here, participants rarely, if ever, found that character-based embeddings starkly contrasted with distributional semantic representations.

Second, one can question whether definition modeling and reverse dictionary are fit for building lexical resources for under-tooled languages: the crosslingual route proposed by Bear and Cook (2021) seems more practical than training models from scratch, even with relatively large datasets. Our embeddings were trained on corpora comparable in size to the 1B Words benchmark (Chelba et al., 2013): while modern text corpora are now several orders of magnitude larger, this dataset remained a landmark for several years. Our definitions were selected from DBnary (Sérasset, 2012), which focuses the largest Wiktionary projects.

Overall, the CODWOE shared task has been a success: we were able to show that the task at hand was far from trivial and we drew significant interest towards the issues addressed in the Definition Modeling and Reverse Dictionary literature. In future work, we plan to investigate better ways to perform NLG evaluation for the Definition Modeling task (in particular relying on human annotations) and we plan to focus on existing embeddings trained from very large corpora.

Acknowledgements

We thank the annotators who have helped us in putting an annotated dataset in a very short amount of time: Elena del Olmo Suárez, Hermès Martinez, Maria Copot, Nikolay Chepurnykh and Toma Gotkova, as well as Cyril Pestel for his help with data hosting.

Abstract

This paper describes our system for the SemEval2022 task of matching dictionary glosses to word embeddings. We focus on the Reverse Dictionary Track of the competition, which maps multilingual glosses to reconstructed vector representations. More specifically, models convert the input of sentences to three types of embeddings: SGNS, Char, and Electra. We propose several experiments for applying neural network cells, general multilingual and multitask structures, and language-agnostic tricks to the task. We also provide comparisons over different types of word embeddings and ablation studies to suggest helpful strategies. Our initial transformer-based model achieves relatively low performance. However, trials on different retokenization methodologies indicate improved performance. Our proposed Elmo-based monolingual model achieves the highest outcome, and its multitask, and multilingual varieties show competitive results as well.

1 Introduction

Reverse dictionary Task is defined as word generation based on user descriptions (Hill et al., 2016). Following competition rules, pre-trained models and external information should be avoided, and large-scale language models are unsuitable for the task. Our paper is devoted to the performance comparison of different neural network structures, multilingual and multitask tricks, and elaborating on language-agnostic or bidirectional structure helpfulness. The competition (Mickus et al., 2022) has significant potential in contributing pretraining process acceleration, low-resource language model development, and commonsense using. Furthermore, the task is of high importance for explainable AI and natural language processing since it models direct mapping from human-readable data to machine-readable data.

Known word representation methods using dictionaries, knowledge databases, or glosses have been a common approach for years. Related models can be divided into two major groups. In the former, category methods highly rely on large-scale model construction. Levine et al. (2019) develop SenseBert, introducing super-senses from Wordnet (Miller, 1995) into general Bert model. Ernie (Sun et al., 2019) combines node embeddings from knowledge graph and matched entities to enhance word representations. KnowBert (Peters et al., 2019) subsumes the entity connection and Bert models, which are trained together. There are similar research works relevant to the topic (Wang et al., 2021, 2020; Yin et al., 2020). Still, their models' performances are dependent on the basic large-scale language model trained by sentence samples. In the latter group, traditional dependency-based language models learn directly from word dependency and glosses. They have two major disadvantages: incompatibility with modern language models and relatively low performance (Tissier et al., 2017; Levy and Goldberg, 2014; Wieting et al., 2015). There is ambiguity about whether recent embeddings and dictionary glosses are mappable from each other.

The paper specifically focuses on progressing utilization of the glosses, different word representations, and languages. **First**, we discuss ablation studies for language-agnostic trick, bidirectional, multilingual, and multitask models and explain the experimental results. **Second**, we apply and analyze different re-tokenization methods. **Finally**, we give instructive conclusions about encoder structures, distinctive word representation relations, and cross-lingual dictionary performance based on our experiment results. We find that **(1)** transformer-based model performance is inferior to other models for its high complexity, **(2)** bidirectional models with similar parameter size outperform the unidirec-

[*] The two authors contributed equally to this work.

tional model because of their better understanding of context-environments even in the low-resource condition, and **(3)** different word embeddings have a potential relations and can be collaboratively learnt from glosses using a multitask learning structure. We make our codes and results publicly available[1].

2 Task Description

The competition, comparing dictionaries and word embeddings, proposes definition modeling (Noraset et al., 2017) and reverse dictionary sub-tracks (Hill et al., 2016). These sub-tracks are designed to test the equivalency of dictionary glosses and word embedding representations. This paper focuses on the reverse dictionary direction. The task refers to word recalling using gloss input and provides word representations that are separately generated by word2vec (SGNS) (Mikolov et al., 2013), character (Wieting et al., 2016), and Electra (Clark et al., 2020) embeddings as training data. External data and large-scale language models are strictly restricted from this competition since the models might learn the word embeddings majorly from the sentence samples instead of the dictionary glosses. The words matched with the dictionary glosses are hidden in the datasets, implying that dependency-based word representation algorithms cannot be applied directly.

3 Methodology

To clarify, we affirm that we only refer to the model structures instead of the trained models when we mention Elmo and MBert in the section and use no external data.

3.1 Language Model Structure

Baseline monolingual models with five distinctive structures were trained: RNN, LSTM, Bi-RNN, Elmo, and Transformer.

We experiment how bidirectional and different feature generator cell structures help.

RNN is the classical deep learning model dealing with ordinal or sequential data (Zaremba et al., 2014). Its major disadvantage is the vanishing and exploding gradient issue. Nevertheless, the model is fast to converge and works well on smaller sentences. Our experiments show that RNN, having similar results to the LSTM-based model, performs slightly better than the transformer-based one.

[1] https://github.com/ravenouse/Revdict_1Cademy

LSTM is another classical and widely-used feature generator structure in natural language processing. The comparison of LSTM-based and RNN-based models can suggest whether vector representation of glosses suffers from the long-term dependencies problem. Earlier works (Jozefowicz et al., 2015) demonstrate that variants of LSTM achieve similar performances in the majority of natural language processing tasks. We select the classical LSTM structure for the experiments.

Transformer (Vaswani et al., 2017) is a milestone feature extractor allowing deeper neural network design for natural language processing tasks. However, given the much smaller size of the competition data, it performs relatively worse compared to the expectation.

3.2 Multitask Structure

Although character embedding generation has a similar algorithm to general word embedding methods, it focuses on character representation and is mightier to better tackle the Out Of Vocabulary (**OOV**) problem. We applied Mean Squared Loss (**MSE Loss**) and Dynamic Weight Averaging (**DWA**) (Liu et al., 2019) as a basic multitask structure for predicting word2vec, Char, and Electra embedding together. It achieves competitive performance in both tasks.

DWA (Liu et al., 2019) is designed for keeping different tasks converging at the same pace. N denotes the number of tasks, T adjusts the weight-changing sensitivity according to loss difference of the tasks, $L_n(t-1)$ and $r_n(t-1)$ represent the loss and the training speed of task n at $(t-1)$th step. $w_i(t)$ is the loss weight of task i at tth step. The key update equations can be expressed as follows:

$$w_i(t) = \frac{N\, exp(r_i(t-1)/T)}{\sum_n exp(r_i(t-1)/T)} \tag{1}$$

$$r_n(t-1) = \frac{L_n(t-1)}{L_n(t-2)} \tag{2}$$

3.3 Retokenize Algorithm

We tried 3 widely-used retokenization algorithms for vocabulary generation including Byte Pair Encoding (**BPE**) (Sennrich et al., 2015), **WordPiece** Model (Schuster and Nakajima, 2012), and Unigram Language Model (**ULM**) (Kudo, 2018). BPE is a greedy algorithm that can not model word relation probability successfully. WordPiece considers

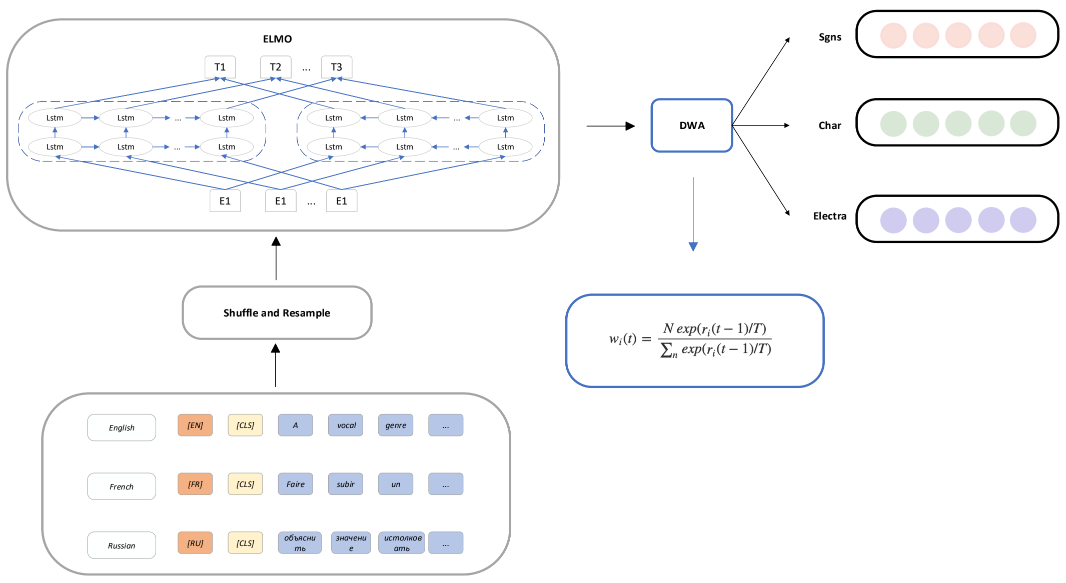

Figure 1: Sketch Map of the multilingual and multitask Elmo-based model structure.

word co-occurrence probability and is influenced by the source data. ULM assumes that all subwords are independent and the probability of a subword sequence is the multiple of its element subwords' probability.

3.4 Multilingual Structure

We applied two basic multilingual structures for the task: mBert (Pires et al., 2019) and adding the language tag. **MBert** has a shared vocabulary for all source languages. The results show that mBert can successfully model similar grammar structure, and sentences with similar meanings have akin representations using mBert. By applying mBert structure, we can estimate how these important conclusions would work for the reverse vocabularies task. We **add the language tag** as the first token to improve models' ability to separate different languages' representations.

We speculate that language-agnostic representations might aid multilingual models in achieving better performance. Residual connection cutting trick proposed by (Liu et al., 2020) was tried, to test how the research findings would work for our specific task.

3.5 Selected Model Design

Following experiment results and ablation studies, our best model is the monolingual Elmo with WordPiece tokenizer. The Multitask and multilingual tricks have proved to achieve competitive results with the Elmo language model. Adding language tokens achieves a better performance than the plain mBert structure while the Residual Cutting trick does not. It implies that the language-specific information is beneficial for the multilingual word representations of the reverse dictionaries task. Adding language tokens has demonstrated to help the Elmo-based multilingual model as well. The most promising multilingual and multitask Elmo-based model structure is shown in Figure 1.

4 Results and Discussion

4.1 Implementation Details

We apply **Bidirectional RNN** and **Elmo** (Peters et al., 2018) models with the same parameter size to find whether bidirectional structure helps. We selected AdamW (Loshchilov and Hutter, 2017) as optimizer. All monolingual models share the same hyper-parameters: the number of layers - 4, the hidden/input size - 256, and the dropout rate - 0.3. WordPiece tokenization was used as the best model design. We follow Devlin et al. (2019) to set the [CLS] token as the first token for monolingual models. We keep the [CLS] token when adding language tokens but set the language token as the first token instead.

Word Representations	SGNS			Char			Electra		
Monolingual Models	MSE	COS	RANK	MSE	COS	RANK	MSE	COS	RANK
RNN+WordPiece	1.000	0.249	0.310	0.158	0.778	0.442	**1.454**	**0.832**	0.433
LSTM+WordPiece	0.990	0.228	0.375	0.148	0.791	0.458	1.491	0.831	0.449
Transformer+WordPiece	1.042	0.214	0.367	0.194	0.780	0.453	1.796	0.827	0.486
BiRNN+WordPiece	0.989	0.221	0.395	0.150	0.791	0.454	1.483	0.832	0.449
Elmo+WordPiece	1.041	0.252	0.282	0.161	0.772	0.430	1.512	0.829	0.434
Elmo+BPE	1.037	0.250	**0.250**	0.162	0.774	0.443	1.537	0.822	0.436

Table 1: Experiment results on English resource test data using the monolingual models. Check section 2 for word algorithm representations' abbreviation. Check section 3 for details of monolingual models.

4.2 Main Results

Reverse dictionary results are evaluated using three metrics: mean squared error (**MSE**) between the reconstructed and reference embeddings, cosine similarity (**COS**) between the reconstructed embedding and the reference embedding, and the cosine-based ranking (**RANK**) between the reconstructed and reference embeddings, measuring the number of other test items having higher cosine with the reconstructed embedding than with the reference embedding(Mickus et al., 2022).

4.2.1 Monolingual Model Performance

We show monolingual models' results in Table 1. As depicted, our proposed model demonstrates competitive if not the best results across the metrics. English, for having the most detailed dictionary data, is selected to present monolingual models' performance[2].

We notice that the transformer-based model has inferior performance on the task. The competition provides a low-resource data set that can explain poorer outcomes for models with high complexity. We tried unidirectional and bidirectional models with similar feature extractors and parameter sizes. The results confirm that bidirectional models perform better and benefit from grasping the context-environment more accurately.

4.2.2 Multilingual Model Performance

We show two ablation experiment results to explain the influence of adding language tags and residual connection removal. **First**, experiment results of the Transformer-based multilingual model on SGNS embedding can suggest the benefits of language tags and curbing residual connection separately or jointly. **Second**, we propose experimental results of the original and adjusted Elmo-based multilingual models. The latter subsumes added language tokens. Such a comparison would clarify whether adding language tokens lead to a general improvement across different languages and word representations.

Electra word representations of Spanish and Italian are not available, implying no related experimental results. The outcomes demonstrate that multilingual models benefit from language-specific information but not from language-agnostic structure. Adding language tags has proved a positive influence on various language models.

4.3 Ablation Study

4.3.1 Tokenizer

We tried three widely-used tokenizers for our proposed model: BPE, ULM, and WordPiece. Both ULM and WordPiece show competitive performance in transformer- and Elmo-based structures. BPE has relatively low performance since the data resource is insufficient and has higher resource requests.

4.3.2 Multitask Model

According to the performance comparison in Table 1, DWA helps the Elmo model achieve better performance and reconstructs three-word representations simultaneously. It demonstrates that differently learned word representations have an internal relation and can be learned together using a shared bottom structure.

4.3.3 Difficulty of Reconstructing Different Word Representations

Compared with the Char and Electra, we find that the SGNS is harder to learn from the gloss corpus, suggesting that the contextualized information of words in sentences might be missing from the pure dictionary glosses. Additionally, the result along with (Kaneko and Bollegala, 2021) indicates dictionary corpus can be a promising way to remove the unfair biases rooted in large corpus learned word embeddings.

4.3.4 Difficulty of Learning Different Languages

Languages	Gloss Num	Dict.Size	Avg.Gloss Len	Elmo SGNS COS
English	43608	29042	11.7	0.252
French	43608	40028	14.3	0.333
Italian	43608	40126	13.6	0.352
Spanish	43608	46761	14.8	0.362
Russia	43608	57137	11.3	0.387

Table 4: Language Vocabulary Size Ablation Study. **Dict. Size** means the number of non-repeating tokens shown in the glosses. **Avg. Gloss Len** means the average token numbers contained in a gloss.

Our results of experiments show a strong positive correlation between language's tokens dictionary size and the models' achievable performance Table 4.

There are several possible reasons for the observation. First, as the language model dictionary size decreases, the models' and glosses' ability to explain the slight differences between words, especially the polysemies and synonyms, decreases. Second, a smaller dictionary size indicates that the covered tokens in the language model are a relatively incomplete part of words of the language.

Noted that the second explanation above does not consider the intrinsic differences between languages. The morphologically rich languages, like Russian, tend to have larger vocabulary sizes and bring many unknown words that influence performance negatively (Jurafsky and Martin, 2020).

5 Conclusion

The paper proposes a model showing competitive results in most cases of the reverse dictionaries task. Several conclusions are provided about the reverse dictionaries task by the paper based on the ablation studies. **First**, the transformer-based model, for its high complexity, performs worse compared to RNN- or LSTM-based models. Multilingual transformer-based model benefits from specifying languages and including language-related grammar positional information. **Second**, bidirectional models with similar parameter sizes outperform the unidirectional one since they better grasp the context in low-resource conditions. **Third**, different word representations are potential connections and can be collaboratively learned from glosses using a multitask learning structure. SGNS embedding is much harder to model compared to Character embedding and Electra embedding.

6 Acknowledgements

We express our gratitude to Prof. Shi Wang and Prof. Alexis Palmer for providing computing resources and guidance. We are grateful to the organizers for providing such a fascinating and inspiring competition and promptly resolving all our questions. Special thanks to Rebecca Lee, Xingran Chen, and Natalia Wojarnik for idea sharing and a deep discussion in the initial stage.

Abstract

This paper describes the BLCU-ICALL system used in the SemEval-2022 Task 1 Comparing Dictionaries and Word Embeddings, the Definition Modeling subtrack, achieving 1st on Italian, 2nd on Spanish and Russian, and 3rd on English and French. We propose a transformer-based multitasking framework to explore the task. The framework integrates multiple embedding architectures through the cross-attention mechanism, and captures the structure of glosses through a masking language model objective. Additionally, we also investigate a simple but effective model ensembling strategy to further improve the robustness. The evaluation results show the effectiveness of our solution. We release our code at: https://github.com/ blcuicall/SemEval2022-Task1-DM.

1 Introduction

Word embeddings (Mikolov et al., 2013a; Pennington et al., 2014; Yogatama et al., 2015) are dense and low dimensional vectors used in many NLP tasks because they are found to be useful representations of words and often lead to better performance in various tasks. In recent years, large pretrained language models (PLMs), such as BERT (Devlin et al., 2019) and GPT (Petroni et al., 2019) families of models, have taken the NLP field by storm, achieving state-of-the-art performance on many tasks (Min et al., 2021). The contextual embeddings generated by PLMs are proven to capture syntax and semantic features of words (Jawahar et al., 2019; Turton et al., 2020). But for human beings, word embeddings containing these information is still a *black box* and unexplainable.

There have been many efforts devoted to evaluating the word embeddings' lexical information, such as the word similarity (Landauer and Dumais, 1997; Downey et al., 2007) and analogical relation (Mikolov et al., 2013c) tasks. However, these tasks can only serve as indirect evaluation methods. In light of this, Noraset et al. (2017) proposed the task of definition modeling to evaluate whether a word embedding can be employed to generate a dictionary gloss. Since the gloss is a direct and explicit statement of word meaning, this task provides a more transparent view.

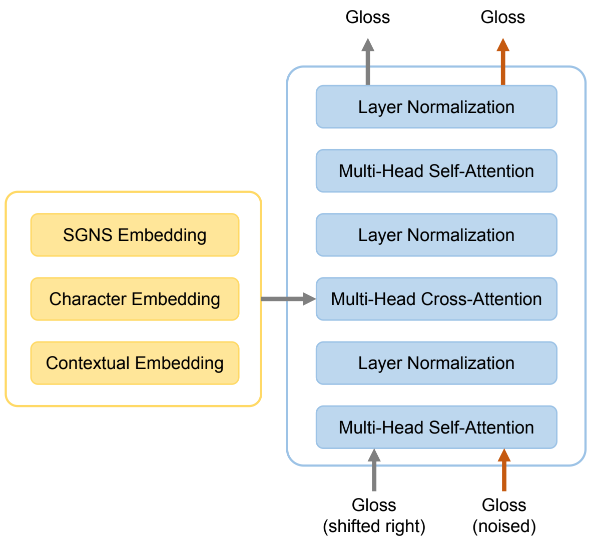

Figure 1: Architecture of the Cross-Attention Multitasking Framework.

The SemEval-2022 Task 1 Comparing Dictionaries and Word Embeddings (Mickus et al., 2022) aims at comparing the two types of semantic descriptions: dictionary glosses and word embeddings. The subtrack 1 is a definition modeling task, which requires models to generate glosses from word embeddings. The task provides data from 5 languages (English, Spanish, French, Italian, Russian) as well as static, character, and contextual embeddings.

Our team propose a transformer-based (Vaswani et al., 2017) Cross-Attention Multitasking Framework to explore the task and apply the framework to all 5 languages. We integrate the multiple embed-

Table 1: Detailed statistics of the dataset. The last column lists the average length of glosses in the training set.

ding architectures through a cross-attention mechanism, which allows the model to query all the embeddings at each time step during generation. To better capture the structure of glosses, we employ an additional masking language model (MLM) (Devlin et al., 2019) into the framework. We also investigate the ensemble strategies to further enhance the robustness.

Therefore, the contributions of our system lie in:

- We propose the Cross-Attention Multitasking Framework as a novel solution to the definition modeling task.
- The evaluation results show the effectiveness of our solution. Our system achieves 1st on Italian, 2nd on Spanish and Russian, and 3rd on English and French.

2 Background

The definition modeling subtrack provides participants with a multilingual dataset in the form of $\{E, \boldsymbol{g}\}$, where E is a set including SGNS (Mikolov et al., 2013b), character (Kim et al., 2016), and Electra (Clark et al., 2020) embeddings, and $\boldsymbol{g}$ is a dictionary gloss. This task takes E as the input, and requires models to generate $\boldsymbol{g}$. Note that all the embeddings have 256 dimensions, and the Electra embeddings are only available for 3 of the 5 languages. More detailed statistics of the dataset are listed in Table 1.

Many previous work used additional data to improve the performance of generation, such as example sentences (Gadetsky et al., 2018; Chang et al., 2018; Ishiwatari et al., 2019; Kong et al., 2020) and semantic features (Yang et al., 2020). Some studies also investigated how to employ PLMs for this task (Reid et al., 2020; Bevilacqua et al., 2020; Huang et al., 2021; Kong et al., 2022).

Differently, to keep the results linguistically significant and easily comparable, the SemEval-2022 Task 1 prohibits the usage of external data and PLMs. Therefore, our system focuses on effectively integrating all given embeddings and modeling the glosses.

3 System Overview

Figure 1 illustrates the entire architecture of our system, which is a Cross-Attention Multitasking Framework based on transformer. The framework consists of two objectives, namely the generation and reconstruction objectives. This section introduces the system in detail.

3.1 The Generation Objective

The generation objective serves as a standard transformer decoder, which generates the gloss as the following language model:

$$P(\boldsymbol{g}|E;\boldsymbol{\theta}) = \prod_t P\left(\boldsymbol{g}_t|\boldsymbol{g}_{<t}, E;\boldsymbol{\theta}\right), \quad (1)$$

where $\boldsymbol{g}_t$ is the t-th token in the gloss, and $\boldsymbol{\theta}$ is the set of parameters. The model is then optimized using the following loss function:

$$\mathcal{L}_{gen}(\boldsymbol{\theta}) = -\sum_{\boldsymbol{g}\in D} \log P(\boldsymbol{g}|E;\boldsymbol{\theta}), \quad (2)$$

where D is the training dataset.

In the above operations, a crucial challenge is to integrate multiple embeddings corresponding to one word. We assume that the SGNS, character, and Electra embeddings contain different lexical features, and better results can be obtained by comprehensively considering all the information. To achieve that, we feed the set E, including all these embeddings, into the cross-attention mechanism:

$$\text{Cross-Attn}(H, E, E) = \text{softmax}(\frac{HE^T}{\sqrt{d_h}})E \quad (3)$$

where H is the hidden-states obtained from by self-attention, and d_h is the dimension of the hidden-states. This operation ensures the given embeddings are adaptively integrated at each time-step.

3.2 The Reconstruction Objective

Our system is a language model specially designed for dictionary glosses. We further enhance this model by incorporating a reconstruction objective.

We corrupt each gloss $\boldsymbol{g}$ by randomly substituting or blanking some words. And then we obtain a corrupted version $\tilde{\boldsymbol{g}}$. We input $\tilde{g}$ into our system and obtain $\boldsymbol{g}$ by solving a self-supervised task of:

$$P(\boldsymbol{g}|\tilde{\boldsymbol{g}};\boldsymbol{\theta}) = \prod_t P(\boldsymbol{g}_t|\boldsymbol{g}_{<t},\tilde{\boldsymbol{g}};\boldsymbol{\theta}). \tag{4}$$

Note that we share exactly the same parameters $\boldsymbol{\theta}$ as in the generation objective. The model is optimized by the following loss function:

$$\mathcal{L}_{rec}(\boldsymbol{\theta}) = -\sum_{\boldsymbol{g}\in D} \log P(\boldsymbol{g}|\tilde{\boldsymbol{g}};\boldsymbol{\theta}), \tag{5}$$

The goal of the reconstruction objective is to better model the glosses. Therefore, we don't use the given embeddings in this operation. In practice, we feed a zero vector into the cross-attention mechanism to mask it out as $\text{Cross-Attn}(H,\mathbf{0},\mathbf{0})$.

3.3 Training and Ensembling

We train the entire multitasking framework by jointly minimizing the weighted sum of both loss functions:

$$\mathcal{L} = \mathcal{L}_{gen} + \lambda\mathcal{L}_{rec}, \tag{6}$$

where λ is a hyper-parameter.

Model ensembling is proven to be effective to improve the robustness (Allen-Zhu and Li, 2020). In our work, we adopt a simple but effective model ensembling strategy. We train a series of models initialized by different random seeds, and then vote with the trained models during inference.

4 Experimental Setup

4.1 Implementation Details

Many neural network-based generation systems struggle with the OOV (out-of-vocabulary) problem. To alleviate the problem, we apply the SentencePiece algorithm (Kudo and Richardson, 2018) to glosses to reduce the vocabulary size. We use the tokenizers[1] toolkit for implementation and set the size to 10k for all 5 languages.

Our system is a 3-layer, 8-head transformer-based model implemented by the Pytorch library (Paszke et al., 2019). We use the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and $\epsilon = 10^{-9}$. We adopt the Noam Optimizer proposed by (Vaswani et al., 2017) with an initial learning rate of $1e-7$, a maximum learning rate of $1e-3$, and a minimum learning rate of $1e-9$. We set the warmup steps to 4000 and batch size to 128. The maximum epochs is set to 500. And we set an early stop strategy in the patience of 5 epochs. To avoid gradient exploding, we clipped the gradient norm within 0.1. We also employ label smoothing technique (Pereyra et al., 2017) with a smoothing value of 0.1 during training. For the gloss corruption in the reconstruction objective, we follow Devlin et al. (2019) to randomly delete and blank words with a uniform probability of 0.2. And the λ (in Equation 6) is set to 1. For model ensembling, we train 5 models with different seeds. Due to the time constraints, our official submission has a result of ensembling three models on English, and results of single models on the reset of 4 languages. We submitted the results of ensembling 5 models in the post-evaluation phase.

For each language, we use the development set released by organizers for model selection. We select the best epoch using the summary of BLEU (Papineni et al., 2002) and MoverScore (Zhao et al., 2019) on the development set.

4.2 Evaluation Metrics

The definition modeling subtrack uses three metrics, which are MoverScore (Zhao et al., 2019), BLEU (Papineni et al., 2002) , and lemma-level BLEU respectively. Readers can refer to the task paper (Mickus et al., 2022) for more details.

5 Results and Analysis

In this section, we present the evaluation results and discuss our analysis of the generated definitions.

5.1 Main Results

Table 2 presents the evaluation scores on all 5 languages. Results show that our system significantly outperforms the baseline models in terms of the sentence BLEU and lemma-level BLEU. This indicates the effectiveness of our proposed cross-attention multitasking framework. However, the SGNS and Char are strong baselines in terms of the MoverScore, and our system only outperforms the baselines on English. We speculate that our results have more coincide words with references, but are not fluent enough, which leads to a low score from

Table 2: Evaluation results of different models in 5 languages. The SGNS, Char, Electra are baseline models provided by the organizers. The CAMF (Cross-Attention Multilingual Framework) is the model of official submission. And the Ensemble is an ensemble of 5 models submitted in the post-evaluation. Bold and underline mark the best and second scores, respectively.

(1) Redundancy and overusing common phrases: 42.00%	
word	explosion
reference	A sudden outburst.
hypothesis	A sudden, sudden, or destruction.
(2) Self-reference: 2.00%	
word	discover
reference	To reveal (information); to divulge, make known.
hypothesis	To make a conclusion of; to discover.
(3) Wrong Part-Of-Speech: 5.50%	
word	genius
reference	ingenious, brilliant, very clever, or original.
hypothesis	A person or thing that is extraordinary.
(4) Under-specified: 23.50%	
word	mayor
reference	The leader of a city.
hypothesis	A person who is a member of authority.
(5) Opposite: 2.00%	
word	solid
reference	Excellent , of high quality , or reliable.
hypothesis	Having no size or value.
(6) Close Semantics: 17.00%	
word	bed
reference	The time for going to sleep or resting in bed.
hypothesis	The state or quality of being a room.
(7) Incorrect: 52.00%	
word	smooth
reference	Lacking projections or indentations; not serrated.
hypothesis	Having the shape of a tree.

Table 3: Error types and examples.

the pretrained model used by MoverScore.

We also observe that model ensembling has brought the improvement of performance. It can be seen from the table that the Ensemble model outperforms the CAMF on 4 of the 5 languages, except for a slight decline on English. This may be due to the randomness of the parameter initialization. We also argue that better performance can be obtained by applying hyper-parameter searching algorithms and ensembling more models.

5.2 Error Analysis

In order to qualitatively analyze the definitions generated by our system, we randomly select several items from the English test set and manually annotate the error types following Noraset et al. (2017). In total, we extract 200 items, of which 197 contain some degree of error. We illustrate the error types and examples in Table 3. Note that each item may contain multiple errors, so the sum of the percentages in the table is greater than 100%.

From the table, we observe that the quality of English definitions generated by our system still need to be improved. Error types (1) to (3) are problems from the system, and types (4) to (6) are shortcomings in the embeddings. As we can see, the former accounts for a much larger proportion than the latter. The 52% incorrectness indicated by type (7) shows that many glosses generated by our system are irrelevant to the word. And the dataset released in this task will support significant future work on the definition modeling task.

6 Conclusion

In this paper, we present the implementation of the BLCU-ICALL system submitted to the SemEval-2022 Task 1, Definition Modeling subtrack. We propose a Cross-Attention Multitasking Framework that leverages multiple embedding architectures and jointly trains two objectives. We also investigate a simple but effective ensembling strategy to enhance the robustness. In future efforts, we plan to further improve our system to better handle the problems of redundancy and incorrect glosses.

Abstract

This paper introduces the result of Team LingJing's experiments in SemEval-2022 Task 1 Comparing Dictionaries and Word Embeddings (CODWOE)[1]. This task aims at comparing two types of semantic descriptions, including the definition modeling and reverse dictionary track. Our team focuses on the reverse dictionary track and adopts the multi-task self-supervised pre-training for multilingual reverse dictionaries. Specifically, the randomly initialized mDeBERTa-base model is used to perform multi-task pre-training on the multilingual training datasets. The pre-training step is divided into two stages, namely the MLM pre-training stage and the contrastive pre-training stage. As a result, all the experiments are performed on the pre-trained language model during fine-tuning. The experimental results show that the proposed method has achieved good performance in the reverse dictionary track, where we rank the 1-st in the Sgns targets of the EN and RU languages. All the experimental codes are open-sourced at `https://github.com/WENGSYX/Semeval`.

1 Introduction

The CODWOE shared task invites the participants to compare two types of semantic descriptions: dictionary glosses and word embedding representations. The intuitions come from the questions: "Are these two types of representation equivalent? Can we generate one from the other?". To study this question, the CODWOE proposes two sub-tracks: a definition modeling track (Noraset et al., 2017), where participants have to generate glosses from vectors, and a reverse dictionary track (Hill et al., 2016), where participants have to generate vectors from glosses. These two tracks are fairly challenging (Hill et al., 2016), where more efficient methods are required to be designed for implementation.

Embedding
sgns: [0.9233651757, -0.526638031, 2.0892603397, … …]$_{256}$
char: [-0.1214295924, -0.2428643405, 0.2625943422, … …]$_{256}$
electra: [0.3655579984, -0.1910238415, 0.0170905143,… …]$_{256}$

Figure 1: An example of the reverse dictionary task. Given the word gloss, it is required to generate the vectors of their corresponding Sgns, Char, and Electra, respectively.

These tasks are also useful for explainable AI, since they involve converting human-readable data into machine-readable data and back (Li et al., 2021). In this paper, we focus on the reverse dictionary track. As shown in Figure 1, given the gloss "A meal consisting of food normally eaten in the morning, which may typically include eggs, sausages, toast, bacon, etc.", the reverse dictionary task requires us to generate corresponding three sets of 256-dimensional word vectors. The Sgns (Mikolov et al., 2013) , char (Vakulenko et al., 2017), and Electra (González et al., 2020) are skip-gram with negative sampling embeddings, character-based embeddings, and Transformer-based contextualized embeddings, respectively.

It is noted that this task comprises datasets in 5 languages: English, Spanish, Italian, French, and Russian. The reverse dictionary task is difficult due to the significant inborn differences between word vectors and glosses and the vast differences between languages (Bosc and Vincent, 2018).

To solve the above problems, we use a multi-task self-supervised pre-training approach with Masked language modeling (MLM) (Taylor, 1953; Devlin et al., 2019) and contrastive learning (Reimers and Gurevych, 2019; Su et al., 2021). On the one hand, MLM can better capture the semantic representation of the input text (Liu et al., 2019). On the other hand, contrast learning can further improve the performance of downstream regression tasks (Jaiswal et al., 2020). Specifically, we use a randomly initialized mDeBERTa-base (He et al., 2021) model to perform MLM pre-training on five text datasets in different languages. Contrastive pre-training (Gao et al., 2021) is then performed using vectors with and without dropout (Srivastava et al., 2014). Afterward, the model is fine-tuned using the Reverse Dictionary dataset. The experimental results show that the proposed method has achieved good performance in the reverse dictionary track. We achieve the top three results on the Sgns evaluation metrics in all languages. Specifically, we get first place in English and Russian, second place in Spanish and French, and third place in Italian.

2 Main method

In this section, we will elaborate on the main methods for the reverse dictionary track. As the pre-training method can enhance the performance of semantic representation (Qiu et al., 2020), we adopt masked language modeling (MLM) task (Devlin et al., 2019) and contrastive pre-training task (Jaiswal et al., 2020) for implementing this regression task.

2.1 Masked language modeling task

Masked language modeling (MLM) task consists of giving the model a random masked sentence and optimizing the weights inside the model to output the unmasked sentence on the other side. We implement the MLM pre-training method with the same original setting as BERT (Devlin et al., 2019). What's more, we adopt the standard implementations of the MLM from the website[2].

2.2 Contrastive pre-training task

Our method follows the SimCSE (Gao et al., 2021) method, where the self-supervised model is adopted for the contrastive pre-training task. For the self-supervised part, we use dropout to add noise to the text twice, thus constructing a pair of positive samples, and pairs of negative samples are sentences processed with the dropout in the batch. The above processes can be formulated as the equation (1)

$$\mathcal{L}_{\text{CL}} = -\log \frac{\exp\left(\text{sim}\left(\tilde{h}_i, h_i\right)/\tau\right)}{\sum_{j=1}^{n} \exp\left(\text{sim}\left(\tilde{h}_i, h_j\right)/\tau\right)}, \quad (1)$$

where the h_i represents the hidden feature of the positive sample, while the h_j is the hidden feature of the negative drop-out sample. The τ is a temperature hyper-parameter and sim(,) means the cosine similarity function.

[2]https://github.com/lucidrains/mlm-pytorch

2.3 Multi-task pre-training

Multi-task learning is known to fully enhance the performance of the single task with multiple related tasks to be designed and optimized (Sanh et al., 2021). We combine the above two pre-training task to the multi-task objectives, where the final loss function can be represented as follows

$$\mathcal{L} = \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{CL}}. \quad (2)$$

2.4 Downstream fine-tuning

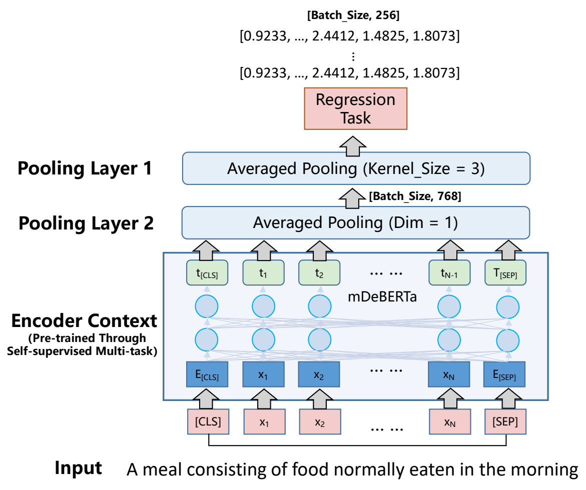

Figure 2: Main structure of the proposed method.

Concretely, given the input sentence, the semantic representation can be obtained through the context encoder with pre-training. As shown in the Figure 2, we use the pre-trained language model through self-supervised multi-task pre-training as the backbone for the regression task. Once obtaining the final representation of the pre-trained language model, two pooling layers (Lin et al., 2013) are designed to get the useful features with the probable size. The mean pooling layer is added on top of the pre-trained model for squeezing the features. Another pooling layer (with the kernel_size=3) is added before the final regression task.

3 Experimental setup

3.1 Data Description

The CODWOE shared task provides datasets in five different languages (EN, ES, FR, IT, RU). For these datasets of five languages, each dataset has 43,608 training sets, 6375 dev sets and 4208 test sets. Each language contains multiple embeddings containing "Char" and "Sgns", while English, French and Russian have the embedding "Electra". We will introduce these datasets as follows.

Char corresponds to character-based embeddings, computed with an auto-encoder on the spelling of a word. In addition, the "gloss" key in each dataset is the source in the reverse dictionary track. We need to use "gloss" to generate the associated embeddings.

Sgns corresponds to skip-gram with negative sampling embeddings (aka. word2vec (Mikolov et al., 2013)).

Electra corresponds to the Transformer-based (Vaswani et al., 2017) contextualized embeddings.

Moreover, the organizers want the shared task to be as linguistically relevant as possible and hope to provide a fair competition environment for all participants. The organizer forbids the use of external resources and pre-trained language models in CODWOE.

3.2 Evaluation metrics

In this task, the performance of the system is evaluated through three evaluation indicators (Mickus et al., 2022).

Mean squared error (MSE) between the submission's reconstructed embedding and the reference embedding.

Cosine similarity (Cossim) between the submission's reconstructed embedding and the reference embedding.

$$\text{MSE} = \frac{1}{n}\Sigma_{i=1}^{n}\left(\frac{A_i - B_i}{\sigma_i}\right)^2$$

$$\text{Cossim} = \frac{\sum_{i=1}^{n} A_i \times B_i}{\sqrt{\sum_{i=1}^{n}(A_i)^2} \times \sqrt{\sum_{i=1}^{n}(B_i)^2}}$$

where the A and B refer to two matrices that need to be calculated.

Cosine-based ranking[3] between the submission's reconstructed embedding and the reference embedding; i.e., how many other test items have a cosine similarity with the reconstructed embedding higher than that with the reference embedding.

[3]Specific implementations can refer to https://github.com/WENGSYX/Semeval.

3.3 Method introduction

The Baseline provided by the organizer[4] uses the encoder structure of the Transformer (Vaswani et al., 2017; Wolf et al., 2020) framework. After each token passes through the embedding layer, positional encoding will be added to indicate the location structure of the token. Then it will be input to the encoder based on the transformer and finally output to the linear layer to make the dimension of the matrix consistent with the label.

In addition, the organizer has made some improvements to the baseline.

1. The principled way of selecting hyper-parameters (using Bayesian Optimization (Snoek et al., 2012; Frazier, 2018)).

2. A sentence-piece re-tokenization, to ensure the vocabulary is of the same size for all languages.

3. The beam-search (Wiseman and Rush, 2016; Freitag and Al-Onaizan, 2017) decoding for the definition modeling pipeline.

Our method uses the randomly initialized mDeBERTa (He et al., 2021) model. The mDeBERTa improves the BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) models using disentangled attention and enhanced mask decoder. It shares the base model with 12 layers and 768 hidden size, which is pre-trained on the multilingual corpus. It has 86M backbone parameters with a vocabulary containing 250K tokens which introduce 190M parameters in the Embedding layer. It supports most languages around the world, since it is believed that there should be some shared semantic features between different languages[5].

3.4 Implementation details

We use the hugging-face[6] (Wolf et al., 2020) framework and train the model based on the Pytorch (Paszke et al., 2019). During training, we employ the AdamW optimizer (Loshchilov and Hutter, 2017). The default learning rate is set to 1e-5 with the warm-up (He et al., 2016). Four 3090 GPUs are used for all experiments.

Table 2: Results of the Char track.

On the MLM pre-training task, we alternately carry out the pre-training tasks of long text and short text. After mixing the data sets of five different languages, we train them for 40 epochs. In detail, we classify all data sets with a text length of 30. In each epoch, firstly, samples with text length less than or equal to 30 are trained with a maximum length of 32 tokens (including <CLS> and <SEP>) and the batch size is set to 70. Then we change the maximum length to 160 tokens and set the batch size to 18 for training the remaining samples.

Referring to the settings of WWM (Cui et al., 2021; Joshi et al., 2020), we use the text mask rate with a probability of 20%, and adopt that the 1, 2, 3, 4 n-gram masking length with a probability of 85%, 5%, 5%, and 5%.

In contrastive pre-training, we repeatedly integrate a sample into the model twice. During this period, because our model has dropout, it will add noise to the input, so that the output of the two times is distinct. As a result, our method can be improved in the sentence representation ability through self-supervised.

Based on the pre-trained language model, we fine-tune with the maximum length of all samples to 100 tokens, the batch size to 50 (there will be 2 * 50 samples for each step to be calculated by the model at the same time). The number of training epochs is 40.

4 Results and discussions

In this section, we introduce the experimental results of the Sgns, the Char and the Electra tracks. The online results and further discussions are also presented.

4.1 Experimental results

The experimental results of the Sgns, Char and Electra can be found in the Table 1, 2 and 3. Specifically, for the Sgns track, we outperform the experiments of each baseline according to all the metrics. The reason may be that the pre-training method with MLM and contrastive learning can well provide well-formed vector space representations between samples. As for the Char and Electra track, the baseline is better than ours. It may be because the word and contextual character features are hard to be captured due to the smaller corpus. In the future, we will explore more efficient methods to perform well definition modeling in these tracks.

4.2 Official online results

As shown in Table 4, we achieve the top three results on the Sgns evaluation metrics in all languages. Specifically, we get first place in English and Russian, second place in Spanish and French, and third place in Italian. Our method is effective on the Electra evaluation metrics, but not the best. Our team ranks the second place, fourth and fourth place in Russian, English, and French, respectively. Our approach does not achieve good results on the char metric, which represents the character level. This result may be that it is difficult for the model to capture semantics while maintaining high precision letter-level fine-grained word vector learning.

5 Conclusion

In this paper, it is mainly introduced that in order to solve the reverse dictionary track in Semeval-22 CODWOE, the LingJing team makes the model have the ability of semantic understanding through the MLM task with contrastive learning in the randomly initialized mDeBERTa model. After that, we report the performance of our model in CODWOE, and obtain the best performance in English and Russian tasks of Sgns dataset, which proves that our method is effective. In the future, we will further study how to make full use of the characteristics of different languages and make the model embed the text into a more accurate vector space.

Abstract

What is the relation between a word and its description, or a word and its embedding? Both descriptions and embeddings are semantic representations of words. But, what information from the original word remains in these representations? Or more importantly, which information about a word do these two representations share? Definition Modeling and Reverse Dictionary are two opposite learning tasks that address these questions. The goal of the Definition Modeling task is to investigate the power of information laying inside a word embedding to express the meaning of the word in a humanly understandable way – as a dictionary definition. Conversely, the Reverse Dictionary task explores the ability to predict word embeddings directly from its definition. In this paper, by tackling these two tasks, we are exploring the relationship between words and their semantic representations. We present our findings based on the descriptive, exploratory, and predictive data analysis conducted on the CODWOE dataset. We give a detailed overview of the systems that we designed for Definition Modeling and Reverse Dictionary tasks, and that achieved top scores on SemEval-2022 CODWOE challenge in several subtasks. We hope that our experimental results concerning the predictive models and the data analyses we provide will prove useful in future explorations of word representations and their relationships.

1 Introduction

The **COmparing Dictionaries and WOrd Embeddings** (`CODWOE`) task (Mickus et al., 2022) is aimed at explaining two different types of semantic descriptions of words: dictionary glosses and word embeddings. A *dictionary gloss* is a brief textual explanation of a word and a *word embedding* is a vector representation that captures the word's semantic and syntactic properties (Smith, 2020).

In order to investigate the relationship between these two types of descriptions, two complementary subtracks were put together: 1. *Definition Modeling* (`DEFMOD`) track, where correct glosses need to be generated from word embedding vectors (Noraset et al., 2017); and 2. *Reverse Dictionary* (`REVDICT`) track, where correct embedding vectors should be generated from dictionary glosses (Hill et al., 2016). The datasets for both tracks cover five different languages: English (EN), Spanish (ES), French (FR), Italian (IT), and Russian (RU).

The key challenge of the `CODWOE` task is that it needs to be performed without external data, which precludes the use of pretrained models and vectors. Additionally, the training dataset is relatively small in comparison to the datasets on which models are typically trained.

Our strategy was to adapt an RNN-based decoder model (Noraset et al., 2017) for the `DEFMOD` track, and to use a transformer-based encoder (Devlin et al., 2019) for the `REVDICT` track. With the limited amount of available data in mind, we hypothesized that models should not be large. Therefore we aimed to limit the model complexity by reducing the number of parameters, for example by using a subword tokenizer (Kudo and Richardson, 2018), which yields a smaller dictionary of optimized subword fragments. All of the models we used were built for a single language, and their structure and parameters were optimized either iteratively or by way of Bayesian hyperparameter optimization (BHO) (Snoek et al., 2012).

We conducted data analyses of the `CODWOE` datasets and analyses of the developed machine learning models. We performed a statistical and visual analysis of the pretrained `CODWOE` embeddings, i.e., of their distributions and relationships. `DEFMOD` analyses include an analysis of model performance factors and a qualitative analysis of generated glosses. In the `REVDICT` predictive analysis,

[*]Equal contribution.

RD-sgns	3 (9)	**1** (7)	**1** (6)	**1** (7)	2 (6)
RD-char	4 (7)	3 (5)	4 (5)	2 (6)	2 (5)
RD-electra	5 (6)		3 (4)		3 (4)

we investigate the impact of many different settings on models' performance defined in terms of distance and similarity scores between predicted and target vectors.

We show that our adaptation of the DEFMOD architecture (Noraset et al., 2017) can perform competitively and that the use of multiple word embeddings can clearly improve the generation of word glosses. For REVDICT, we demonstrate that our approaches achieve top performance in terms of ranking, which makes them suitable for information retrieval applications. Our models perform competitively and our results on the CODWOE challenge can be found in Table 1. We make the code of our models and data analyses publicly available[1].

2 Background

2.1 Related Work

Definition Modeling The Definition Modeling (DEFMOD) task, first introduced in Noraset et al., 2017, is focused on the prediction of dictionary word glosses from word embeddings. Noraset et al. (2017) experimented on two English dictionaries and proposed a successful architecture based on RNN.

Subsequent work on Definition Modeling focused on variations of the problem of prediction of a word gloss from the word sense. These approaches consider gloss prediction based on sense-specific word embeddings (Gadetsky et al., 2018; Kabiri and Cook, 2020; Zhu et al., 2019), and on a word-based context indicating the word sense (Bevilacqua et al., 2020; Gadetsky et al., 2018; Mickus et al., 2019; Yang et al., 2020; Zhang et al., 2020). The proposed approaches are based either on RNNs (Gadetsky et al., 2018; Kabiri and Cook, 2020; Zhang et al., 2020; Zhu et al., 2019) or Transformers (Bevilacqua et al., 2020; Mickus et al., 2019). All of the previous approaches rely on word embeddings pre-trained on large corpora, most commonly word2vec (Mikolov et al., 2013). Sense-aware approaches that take embeddings as input make use of either sense-aware word embeddings (Gadetsky et al., 2018; Kabiri and Cook, 2020) or of decomposition of word embeddings into sense-specific vectors (Zhu et al., 2019).

The initially proposed architecture of Noraset et al. (2017) is often used as a baseline solution. The most commonly used measure of model performance is the BLEU (Papineni et al., 2002) metric. Although there is some overlap in used datasets, most experiments rely on a specific dataset. The reported model performances vary greatly. Noraset et al. (2017) report BLEU of 31 and 23, depending on the dictionary. Subsequent experiments report, for the same approach, BLEU scores that range from as little as 11 (Gadetsky et al., 2018) to as much as 60 (Kabiri and Cook, 2020). The variation can be great even for the same language and experimental setup (Kabiri and Cook, 2020). The original approach of Noraset et al. (2017) remains competitive in the sense-aware setting, with the sense-aware approaches achieving BLEU increases that range between $1-2$ (Gadetsky et al., 2018; Kabiri and Cook, 2020; Zhang et al., 2020) and $5-6$ (Kabiri and Cook, 2020; Yang et al., 2020; Zhang et al., 2020), depending on the setting.

While we view the Definition Modeling primarily as a theoretically interesting task, potential applications include explainability of word embeddings and automatic generation of dictionaries, which might be of interest in low-resource settings.

Reverse Dictionary The Reverse Dictionary (REVDICT) is a task of finding the right word when a word description is given (Bilac et al., 2004; Dutoit and Nugues, 2002; Zock and Bilac, 2004). It is the formulation of the tip-of-the-tongue problem (TOT) (Brown and McNeill, 1966) that occurs during text synthesis. It is a condition in which a person knows a lot about the word, such as its meaning and origin, but is unable to recall it. REVDICT is a complex task. There are countless variations of input definitions that should lead to the same one-word concept. This complexity comes in part from the representation of the one-word concepts in the human mind. People tend to relate concepts on the conceptual and lexical level and form a highly connected network of abstractions (Zock and Bilac, 2004).

Therefore, a natural approach to solving REVDICT is to form a semantic network with nodes (one-word concepts) and edges (associ-

[1] https://github.com/dkorenci/codwoe-irb-nlp/

ations) to search for the target word (Thorat and Choudhari, 2016; Zock and Bilac, 2004). REVDICT can be realized directly by comparing the input definitions with all the definitions in the dictionary and returning the most similar ones, without taking into account any semantic or grammatical information (El-Kahlout and Oflazer, 2004). However, REVDICT systems that include semantics give better results, such as in Méndez et al., 2013 and Calvo et al., 2016 where words are represented as vectors in a semantic space.

Recent REVDICT approaches utilize deep learning (DL) to map arbitrary-length definition phrases to the vector representation of the target word (Hill et al., 2016; Malekzadeh et al., 2021; Qi et al., 2020; Yan et al., 2020). The success of DL approaches indicates that REVDICT can be solved implicitly, i.e. by directly learning from given data, and doesn't require an explicit injection of domain knowledge. According to this observation, the DL approach is a good choice for solving the REVDICT task.

2.2 Dataset

The CODWOE datasets (Mickus et al., 2022) cover five languages (EN, ES, FR, IT, RU) and are derived from the Dbnary lexical data[2]. Each data point corresponds to a single word and contains word embedding vectors and the word gloss. Three types of embedding are used, labeled as sgns (pretrained word2vec), electra (contextual pretrained embeddings) and char (character-based embeddings). Pretrained embeddings are based on large corpora containing approximately 1B tokens.

Each dataset is divided into three sections: training, validation (development), and test. Datasets for training and validation have 43.608 and 6.375 samples, respectively. Each track also has a separate set of test data. The DEFMOD test dataset has 6.221 samples while the REVDICT has 6.208 samples.

More detailed statistics and analyses of the dataset can be found in the Appendices, including the gloss statistics (Table 5) and embedding vector statistics (Table 11). Descriptive analysis of the embedding vectors shows large variation in values that depend on a language and an embedding type (Figures 3 and 4). Additionally, an exploratory analysis showed that the embeddings for different languages are easily separable (Figures 6 and 5). Interestingly, patterns of vector-based word similarity seem to differ significantly across embedding types, and in this regard there are no visible relations between different embeddings (Figure 7).

3 System overview

Both the DEFMOD and the REVDICT models rely on unigram subword tokenizers (Kudo, 2018) trained on glosses from the train datasets.

3.1 Definition Modeling

Our approach to the challenging task of Definition Modeling on a limited dataset consists of preprocessing the input data, extracting the semantic information from the dataset, and controlling the model size and complexity.

The inspection of the learning data revealed that the gloss texts are often long since they consist of several alternative definitions. We opted to include only one definition per learning example. Our intuition is that this approach, also taken in (Noraset et al., 2017), alleviates the learning problem by inducing the model to learn shorter and atomic definitions. The approach should also reduce noise (since the number of alternative definitions in a gloss is arbitrary).

The inspection of glosses also revealed the presence of lexicographic labels that precede the gloss definitions. These labels, present for all languages except English, convey data about, for example, word semantics (ex. geography, history) or temporal category (ex. archaic). We chose to remove these labels since they introduce noise (the presence and the amount of labels appears arbitrary), increase the dictionary size, and thus make the learning problem harder.

To construct the dictionary we use the unigram subword tokenizer (Kudo, 2018) implemented as part of the SentencePiece tool (Kudo and Richardson, 2018). The reasons for using the subword tokenization were the expected improvement in performance for low-resource tasks (Kudo, 2018) and the reduction in the number of model parameters corresponding to token embeddings.

Since we opted for a deep learning model depending on token embeddings, we initialized the token embeddings with GloVe vectors (Pennington et al., 2014) trained on the dataset of normalized and cleaned atomic glosses. To demonstrate that the GloVe vectors capture a degree of word semantics, we aggregated the vectors on a gloss level using tf-idf weighting. Then we inspected, for each "target" gloss from a sample of English glosses, other dataset glosses ordered by cosine similarity to the target. This revealed that GloVe similarity corresponds to the similarity in gloss meaning. Additionally, we found that the models initialized with GloVe vectors achieve a lower final loss.

Machine learning model We decided to use an adaptation of the RNN-based model of (Noraset et al., 2017), that proved competitive in a number of experimental settings. In the context of the DEFMOD task, the model takes as input one or more word embeddings (sgns, electra or char) and produces a gloss (a sequence of tokens) that should correspond to the word's correct gloss.

From the input embeddings, we form two vectors, the *seed* vector s that is used to initialize the RNN, and the *context* vector c. For both the seed and the context vectors we consider using a single embedding, concatenation of embeddings, and a nonlinear transformation of the concatenation. At each position in the sequence the context vector is passed as input, together with the RNN's output, to the special GRU-like gated cell (Noraset et al., 2017). The output of the gated cell is then transformed (via linear transformation and softmax activation) to produce token-level probabilities. The gated cell can learn to effectively combine the semantic context with the RNN-level features in guiding the generation process (Noraset et al., 2017). The network architecture we use is labeled as S+G in Noraset et al. (2017).

The described model performs conditional generation of tokens in a sequence, which is a standard approach in RNN-based language modeling. The probability of a gloss g is factorized under the assumption that each token g_i depends on the previous tokens, the seed embbedding s, and the context c :

$$p(g|s,c) = \prod_{i=1}^{|g|} p(g_i|g_{0:i-1}, s, c)$$

In (Noraset et al., 2017), the context is equal to the seed, i.e., the input word embedding. In our case, both the seed and the context can either be a single embedding or a function of multiple embeddings. This approach enables us to leverage the information from several word embeddings in a flexible way. For example, sgns embeddings can be used as a seed while the context can be formed by passing all the embeddings through a multilayer perceptron. Another important difference is that we use the unigram subword tokenization (Kudo, 2018). Finally, we experiment with using both LSTM and GRU as the network's RNN components.

3.2 Reverse Dictionary

We approach REVDICT as a supervised vector regression task and employ an end-to-end deep learning solution. Our model is based on a transformer architecture (Vaswani et al., 2017) used as a definition sentence encoder, and a fully connected feed-forward network used as an output regression module.

The transformer is used to produce useful representations from given inputs, where the inputs are tokenized definition sentences. For each subword token in the input sequence, the transformer gives a representation in the form of a vector. Our REVDICT systems implement three different approaches for aggregating the output vectors produced by the transformer: 1. *sum*, where we sum the representations given for each token in the input sequence; 2. *average*, where we average the representations given for each token in the input sequence; and 3. *eos*, where we use only the representation of the last token in the input sequence, i.e. end-of-sequence (eos) token. The output module further transforms these representations into word embedding vectors.

Additionally, we utilize a multi-task learning (Caruana, 1997; Ruder, 2017) approach. To support multi-task learning, we implemented multiple output regression modules that simultaneously predict different types of embedding vectors from the same representations produced by a single encoder. Multi-task learning is used during the model training phase and only output from one output module makes final predictions. The motivation for using a multi-task learning approach is to benefit from inductive transfer between tasks that could improve the results of predicting a single task (Caruana, 1997).

4 Model Selection and Experimental Setup

In this section we describe the technical details of data preprocessing and model selection that comprise our methods of constructing the DEFMOD and REVDICT models. The conceptual description of the methods is given in Section 3.

4.1 Definition Modeling

Our choices regarding the technical details of data preprocessing and model construction were guided by what we will call *development experiments*. These experiments consisted of training the model on the train set, and observing both the final development set loss and the quality of the produced glosses.

Output gloss quality was assessed using a separate “trial” dataset - a small dataset of 200 items provided by the organizers, containing gloss information consisting of the embedding vector, the original word, and the gloss text. The assessment was performed for English glosses only and aimed to assess the quality of the generated text, and the similarity of the output and the original glosses. A choice was deemed an improvement if it led to the improvement of development loss and either improved the generated glosses or caused no degradation in gloss quality. The development of the final algorithm was performed iteratively and heuristically. However, the overall improvement over the iterations is confirmed by the results of the test set evaluations.

Dataset transformation The transformation of the original dataset is performed by creating unambiguous training examples and removing the uninformative data that makes the problem harder.

In the original dataset a gloss definition often consists of several equivalent but differently phrased definitions. We divided the dictionary glosses into atomic definitions by splitting the text strings around the “;” character. This heuristic was motivated by gloss sample analysis and the inspection of a sample of atomic glosses revealed that it works in the majority of cases. Each atomic gloss in the new dataset was paired with all the embedding vectors of the original gloss.

In order to remove lexicographical labels from the beginning of the glosses' text, simple language-specific regular expressions and removal rules were formed based on gloss sample analysis. This approach proved to be effective for a large majority of glosses.

To perform further normalization we additionally lowercased all the glosses and removed the punctuation from the end of texts. The code used to preprocess the original dataset, the new dataset, and the transformation log can be found in the code repository. We note that both the SentencePiece dictionary and the GloVe vectors used for `DEFMOD` are derived from the transformed dataset. The statistics of the transformed glosses are presented in Table 6

Dictionary We used the unigram subword tokenizer (Kudo, 2018) available as part of the SentencePiece tool (Kudo and Richardson, 2018). and trained it using the default parameters. Experiments in Gowda and May (2020) suggest that a vocabulary of 8000 subwords is a good default choice for several languages in the case of machine translation. Additionally, our *development experiments* showed that English models using a vocabulary of 8000 subwords are superior to 10000 subword models. Therefore we decided to set the number of unigram tokens to 8000 in case of English, and to 8500 in case of other, highly inflected languages expected to have a higher number of distinct suffixes.

Pretrained token embeddings GloVe embeddings (Pennington et al., 2014) of the subword tokens, introduced to initialize the tokens with corpus-level semantic information, were constructed as follows. The model was trained on the set of transformed glosses, and the embedding size was fixed to 256 (the size of the gloss embeddings). The number of training iterations was set to 50, the “cutoff” parameter x_{max} was set to 10, while all the other parameters retained their default values. No frequency-based vocabulary pruning was performed.

Machine learning model We fixed the maximum sequence length of the RNN models to 64 subword tokens. Our intuition is that this alleviates the learning problem and could lead to models focused on generating shorter but more correct glosses.

The models were optimized using the AdamW algorithm (Loshchilov and Hutter, 2017) and the standard categorical cross-entropy loss. The training process was stopped after a fixed number of epochs, or if the best solution did not improve by more than 0.1% over 10 epochs. During inference, the optimal solution was constructed using the beam search algorithm implementation provided by the competition organizers[3].

We iteratively improved the models using the described *development experiments*, i.e., relying on the development set loss and analysis of model

glosses produced for the trial dataset. We experimented with several architectural elements and hyperparameters: the formulation of the seed (RNN init. value) and context (gate input) of the network, RNN cell type, dropout, learning rate (LR) and LR scheduler, and the number of training epochs.

The most successful variant is constructed by using the concatenation of all the gloss embeddings as the context and the sgns embedding as the seed. This variant uses input dropout of 0.1 and network dropout of 0.3. The input dropout is applied to the seed and context vectors, as well as to the word embeddings. The network dropout is applied to the output of the RNN (final layer) and to the output of the gate cell. The chosen learning rate is 0.001, and the "plateau" LR scheduler is used – LR is multiplied by 0.1 if there is no improvement over 5 epochs.

For the context vector, we tried single embeddings and the combined embeddings merged via a multilayer perceptron. Both variants proved inferior to the concatenation of all vectors. The merged seed vector proved no different from the single embedding seed, so we opted for the simpler solution. Both the development experiments and the results showed no difference between the LSTM and the GRU cell.

Analysis of errors revealed that models sometimes produce a deformed output (very short or non-alphabetic string), and that this almost never occurs simultaneously for two distinct models. Therefore a way of heuristic model improvement is to combine it with another *fallback* model to be used in case of deformed outputs. We combined a model with a concatenated context and a model with a single-embedding context, or two models with distinct RNN cell types. A more detailed analysis of the model variants can be found in Appendix A.2.

4.2 Reverse Dictionary

We conducted various development experiments before deciding on the final configuration of our REVDICT solutions. In all of the experiments, we used the entire set of train data to train the model, and the entire set of validation (development) data for scoring. We used *Mean Squared Error* (MSE) as a loss function during training. We tested the effect of cosine loss if added to MSE with different coefficients, but we obtained the best results without cosine loss. We also used MSE for scoring models during Bayesian hyperparameter optimization (BHO).

To determine the optimal model size, we searched the space of two transformer hyperparameters: the number of heads and the number of layers. We used a grid search approach with these values $v \in \{1, 2, 4, 8\}$ for both hyperparameters. Additionally, we used BHO (Snoek et al., 2012) to find the optimal model for each grid point. However, the increase in model size did not increase the performance of the model. These results were in line with the expectations we had due to the small size of the datasets. Accordingly, we decided to use a transformer with two heads and two layers. Additionally, we experimented with the maximum length of the input sequence and achieved better validation performance with 256 tokens than 512 with tokens.

We compared performance with and without token embeddings initialization with GloVe vectors. Contrary to our expectations, there was no significant difference in validation performance between these two options, so we skipped the GloVe initialization in the REVDICT system settings. Another development experiment we conducted was to find the optimal method for aggregating the output vectors produced by the transformer, described in Section 3.2. We found that the *average* method gives the best results in all cases. Furthermore, we examined the influence of the number of layers in the output module on the final prediction. According to the results, there is no benefit in increasing the number of layers in the output module, so we chose a single-layer fully connected network. We also chose Rectified Linear Unit (ReLU) activation function for the output regression module, because it yielded better performance than hyperbolic tangent (Tanh) activation.

Finally, we made six different solutions for REVDICT task. All of these solutions used a two-

Table 3: Results for the IRB-NLP team systems on the DEFMOD task. MoverScore, BLEU, and lemma-BLEU results are given for each of the five languages. Best result across all teams and models is given, followed by the results of our two best systems. Overall best results of our team are bolded and the rankings can be found in Table 1.

head transformer architecture, where each head consists of two layers. We used a vocabulary size of 8000 tokens and a maximum sequence length of 256 tokens. The unigram SentencePiece tokenizers used were trained on lowercased but otherwise unmodified glosses contained in a train set. We used the *average* method for combining an encoder's output representations and fed them to the output module, which is a single fully-connected layer with RELU activation functions. We varied five hyperparameters between solutions (Table 2): batch size, max. epochs, number of BHO points, scheduler type, and learning approach. We used the *Cosine Annealing with Linear Warmup* scheduler (CS) for the first four solutions, and the *Plato* scheduler (PS) for the final two solutions. We utilized BHO (Snoek et al., 2012) to automatically search for optimal hyperparameters and submitted for testing only models with the best MSE validation scores.

5 Results

Definition Modeling On the DEFMOD task, the models were evaluated using three metrics: BLEU score (Papineni et al., 2002), lemma-level BLEU score, and MoverScore (Zhao et al., 2019). While the BLEU score is based on matching token n-grams between the reference and the model-produced text, MoverScore calculates a measure of distance between texts embedded in a semantic space, i.e., between two sets of contextual word embeddings computed using a transformer model.

Table 3 contains scores for two of our best model configurations, "version 3" and "version 4". Both model configurations are described in detail at the end of Section 4.1. While version 3 models are based on GRU RNN and trained using 300 training epochs, version 4 models are built with either GRU or LSTM and 450 epochs. The fallback strategy, which yields slight performance gains, is also used. These results are presented and analyzed in a more detailed manner in Appendix A.2.

Results in Table 3 show that our models are competitive with other teams' models on English, Spanish and French, especially in terms of the BLEU scores. MoverScore results are weaker than those produced by the top models, but rank among the upper half of the systems except for Italian and Russian, languages for which our models' performance is below average. Rankings aggregated across all the scores, displayed in Table 1, reflect the above observations and show that the models we produced can perform quite competitively.

Our approach shows inter-language variation, both in relative (ranks) and absolute (score values) terms. The full results provided by the organizers[4] show that this is also true for other teams – for example, few of the high-performing models perform markedly better for Italian and Russian than for other languages. However, some approaches yield more stable results across all languages.

All of the models yielded by the CODWOE shared task perform weakly in terms of BLEU. Namely, the BLEU scores of the existing DEFMOD approaches commonly achieve BLEU scores in the range of 20 to 30 (Kabiri and Cook, 2020; Noraset et al., 2017), with some settings yielding BLEU as high as 60 (Kabiri and Cook, 2020). The experiments with the weakest reported BLEU scores (Gadetsky et al., 2018; Kabiri and Cook, 2020) reports BLEU scores of approx. 12, while the best CODWOE scores are below BLEU 10.

CODWOE DEFMOD models perform better in terms of MoverScore, a metric designed for machine summarization (Zhao et al., 2019). An analysis of a number of summarization systems showed that MoverScore values range between 15 and 24, with an absolute minimum of 10 and an average slightly below 20 (Fabbri et al., 2021). In comparison, top CODWOE systems reach scores between 12 and 15, except in the case of French, which puts them on the lower end of the summarization scale.

We hypothesize that the main reason for the described weak performance is comparatively small amount of CODWOE training data (for each indi-

vidual language), as well as the lack of word embeddings pre-trained on a large outside corpus. Namely, most of the other DEFMOD approaches use at least 2–3 times more training data, both in terms of the number of (embedding, text) examples, and the overall number of tokens (Bevilacqua et al., 2020; Gadetsky et al., 2018; Mickus et al., 2019; Noraset et al., 2017; Yang et al., 2020; Zhang et al., 2020; Zhu et al., 2019). Additionally, these approaches make use of the pre-trained word embeddings that carry the semantic information extracted from a huge corpus.

As for the representativeness of the test data, the visual analysis performed in A.1 shows that the distribution of test gloss embeddings matches the train distribution well. Another factor that potentially influences performance is word rarity. We observed that the English test examples contain a significant amount of rare words (such as "pelta", "akimbo", "gothy", or "dungarees"), while some DEFMOD experiments explicitly focus on the most frequent words (Noraset et al., 2017).

The greatest performance gains for the models we used come from using all three vector embeddings to form a context vector. This suggests that future approaches can benefit from leveraging several distinct embeddings types as input for gloss generation.

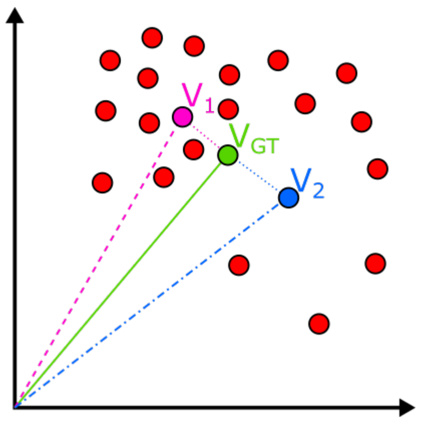
We believe that the question of the influence of various factors on the performance of DEFMOD systems is important and under-explored. These factors include model structure and parameters, performance metric, dataset size (both for training and pre-training), and the semantic relation between training and test data. Closely related is the question of the nature of semantic generalization that DEFMOD systems are capable of – what kind of examples (and relations contained within them) can inform a successful inference of glosses for unseen embeddings.

Further performance-related analyses can be found in Appendix A.2. Appendix A.3 contains a qualitative analysis of glosses that shows that generated glosses can capture varying levels of semantic properties of the correct glosses. We hypothesize that these variations in similarity are hard to capture with metrics such as MoverScore and BLEU.

Reverse Dictionary We used the following metrics for internal validation of our REVDICT solutions (described in Section 4.2): *Mean Squared Error* (MSE), *Cosine Similarity* (COS), and *Central Kernel Alignment* (CKA) (Cortes et al., 2012; Kornblith et al., 2019). COS measure has noted drawbacks (Heidarian and Dinneen, 2016). Therefore, we use the linear CKA similarity measure to gain another perspective on model performance. Validation scores can be found in Appendix B.2, Table 12. It is evident that each subsequent approach gives better validation results than the previous ones.

Test predictions were scored by the following metrics: MSE, COS, and *Cosine-Based Ranking* (RNK). The RNK measure is defined as the proportion of test samples with cosine similarity to the model output embedding higher than the ground

Figure 1: Example of two different predictions for ground truth vector V_{GT}, where predicted vector V_1 has better MSE and COS scores than V_2, and V_2 has better RNK score than V_1. The rest of the points represent vectors of other test samples.



truth embedding. The final results of our solutions can be found in Table 13 (see Appendix B.2). Here, each subsequent approach has lower scores than the previous ones, which is the complete opposite of the validation results. This suggests potential overfitting to the dev dataset that could be the result of BHO. However, this is contrary to expectations as the last two solutions have three times fewer BHO points and should not overfit to the dev dataset. The reason for this phenomenon is unclear and needs further investigation. Finally, the best `REVDICT` results for each team can be found in Appendix B.2 (Table 14 for MSE, Table 15 for COS, and Table 16 for RNK). The test results and overall rankings of our solutions are summarized in Table 4.

Compared to other solutions, our systems have average or below-average performance in terms of MSE and COS test scores. However, they perform significantly better than the other approaches in terms of RNK test scores, from which we conclude that our solutions are better suited for the retrieval task. This is an interesting situation which we elaborate with the following example, shown in Figure 1. It depicts two different predictions, V_1 and V_2, the first with better MSE and COS scores, and the second with a better RNK score. The second solution prefers a vector subspace with a lower density of test samples even if the absolute distance from the correct vector is greater. With a smaller set of possible surrounding solutions, retrieving the vector V_{GT} from the vector V_2 is more precise than retrieving it from the vector V_1.

6 Conclusion

Definition Modeling and Reverse Dictionary are two opposite learning tasks for exploring the relationship between different semantic representations of words. `CODWOE` SemEval task (Mickus et al., 2022) is designed to investigate these tasks on five different languages using three different types of word embeddings.

We propose an adaptation of an existing `DEFMOD` model and analyze its performance and the glosses generated by the model. We believe that `DEFMOD` is a theoretically interesting problem and that further investigations should focus on discovering which types of semantic generalization the models are able to perform, and how this generalization ability is influenced by both the data and the models' structure. The existing `DEFMOD` experiments are largely incomparable since they are based on different data and setups. We believe that a contribution of the `CODWOE` task is the creation of a multilingual evaluation setting, as well as the use of the flexible MoverScore as an evaluation metric.

Our `REVDICT` systems are based on deep regression models based on transformer architecture that achieved top scores for the difficult-to-predict `sgns` (word2vec) embeddings. In most cases our `REVDICT` solutions perform significantly better then the other systems in terms of the RNK score. These results imply that our solutions could be the appropriate approach for retrieving the right word from its description, a problem crucial for solving the TOT problem (Brown and McNeill, 1966) in machine-assisted text synthesis.

In summary, the models that we produced for the `CODWOE` task perform competitively when compared to other participants' models, and can therefore serve as a reasonable starting point for future tackling of `DEFMOD` and `REVDICT` problems. We believe that the promising directions for future optimizations include the construction of multilingual and multi-task models, as well as investigations of the influence of the external data, primarily in the form of huge pre-training corpora.

A Appendix - Analysis of DEFMOD Data and Models

A.1 Train and Test Data

Motivated by the weak performance of DEFMOD models (see Section 5), we examined whether the distributions of train and test data are comparable. To this end we created 2D projections of sgns and electra embedding for all five languages using the t-SNE method (Van der Maaten and Hinton, 2008).

The projections, depicted in Figure 2, show that the train and test distributions of the embeddings match well. It is therefore reasonable to expect that the distributions of the gloss texts are similar as well, as the gloss semantics expectedly matches the semantics of the corresponding words. However, this conjecture should be confirmed experimentally, for example by per-gloss aggregation of pretrained word embeddings extracted from huge corpora.

Figure also shows that the electra vectors are more separable than the sgns vectors. The separability of the embedding vectors varies across languages, probably influenced by the corpora used for pre-training of the embeddings. We note that the observations about the train and test embedding distributions are also applicable to the REVDICT problem aimed at the prediction of the embeddings from gloss texts.

Basic gloss statistics can be found in Table 5. There exists a large variation in gloss size between languages, e.g., the longest gloss from the ES dataset is almost twice the size of the longest EN gloss. In addition, the longest glosses in the validation (development) datasets are significantly smaller then those in the train datasets, on average 42.55% smaller. The 'dictionary size' column in the table is the number of distinct tokens in each dataset. Dictionary sizes vary, for example, EN dictionary is approximately half the size of the RU dictionary. Differences between the gloss and dictionary sizes suggest that it is reasonable to use a separate model for each language.

Basic statistics of the transformed dataset can be found in Table 6. As expected, the transformed glosses are significantly smaller then the glosses in the original dataset. For example, the median transformed gloss size is on average 29.25% smaller.

Lang.	Split	Dict. size	#Tokens	#Glosses	Gloss size						
					mean	st.dev	min	q25	median	q75	max
EN	train	29.046	511.531	43.608	11.73	7.98	1	6.0	10.0	15.0	129

Table 5: Statistics of the gloss and dictionary sizes for the original train and validation (development) datasets. Sizes are calculated by counting the number of whitespace-delimited tokens.

A.2 DEFMOD Models' Performance

Here we append Section 5 with a more fine-grained analysis of the DEFMOD models. Table 8 contains the models' performances. As can be seen, the largest gains are achieved by using all of the embedding vectors as input for gloss generation (context=allvec). There exists a negligible difference between the LSTM and GRU RNNs, with GRU performing slightly better. Using a fallback model always slightly improves the MoverScore of a model. In Table 8 the architecture of the fallback model is the architecture of the main model with the corresponding parameter replaced with the value in the 'fallback' column. Interestingly, using contextual electra vectors does not help, i.e., the sgns (word2vec) vectors which are not context-aware perform comparably. This is true even when only a single embedding is used, i.e.,

Lang.	Split	Dict. size	#Tokens	#Glosses	Gloss size						
					mean	st.dev	min	q25	median	q75	max
EN	train	25.921	456.673	58.792	7.77	6.97	1	3.0	6.0	10.0	128

Table 6: Statistics of the gloss and dictionary sizes for the transformed train and validation (development) datasets. Sizes are calculated by counting the number of whitespace-delimited tokens.

when context equals `electra`. The equality of `sgns` and `electra` is unexpected since both the train and test datasets contain polysemous `electra` vectors and words with multiple senses.

It is also interesting to consider the influence of the training data on the model's performance. We hypothesize that a `DEFMOD` model's score on a single test example is positively correlated with the semantic closeness of the example to the examples in the train set. To test this hypothesis we calculate Spearman correlation between test MoverScore and BLEU on one, and the cosine similarity of the test embedding and most similar train embeddings. This is done for the best-performing submitted model from Table 8. We also calculate the average scores on two sets of 10% test examples that are least similar and most similar to the train examples. Since the embeddings (`sgns` and `electra`) were built on large outside corpora, it is reasonable to believe that they capture semantic similarity of the associated words and glosses. Surprisingly, the results show a lack of consistent and strong correlation and the correlations range from weakly negative to weakly positive, depending on both the language and the embedding type. This lack of correlation could be caused by many factors, including the nature of the model, the nature of the pretrained embeddings, and the semantics of the cosine similarity measure.

The future extensions and improvements of the proposed analysis could reveal the nature of the train data necessary for the `DEFMOD` models to successfully generalize, and perhaps point to a similarity measure that reveals more fine-grained properties of such a generalization.

Table 7: Correlation between the best `DEFMOD` model's scores on one, and the closeness of the test examples to the train set on the other side. The unit of correlation is an example from the test set, and its similarity to the train set is calculated as the average cosine similarity with the 10 most similar train embeddings. The last two columns contain average model scores on 10% of the least and most train-similar test examples.

A.3 Qualitative Analysis of Generated Glosses

The `DEFMOD` models achieve weak results in comparison to the previous state-of-art approaches, which is probably due to the comparably small amount of training and pretraining data. Here we demonstrate that the generated glosses can nevertheless capture a degree of the semantics of the correct glosses.

Table 9 shows four categories of semantic similarity between the correct and model-generated glosses, in descending order (highest similarity first). These categories include hits or near hits (correct glosses), "near misses" (glosses that capture a significant amount of the original meaning), somewhat similar glosses, and complete misses. Several examples demonstrate that the subword-based models can produce syntactically incorrect glosses.

Table 10 contains generated glosses for different senses of the word "consider", which demonstrate that the model was able to approximate, to a degree, the semantics of the senses.

A principled analysis of the generated and correct glosses, based on a well defined semantic annotation scheme, might prove revealing but it would be time-consuming and impractical. Therefore it would be of interest to automatize such efforts. It would be interesting to explore if this can be done using large pretrained transformers able to measure fine-grained semantic similarity.

Table 9: Glosses generated by the top submitted `DEFMOD` model, alongside the correct glosses. The examples are ordered by descending semantic similarity between the correct and the generated gloss.

Word	True Gloss / `Generated Gloss`
lamebrain	A fool
	`A fool , idiot`
sentiment	A general thought , feeling , or sense
	`A feeling or feeling of thinking`
available	Capable of being used for the accomplishment of a purpose
	`Able to be used`
model	A representation of a physical object , usually in miniature
	`An act of designing`
supernumerary	Of an organ or structure : additional to what is normally present
	`Having four wings`
navy	Belonging to the navy ; typical of the navy
	`To be armed`
fuzzy	Vague or imprecise
	`lacking`
co-opt	To absorb or assimilate into an established group
	`To conceal`
misinformation	Information that is incorrect
	`prejudice`
cutthroat	Ruthlessly competitive , dog-eat-dog
	`Very large`
discretional	discretionary
	`Of or pertaining to`
abundantly	In an abundant manner ; in a sufficient degree ; in large measure
	`In a very manner`

Glosses generated by the top submitted `DEFMOD` model, alongside the correct glosses, for the multiple senses of the word “consider”.

Table 10

Word	True Gloss (describing the sense) / `Generated Gloss`
consider	To assign some quality to
	`To hold the opinion`
consider	To look at attentively
	`To make something certain`
consider	To have regard to ; to take into view or account ; to pay due attention to ; to respect
	`To hold into`
consider	To think of doing
	`To permit`
consider	To debate (or dispose of) a motion
	`To make something certain`

B Appendix - Analysis of `REVDICT` Data and Models

B.1 Data Analysis

Here we analyze the properties of the pretrained embedding vectors assigned to the words defined by the glosses. We start by analyzing the numeric values contained in the vectors. Basic statistics of vector elements can be found in Table 11. It is noticeable that there are large variations in value depending on the language and the embedding type. For example, there is a significant difference between maximum values, especially between `electra` and `sgns`. To further investigate the vector elements, we visualize the shapes of their distributions for train datasets (Figure 3 and 4). Distribution shapes look similar for dev datasets.

Next, we explore the vector data by reducing dimensionality to the 2D space using the Pairwise Controlled Manifold Approximation Projection (PaCMAP) algorithm (Wang et al., 2020). Figure 5 shows the distributions of all three types of embeddings in the train and validation (development) datasets for English, French, and Russian. We also visualize distributions of `sgns` (word2vec) and `char` embeddings for all languages, in Figure 6. As can be seen, the vector distributions vary greatly between the embedding types. Additionally, for all the embedding types, the vectors of different languages occupy a distinct area and are easily separable.

We further investigate the relationships between different embeddings in the following way. We first cluster the values of the `electra` vectors with k-means algorithm. We set the number of clusters to five and assign a different color to each cluster. We retain the `electra` cluster-based color of the samples (glosses) while visualizing the vectors of other embedding types, as shown in Figure 7. It can be clearly seen that the `electra`-based clusters are not preserved for other embedding types.

B.2 Model Performance

Here we present validation and test scores for our six `REVDICT` solutions described in Section 4.2. We use the following metrics for internal validation of our `REVDICT` solutions: *Mean Squared Error* (MSE), *Cosine Similarity* (COS) and *Central Kernel Alignment* (CKA) (Cortes et al., 2012; Kornblith et al., 2019). Validation scores for each `REVDICT` approach can be found in Table 12. The last three rows contain the total scores for each metric and each of our `REVDICT` solutions. A total score is the sum of the values of all datasets and we use it for a simple comparison of solutions. It is evident that each subsequent approach gives better validation results than the previous ones.

Test predictions are scored by these metrics: MSE, COS, and *Cosine-Based Ranking* (RNK). The RNK measure is defined as the proportion of test samples with cosine similarity to the model output embedding higher than the ground truth embedding. The final results for all our solutions can be found in Table 13. Here, each subsequent approach has lower scores than the previous ones, which is the complete opposite

Table 11: Statistics of the elements of the embedding vectors from the train and validation (development) datasets.

of the validation results. This suggests potential overfitting to the dev dataset that could be the result of Bayesian hyperparameter optimization (BHO). However, this is contrary to expectations as the last two solutions have three times fewer BHO points and should not overfit to the dev dataset. The reason for this phenomenon is unclear and needs further investigation.

The best `REVDICT` results for each team can be found in Table 14 for MSE score, Table 15 for COS score, and Table 16 for RNK score. When compared to other solutions, our systems have low to average performance according to the MSE scores. For the COS scores, our systems have very good performance on `sgns` (word2vec) vectors, and low performance on other embedding types. In terms of the RNK (ranking) our systems almost always yield the top performance, and this result is consistent across languages and embedding types.

Abstract

We propose a pair of deep learning models, which employ unsupervised pretraining, attention mechanisms and contrastive learning for representation learning from dictionary definitions, and definition modeling from such representations. Our systems, the **T**ransformers for **L**earning **D**ictionaries and **R**epresentations (**TLDR**), were submitted to the *SemEval 2022 Task 1: Comparing Dictionaries and Word Embeddings (CODWOE)*, where they officially ranked **first on the definition modeling subtask**, and achieved competitive performance on the reverse dictionary subtask. In this paper we describe our methodology and analyse our system design hypotheses.

1 Introduction

Dictionaries are some of the linguistically richest resources available for a language, in addition to being extremely clean and unbiased in comparison to most naturally occurring language data, which is noisy and shows domain specific bias based on its source. Thus, there has been considerable interest towards using NLP models to harness this knowledge, especially for low-resource languages. Broadly there are two sets of approaches towards the same - the first is to use dictionaries for representation learning and using these representations for transfer learning in other tasks, such as in the work by Bosc and Vincent (2018) where they use an LSTM based auto-encoder to learn rich representations from dictionary definitions such that the definitions can also be generated back from the representations. Tissier et al. (2017) also used dictionary definitions to build sets of 'strong' and 'weak' pairs of words to get improved word representations with greater interpretability by moving words which show a stronger semantic-relatedness closer together in the embedding space.

[†] *Authors contribute equally to this work.*

The second approach has been to move in the opposite direction, such as in the work by Chang and Chen (2019) where the authors try to map contextualized word representations to their dictionary definitions in an effort towards word-sense disambiguation. This has been further explored by Noraset et al. (2016), where they use an RNN based language model to generate definitions for representations. Recent work by Bevilacqua et al. (2020) improves upon this by leveraging pre-trained encoder-decoder models like BART (Lewis et al., 2019) in order to generate the definitions of words. These pre-trained language models, significantly outperform the RNN based models. The ability to generate definitions for representations makes these contextual representations of words explainable.

NLP has advanced leaps and bounds within the past decade, with a major push coming from the advent and utilization of transfer learning via representation learning techniques such as Word2Vec (Mikolov et al., 2013a) and ELMO (Peters et al., 2018). The more recent methods to employ transfer learning use large pretrained language models, such as BERT (Devlin et al., 2019) and XLM (Conneau et al., 2020). These models are jointly used with unsupervised training objectives such as MLM and Causal-LM, to transform natural language into information rich meaning representations which are then used for many different downstream tasks. We aim to replicate the same in our experiments to give a better prior for the model, before it learns to generate desired representations.

One of the characteristics common to all the language models mentioned above is that they are all based on transformers. Transformers use the multi-headed attention and self-attention mechanisms to learn extremely effective language representations. Transformers also scale well since unlike their predecessors, the RNNs, they process information in parallel and thus are much faster.

For SemEval 2022's Task 1, Comparing Dictionaries and Word Embeddings (Mickus et al., 2022), the participants were asked to design systems for the following two subtasks;

1. Subtask 1: Reconstruct SGNS (Mikolov et al., 2013b), character and ELECTRA (Clark et al., 2020) embeddings from their dictionary glosses.
2. Subtask 2: Reconstruct the dictionary glosses from their SGNS, character and ELECTRA embeddings.

The subtasks are called the Reverse Dictionary and Definition Modeling subtasks respectively. The first subtask is evaluated on the Mean Squared Error (MSE), Cosine Similarity and Cosine Ranking between the generated representations and the gold representations. The second subtask is evaluated on Mover score, Sense level BLEU score (S-BLEU) and Lemma level BLEU score (L-BLEU).

In this system description paper we detail our model architectures, training, evaluation and testing methodologies, and try to analyse our hypotheses and their impact on the final scores. For the reverse dictionary subtask we designed a simple BERT-like model, pretrained it on the MLM objective, and finetuned it for the subtask on a combination of cosine embedding loss and MSE loss, alongside negative sampling of the dataset to add a contrastive loss to the overall objective function. For the definition modeling subtask we designed a model based on transformer decoders for natural language generation, with masked self-attention over the inputs in addition to multi-head attention over the representations from the three embeddings spaces. We submitted our systems for evaluation over English data and our systems demonstrated very good performance in the contest itself, with the definition model system outperforming all other submissions and taking first place, and the the reverse dictionary system achieving the fifth, sixth and seventh place on the character, ELECTRA and SGNS targets respectively. Lastly, we also show some post-contest improvements on the reverse dictionary system. The code for our experiments has been open sourced and is available on GitHub.[1]

2 Subtask 1: Reverse Dictionary

2.1 Data Preprocessing

We maintain the data splits provided by the task organizers (43608 training samples, 6375 dev samples and 6221 test samples) with each sample containing the dictionary gloss and its SGNS, character and ELECTRA representations. All models were trained on the training split, with the best model picked from evaluation over the dev split.

The dictionary glosses were lower-cased and stripped of all whitespace characters except those essential to maintaining word boundaries for tokenization. We also padded and truncated all sequences to a maximum sequence length of 256 tokens.

For contrastive learning we performed negative sampling to augment each gloss-embedding pair with three other embeddings from the same semantic space and the same data split.

2.2 System Overview

We designed our system around three hypotheses - firstly, using pretraining would work better than starting from scratch since it would give the model a good prior for the downstream tasks (transfer learning). Secondly, training individual models for each representation would outperform training a single multitask model, as the representations do not reside in a common semantic space. Thirdly, optimizing over a combination of losses for each of the metrics that we're being evaluated upon, i.e. MSE loss for MSE, Cosine Embedding (CE) loss for cosine similarity, contrastive loss for cosine-rank, would work better than using any of them individually.

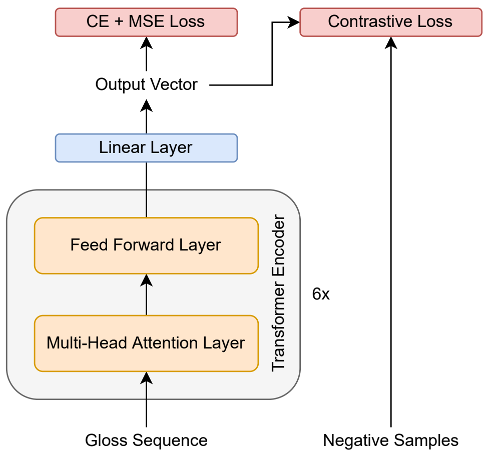

Figure 1: System architecture for the Reverse Dictionary subtask.

The foundation of our representation learner is based on the DistilBert (Sanh et al., 2019) architecture and comprises of a stack of 6 transformer

[1]https://www.github.com/IamAdiSri/tldr-semeval22

encoders, with 12 attention heads each, hidden dimension of 3072 and embedding dimension of 768.

We start by pretraining the model via unsupervised masked-language-modeling (Devlin et al., 2018) over only the texts from the dictionary glosses in the task dataset. Individual instances of this pretrained model are then appended with a linear layer of dimension 256 to project outputs in the required dimensions, and fine-tuned for each semantic space, optimized over the following loss function;

$$
\begin{aligned}
L = e^{-\log(p_0)} * \mathit{MSE}(\phi(g), v_p) + \\
e^{-\log(p_1)} * \mathit{CE}(\phi(g), v_p) + \\
e^{-\log(p_2)} * \mathit{CL}(\phi(g), v_{n0}, v_{n1}, v_{n2})
\end{aligned} \tag{1}
$$

where, $\phi(g)$ is the sentence embedding for a gloss g, v_p is the true (or *positive*) embedding, v_{n0}, v_{n1} and v_{n2} are the negative samples and p_0, p_1 and p_2 are trainable parameters for weighting the different loss functions. **MSE** and **CE** are the **Mean Squared Error** and **Cosine Embedding Loss** respectively, which function as the reconstruction loss between the generated representation and true representation. Lastly, **CL** is the **Contrastive Loss** between the generated representations and the false representations from negative sampling. The equations for the three are given below;

$$\mathit{MSE}(a, b) = \frac{1}{d}\sum_{i=0}^{d}(a_i - b_i)^2 \tag{2}$$

$$\mathit{CE}(a, b) = 1 - \frac{a.b}{|a||b|} \tag{3}$$

$$\mathit{CL}(p, n_0, n_1, n_2) = \sum_{i=0}^{2} 1 - \mathit{CE}(p, n_i) \tag{4}$$

where a, b, p and n are all vectors of size d.

2.3 Experimental Setup

We used Pytorch (Paszke et al., 2019) and the HuggingFace (Wolf et al., 2019) library to write our experiments in Python. Though the HuggingFace library does provide ready-to-go pretrained language models, they were not used in our experiments or submissions. We did however use a ready-made pretrained tokenizer from the library to tokenize our texts.[2] This was permitted by the organizers and we believed would be a significant advantage over training a new tokenizer from scratch, considering that the dataset is rather small and homogeneous in its linguistic variation. All models were trained on Nvidia's GTX-1080 Ti and RTX-2080 Ti GPUs.

We pretrained our model on the unsupervised MLM objective, with a learning rate (LR) of $5e-5$, masking probability of 0.15, and an effective batch size of 64 samples. For fine-tuning we use an LR of $5e-3$ with a linear LR scheduler and an effective batch size of 64 samples per batch. Any remaining hyperparameters were left as their default values. We selected the language model that attained the lowest perplexity score (55.25) over the dev split.

For models that were multitask trained, instead of a single output layer (as shown in figure 1) we have three output layers (one for projecting into each semantic space), all receiving the same output vector from the transformer encoders below them.

While finetuning we train all models for 50 epochs in total, and select a model for each semantic space and metric based on the epoch that attains the best score over the dev split. The same model is used for producing results over the test split.

2.4 Results and Analysis

The experiments here were designed with the intent to evaluate the three modeling hypotheses outlined at the beginning of section 2.2, with tests on pretraining, mutitasking and the objective function. The results for these experiments are given in tables 1, 3 and 4.

Repr.	Metric	Pretrained	RndInit.
sgns	mse	0.8990793	**0.8987827**

electra	mse	**1.3292400**	1.5150244
electra	cos	0.8451633	**0.8452746**
electra	rnk	**0.5000672**	0.5000801

Table 3: Comparison between individual models for each semantic space versus a single multitask model.

Table 3 displays the results of our tests comparing a single multitask model for all three semantic spaces versus training individual models for each. Again the results are quite inconclusive whether one reliably outperforms the other, however considering differences of over $1e-3$ to be significant (as they affect the leaderboard rankings) we can see that individual models outperform multitask models on a greater number of metrics.

Finally, from the ablation tests in table 4 we can clearly see that while optimizing over the combination of losses or MSE alone gives comparable scores, optimizing over CE loss alone causes the MSE score to worsen manyfold. This seems to imply that MSE contributes significantly more than CE and CL losses to the performance of the models. The scores also demonstrate that tuning over MSE tends to improve the MSE metric, while tuning over CE improves the cosine similarity, agreeing with our hypothesis about the same. Contrary to our expectations however, we can also observe that adding contrastive learning by negative sampling does not improve the cosine-ranking by much.

3 Subtask 2: Definition Modeling

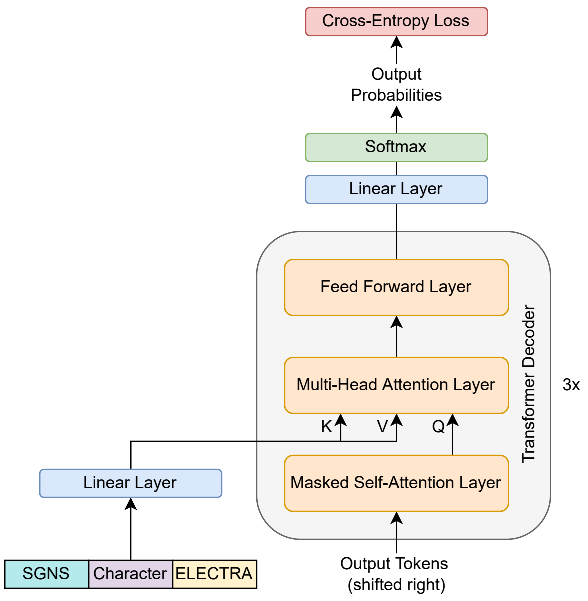

Figure 2: System architecture for the definition modeling subtask.

3.1 Data Preprocessing

The dictionary glosses were first normalized for punctuation and then tokenized using the Moses scripts (Koehn et al., 2007). We then learn a subword tokenizer on the training data, in order to create a fixed vocabulary of subwords. The Moses tokenized sentences were used to learn Byte Pair Encodings (BPE) with a vocabulary size of 10,000 using the subword-nmt library (Sennrich et al., 2016).

Repr.	Metric	All Losses	Only MSE	Only CE
sgns	mse	0.8991734	**0.8956623**	694685.50
sgns	cos	0.1787637	0.1547712	**0.1852663**

electra	rnk	0.5000807	**0.5000807**	0.5000808

Table 4: Ablation tests on the reverse dictionary objective function.

3.2 System Overview

The definition modeling problem is posed as one of text generation, generating the definition D_* of a word w_* autoregressively, given the semantic representation of the word in the form a vector v_*. Therefore, we maximise the likelihood of the definition $D_* = \{w_0, w_1, .., w_n\}$, where w_i corresponds to the ith word of the definition, given the vector v_*.

$$P(D_*/v_*) = \prod_{i=0}^{n} P(w_i/w_0, ..w_{i-1}, v_*) \tag{5}$$

The definition modeling architecture that has been used in this system is a transformer decoder, whose output softmax layer approximates the above likelihood.

In a vanilla transformer-seq2seq architecture (Vaswani et al., 2017), the decoder in the self-attention layer projects the decoder states into three matrices called Query (Q), Key (K) and Value (V) and using the below equation, attention values are computed.

$$\mathit{Attn.}(Q, K, V) = \mathit{Softmax}\left(\frac{Q \cdot K^T}{\sqrt{d}}\right) \cdot V \tag{6}$$

This is followed by a cross-attention layer where the decoder attends to the encoder states by projecting the encoder states as the Keys, Values and using the decoder states as the Queries.

In our model, since the input vectors are not in the same space as the decoder embeddings, a linear layer is used to learn a projection between them. The output of this layer is then projected into the Key (K) and Value (V) matrices which are used along with the decoder self-attention outputs to compute the cross attention values.

$$f = \mathit{linear}(v_{sgns} \oplus v_{char} \oplus v_{electra}) \tag{7}$$

where v_{sgns}, v_{char}, $v_{electra}$ represent the SGNS, character, ELECTRA vectors respectively and $\oplus$ denotes concatenation.

$$\begin{aligned} K &= f \cdot W^K \\ V &= f \cdot W^V \\ Q &= o \cdot W^Q \end{aligned} \tag{8}$$

where W^K, W^V are the matrices learnt to project the output of linear layer (f) to Key, Value matrices and W^Q is the matrix to project the output of the decoder self-attention layer o to the Query matrix.

3.3 Experimental Setup

The experiments for the defmod subtask were carried out using the Fairseq framework (Ott et al., 2019) in Python. All the models were trained on Nvidia GTX 1080 Ti GPUs.

The transformer decoder model consists of 3 decoder layers, with each layers consisting of 8 attention heads and an embedding dimension of 512 with the input and the output embeddings of the decoder being tied. The model is trained using label smoothed cross entropy loss with label smoothing of 0.2. A learning rate of 5e-4 using an inverse square root scheduler with a weight decay of 0.0001 was used to optimize over a batch size of 4096 tokens.

The model was trained for over 50 epochs and the checkpoint with the least validation perplexity

Word	Gloss	Predicted Gloss
farming	A farming operation ; a farm , or instance of farming on a piece of land .	The act or process of producing food
hazard	The chance of suffering harm ; danger , peril , risk of loss .	Something that causes trouble or destruction
hardware	Equipment .	Of or relating to a computer system
transition	The process of change from one form , state , style or place to another .	The act or process of converting
hastily	In a hasty manner ; quickly or hurriedly	In a hurried manner
chesty	Not dry ; involving the coughing of phlegm .	Of, pertaining to, or characteristic of a dove
Solarian	Of or relating to the Solar System .	Of or pertaining to the planet Mars.
valid	Well grounded or justifiable , pertinent .	Not able to be true.
alt-left	The extreme or radical left of the political spectrum .	A member of the United States of the United States of the United States of the United States of the United States.

Table 5: Examples of generated glosses.

was selected to generate definitions for the test set using beam search with a beam size of 10.

3.4 Results and Analysis

The ablation study results in table 6 shows the impact of each vector, namely SGNS, char and ELECTRA, against the best performing model where features were extracted using a concatenation of all three.

Repr.	Mover Score	S-BLEU	L-BLEU
All	**0.12847**	**0.03278**	**0.04250**
Electra	0.11008	0.02957	0.03629
Char	0.10403	0.02884	0.03643
SGNS	0.03622	0.01743	0.02114

Table 6: DefMod scores using all vs individual representations

We can clearly see that the ELECTRA representations outperform char and SGNS, with the SGNS vectors falling significantly behind on all three metrics. It can also be observed that by concatenating all three representations and extracting useful features using attention significantly boosts performance. This allows one to infer that char and SGNS vectors do contain semantic information that ELECTRA does not.

The submission utilizing all representations outperformed all other submissions in the defmod subtask and ranked first for English.

3.4.1 Observations Post Dataset Release

After the passing of the task deadline, the organizers released the full dataset, complete with all annotations. With this data we were able to make further observations about our model by comparing the generated glosses to the actual glosses in the dataset. A few examples are shown in table 5. Examples marked in red indicate wrong or irrelevant definitions, and the ones marked in green describe the relevant ones.

From the generated glosses in green, we can see that the model shows a remarkably good mapping between the words and their representations, and makes close approximations of their meanings when generating glosses. In the example of *farming*, we can see that the model is able to correctly associate the act of farming with that of producing food. The words *hazard* and *transition* are also correctly associated with *trouble (danger)* and *conversion (change)* respectively, demonstrating that the model is able to recall similar concepts. The model shows good language proficiency as well, with syntactically correct utterances.

In case of words like *hardware*, which have multiple meanings, we can see that the model outputs one of the secondary definitions that it has learnt from the dataset. From this, we can infer that in the absence of appropriate context (i.e. how the word is being used in a sentence), the model has difficulty in disambiguating the word's meaning, although it still recognizes the word and picks one of the correct definitions.

Finally, the model tends to learn definition templates from the training data, such as *"Of, pertaining to"* or *"Of or relating"*, that it reuses during generation. As a result of being a sequence to sequence model, it also occasionally exhibits degenerate repetition, as seen in the *"alt-left"* example.

4 Conclusion

In this paper, we explored a variety of approaches towards dictionary definitions and embeddings generation, especially under the constraint of being unable to use external monolingual data. We have analyzed the effectiveness of each of these methods, performing ablation studies showing the impact that various objective functions like MSE, cosine embedding loss and contrastive loss have in reconstructing representations from text, and coming up with an attention mechanism utilizing all the provided representations to generate definitions to produce exceptional results.

As part of future work, we plan to explore the performance of our models in multilingual settings. We would also use test the performance of these models against pre-trained language models like BART, BERT etc. to gauge the impact language model pre-trainig since we did not have enough monolingual data in the tasks to train them. Finally, we plan to experiment with a joint training mechanism where instead of training on each subtask independently, the models can inform and improve each other by collaboratively learning both the subtasks.

Abstract

This paper presents a novel and linguistic-driven system for the Spanish Reverse Dictionary task of SemEval-2022 Task 1. The aim of this task is the automatic generation of a word using its gloss. The conclusion is that this task results could improve if the quality of the dataset did as well by incorporating high-quality lexicographic data. Therefore, in this paper we analyze the main gaps in the proposed dataset and describe how these limitations could be tackled.

1 Introduction

The CODWOE (Comparison of Word Glosses and Word Embeddings) task at SemEval-2022 (Mickus et al., 2022) encouraged participants to analyze the relation between two types of semantic descriptions, word embeddings and dictionary glosses, by proposing two sub-tasks: Reverse Dictionary (RD) (Hill et al., 2016), in which participants must generate vectors from glosses, and Definition Modeling (DM) (Noraset et al., 2017), in which participants must generate glosses from vectors. These subtasks aim to be useful for explainable Artificial Intelligence (AI) by including human-readable and machine-readable data.

Given the didactic nature of these tasks, the output generated by these models should be as accurate as the most prestigious dictionaries. Hence, the process of selecting a quality dataset is a critical phase, as Garg et al. (2020) state: "a small number of data examples prevents an effective convergence to the task, while noisy data leads to incorrect convergence". In this case, tasks require that the glosses used in the training represent the exact meaning of the word being defined in the context that the embeddings were extracted. However, as per our understanding, coherence, rigour and lexicographical prestige of the provided dataset should be improved; although accessing a prestigious dictionary is not an easy task.

A Reverse Dictionary takes a description in natural language and generates a list of words satisfying it (Siddique and Sufyan Beg, 2018). First RD were Information Retrieval systems for Turkish (El-Kahlout and Oflazer, 2004) and Japanese (Bilac et al., 2004). Other approaches used lexical graphs (Thorat and Choudhari, 2016; Ortega-Martín, 2021) that capture the relationships between the words of the definition itself and between these and others similar to them at different levels (synonymy, hyperonymy, etc.). Other systems create a vector space from these lexical resources, such as Wordnet (Dutoit and Nugues, 2002; Calvo et al., 2016; Méndez

ID: Definition

es.train.250: “Zoología.— Cualquiera de los colibríes del género Chlorostilbon .”
es.train.119: “Servirse , darse ayuda mutuamente .”
es.train.120: “Trabajar (uso pronominal de ...)”

Table 1: Examples of glosses

et al., 2013). As in many other NLP fields, more recently have appeared approaches based on Neural Networks (NNs) such as Long Short-Term Memory (LSTMs) (Malekzadeh et al., 2021; Zhang et al., 2020b) or Transformers (Qi et al., 2020; Yan et al., 2020). Language Models (LMs) based on Recurrent Neural Networks (RNNs) (Hill et al., 2016) have also been used. Finally, from a linguistic point of view, Shaw et al. (2011) add syntactic knowledge, Zock and Schwab (2008) try to replicate the model of the mental dictionary and Zhang et al. (2020b) use morphological knowledge in their system.

Definition Modeling is a relatively new task based on using distributed word representations to generate its definition. Noraset et al. (2017) use an RNN to compute the probability of a word being part of the definition. Different approaches have been proposed to this Natural Language Generation (NLG) task. Usually these new methods are heavily focused on the importance of the context of the word being defined, like fine-tuning a BART model to define groups of words (Bevilacqua et al., 2020), using attention and a Skip-gram model to smooth the problems of word selection in the generation step (Gadetsky et al., 2018), or exploring new ways to understand the embeddings and their capabilities, resulting these in a new task named “usage modeling” (Zhang et al., 2020a). There have been few attempts to use pure linguistics traits to improve definition generation, like accounting polysemy as a generative target using multi-sense word embeddings (Kabiri and Cook, 2020) or using sememes to condense the semantic core of generated sentences (Yang et al., 2020).

This paper has the following structure. Chapter 2 contains a review of the data along with some linguistic knowledge we consider relevant. In chapter 3 the RD approach and results are presented. Finally, chapter 4 contains the conclusions and future work. Our contributions are the following:

- We point out the main problem of this task, the lack of high-quality lexicographic data.
- We present the third best model for the Spanish “sgns” embeddings Reverse Dictionary task, which due to the use of external resources is not valid for the challenge.
- We compare various approaches for the previous task, analysing different preprocessing strategies, model architectures, loss functions and embedding initialization tactics.

2 Data analysis

This section contains a review of the Spanish dataset structure, an introduction about relevant lexicography concepts and the RD task preprocessing techniques.

2.1 The data

The dataset can be used for both subtasks. It is stored in a JSON file where each element contains four or five keys: its ”ID”, its ”gloss” or definition, the character-based embeddings (”char”), the Word2Vec Skip-gram Negative Sampling embeddings (”sgns”) and, just for some languages, the ”ELECTRA” (Clark et al., 2020) embeddings. All of these embeddings have a dimensionality of 256. For the development of the Spanish RD model “sgns” embeddings were used, since it was considered that using a more static approach such as “char” would lower the performance of the model and ”ELECTRA” embeddings were not available. However, as it will be explained later, the model was found out to be scalable to other embedding types and languages. Table 1[1] contains some words from the Spanish dataset that will be useful in the subsequent analysis.

2.2 Linguistic analysis

Even though this is not a linguistic paper, there are lexicographic concepts that should be explained in order to reach a deeper understanding of the dataset flaws. One of the most common approaches to

[1]Appendix A contains the translation of these examples

classify lexical dictionaries distinguishes between general dictionaries (also known as usage dictionaries) and specific dictionaries (this classification includes, to name a few, encyclopedic, synonym and scientific dictionaries). Therefore, given the significant number of different possible uses of the CODWOE tasks, the dataset should only include generic term definitions found in usage dictionaries, not specific ones.

In second place, there is no consensual standard structure for definitions. However, two principles must be followed (del Teso Martín, 1987).

1. The definitions must specify the hyperonym of the word being defined.
2. The definition should explain the main distinction between the class and its instance.

In other words, the definition has to include a hyperonym which clusters the word being defined into a category (for instance, "person who...", "a block of rock that...") and the definition should specify the specific traits of its meaning (following the last examples, "...plays badminton", "...shines even at night").

Lastly, a given definition is not the only way that a word could be defined, but just a context related meaning. This is why, from our perception, static embeddings should be avoided in modern Natural Language Processsing (NLP) tasks. For that reason, "ELECTRA" embeddings, used in other languages but not available for Spanish, could be more representative than "sgns" or "char" embeddings. Furthermore, these contextual embeddings should have been extracted from solid examples of use which represent the exact meaning of the gloss.

2.3 Dataset review

Dataset review revealed that glosses did not only go against the previously explained notions, but also lack coherence and exactitude. As seen in table 1, many definitions include the category which they belong (for instance, "Zoology"), or some grammatical information ("pronominal use"). Although dictionaries usually include this kind of information, it should not be in the definition (García and José, 2017).

Another drawback is that the dataset combines generic and specific definitions. Generic definitions usually can be found in usage dictionaries like "DLE" for Spanish or "Oxford Dictionary" for English, meanwhile specific definitions include terms from a certain domain, like zoology or linguistics. In our opinion, using specific definitions in this phase of the task just add noise to the training and evaluation.

It should also be noted that the terms glosses have not global coherence, and most of them do not follow the hyperonym and main distinction principles. There are plenty of synonym definitions (not optimal for these tasks as the definition length is too low) and encyclopedic definitions (which add a lot of noise as they have to fully describe the word being defined). Data could be improved if basic lexicographic notions were applied, but it is understood that being a multilingual dataset and given the available resources, CODWOE team has done a great work.

2.4 Data preprocessing

Data was preprocessed by deleting stopwords and category words (a term at the beginning of the definition that indicates its semantic category). In the second RD approach, the lexical graph, which is explained in section 3, words from the definitions were also lemmatized using the Spacy Spanish models lemmatizer [2]. Evaluation showed that the definitions preprocessing has been the most useful factor in the RD task, which indicates that the quality of the original definitions is what has penalized the model the most.

3 Our approach

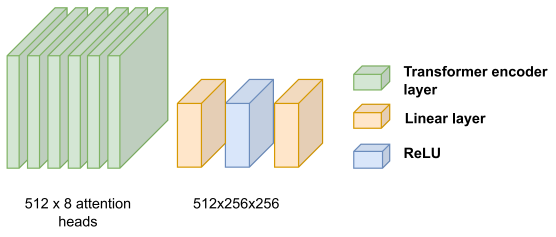

Figure 1: Model architecture

For the RD task, model was trained trying to make the definition embeddings as similar as possible as the defined word ones, focusing just on Spanish "sgns" (Word2Vec Skip-gram Negative Sampling embeddings of 256 dims) embeddings, al-

[2]`https://spacy.io/api/lemmatizer`

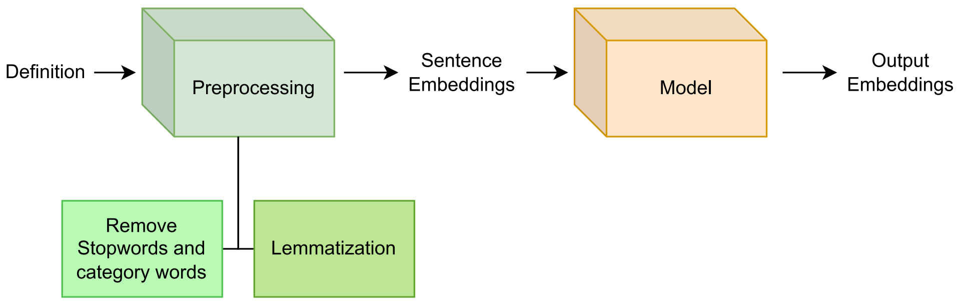

Figure 2: Full Reverse Dictionary pipeline

though system architecture was found scalable to other languages and embedding types. After test phase the model was applied also to Spanish “char” and to English “sgns” embeddings, achieving proportionally similar results which will be mentioned later.

Different tactics to initialize definition embeddings were also used. In our first approach we use Sentence-Transformers (Reimers and Gurevych, 2019). The “distiluse-base-multilingual-cased-v2”[3] was found to be the most appropriate model for Spanish tasks. Secondly, a lexical graph was built with the training dataset, in such a way that each defined word is related to the words in its definition. Then a SAGE Graph Neural Network (GNN) (Hamilton et al., 2017) with 2 SAGE layers with dimensions of sizes 256, 512 and 512 was used to perform message passing from every defined word to the words in its definition. To train this GNN we used 1 negative example for every positive edge, and trained the model for 50 epochs. Adam with 0.001 as learning rate was used as optimizer.

More than one model architecture were compared. As seen in figure 1, the final model was built with a Transformer encoder and an additional Multi-Layer Perceptron (MLP) with two linear layers with dimensions of sizes 512, 256, 256 and a ReLU layer between them, which during evaluation in the development set achieved better results than models based just on Transformer encoders or MLPs. Adam was used as optimizer. During training two loss functions from PyTorch were compared: Cosine Embedding Loss and Mean Square Error (MSE) Loss, which correspond to two of the task evaluation metrics. Regarding the hyperparameters, the following optimized the evaluation on the development set: 8 attention heads, 6 encoder layers, batch size=2048, learning rate=0.001. Model converges after around 10 epochs. Models were trained using 4 Nvidia Tesla v100 32GB.

As seen in figure 2, during training and prediction the process was the following. For a given sentence, stopwords and category tokens were removed. In the lexical graph model every remaining word was also lemmatized. After that the sentence embeddings are initialized, either with the Sentence-Transformers model, either by the mean of the lexical graph embeddings of every word in the definition. These initial embeddings are fed into the model along with some negative examples for the Cosine Embedding Loss model, receiving these a target label of 0. In the case of MSE Loss, negative sampling was not performed.

As stated in the CODWOE task guidelines, Reverse Dictionary submissions were evaluated using three metrics:

- mean squared error between the predicted embedding and the word embedding.
- cosine similarity between the predicted embedding and the word embedding.
- cosine-based ranking between the predicted embedding and the word embedding, which means how many other predicted embeddings have a higher cosine similarity with the target word than the right predicted one.

Since the Sentence-Transformer model was faster at generating the initial definition embeddings, it was used to initialize the definition embeddings in the final training and predictions. We understand that because of this our results in the task are not valid. However, the lexical graph approach can achieve almost similar results without the use of external data.

As seen in table 2, two different loss functions were used separately during training. Therefore,

[3]`https://huggingface.co/sentence-transformers/distiluse-base-multilingual-cased`

	MSE	Cosine Similarity	Cosine-based ranking
Cosine Embedding Loss	2.0157	0.4029	0.1665
Mean Square Error Loss	0.9106	0.2274	0.5003

Table 2: Reverse Dictionary results

two models were eventually presented. During evaluation, the first model trained with Cosine Embedding Loss reached more than 0.4 in cosine score and 0.16 in cosine ranking, which we consider remarkable and, according to the rankings[4], better than the top result for these particular Spanish embeddings. However, this model reached more than 2 in MSE, which considerably worsens the baseline (0.92) and the top results (0.85). On the other hand, the MSE Loss trained model slightly improves the baseline test MSE (0.91) and cosine score (0.22) but worsens the cosine ranking score. Other attempts to combine both loss functions did not success and achieved worse results in each of the evaluation metrics.

In the end, these results were found to be scalable to another languages and embedding types by using this same model architecture, and encountering in the way the same issues as for the Spanish "sgns" embeddings, that is, trouble combining MSE and cosine metrics. A Cosine Embedding Loss model for English ”sgns” embeddings achieves 0.34 cosine and 1.58 MSE, and using Spanish ”char” embeddings it reached 0.84 cosine and 1.66 MSE. As for the case of Spanish ”sgns”, compared to the top-ranked participants, a better cosine was achieved in exchange of a worse MSE. This leads to the opinion that the system architecture is easily scalable to other inputs, but it suffers from the same issues that with other languages and embeddings: a higher cosine similarity score can be achieved by using Cosine Embedding Loss, but in exchange of a worse MSE score.

4 Conclusions

For these tasks a combination of Machine Learning techniques and linguistic knowledge was proposed, in order to achieve good results and to understand the problems and the future challenges of these tasks.

In this paper, the main gaps in the dataset from a lexicographic perspective and its lack of coherence and exactitude were explained, and then a preprocessing solution was proposed, which was finally used in the RD system to avoid the problems that the dataset could carry in the model. Eventually, MMG team has presented a novel approach with an architecture that is easily scalable to other languages and embedding types. We understand that due to the use of external resources our results in the task are not valid for the challenge. However, we would like to remark that the lexical graph approach, which in the end we did not submit due to speed issues, achieved almost similar results.

These tasks are considered to represent an excellent starting point for research on the relationships between dictionaries and word embeddings. Both subtasks in general and our research on them in particular open up many options for further investigation. In our case, our intention is to use more linguistic knowledge at different levels, further exploring the power of linguistic graphs and putting into practice what we have learned in the Reverse Dictionary task to create quality Definition Modeling systems.

Edinburgh at SemEval-2022 Task 1: Jointly Fishing for Word Embeddings and Definitions

Pinzhen Chen **Zheng Zhao**
School of Informatics, University of Edinburgh
{pinzhen.chen, zheng.zhao}@ed.ac.uk

Abstract

This paper presents a winning submission to the SemEval 2022 Task 1 on two sub-tasks: reverse dictionary and definition modelling. We leverage a recently proposed unified model with multi-task training. It utilizes data symmetrically and learns to tackle both tracks concurrently. Analysis shows that our system performs consistently on diverse languages, and works the best with *sgns* embeddings. Yet, *char* and *electra* carry intriguing properties. The two tracks' best results are always in differing subsets grouped by linguistic annotations. In this task, the quality of definition generation lags behind, and BLEU scores might be misleading.

1 Introduction

We describe the University of Edinburgh's participation in SemEval 2022 Task 1 on comparing dictionaries and word embeddings (CODWOE), organized by Mickus et al. (2022).[1] The task features two directions: *reverse dictionary* and *definition modelling*. The former is to construct the embedding of a word given its definition gloss, and the latter is to generate the definition from a word embedding. The organizers provide datasets of word embedding-definition pairs across three types of embeddings and five languages. The training data has a size of 43.6k for each language, which is smaller than the data released in prior research (Hill et al., 2016; Chang et al., 2018). However, it provides a precious chance for a comprehensive study of lower-resourced reverse dictionary and definition modelling on languages other than English, as well as on different embedding architectures.

As our system architecture, we use a recently proposed unified model, which deals with both tracks concurrently and achieves superior results (Chen and Zhao, 2022). The model enables multi-task training by using word embeddings and definitions symmetrically. We also create ensembles and handcrafted phrases. Our code implementation builds on the organizers' and is publicly available.[2]

We submit to both reverse dictionary and definition modelling tracks, and cover all language and embedding combinations. Furthermore, we examine model generations and scores from three aspects: embedding architectures, languages, and linguistic annotations, aiming to figure out how these affect performance, subject to the models we have adopted. We finally show the information captured by different word embeddings and discuss the limitations in task evaluation and ranking.

Regarding the shared task outcome, we are the team with the most "gold medals": out of 18 sub-tracks, we attain first place in 8, second place in 4 and third place in 4. Our final ranks in the sub-tracks are detailed in Table 1.

Langauge		en	es	fr	it	ru
Reverse dictionary	sgns	2	4	3	2	3
	char	3	1	1	1	1
	electra	1	n/a	1	n/a	1
Definition modelling		4	3	2	2	1

Table 1: Our ranks in each sub-track.

2 Background

2.1 Datasets

The organizers provide datasets for five languages: English (*en*), Spanish (*es*), French (*fr*), Italian (*it*), and Russian (*ru*). Also, they supply 256d word embeddings from three architectures:

- *sgns*: static (non-contextualized) embeddings learned using skip-gram with negative sampling (Mikolov et al., 2013);
- *char*: character-based embeddings from an autoencoder trained on the spelling of a word;
- *electra*: contextualized embeddings produced by a generator-discriminator model (Clark et al., 2020).

[1] https://competitions.codalab.org/competitions/34022

[2] https://github.com/PinzhenChen/UnifiedRevdicDefmod

Despite that *electra* is not available for *es* and *it*, the data still covers 13 combination. All embedding architectures are trained on comparable corpora for all languages. Participants are not allowed to use any external resources, and words are provided as embeddings rather than actual words.

For each language, data is split into train, validation, test, and trial sets, at sizes 43.6k, 6,4k, 6.2k, and 0.2k. Human annotations are included in the trial split for analysis, but only word embeddings and definition glosses can be used for training. The snippet below exemplifies a single data instance with all possible fields. Training, validation, and test sets consist of only the bolded key-value pairs; all fields are found in the tiny trial set.

```
{"id":"en.trial.2",
 "sgns": [2.08729, 0.26177, ...],
 "char": [0.38789, 0.19716, ...],
 "electra": [-1.47715, -0.47424, ...],
 "gloss": "A mixture of other substances or things .",
 "word": "cocktail",
 "pos": "noun",
 "example": "a cocktail of illegal drugs",
 "type": "hypernym-based",
 "counts": 4187,
 "f_rnk": 13245,
 "concrete": 1,
 "polysemous": 0}
```

2.2 Evaluation metrics and ranking

Reverse dictionary is evaluated by three metrics:

- *MSE*: mean squared error between references and generated embeddings;
- *cosine*: cosine similarity between references and generated embeddings;
- *ranking score*: a percentage score measuring how many other test instances have a higher cosine similarity with a generated embedding than its reference does.

The definition modelling performance is measured by three too:

- *sense-BLEU*: sentence-BLEU implemented in NLTK with smoothing method 4 (Papineni et al., 2002; Chen and Cherry, 2014);
- *lemma-BLEU*: the maximum sense-BLEU between a generated gloss and all possible references of the same word and part of speech;
- *MoverScore*: a neural distance measure based on multilingual BERT (Zhao et al., 2019).

Finally, participants are ranked by rank scores instead of scalar numbers from the above metrics. A rank score is simply the rank of a particular submission among all submissions. For each sub-track, the average rank score of all three metrics is used to rank each team.

3 System Overview

3.1 Model Architecture

We select Chen and Zhao (2022)'s model as our system architecture because it has demonstrated great success on previous datasets for reverse dictionary and definition modelling. It is a "unified" model as it learns both tasks simultaneously, based on the intuition that a word and its corresponding definition share the same meaning, thus can be cast into the same neural semantic space.

We attach a diagram of this architecture as Figure 1. Technically, the model encodes glosses or word embeddings as the input, maps it into a shared representation, then generates embeddings or glosses accordingly. The shared representation serves as an autoencoding of both a word and its definition. Specifically, Linear layers (L) transform embeddings, and Transformer (Vaswani et al., 2017) blocks (T) encode or decode definitions.

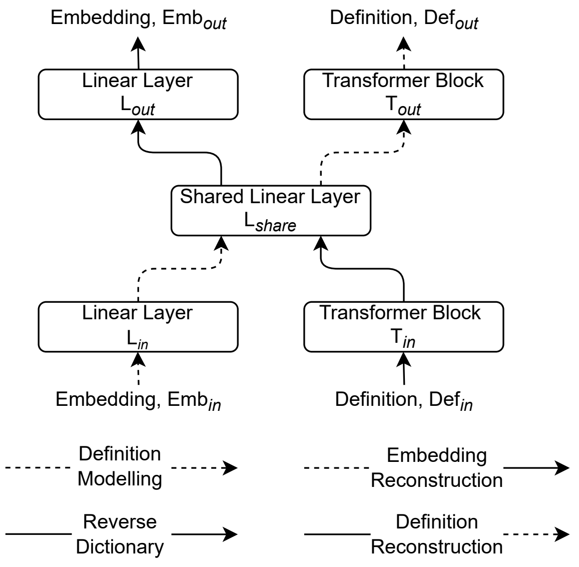

Figure 1: Chen and Zhao's illustration of the unified model.

3.2 Multi-task training

At the bottom of Figure 1, four trainable objectives are depicted: definition modelling, reverse dictionary, along with word embedding and definition reconstruction. The first two are CODWOE tasks, and the rest are auxiliary autoencoding tasks. Besides, another objective is to bring the vector representations of a word and its definition close in the shared layer. Our overall objective function combines the five objectives with equal weights.

3.3 Ensembling for reverse dictionary

Ensembling is a commonly employed technique to enhance machine learning performance. Specifically for reverse dictionary, we perform average ensembling: for each test instance, its final prediction is obtained by averaging all the corresponding predictions from different models. We ludicrously ensemble up to 21 models, of the same unified architecture, trained with various random seeds.

3.4 Handcrafting for definition modelling

Upon our initial inspection of definition modelling on the trial set, the generated definitions are mostly meaningless hallucinations, scoring a very low sense-BLEU of about 3. To understand how indicative BLEU is in this case, we handcraft a nonsensical n-gram submission. The rule is that for each test instance, we simply concatenate the most frequent bigram with the most frequent unigram, computed on all definitions in the training data. The phrases we prepare for each language are:

en	es	fr	it	ru
, or .	de la .	) (.	) (.	в . ,

4 Experiments and Results

4.1 Experimental setup

We tokenize glosses by whitespaces, add tokens into an open vocabulary, and embed them using one-hot. Word embeddings are used as provided. Loss functions are cross-entropy for tokens and MSE for embeddings. We also try cosine similarity for embeddings, but the model fails to converge. For definition modelling, we do not combine various embeddings as the input; this might put us at disadvantage in the team ranking.

While Transformer components are connected to form a unified model, most hyperparameters remain the same as in the provided baseline, which we specify in Appendix A. Following the original work, we tie Transformer embeddings and add a residual connection. We follow the same configurations for all language-embedding combinations. Training a unified model on an Nvidia GeForce RTX 2080 Ti takes roughly three hours.

4.2 Results

During the evaluation, we submit the provided baseline and our unified model. Also, we add ensembles of 17 and 21 models, as well the handcrafted n-grams. The submission scores, computed by the task organizers, are reported in Table 2 and 3. In the direction of reverse dictionary, the unified model steadily beats the baseline; ensembling adds a cherry on top for some languages but not all.

In definition modelling, our n-grams surpass genuine models on *en* BLEU scores, and even rank first in *fr* sense-BLEU among all participants' entries. This implies that either BLEU scores are not informative, or the model outputs are as embarrassing as the n-grams. On contrary, MoverScore is effective in downing the n-grams, probably by penalizing disfluency or semantic mismatch. Sadly, our manual review suggests that most model-generated

Figure 2: Visualization of gold and output embedding distributions across languages and embedding architectures.

glosses are inaccurate. The dissatisfying results might be due to the modest training data size.

5 Performances across *embeddings*

Reverse dictionary MSE and cosine are incomparable across different embedding types, whereas ranking scores can tell which embedding architecture is preferred for indexing and retrieving a word. A random baseline ranking score is 0.5, and most *char* and *electra* figures, unfortunately, fall between 0.4 and 0.5. On the other hand, *sgns* is more useful as its baseline scores start at around 0.45, and our models can improve these up to 0.25.

We employ principal component analysis (PCA) to reduce the gold and output embeddings to 2 dimensions. Then in Figure 2 we visualize *en*, *fr*, and *ru*, which come with all embeddings. The unified model usually outputs to a larger space than the baseline, hinting at a positive correlation between output spread and performance. Gold *electra* has the most isotropic space, but neither model could imitate the distribution. *Char* has a crescent shape with several clusters inside, which is unlikely to be cosine-friendly. These problems are alleviated on *sgns*, which witnesses the best ranking scores.

Definition modelling *Sgns* is again the winner, as models trained with it reach the top in many metrics. *Char* is also favourable. This is counterintuitive as *electra* should be fitter, for it retains more sense-specific knowledge. A possible reason is that *electra* needs to go through more training data than *sgns* and *char* to reach perfection.

6 Performances across *languages*

As seen in the result and rank tables, our system's behaviour is relatively consistent on various languages, except that English is more challenging. Assuming that the datasets are of similar quality, it is questionable to conclude that our model suits other languages more than English. Moreover, Figure 2 confirms that the English embeddings are not more peculiar than those of other languages.

We guess that other teams have focused on English (e.g. only submitted English), as it is a centred language in the research community. Instead, our hyperparameter search is based on the average loss from all languages, neglecting that the losses are not directly comparable.

7 Performances across *linguistic features*

We look into the unified model's trial set predictions, to interpret how scores vary across diverse linguistic annotations: polysemy, part of speech (POS), word length in characters, definition length in words, and word frequency. For categorical features, we group data by annotations; for numerical features, we divide the data into three subsets, by percentile ranges: 0-33, 33-67, and 67-100. Statistics of the subsets are in Table 4. We list cosine similarity for reverse dictionary, and lemma-BLEU for definition modelling. A generic discovery is that, the best scores of the two tracks emerge in differing subsets, regardless of what the feature is.

Linguistic feature	**Category / Range**	**No. of instances**
Polysemy	Yes	65
	No	135
Part-of-speech	Adj	56
	Adv	11
	Verb	37
	Noun	96
Word frequency (frequency rank in the whole corpus)	67 – 11145	67
	11146 – 44416	66
	44417 – 905726	67
Word length	3 – 5	85
	6 – 7	60
	8 – 17	55
Definition length	1 – 6	71
	7 – 10	65
	11 – 39	64

Table 4: Statistics of the different subsets grouped by features.

Polysemy Table 5 exhibits the results for the words with either one or multiple definitions. It is slightly easier to achieve better cosine similarity for unambiguous words. Polysemous words have better BLEU, and *electra* has worse BLEU than *sgns*. This is illogical, as defining a polysemous word is harder, especially without context. We hypothesize that BLEU is not reflective, and *electra* embeddings might be of sub-optimal quality.

Polysemy	sgns		char		electra	
	cosine	l-B	cosine	l-B	cosine	l-B
Yes	0.232	**4.34**	0.804	**3.20**	0.836	**3.61**
No	**0.360**	2.82	**0.813**	2.53	**0.845**	3.09

Table 5: Performances across polysemy annotations for *en*.

Part of speech Next, numbers for the four POS tags that exist in *en* trial, are laid out in Table 6. Strong cosine similarity is associated with verbs, although cosine numbers are close, except for adverbs. Adverbs, which have a small sample size, dominate high lemma-BLEU, perhaps because they are the least ambiguous.

POS	sgns		char		electra	
	cosine	l-B	cosine	l-B	cosine	l-B
Adj	0.319	3.36	0.801	2.76	0.811	2.81
Adv	0.134	**6.56**	0.798	**5.45**	0.815	**5.93**
Verb	**0.383**	3.20	**0.839**	2.50	0.853	3.83
Noun	0.314	2.97	0.806	2.53	**0.860**	2.99

Table 6: Performance across POS tags for *en*.

Word length We then make three partitions according to different word length ranges. Results in Table 7 suggest that shorter words have higher cosine, while longer words have higher lemma-BLEU. Numbers are closer for *sgns* and *electra*; we further investigate on *char* in Section 8.1.

Word length	sgns		char		electra	
	cosine	l-B	cosine	l-B	cosine	l-B
short	**0.332**	3.19	**0.845**	2.58	0.817	3.10
medium	0.314	3.19	0.842	2.74	**0.867**	**3.41**
long	0.327	**3.66**	0.694	**3.00**	0.854	3.33

Table 7: Performances across word lengths for *en*.

Definition length Likewise in Table 8, we separate the trial data by the gold definition length. Much higher BLEU is seen when the model defines words linked with a shorter gold gloss, as generating a shorter sequence is easier. As we anticipate, when the model produces word embeddings for longer glosses, results are better too, potentially because more information can be encoded.

Definition length	sgns		char		electra	
	cosine	l-B	cosine	l-B	cosine	l-B
short	0.280	**4.51**	0.796	**3.60**	0.824	**4.89**
medium	0.318	3.48	0.814	2.73	0.848	2.76
long	**0.361**	1.83	**0.822**	1.80	**0.856**	1.93

Table 8: Performances across definition lengths for *en*.

Word frequency Finally, Table 9 summarizes the results of the low, medium, and high frequency word groups. From the results, we cannot establish an explicit trend across different task directions, embeddings, or word frequencies. This implies that the embedding quality and model performance might be word frequency-agnostic.

Frequency	sgns		char		electra	
	cosine	l-B	cosine	l-B	cosine	l-B
low	0.250	3.53	0.805	**2.82**	0.850	3.30
medium	0.348	**3.54**	0.786	2.76	**0.864**	**3.38**
high	**0.357**	2.89	**0.839**	2.66	0.814	3.10

Table 9: Performances across word frequencies for *en*.

8 Qualitative Analysis and Discussions

8.1 Observing the crescent with a telescope

After PCA retains the most distinguishing components, Figure 2 shows interesting patterns, especially for *char*. We randomly label 25 English words and present them in Figure 3 and Figure 4, respectively for *char* and *electra*. The sub-clusters in *char*'s crescent are perfectly in tune with word lengths; for *electra*, more frequent words are closer to the origin. We do not notice a clear trend for *sgns*, for which a plot is attached as Figure 5.

We attribute the distinct patterns to the training paradigms: character-level word autoencoding for *char*, and contextualized modelling for *electra*. This accounts for the largest cosine gap on *char* between long and short words, seen earlier in Table 7. Intuitively, it is more difficult to train *char* autoencodings for longer words, so, in turn, embeddings for longer words possess inferior quality.

Within *char* embeddings, words are grouped by lengths, so we may utilize this for word retrieval in future work. Nonetheless, we are unsure of how length or frequency information aids sense-based tasks, like definition generation in our context.

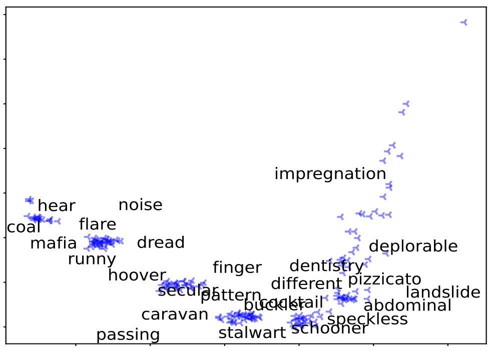

Figure 3: Gold English *char* embeddings with word labels.

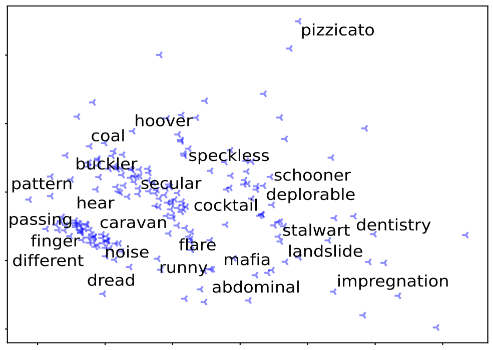

Figure 4: Gold English *electra* embeddings with word labels.

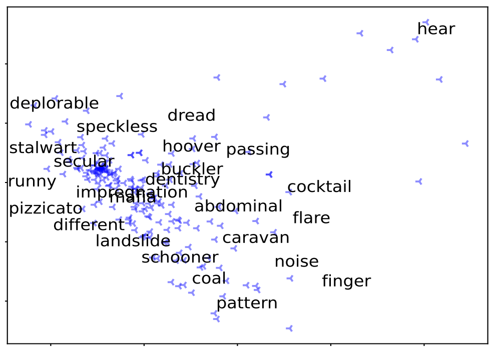

Figure 5: Gold English *sgns* embeddings with word labels.

8.2 Sense-BLEU with no sense

We design a sanity check on the representativeness of BLEU. On the English trial set, we remove punctuation marks and NLTK-defined stop words from both references, and our unified model's definitions generated from *sgns*. Sense-BLEU drops from 3.31 to 0.39, and surprisingly, it worsens to 0 with smoothing disabled. Evidently, sense-BLEU and thereby lemma-BLEU are hugely inflated by functional tokens as well as smoothing.

8.3 Evaluating task evaluation and ranking

We point out the limitations associated with the evaluation and ranking process, which can benefit from a rethink. First, as shown above, the two BLEU metrics may not be practical. Second, some metrics are correlated, i.e., cosine with the ranking score, and sense-BLEU with lemma-BLEU. These problems are amplified by the team ranking protocol, which averages a team's ranks in individual metrics to produce a final standing. It might not be meaningful to compare the individual metric ranks, not to mention averaging them since metrics are not equally weighted.

Nonetheless, we are not in a knowledgeable position to propose a better approach, other than clumsily displaying ranks in individual metrics.

Abstract

Described are our two entries "emukans" and "guntis" for the definition modeling track of CODWOE SemEval-2022 Task 1. Our approach is based on careful scaling of a GRU recurrent neural network, which exhibits double descent of errors, corresponding to significant improvements also per human judgement. Our results are in the middle of the ranking table per official automatic metrics.

1 Introduction

The definition modeling track of SemEval-2022 Task 1: CODWOE - COmparing Dictionaries and WOrd Embeddings (Mickus et al., 2022) challenged participants to generate dictionary glosses from individual word embedding vectors. This paper describes two CODWOE submissions, "emukans" and "guntis", where the first focuses on the automatic CODWOE scores, but the second attempts to gauge the relationships between scaling laws, the automated metrics, and human evaluation. Our submissions achieved competitive results (see Figure 3) on the MoverScore official metric - scoring 1st for French, 2nd for Spanish, and 3rd for Russian.

Our approach was to apply classical recurrent networks, such as Long Short-term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Units (GRU) (Cho et al., 2014), to definition modeling and investigate how model scaling impacts performance. The scaling effect is well investigated for transformers, but not so much for RNNs. Recently, the main focus in deep learning has skewed from searching for new model architectures to investigating how various factors impact the training process and overall system performance (Nakkiran et al., 2019; Kaplan et al., 2020; Gordon et al., 2021). The main factors are: the amount of data, the amount of compute, and the size of the model (parameter count). In the competition the data amount is fixed and no use of external data is permitted, thus we investigate how scaling model size and training time impacts training progress and model performance for recurrent models.

In our experiments we did observe deep double descent effects: epoch-wise double descent with respect to both cross-entropy loss and prediction accuracy on a validation data set, more pronounced with increasing model size.

We also investigated the automatic metrics used for evaluating submissions and their correlation with human evaluation, focusing primarily on the MoverScore metric (Wei Zhao, 2019). MoverScore does correlate with human evaluation, but not necessarily very strong, at least for this dataset. We find that the double descent effect seen with respect to prediction accuracy can also be observed for MoverScore.

2 Background

The CODWOE shared task invites participants to compare two types of semantic descriptions: dictionary glosses and word embedding representations. The task consists of 2 subtracks: definition modeling and reverse dictionary. In definition modeling participants have to generate glosses from word embedding representations. The reverse dictionary task is the inverse: reconstruct a word embedding from the corresponding gloss. Considering results achieved by the baseline models provided by the organisers, we decided to participate only in the definition modeling track, as it seems the more challenging task, with more room for potential improvement.

For the definition modeling track, inputs are 256-dimensional embedding vectors and outputs are plain text. Data is provided for 5 languages: English, French, Spanish, Italian and Russian. Every language is scored separately. We submitted for all 5 languages. The provided word embedding vectors are of 3 types: CHAR, SGNS, and ELECTRA.

3 System overview

For the definition modeling task, we used classical recurrent networks, experimenting with both LSTM and GRU architectures. We added an initial fully connected input layer to scale a given word embedding vector to higher dimensions. We used the ADAM optimizer (Kingma and Ba, 2014) in the training process. The learning rate was set in the range ∈ [1e-5, 3e-5, 1e-4]. A linear learning rate decay schedule with warm-up over 0.01 was used. No preprocessing was applied to training data. The code is available on GitHub [1]

The very first step is creating a tokenizer and building its vocabulary. We use SentencePiece tokenization (Kudo and Richardson, 2018), trained on the training dataset only. We carried out experiments across a range of vocabulary sizes.

We used a classical approach and a decoder only part of standard seq2seq (sequence to sequence) recurrent neural network models without attention. The GRU/LSTM state vector is initialized from the given defmod embedding vector. In our case, we use a single word embedding vector type. For the first time step we pass a single <seq> token to model as input. The model outputs a single predicted token and a new state vector. To avoid exploding gradients, the outputs of the model are normalized. The token selected by the model is appended to the generated gloss, and is also used as input to the model for the next time step. This process is repeated until reaching the iteration limit.

At every time step, the model can make mistakes. If the initial part of the input sequence fed to a seq2seq model is bad, most likely the subsequent output sequence will also be wrong. To mitigate this accumulation of errors and speed up the training process, we use the teacher forcing technique (Williams and Zipser, 1989). With teacher forcing, the model is trained by supplying input tokens from the target sequence of the dataset and using the network's one-step-ahead predictions to do multi-step sampling. We also tried a more advanced teacher forcing technique: scheduled sampling (Duckworth et al., 2020), where input sequence tokens are given ground-truth values only with some probability. Unfortunately, scheduled sampling did not give good results - the loss plot was very noisy. It is likely that the CODWOE definition modeling task itself is a very hard task with too much variability relative to the amount of provided training data; scheduled sampling might be better suited for language model fine-tuning when the model weights are pretrained on a large corpus and already correlate fairly well with natural language syntax and semantics.

After each training epoch, the model is evaluated on a validation dataset using the same cross-entropy loss function as used for training. We also use an accuracy metric for evaluating model performance, as it correlates with perplexity and human judgement for large language models. The accuracy is calculated by dividing the count of correctly predicted tokens (under teacher-forcing) by the number of total tokens.

For "emukans" submissions, model training is stopped using early stopping (Prechelt, 2012) based on the accuracy score for the validation data, while "guntis" submissions were intentionally trained long past the overfitting point to observe scaling and double descent effects.

4 Experimental setup

For our experiments, we have 5 Tesla v100 16GB GPUs provided by our institute. During the competition, our focus was on exploring different training effects and model tuning. Most of the experiments were focused on primary factors of "scaling laws": model size and the amount of compute (training epochs).

For simplicity and consistency of presentation, in most of the following tables and figures (all except for Figure 3) we report experimental performance evaluated against a trial dataset provided by the CODWOE organizers, which consists of only 200 glosses. Apart from the automatic metrics, our focus was on (informal) manual evaluation of generated glosses.

4.1 Vocabulary size

The vocabulary of distinct tokens available for use by an NLP model is generally built during a data preparation stage, and the size of this vocabulary is a key factor in model performance. Therefore we started our experiments by tuning the size of the vocabulary.

We build our token vocabulary from the training dataset only. Taking into account the relatively small training dataset - only 43k glosses and 18k unique words, we reasoned that the token vocabu-

15000	0.09638	0.02053	0.02056

Table 1: Influence of vocabulary size on the automatic metrics

lary size should be fairly small. Therefore we set our hypothesis as the following:

Hypothesis 1 (H1): *Optimal vocabulary size is around 10% of the unique word tokens.*

During initial training experiments, we noticed a tendency of the model to repeat the same gloss for many different word embeddings. We speculate that repeating such 'most popular' glosses might give the model higher chances of matching frequently occurring words or phrases in the dataset.

In the vocabulary size optimization experiment, we used the GRU model with 2 layers, hidden dimension 768, and 30 tokens limit during training. Table 1 summarizes our results on the trial set. We selected vocabulary size *1500* as it has the highest BLEU scores, relatively good MoverScore and the most promising glosses during manual evaluation. 1500 tokens are 8.3%, the result is close to 10%, confirming hypothesis 1 experimentally.

4.2 Model size scaling

Recent trends in deep learning suggest that bigger models increase performance on most tasks (Brown et al., 2020; Rae et al., 2021). However, the focus in these cited papers is given to Transformer (Vaswani et al., 2017), Convolutional (ConvNets) or Residual networks (ResNets). Classical recurrent neural networks (RNN) such as GRU or LSTM have been left out of the mainstream investigation of scaling effects. In the following experiments, we show that scaling RNNs also gives similar positive effects as for other network architectures. Our approach could be formulated with the following hypothesis:

Hypothesis 2 (H2): *Scaling RNNs in depth or width improves their performance.*

We summarize our experiments in tables 2, 3 and 4. The results tentatively confirm hypothesis 2. We observe that no matter how one scales the model, in width (higher hidden dimension) or depth (more layers), the performance does increase in both cases. Of course, these results are only for relatively small models fitting into our compute capacity (trained using a single Nvidia V100 GPU).

Layers	MoverScore	S-BLEU	L-BLEU

4096	0.11071	0.02453	0.02450

Table 3: Scaling hidden dimensions for 2 layer GRU model.

4.3 Double descent

Classical machine learning theory says that increasing the model size or training time beyond some optimum, while keeping the amount of data constant, will eventually lead to the model overfitting. (i.e., bigger models would give worse performance than optimally sized smaller models). Recently, a new effect was discovered (Nakkiran et al., 2019) which contradicts, or amends, this traditional wisdom. The double descent effect states that increasing the model size (i.e., model-wise double descent) or compute resources invested into training (i.e., epoch-wise double descent) indeed leads to overfitting at first, but further increasing the size of the model or the training time can, at some critical point, reverse the trend, so that performance starts increasing again.

During our model scaling experiments we aimed

Hidden	MoverScore	S-BLEU	L-BLEU
1024	0.07284	0.02018	0.02014
2048	0.11915	0.02430	0.02427
3072	0.12454	0.02548	0.02548

Table 4: Scaling hidden dimensions for 4 layer GRU model.

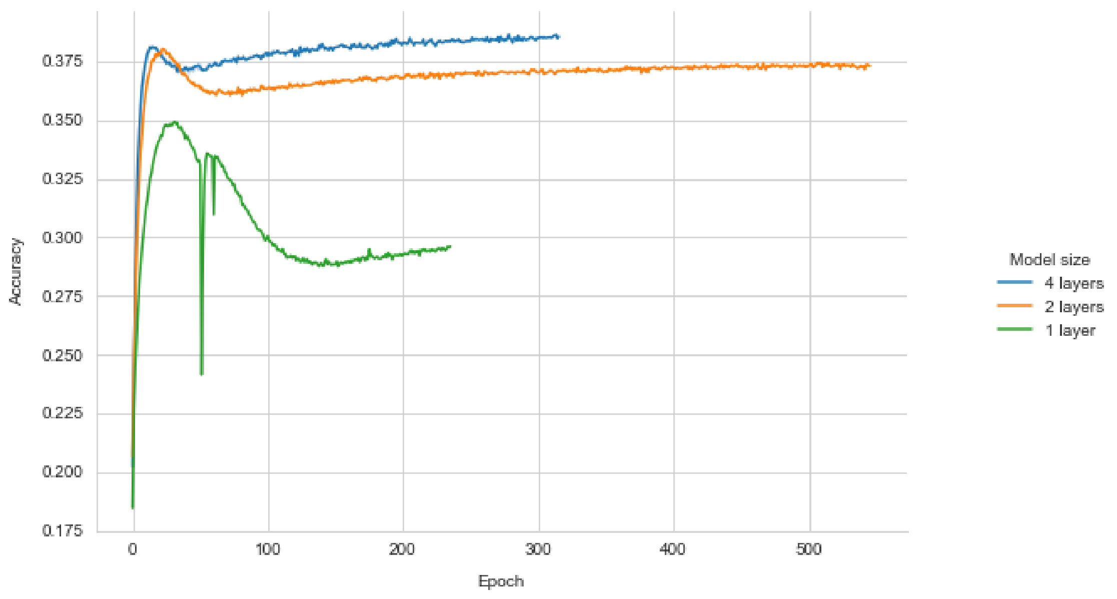

Figure 1: Accuracy: Correctly predicted word tokens, assuming that all previous word tokens were correct. The scores are calculated on the development (validation) dataset. In all cases, the hidden layer size is 3072 dim.

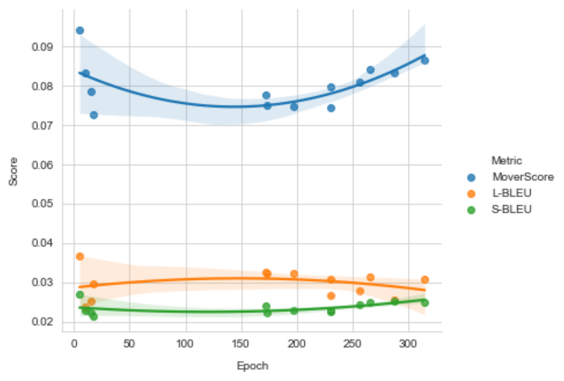

Figure 2: Automatic metric change during the 4-layer model training. The scores are calculated on the trial dataset.

to replicate the double descent effect and bring the model quality to a new level after initial overfitting. Since our compute resources were limited and we could not scale our model size endlessly, we investigate the following hypothesis:

Hypothesis 3 (H3): *Training the GRU model longer leads to an epoch-wise double descent effect.*

For our experiments, besides automatic evaluation metrics for the defmod task we introduced also an accuracy score.

Definition 1 (Accuracy): *Percent of correctly predicted tokens when all previous input tokens are correct.*

In figure 1 are 3 plots for 1-, 2- and 4-layer GRU models. The 4-layer model shows a clear epoch-wise double descent effect. We can also observe that, as previously demonstrated for other kinds of models, the effect occurs only when the model size is big enough relative to the training set. The 1- and 2-layer models are apparently too small for this training set and the task complexity.

Figure 2 is for the same 4-layer model, but in this case plotting scores on the metrics used for the CODWOE defmod task. We can see some correlation with the accuracy plot in figure 1, but these metrics seem to be less sensitive overall.

In the table 5 we illustrate the continuing gloss quality improvement according to human judgement after the first accuracy spike in the automatic metrics (epoch 5). Glosses become semantically closer to the original word. Hence, we conclude that hypothesis 3 is empirically confirmed.

5 Results

Our team "emukans" and "guntis" placed in the middle of the final ranking table. However, if we inspect the scores in figure 3, we see that our solution (a green line) does outperform others in some metrics for some languages (i.e., top score for French, 2nd for Spanish, 3rd for Russian).

Analysing our submission results, we noticed that MoverScore can give even negative scores and is quite variable from one example to another. The score is generally very low if the generated gloss length differs substantially (either too long or too

Word	Ground-truth	Epoch	Predicted	MoverScore

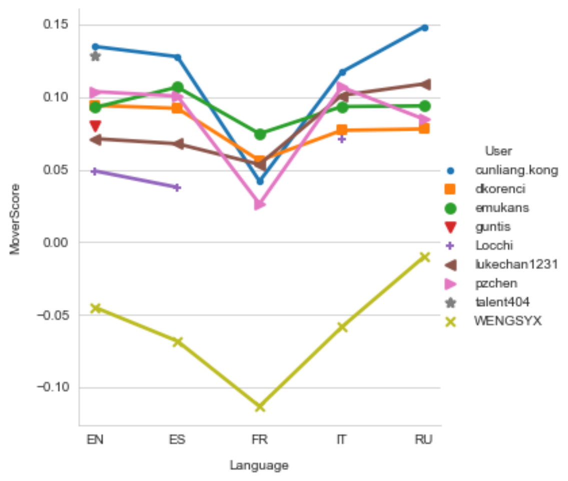

Figure 3: Best MoverScore results for all participants in all languages.

short) from the length of the ground-truth gloss, irrespective of whether a human can perceive some semantic alignment between the two.

Analysing the available data, we see that many of the glosses are relatively short: up to 20 tokens (but there are also very long examples). We conjecture that one strategy for increasing MoverScore might be to simply limit all generated glosses to 20 tokens or less.

6 Conclusion

In this competition, we tried a classical recurrent neural network approach for the CODWOE definition modeling task, and obtained positive results.

Several topics require deeper investigation. A good metric for automatically measuring how semantically close are two sentences is still an unsolved problem. MoverScore is still too far from human judgement. Taking into account even the best scores for the definition modeling task, the task is still in very early stages, and models that are trained only on the provided data cannot generate any practically useful outputs. This could possibly be addressed with much larger training datasets, or by allowing the use of external data (or of large pretrained language models). In general, it seems that a word semantic could not be represented using a single vector. The task requires more context to capture the semantics. Maybe the task could be changed to generating a gloss for a set of synonyms or semantically close words.

Abstract

We present the Uppsala University system for SemEval-2022 Task 1: Comparing Dictionaries and Word Embeddings (CODWOE). We explore the performance of multilingual reverse dictionaries as well as the possibility of utilizing annotated data in other languages to improve the quality of a reverse dictionary in the target language. We mainly focus on character-based embeddings. In our main experiment, we train multilingual models by combining the training data from multiple languages. In an additional experiment, using resources beyond the shared task, we use the training data in Russian and French to improve the English reverse dictionary using unsupervised embeddings alignment and machine translation. The results show that multilingual models occasionally but not consistently can outperform the monolingual baselines. In addition, we demonstrate an improvement of an English reverse dictionary using translated entries from the Russian training data set.

1 Introduction

In a reverse dictionary, one can look up a gloss, an explanation of a word's meaning, to find the most relevant word or word form. The applications of reverse dictionaries are numerous, as they can help language learners in expanding their vocabulary, authors and writers in looking for the most suitable word, and avid cruciverbalists in taking on some of the most challenging crosswords.

Reverse dictionary modelling has seen approaches ranging from traditional information retrieval using relevance scores (Zock and Bilac, 2004) to ones involving node-graph architectures (Zhang et al., 2020). As a general rule, the quality of a reverse dictionary appears to largely depend on the availability of annotated data. However, annotated data are scarcely available and expensive to produce for low-resource languages. We therefore explore the viability of multilingual approaches to improve the quality of a reverse dictionary.

This work is performed in the context of the reversed dictionary subtask of the SemEval 2022 task 1, COmparing Dictionaries and WOrd Embeddings (Mickus et al., 2022). Unlike standard reverse dictionaries, the target is to predict a word embedding vector for each gloss, rather than a word form. Three types of word embeddings are available: character-based embeddings (*char*), Skip-grams (*sgns*), and contextual embeddings (*electra*). No additional resources are allowed in the shared task. In this paper, we do present additional experiments, though, where we also used an external machine translation engine. While five languages were made available in the shared task, we mainly focus on English, but also give some results for Russian and French.

The main research question of this study is thus whether the performance of a monolingual reverse dictionary can be improved using data in other language(s) in a low supervision setup. We first explore what are the most suitable type of embeddings for a Transformer-based reverse dictionary. Having found the best-performing embeddings, we use them to train a joint model for multilingual reverse dictionary, which can map glosses to words in multiple languages. Finally, we use the training data in French and Russian to improve the quality of an English reverse dictionary by means of unsupervised embeddings alignment and machine translation.

We did not submit our results in the evaluation period since in one of the experiments we used a pre-trained neural machine translation model, which is prohibited in the shared task. Nevertheless, we report the performance of our jointly trained multilingual models on the test sets, as no additional data or pre-trained models were involved in training. For character-level embeddings, our best multilingual models, when tested on English, would rank 25th in terms of mean squared error (MSE), 20th in terms of cosine similarity (COS), and 9th in terms of cosine-based ranking (CRK); on French: 22nd (MSE), 10th (COS), 3rd (CRK); on Russian: 7th (MSE), 7th (COS), 13th (CRK).

2 Related Work

Recent research has explored bilingual and cross-lingual reverse dictionaries, the task of which is to map a gloss in a source language to a word in target language. An implementation by Qi et al. (2020) involved a machine translation API and bilingual dictionaries to re-direct a query in the source language through the target language pipeline. Yan et al. (2020) implemented the first cross-lingual reverse dictionary based on mBERT (Devlin et al., 2019), a Transformer-based language model trained on Wikipedia articles in 104 languages. Their study revealed that unaligned cross-lingual reverse dictionary achieves best performance when mBERT is tuned on unaligned multilingual data; its quality is substantially worse than that of a monolingual model. Yan et al. (2020) thus concluded that it remains unclear how multilingual data is to be utilized to improve the quality of unaligned reverse dictionary, which is to be explored in this project.

Joint multilingual models, which are trained on multiple languages at once, offer a solution for low-resource languages that often have little to none annotated data. This has for example been explored for dependency parsing, with positive results (Kondratyuk and Straka, 2019; Smith et al., 2018).

Cross-lingual embeddings are of central importance in word meaning similarity across languages (Jimenez et al., 2017), and are thus a crucial component of cross-lingual reverse dictionaries. As noted by Ruder et al. (2019), the applicability of cross-lingual embeddings relies on their quality, which, in turn, depends on the availability of bilingual corpora and dictionaries. Nevertheless, an unsupervised cross-lingual embeddings alignment method proposed by Lample et al. (2018) enables high quality cross-lingual embeddings with no or little supervision, further allowing for unsupervised machine translation. Unsupervised cross-lingual embeddings alignment thus offers a solution for both mapping the word embeddings and its glosses from one language to another.

3 System Description

We focus on the strategies of utilizing the data in foreign languages to improve reverse dictionary rather than the choosing of most suitable model. Therefore, we use the SemEval 2022 task 1 baseline system, a Transformer-based architecture with all parameters unchanged for all of our models.

3.1 Methodology

The methodology adopted can be divided into a preparatory step and two main experiments. The initial step sought to learn the most suitable type of embeddings for a Transformer-based English reverse dictionary. A baseline model was trained and tested three times on each type of embedding to learn whether there were notable deviations between the runs and the official baseline scores of the shared task. This was done to select the best performing type of embedding to be used in further experiments, thus avoiding spending the computational resources on numerous models with different embeddings.

The two main experiments build on the research of He et al. (2017), as they investigate joint training of multilingual models as well as cross-lingual embedding alignment. In the first experiment, the French and Russian training sets are concatenated to the English training set, one or both at a time. The joint models are then trained with a joint development set containing entries in all languages used in training. We choose the source languages, namely French and Russian, so as to investigate whether the similarities between the source and target language, such as shared words, similar script, and typological proximity can affect the performance of a multilingual reverse dictionary.

In the second experiment, the embeddings of source entries (in French and Russian) are firstly aligned to the target embedding space (English) with no supervision using the MUSE library (Lample et al., 2018). To ensure a fully unsupervised setup, the refinement and evaluation steps involving bilingual corpora are disabled. The alignment is conducted in five epochs using all standard parameters. In the process, the target embeddings are anchored. Their values are not updated in order to preserve the quality of the pre-trained embeddings. Secondly, the glosses of the first 4,500[1] entries from the now-aligned source training set are

[1]A relatively small number of glosses were translated due to the limited access to the tool used for machine translation.

Embeddings	MSE	σ	COS	σ	CRK	σ
sgns	1.193	0.009	0.259	0.007	**0.405**	0.012
char	**0.156**	0.014	0.810	0.003	0.469	0.003
electra	1.846	0.172	**0.840**	0.001	0.483	0.002

Table 1: The baseline performance of a Transformer-based English reverse dictionary trained on different types of pre-trained embeddings, averaged over 3 runs. The standard deviation (σ) shows the fluctuation of the scores over the three runs.

translated and attached to the target (English) training set. Since the word forms are masked in the training data, we were unable to train an unsupervised machine translation model. The glosses are thus translated using a pre-trained neural machine translation model, namely Watson API[2]. Lastly, the translated glosses are tokenized using the spaCy tokenizer to mirror the tokenization in the original data sets provided by the organizers of the shared task.

3.2 Evaluation

All models are primarily evaluated on the trial data set. This is due to the fact that Experiment 2 used a pre-trained machine translation model, which goes against the rules of the contest. We, however, additionally evaluate our jointly trained multilingual models on the test set, as the model does not use any additional resources.

The models were evaluated based on the three official metrics of the shared task: mean squared error (MSE), cosine similarity (COS), and cosine-based ranking (CRK) (Mickus et al., 2022).

4 Results and Discussion

4.1 Choice of Embeddings

The performance of the baseline models trained on the English training data set with different embeddings can be seen in Table 1. The scores are highly similar to the baselines published by Mickus et al. (2022) and are primarily included to estimate the stability of the performance of a Transformer architecture on each type of embeddings.

Individually, each type of embedding achieves the highest score on one of the parameters, with *char* achieving lowest MSE, *electra* securing highest cosine similarity, and *sgns* having best cosine-based ranking. Overall, *char* embeddings demonstrate the most stable and good performance across all three parameters. The *char* embeddings also had a relatively low standard deviation between runs for all metrics, as opposed to *electra* on MSE.

The results seem to have several implications. Firstly, the three evaluation parameters favour divergent information encoded by the three types of embeddings. Most notably, character-level information stored in *char* embeddings substantially minimizes MSE of the predicted embeddings of a word. This might be because character-level embeddings are effective in addressing out-of-vocabulary words (Polatbilek, 2020). In other words, they seem to enable the Transformer model to learn the mapping between glosses and characters that add up to words denoting the glosses. However, such mapping suffers from a major limitation, as character-level embeddings do not differentiate between the senses of a word. Most effective in handling this task are the contextualized embeddings (*electra*), for they encode a word depending on the surrounding context. Depending on the context, the sense might differ, thus leading to completely different values in the embeddings space. It can thus be argued that both character-level and contextualized features are important for a reverse dictionary model; an ideal solution could perhaps utilize using both types of embeddings for fine-grained retrieval of words.

Seeing as *char* embeddings had a good and stable performance overall, we further explore them in the following experiments.

4.2 Multilingual Model

The performance of multilingual models jointly trained for two or three languages at a time is reported in Tables 2 and 3.

The multilingual models perform similarly to the monolingual baselines. As can be seen from comparing the models' performance across trial and test sets, some differences are likely due to chance and fall within the range of a standard deviation reported in 1. Nevertheless, it is rather surprising that the English reverse dictionary seems to bene-

fit from the Russian data more than it does from the French data. In addition, when trained on both English and Russian, the model performs better on Russian.

In the case of multilingual models, it might be productive to focus on the lack of losses rather than the lack of gains. The results indicate that the performance of Transformer-based English reverse dictionary remains unaffected by both a relatively close language (French), and a distant language (Russian). This might be due to the fact that the high-quality pre-trained embeddings exist in different vector spaces. Despite the fact that the data are concatenated, the Transformer architecture learns to differentiate between the two and only retrieve words from the relevant vector space.

The shared space of models like mBERT is arguably the main reason why the joint tuning of models on data in multiple languages at once leads to best performance of a cross-lingual reverse dictionary for Yan et al. (2020). Overall, it is debatable whether there is reason to train a multilingual reverse dictionary on several unaligned languages. Such a model takes longer to train and tune, occupies more space, and does not offer much apart from the convenience of not having to switch between multiple models.

4.3 Embeddings Alignment and Machine Translation

The last experiment involved unsupervised embeddings alignment and machine translation of the glosses from source language (French and/or Russian) to target language (English). During alignment, the target embeddings were anchored to retain the values of the pre-trained embeddings. However, due to system constraints, the target embedding values changed from ten decimal points to five. To address this and to see whether this could affect the results in a negative way, an additional model was trained with the restored original values (with ten decimal points) of the embeddings in English, while the source (French and Russian) embeddings were kept at five decimal points. The results are presented in Table 4 alongside the baseline results.

Alignment without translation of glosses in most cases affected the model in a negative way, as it only introduced noisy foreign data. However, the machine translated glosses attached to the aligned values from source language seemed to have a positive effect on the English reverse dictionary when the source language was Russian. In the case of French, the approach failed completely. The retention of the original embedding values as opposed to the last five digits being lost led to mixed results. Though in most cases the difference is small and might have occurred by chance, the results could also indicate that it is crucial for the source and target embeddings to be similar in terms of the quality

		English + French			English + Russian		
Metric	Baseline	Al	Al+T	Al+TR	Al	Al+T	Al+TR
MSE	0.156	0.184	0.171	0.184	0.162	**0.135**	0.171
COS	0.810	0.799	0.810	0.801	0.807	**0.811**	0.810
CRK	0.469	0.474	0.500	0.483	0.477	0.501	**0.463**

Table 4: The performance of a Transformer-based English reverse dictionary trained on aligned and joined data (Al), aligned with target embeddings cut off past five digits and machine translated glosses (Al+T), as well as aligned with recovered target embeddings and machine translated glosses (Al+TR).

in a cross-lingual space.

A rather surprising finding of the experiment was the improvement of an English reverse dictionary using the data in Russian. Contrary to the findings of Yan et al. (2020), a more substantial improvement for English was observed with a distant source language, which uses a completely different script. The Russian language has been previously proposed as a generally good source language across several tasks and target languages, though (Turc et al., 2021). As for this experiment, perhaps the alignment produced with no supervision was of higher quality with Russian, allowing to correctly project the foreign source entries in the target space. It is also possible, though unlikely, that the translations of glosses from Russian to English were of higher quality than those of French to English.

5 Conclusions

This project has investigated whether an English reverse dictionary can be improved using data in foreign languages. This research question was addressed by firstly determining the most suitable type of embeddings for a Transformer-based reverse dictionary. Secondly, multilingual joint models were trained to see the affects on the performance of English as target language and two source languages, namely French and Russian. Lastly, the embeddings from source language were aligned to the target embedding space, followed by machine translation of the respective glosses.

Three key findings emerged. Firstly, character-level features lead to best performance of an English Transformer-based reverse dictionary. Secondly, multilingual reverse dictionaries perform comparably with monolingual ones, as no substantial improvement or decline was observed. Thirdly, an English reverse dictionary can be improved using the available data in foreign languages, such as French and Russian, though the improvement is rather small. In the reported experimental setup, Russian was found to be a more suitable source language in enhancing an English reverse dictionary.

There are numerous possible extensions of the present study. One could, for instance, recreate the study in a fully supervised or fully unsupervised setup so as to see to what extent the lack of supervision affected the results. It would also be interesting to investigate whether combinations of embeddings, e.g. contextual and character-level, would lead to better performance of reverse dictionary models. Overall, the improvements recorded in this study were, arguably, hardly significant. It may therefore be productive to search for more successful ways of using data in foreign languages in creating or improving reverse dictionaries.

Abstract

This paper describes our two deep learning systems that competed at SemEval-2022 Task 1 "CODWOE: Comparing Dictionaries and WOrd Embeddings". We participated in the subtask for the reverse dictionary which consists in generating vectors from glosses. We use sequential models that integrate several neural networks, starting from Embeddings networks until the use of Dense networks, Bidirectional Long Short-Term Memory (BiLSTM) networks and LSTM networks. All glosses have been preprocessed in order to consider the best representation form of the meanings for all words that appears. We achieved very competitive results in reverse dictionary with a second position in English and French languages when using contextualized embeddings, and the same position for English, French and Spanish languages when using char embeddings. Our source code can be found at GitHub[1].

1 Introduction

Distributed representations of words (or word embeddings) (Bengio *et al.*, 2003; Mikolov *et al.*, 2013; Pennington, Socher and Manning, 2014) have shown to provide useful features for various tasks in natural language processing (NLP) and computer vision. While there seems to be a consensus concerning the usefulness of word embeddings and how to learn them, this is not yet clear with regard to representations that carry the meaning of a full sentence. That is, how to capture the relationships among multiple words and phrases in a single vector remains a question to be solved.

Much recent research in computational semantics has focused on learning representations of arbitrary-length phrases and sentences. The reverse dictionary represents one of the most common cases to solve this problem of learning sequence representations. That said, the reverse dictionary is the task to find the proper target word given the word description (Hill *et al.*, 2016; Hedderich *et al.*, 2019; Zhang *et al.*, 2019; Yan, Li and Qiu, 2020). For example, the composed meaning of the words in a dictionary definition (*A mixture of other substances or things*) should correspond to the meaning of the word that define it (*cocktail*). As mentioned by Hill *et al.* (2016), this bridge between lexical and phrasal semantics is useful because high quality vector representations of single words can be used as a target when learning to combine the words into a coherent phrasal representation.

In this paper, we present our contributions to solve the reverse dictionary problem using very specific neural architectures and applying supervised learning. For more information on task 1 of SemEval-2022 as described by its organizers, we invite the reader to consult the paper of Mickus, Timothee *et al.* (2022).

Our approaches require a model able of learning to map between arbitrary-length phrases and fixed-length continuous-valued word vectors. For this purpose, we experiment with two broad classes of neural language models (NLMs): Recurrent Neural Networks (RNNs) with (Bidirectional) Long-Short

[1] https://github.com/jln-brtn/BL.Research-at-SemEval-2022-Task-1

Term Memory (BiLSTM and LSTM), which naturally encode the order of input words (or characters), and simpler (feedforward) lexical units embedding models. These lexical units can be bag-of-words (BOW) or a sequence of characters.

After having described in section 2 in more detail the problem to be solved in the SemEval-2022 evaluation campaign and the data provided, we present in section 3 the previous works of reverse dictionary. Then, in section 4, we present our neural architectures with all data preprocessing having been performed. Thereafter, in section 5, we describe the experimental setup implemented before presenting the results in section 6 and concluding in section 7.

2 Background

2.1 Problem Description

The CODWOE shared task[2] consists of compare two types of semantic descriptions: dictionary glosses and word embedding representations. The problem can be defined as follows: given a definition, can we generate the embedding vector of the target word? That said, there are several questions to be solved: (1) How should we compare two very different types of semantic representation? (2) Will contextualized embeddings help better define polysemous (ambiguous) words that have multiple senses? and (3) Can we have the same evaluation performances of the same neural architecture for different natural languages? In other words, five natural languages are studied in this task, namely: English, French, Spanish, Italian and Russian language. Our goal is to answer the following question: can the same model or the same neural network architecture be beneficial for all languages?

2.2 Data Description

The organizing members of the reverse dictionary task proposed different JSON files that contain definitions and their vector representations. Each JSON file describes information about a one natural language for a list of five languages, namely: French, English, Spanish, Italian and Russian language. The corpus is therefore multilingual. Before having the test corpus, the data have been split in different sets: trial, train, and development corpus. All the models we will present have been trained and validated on train and development corpus.

Before describing the data, we can do a quick focus on the size of these data. As we mentioned, the data are split into 3 groups. For each language, the trial dataset contains 200 elements pairs (definitions and their embedding vectors), the train dataset contains 43,608 elements pairs, and the development dataset contains 6,375 elements pairs. Regarding the test corpus, we have 6,208 definitions for each language. The organizers have provided different vector representations for the definitions. All these representations are continuous vectors (embedding vectors). They have 256 dimensions and are built with well-known three techniques:

- "char" corresponds to character-based embeddings, computed using an auto-encoder on the spelling of a word.
- "sgns" corresponds to Skip-Gram with negative sampling embeddings, aka. Word2Vec (Mikolov *et al.*, 2013).
- "electra" corresponds to Transformer-based contextualized embeddings.

As mentioned above, all datasets of SemEval-2022 task 1 are multilingual. This is an important point because we can imagine and create a system that manages these multilingual datasets, or several systems specialized in one language. We will explore this option in the “Experimental Setup”.

3 Related Work

In the field of natural language processing, word embeddings have been the subject of several research problems for many years. Indeed, a text contains various information, and the idea is to resorb the target information in a continuous vector representation. Embedding’s methods improve significatively the results against standard statistical approaches and justified the interest these last years. In order to create embeddings, the scientific research community is experimenting with two approach types: unsupervised and supervised learning of embeddings.

The unsupervised approaches are the most common and consist in using a pretrained language model on a large corpus such as Word2Vec (Mikolov *et al.*, 2013) or Glove (Pennington, Socher and Manning, 2014). From the word

[2] https://competitions.codalab.org/competitions/34022

embeddings we can obtained, we must then choose a technique in order to find the right combination of words that will best convey the desired information. For example, it's possible to apply combinations such as: average, sum, or centroid to obtain a vector that reflect the representation for a sequence of words. We can find an example of centroid usage with Lwin and Nwet (2019) for news summarization extraction or a centroid vector weighted by IDF (Inverse Document Frequency) (Arora, Liang and Ma, 2017).

For the supervised approaches to produce sequence text vector representation, the idea is consisting of modeling the link between a content and an embedding representation. The reverse dictionary is a common case of sequence or short content representation. Some state-of-the-art models are used to perform this task, for example neural networks LSTM (Sherstinsky, 2018) and Bert (Pre-training of Deep Bidirectional Transformers for Language Understanding) (Devlin *et al.*, 2018). Notably in the paper of Yan, Li and Qiu (2020), they experiment with word generation from a definition using Bert multilingual architecture. As it's mentioned in their paper, the use of a Bert model is a great idea and can, at least, achieves state-of-the-art performances for both monolingual and cross-lingual reverse dictionary task. Even better, the proposed framework here can perform cross-lingual reverse dictionary task without aligned data.

We can also talk about the work of Morinaga and Yamaguchi (2020), Malekzadeh, Gheibi and Mohades (2021) which are based on a Long Short-Term Memory (LSTM) architecture. With always our objective to produce a vector of a contextualized text, the LSTM offers great prospect in this field of research. Indeed, the recurrent neural network architecture of the LSTM allow models to perform on sequential data which is exactly our case study in this task.

4 System Overview

In this section, we describe the models we proposed in the CODWOE – Reverse dictionary shared task. In order to keep comparable and linguistically significant the results submitted by the different participants, the organizers of CODWOE disallowed any use of external resources, including standard datasets as well as pretrained models that could be used for this task (such as Word2Vec models or contextual pretrained models based on Transformer's architectures like Bert). Given this condition, we decided to explore the sequential models, and particularly the LSTM and BiLSTM models. All the following models' architecture we created are based on TensorFlow[3] and Keras[4] (Chollet and others, 2015) libraries.

4.1 Data preprocessing

Before introducing our models, we want to mention that we have performed preprocessing on the content data. By using Stanza[5] (Qi *et al.*, 2020), we lemmatized all definitions and removed all punctuations. We decided to do this to minimize alternative words for the same concept and help our models to correctly process the vocabulary.

To optimize our workflow, we worked on the data before and independently from the neural network architectures. In this way, we built new files based on the lemmatization of the main corpus. This process is possible because all languages are covered by Stanza[6].

4.2 Baseline Model

In this section, we will introduce our first model, called: Baseline Model. This model is intentionally simple in order to create baseline scores and introduce manipulation on the datasets. The figure 1 presents our first architecture.

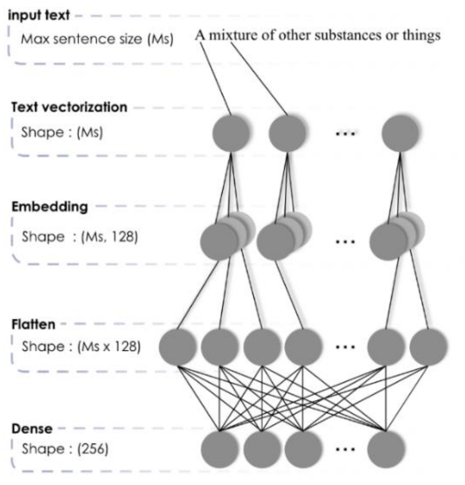

Figure 1 : Baseline Model Architecture.

[3] https://www.tensorflow.org/

[4] https://keras.io/

[5] https://stanfordnlp.github.io/stanza/

[6]https://stanfordnlp.github.io/stanza/available_models.html

As you can see on the figure 1, our model created with Keras contains four different layers and starts with the text vectorization. This first layer will transform the input text in a vector to be process by the next layers. To perform this operation, we must give an identifier to each different word in our corpus. After that, each sentence will be represented as a vector of identifiers. To be processed, the vector of a sentence must have the same size for all sentences. That said, we take the maximum sentence size (Ms in figure 1) and normalize all the vectors by adding zero values in the end.

Now, each vector's sentence is ready to be processed by the embedding layer. This layer turns positive integers (indexes) into dense vectors of fixed size. After this operation, the flatten layer will change the dimensionality of the data from two dimensions to one dimension without losing any value. The shape of this layer will be the multiplication of the two dimensions of the previous layer. Finally, we model the output data by using a fully connected layer (Dense layer) with 256 dimensions to match with the gloss embeddings gave by the organizers.

4.3 Advanced Model

LSTMs are a Recurrent Neural Networks (RNN) (Medsker and Jain, 2001) which have an internal memory that allows them to store the information learned during training. LSTMs are frequently used in the reverse dictionary task (Sherstinsky, 2018) and in word and sentence embeddings tasks in general (Augustyniak, Kajdanowicz and Kazienko, 2019; Liu *et al.*, 2020), as they can learn long-term dependencies between existing words in the sentence and thus compute context representation vectors for each word. BiLSTM for its part, is a variant of LSTMs, it allows a bidirectional representation of words (Augustyniak, Kajdanowicz and Kazienko, 2019).

Our second model, named Advanced Model, is therefore a BiLSTM-LSTM network. As for the baseline model, we use a sequential model which can be provided by Keras. The figure 2 presents our second architecture. This last one starts with a text vectorization layer, followed by an Embedding layer and a dense layer producing vectors of the words passed as an input, the vectors have (length of the longest sentence, 128) dimensions. Then we added a BiLSTM layer, which takes a recurrent layer (the first LSTM of our network) which in turn takes the "merge mode" as an argument. This mode specifies how the forward and reverse outputs should be combined; in our case the average of the outputs is taken.

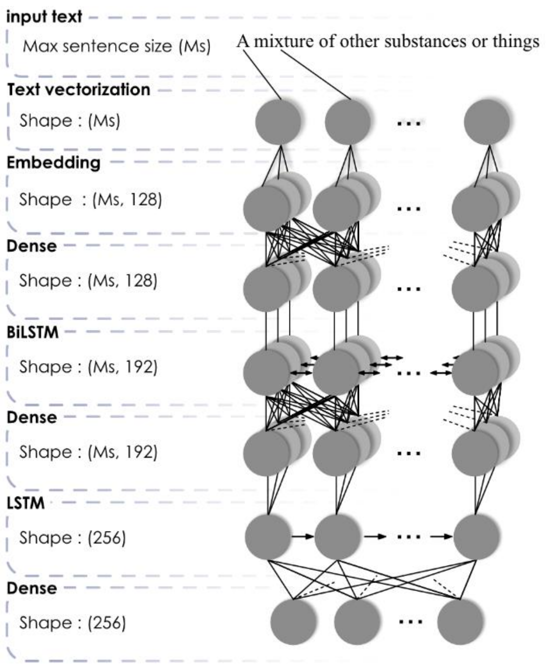

Figure 2 : Advanced Model Architecture.

To these three layers, we added another fully connected Dense layer and a LSTM layer of 256 dimensions corresponding to the dimensions of the output vectors and a final Dense layer with the same dimensions as illustrated in figure 2. We use the Softmax as an activation function. For the hyper-parameters to train the model, we use the following: epochs = 10; batch size = 192; learning rate = 1e-3 and AdamW as an optimizer.

5 Experimental Setup

In this section, we describe different variants we tested. Since there were 3 types of vector representations proposed to us in this shared task, we used the same architectures to produce the 3 types of vectors. However, the data format given as input to the model is not the same for the 3 types. For the 'electra' and 'sgns' representation types, we prepare a vocabulary containing the words of the glosses of the 'training dataset', the words of this vocabulary were obtained by following the preprocessing described in section 4.1.

For the 'char' vector type, we construct a vocabulary of all the characters used in the glosses without preprocessing the data. The idea being that, for the 'char' type representation, the model encodes the characters of the glosses into vectors and then produce the vectors encoding the glosses based on the vectors of the characters constituting the glosses.

The model that we propose is a monolingual model, i.e., we trained it separately on the training dataset of each language provided. However, in order to evaluate the impact of using a multilingual model, we trained the same neural networks on five languages (with character vector) at the same time and compared the results obtained with those obtained by the monolingual models.

For the 'sgns' and 'electra' representation types, we built a vocabulary containing the words of all glosses on the five languages, which contains in total 121,147 words. We did the same with the 'char' vectors but with preparing a vocabulary of characters instead containing 405 characters, in total. The table 1 describes the vocabulary size for each monolingual model and for multilingual model.

Model Type	Language	Vocab Type	
		Words	Chars
Monolingual Model	English	21,001	139
	French	24,089	170
	Spanish	**29,383**	**229**
	Italian	25,414	162
	Russian	29,289	212
Multilingual Model	All languages	**121,147**	**405**

Table 1: Vocabulary size of models.

We can see that there are common words between the different languages since the multilingual model has a vocabulary of 121,147 words instead of 129,176. That said, there are 8,029 common words between at least two language vocabularies. Moreover, we find that the vocabulary of the Spanish language is the best represented in the train dataset.

6 Results and Analysis

In this section, we present the performance results on using architectures that we described in section 4 and try to give clue to understand them. Our main goal was to outperform the organizers' baseline model and results (Mickus, Timothee *et al.*, 2022).

For our first model (our baseline), the model is not better than the state-of-the-art models for this task. However, we can analyze an interesting point: this simple model surprisingly produces better results on the rank cosine (Rank) measure. To illustrate this remark, we can look the model results in table 2. On results for the MSE measure, only 3 cases outperform the organizers' baseline model. Moreover, every rank cosine measure is better. At this point, we can reach our first analyze, it's hard to perform in the MSE and Cosine (Cos) with, at the same time, trying to obtain good results in Rank (and vice-versa). This analyze is supported by the following table 3 based on advanced model.

Language	Emb-type	MSE	Cos	Rank
EN	char	**0.216**	0.709	0.449
	electra	1.638	**0.805**	0.433
	sgns	1.217	0.165	0.311
FR	char	0.501	0.690	0.428
	electra	1.394	**0.813**	0.441
	sgns	1.867	0.166	0.314
ES	char	0.632	0.787	0.411
	sgns	1.089	0.251	**0.253**
IT	char	0.691	0.572	0.417
	sgns	1.329	0.245	**0.246**
RU	char	**0.165**	0.787	0.409
	electra	0.946	0.694	0.398
	sgns	0.690	0.219	0.289

Table 2: Our Baseline model results.

Language	Emb-type	MSE	Cos	Rank
EN	char	**0.143**	0.795	0.500
	electra	1.326	**0.843**	0.500
	sgns	0.895	0.153	0.500
FR	char	0.365	0.769	0.500
	electra	1.112	**0.857**	0.500
	sgns	1.106	0.211	0.500
ES	char	0.510	0.824	0.500
	sgns	0.910	0.227	0.500
IT	char	0.358	0.728	0.500
	sgns	1.111	0.227	0.500
RU	char	**0.132**	0.829	0.500
	electra	0.864	0.719	0.500
	sgns	0.566	0.298	0.425

Table 3: Advanced model results.

With our second model, the results are completely opposite. We performed in MSE and Cosine measure. With these two measures, we're doing better than the organizers' baseline model. On the other hand, the Rank cosine seems to be stuck on 0.5. We can also compare our results with the other participants. Our BiLSTM-LSTM architecture is efficient on 'char' and 'electra' embeddings. For example, in 'char' with English, French and Spanish languages, we obtain the second-best score over the seven participants in SemEval-2022 campaign at task 1. We can conclude this analyze for the advanced architecture with this open-ended question: Why our architecture performs on English, French and Spanish but seam to give worse results on the Italian and Russian languages?

As we mentioned earlier, we tried to create a multilingual model. Unfortunately, after trained this model on all five languages and test on French Character embeddings, the model gave us poor results: 0.67 for MSE and 0.48 for Cosine measure. These are the worst results we've had in this competition, so we decided to drop this architecture and focus on the models presented in the system overview section.

Given the set of results obtained, we find that the best cosine score was obtained by using electra (contextualized) vector embeddings and the best MSE score was obtained by using character vector embeddings. More generally, the use of BiLSTM-LSTM architecture neural network has been beneficial in having results that surpass baselines when cosine and MSE are used as evaluation measures.

7 Conclusion

In this paper, we have presented our contributions to solve the task 1 problem of the semeval-2022 evaluation campaign. We studied the effects of training sentence embeddings with supervised data by testing on five different languages, namely: English, French, Spanish, Italian and Russian language. We showed that models learned with char embeddings or contextualized embeddings can perform better than models learned with Skip-Gram word embeddings. By exploring various architectures, we showed that the combination of Embedding/Dense/BiLSTM/ Dense/LSTM layers can be beneficial than the simple use of Embedding layer.

We believe that the neural architecture of our advanced model can be used to solve other tasks such as Definition Modeling (Noraset *et al.*, 2017), where the objective would be to reverse the inputs/outputs of the model, or other natural language processing tasks where the objective is to add a specific output layer to adopt the specific problem like sequence classification, for example.

Acknowledgments

We would like to thank Berger-Levrault for giving us the opportunity to participate in the 2022 edition of SemEval. Our thanks also go to the research and technological innovation department (DRIT) which is an important part of Berger-Levrault.

Abstract

The *reverse dictionary* is a sequence-to-vector task in which a gloss is provided as input, and the model is trained to output a semantically matching word vector. The reverse dictionary is useful in practical applications such as solving the tip-of-the-tongue problem, helping new language learners, etc. In this paper, we evaluate the Transformer-based model with the added LSTM layer for the task at hand in a monolingual, multilingual, and cross-lingual zero-shot setting. Experiments are conducted in five languages in the CODWOE dataset, namely English, French, Italian, Spanish, and Russian. Our work partially improves the current baseline of the CODWOE competition and offers insight into the feasibility of the cross-lingual methodology for the reverse dictionary task. The code is available at https://github.com/honghanhh/codwoe2021.

1 Introduction

The CODWOE 2021 shared task on dictionary glosses and word embedding representations, organized as part of the SemEval workshop, presented one of the first opportunities to systematically study and compare these semantic descriptions by two sub-tracks: model definition and reverse dictionary.

While definition modeling consists in using the vector representation of e.g. “giraffe” to produce the associated gloss, e.g. “a tall, long-necked, spotted ruminant of Africa”, the reverse dictionary is the mathematical inverse: reconstruct an embedding for the word “giraffe” from the corresponding gloss. In this paper, we dive into the reverse dictionary task modelling to learn the ability to infer word embeddings from dictionary resources.

A reverse dictionary is useful in real-world applications. First of all, it can effectively solve the tip-of-the-tongue problem (Brown and McNeill, 1966): the inability to retrieve a word from memory. People who suffer from this problem such as copywriters, novelists, researchers, students, etc. can quickly and easily find the words they need thanks to reverse dictionary. Furthermore, new language learners who grasp a limited number of words can also take advantage of the reverse dictionary to express correctly. Besides, it plays an important role in word selection for anomia patients (Benson, 1979), who can recognize and describe an object but fail to name it due to neurological disorder.

The contributions of this paper are as follows:

1. We evaluate the performance of the Transformer-based model with an additional LSTM, BiLSTM, and the combination of both additional layers on separate languages as well as the performance of a multilingual model trained on the concatenated corpus containing text for all five given languages.

2. We analyze the effectiveness of zero-shot learning by training the model on a particular language and apply it for prediction on the rest.

This paper is organised as follows: Section 2 presents the related works in reverse dictionary. Next, we introduce our methodology in Section 3, and the experimental details in Section 4. The results are discussed in Section 5, before we conclude and present future works in Section 6.

2 Related Work

The reverse dictionary systems tend to employ two distinct approaches. The first approach takes advantage of sentence matching (Bilac et al., 2004; Zock and Bilac, 2004; Méndez et al., 2013; Shaw et al., 2011) to return the words whose dictionary definitions are most similar to the corresponding gloss.

The second approach focuses on neural language models to encode the glosses into a vector representation and returns the words with the closest embeddings to the vector of the glosses (Hill et al.,

Figure 1: The overall model architecture.

2016; Kartsaklis et al., 2018; Morinaga and Yamaguchi, 2018; Hedderich et al., 2019; Pilehvar, 2019). As a result, the performance depends largely on the word representation's quality. However, many words are low-frequency and usually have poor embeddings regarding Zipf's law.

To tackle the above issue, a multi-channel reverse dictionary model has been proposed (Zheng et al., 2020; Qi et al., 2020). The system includes a sentence encoder (e.g. a BiLSTM (Hochreiter and Schmidhuber, 1997), BERT (Devlin et al., 2018)) with attention (Bahdanau et al., 2014), and diverse characteristic predictors that are useful to find the target words with poor representations and exclude wrong words with similar embeddings to the target words, for example, antonyms.

In terms of production, OneLook[1] and ReverseDictionary[2] are two successful commercial English reverse dictionary systems. However, their architectures are undisclosed and their performance is far from perfect. Meanwhile, open-sourced WantWords[3] (Qi et al., 2020) is a rising star with state-of-the-art (SOTA) performance in English and even competitive results in a cross-lingual Chinese-English and English-Chinese setting.

3 Methodology

As the competition does not allow the use of external data or pretrained language models in order to make approaches easily comparable, we start by experimenting with the simplest form of Transformer, a deep learning model that adopts the self-attention mechanism, differentially weighting the significance of each part of the input data. This is also the baseline shared by CODWOE's organizers. Then we experiment by adding an additional LSTM layer (Model 1), BiLSTM layer (Model 2), and combining the prediction from these two mentioned layers (Model 3). The overall architecture is presented in Figure 1.

The objective of the model is to map the glosses to the vector representation of the word that the gloss defines. The target embeddings are learned by a skip-gram with negative sampling (sgns) approach (word2vec). During training, the input is the gloss, which is tokenized using the Byte Pair Encoding (BPE) algorithm[4] and then converted into word embeddings. The positional encoding is applied to each embedding to inject meaningful information about the position of the tokens in the sequence. After that, they are fed into a Transformer Encoder, which is a stack of four identical encoder blocks. As illustrated in Figure 2, each block includes the following layers in the same order: a multi-head self-attention layer that explores the word correlations followed by a normalization layer (both of them are surrounded by a residual connection), and then a linear layer followed by a second normalization layer (both of them are also

[1]https://onelook.com/thesaurus/
[2]https://reversedictionary.org/
[3]https://wantwords.thunlp.org/

[4]We employ the SentencePiece library: https://github.com/google/sentencepiece

surrounded by a residual connection). A dropout layer is then added to avoid overfitting. In the baseline model suggested by the CODWOE's organizers, the results from the above architecture are then passed into a linear layer to achieve the final model.

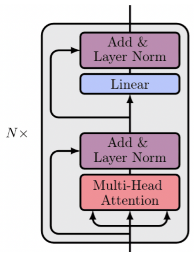

Figure 2: Transformer encoder (Vaswani et al., 2017).

We propose three settings regarding three different models constructed from the baseline architecture. We hypothesize that with an additional LSTM or BiLSTM layer, we can improve the modeling of the word-level sequential context, same as in (Wang et al., 2019), and therefore improve the performance of the model. In Model 1, we add one additional LSTM layer after the linear one. We take advantage of the BiLSTM layer in Model 2 to capture the information bidirectionally. We combine the result from the two mentioned layers by averaging their weights in Model 3. In the final step, we fed the LSTM or BiLSTM outputs into a linear layer to obtain the final vector representation. During the prediction phase, for each new data example, we feed the gloss into the trained model to obtain the vector presentation similar to the sgns.

The proposed three models are first tested in a monolingual setting, to determine which architecture achieves the best performance. Next, we explore if the target sgns embedding spaces may already be aligned to some degree across languages, even though the CODWOE organizers did not explicitly mention any cross-lingual alignment in the shared task description. We first attempt a multilingual experiment to examine the degree to which training in multiple languages affects performance. Finally, the best performing monolingual models are tested in a zero-shot cross-lingual setting, where we train the model in a specific language and evaluate it in different languages that the model has never seen before. The implementation details are in Section 4.2.

4 Experimental Setup

4.1 Dataset

The experiments were conducted on the dataset from the CODWOE 2021 competition. The data consists of glosses for five languages (English - **en**, Spanish - **es**, French - **fr**, Italian - **it**, and Russian - **ru** and three different word embedding representations for each gloss. In this paper, we focus only on skip-gram with negative sampling (sgns) embeddings trained on around 1 billion sentences in total with 50% of the sentences coming from Wikipedia, 40% coming from open subtitles, and the rest drawn from the corpora (e.g. Wikisource, gutenberg.org). All sentences were tokenized with the default NLTK's[5] tokenizer.

Each language contains 3 different sets, including the training set with 43,608 samples, the development set with 6,375 samples, and a test set containing 6,208 samples. Although the number of samples for each set is distributed equally among languages, a word can have a different number of glosses (polysemy), and vice versa, a gloss can belong to more than one word (synonymy).

Note that the training and development data hide the exact words matching each gloss and only release their sngs, char, and electra embeddings. However, on the full test set, the words are provided.

4.2 Experimental Settings

Due to time limitations, we have not conducted any hyperparameter search on the development sets over the space of possible model configurations, such as embedding dimension, learning rate, weight decay, size of hidden layers, etc. Alternatively, we decided to use a standard configuration based on previous research as well as suggested by the competition organizers for all the experiments. The configuration is presented in Table 1.

All models were implemented with Pytorch and trained on GPUs from Google Colab[6]. Further tuning and optimization will be left for future work.

4.3 Evaluation Metrics

The performance of the reverse dictionary system is evaluated by Mean squared error (MSE), Cosine similarity, and Cosine-based ranking (Dinu and Ionescu, 2012). These are the evaluation metrics suggested in the CODWOE 2021 competition,

[5]`https://www.nltk.org/`
[6]`https://colab.research.google.com/`

Table 1: Model configuration.

Settings	Values
Number of heads	4
Number of encoder layers	4
Number of epoches	20
Learning rate	1e-4
Weight decay	1e-6
Drop out	0.3
Optimizer	AdamW
Max length	512
Patience	5

which hereby facilitates the comparison between our approaches and the baseline. Further details about each evaluation metric can be found on the CODWOE 2021 website. Here, in this research, we aim to minimize the MSE and the cosine-based ranking, and maximize the cosine similarity.

5 Results

The test set results of our approach on the reverse dictionary task are presented in Table 2. We compare our three different models (LSTM, BiLSTM, and combined) with the baseline as well as with the winning approach on this shared task. In addition, we also present the results for a multilingual LSTM trained in all available languages.

In terms of MSE, the performance of the Transformer-based model with an additional LSTM layer is the most competitive for all languages except English when compared to our other approaches, namely BiLSTM and combined LSTM and BiLSTM. This model surpasses the baseline in Spanish and French according to most criteria. Meanwhile, the combination of the LSTM and BiLSTM layers after the Transformer encoder layer offers the best results on the English dataset, outperforming the baseline in terms of MSE. We also investigate a multilingual configuration where we train in all languages and employ the model on each language's test set. The results for the multilingual model are substantially lower compared to all other monolingual settings according to the MSE score. Compared to the best solution in the CODWOE competition proposed by WENGSYX team[7], the gap between our solution and theirs is on average 0.1 in terms of the MSE score.

In terms of Cosine similarity, the model with an additional LSTM layer proves to have better performance in English, Spanish, and French compared

ru	Baseline	0.577	0.253	0.490
ru	#1 solution	**0.528**	**0.424**	**0.187**

to other tested models. This model also surpasses the baseline model on Spanish and French test sets. In addition, the multilingual model also achieves a slightly better Cosine similarity than the baseline on the Spanish test set.

In terms of Cosine ranking, all models demonstrate a slightly higher ranking in comparison to the baseline on the Spanish test set, with the multilingual model achieving the best ranking. In other languages, the baseline model performs the best.

Overall, training the additional LSTM layer on a multilingual training set does not seem to improve the results compared to the monolingual settings, the only exception being the performance of the multilingual model on the Spanish test set in terms of Cosine ranking.

Given the fact that the Transformer-based model with an additional LSTM performs the best in a monolingual setting, we use this model for the zero-shot cross-lingual experiments. The results

	Ranking	0.501	0.500	0.500	0.500	**0.500**

for these experiments are displayed in Table 3. The first column indicates the language used for training and development, the second column displays the evaluation metrics including MSE, Cosine similarity, and Cosine ranking. The rest demonstrate the evaluation results of each metric on a specific test dataset per language. For example, in the first row where the training set is *en*, we train on the English training and development set and predict each of the five language's test sets.

In general, if the model is trained on a language matching the language of the test data, it performs better except in the French corpus. However, the interesting exception is that, for example, the Spanish test set, on which all models, no matter on which language they were trained, offer very consistent performance according to all measures. It is also interesting that the models trained in English and Spanish have exactly the same results on French, Italian, and Russian test sets. This might suggest that these models were not able to make sense of the examples in the test set and that their performance is on par with a random baseline. Further analysis of this behavior will be left for the future.

6 Conclusion

In this paper, we have investigated the performance of monolingual and multilingual Transformer-based models on the reverse dictionary problem, a sequence-to-vector task where a word representation needs to be constructed from the corresponding gloss. We have experimented with two additions to the original architecture, namely adding either an additional LSTM or a BiLSTM layer on top of the original architecture. We have also explored whether combining these two architectures improves the performance. Besides that, we explored the cross-lingual performance of the monolingual models and compared them to monolingual and multilingual classifiers.

On the task of reconstructing sgns embeddings, the monolingual Transformer-based model with an additional LSTM layer in most cases offers the best performance for English, Spanish, and French according to MSE and Cosine similarity. The model also offers competitive performance in terms of MSE for Italian and Russian compared to the baseline. Therefore, the results to some extent confirm the initial hypothesis that with an additional LSTM layer, we can improve the modeling of the word-level sequential context. Nevertheless, the improvements are worse than expected and the multilingual and zero-shot experiments yield unexpected results that require further analysis. We can therefore summarize our findings by saying that the reverse dictionary task of restoring sgns embeddings seems to be very challenging, and none of our models (and also other models in the competition) were able to successfully solve it, at least according to the scores achieved during the competition.

This means that there remains a lot of room for improvement. In the future, we would like to investigate the effect of different text representations on the performance of the model, e.g., by feeding the model graph representations. Combinations of several text representations will also be explored. Furthermore, the effectiveness of multilingual models compared to monolingual ones should be additionally explored. Despite zero-shot learning not working well in our studies, it is worth evaluating the performance of one-shot learning and few-shot learning with the hypothesis that the models can understand new concepts from only one or a few examples. Further experiments on the topic of adapting the Transformer architecture for the specific task at hand will also be conducted.

Abstract

This paper presents the shared task on *Multilingual Idiomaticity Detection and Sentence Embedding*, which consists of two Subtasks: (a) a binary classification task aimed at identifying whether a sentence contains an idiomatic expression, and (b) a task based on semantic text similarity which requires the model to adequately represent potentially idiomatic expressions in context. Each Subtask includes different settings regarding the amount of training data. Besides the task description, this paper introduces the datasets in English, Portuguese, and Galician and their annotation procedure, the evaluation metrics, and a summary of the participant systems and their results. The task had close to 100 registered participants organised into twenty five teams making over 650 and 150 submissions in the practice and evaluation phases respectively.

1 Introduction

Multiword Expressions (MWEs) are a challenge for natural language processing (NLP), as their linguistic behaviour (e.g., syntactic, semantic) differs from that of generic word combinations (Baldwin and Kim, 2010; Ramisch and Villavicencio, 2018). Moreover, MWEs are pervasive in all domains (Biber et al., 1999), and it has been estimated that their size in a speaker's lexicon of any language is of the same order of magnitude as the number of single words (Jackendoff, 1997; Erman and Warren, 2000), thus being of crucial interest for language modelling and for the computational representation of linguistic expressions in general.

One distinctive aspect of MWEs is that they fall on a *continuum* of idiomaticity (Sag et al., 2002; Fazly et al., 2009; King and Cook, 2017), as their meaning may or may not be inferred from one of their constituents (e.g., *research project* being a type of 'project', vs. *brass ring* meaning a 'prize'). In this regard, obtaining a semantic representation of a sentence which contains potentially idiomatic expressions involves both the correct identification of the MWE itself, and an adequate representation of the meaning of that expression in that particular context. As an example, it is expected that the representation of the expression *big fish* will be similar to that of *important person* in an idiomatic context, but closer to the representation of *large fish* when conveying its literal meaning.

Classic approaches to representing MWEs obtain a compositional vector by combining the representations of their constituent words, but these operations tend to perform worse for the idiomatic cases. In fact, it has been shown that the degree of idiomaticity of a MWE can be estimated by measuring the distance between a compositional vector (obtained from the vectors of its components) and a single representation learnt from the distribution of the MWE in a large corpus (Cordeiro et al., 2019).

Recent approaches to identify and classify MWEs take advantage of the contextualised representations provided by neural language models. On the one hand, some studies suggest that pre-training based on masked language modeling does not properly encode idiomaticity in word representations (Nandakumar et al., 2019; Garcia et al., 2021b,a). However, as these embeddings encode contextual information, supervised approaches using these representations tend to obtain better results in different tasks dealing with (non-)compositional semantics (Shwartz and Dagan, 2019; Fakharian and Cook, 2021; Zeng and Bhat, 2021).

As such, this shared task[1,2] presents two Subtasks: i) Subtask A, to test a language model's

[1]Task website: https://sites.google.com/view/semeval2022task2idiomaticity

[2]GitHub:https://github.com/H-TayyarMadabushi/SemEval_2022_Task2-idiomaticity

ability to detect idiom usage, and ii) Subtask B, to test the effectiveness of a model in generating representations of sentences containing idioms. Each of these Subtasks are further presented in two *settings*: Subtask A in the Zero Shot and One Shot settings so as to evaluate models on their ability to detect previously unseen MWEs, and Subtask B in the Pre Train and the Fine Tune settings to evaluate models on their ability to capture idiomaticity both in the absence and presence of training data. Additionally, we provide strong baselines based on pre-trained transformer-based language models and release our codetr which participants can build upon.

2 Related Tasks

The computational treatment of MWEs has been of particular interest for the NLP community, and several shared tasks with different objectives and resources have been carried out.

The SIGLEX-MWE Section[3] has organised various shared tasks, starting with the exploratory *Ranking MWE Candidates* competition at the MWE 2008 Workshop, aimed at ranking MWE candidates in English, German and Czech.[4] More recently, together with the PARSEME community, they have conducted three editions of a shared task on the automatic identification of verbal MWEs (Savary et al., 2017; Ramisch et al., 2018, 2020). In these cases, the objective is to identify both known and unseen verb-based MWEs in running text and to classify them under a set of predefined categories. Interestingly, these PARSEME shared tasks provide annotation guidelines and corpora for 14 languages, and include 6 categories (with additional subclasses) of verbal MWEs.

The *Detecting Minimal Semantic Units and their Meanings (DiMSUM 2016)* shared task (Schneider et al., 2016) consisted of the identification of *minimal semantic units* (including MWEs) in English, and labelling some of them according to a set of semantic classes (supersenses).

Focused on the interpretation of noun compounds, the *Free Paraphrases of Noun Compounds* shared task of SemEval 2013 (Hendrickx et al., 2013) proposed to generate a set of free paraphrases of English compounds. The paraphrases should be ranked by the participants, and the evaluation is performed comparing these ranks against a list of paraphrases provided by human annotators.

Similarly, the objective of the SemEval 2010 shared task on *The Interpretation of Noun Compounds Using Paraphrasing Verbs and Prepositions* (Butnariu et al., 2010) was to rank verbs and prepositions which may paraphrase a noun compound adequately in English (e.g., *olive oil* as 'oil *extracted from* olive', or *flu shot* as 'shot *to prevent* flu').

Apart from these competitions, various studies have addressed different tasks on MWEs and their compositionality, such as: classifying verb-particle constructions (Cook and Stevenson, 2006), identifying light verb constructions and determining the literality of noun compounds (Shwartz and Dagan, 2019), identifying and classifying idioms in running text (Zeng and Bhat, 2021), as well as predicting the compositionality of several types of MWEs (Lin, 1999; McCarthy et al., 2003; Reddy et al., 2011; Schulte im Walde et al., 2013; Salehi et al., 2015).

3 Dataset Creation

The dataset used in this task extends that introduced by Tayyar Madabushi et al. (2021), also including Galician data along with Portuguese and English. Here we describe the four step process used in creating this dataset.

The first step was to compile a list of 50 MWEs across the three languages. We sourced the MWEs in English and Portuguese from the Noun Compound Senses dataset (consisting of adjective-noun or noun-noun compounds) (Garcia et al., 2021b), which extends the dataset by Reddy et al. (2011) and provides human-judgements for compositionality on a Likert scale from 0 (non-literal/idiomatic) to 5 (literal/compositional). To ensure that the test set is representative of different levels compositionality, we pick approximately 10 idioms at each level of compositionality (0-1, 1-2, . . .). For Galician, we extracted noun-adjective compounds from the Wikipedia and the CC-100 corpora (Wenzek et al., 2020) using the following procedure: First, we identified those candidates with at least 50 occurrences in the corpus. They were randomly sorted, and a native speaker and language expert of Galician selected 50 compounds from the list. The language expert was asked to take into account both the compositionality of the compounds (including idiomatic, partly idiomatic, and literal expressions),

[3] https://multiword.org/

[4] http://multiword.sourceforge.net/mwe2008

and their ambiguity (trying to select potentially idiomatic examples, i.e. compounds which can be literal or idiomatic depending on the context).

In the second step of the dataset creation process, in English and Portuguese, annotators were instructed to obtain between 7 and 10 examples for each possible meaning of each MWE from news stories available on the web, thus giving between 20 and 30 total examples for each MWE. Each example consisted of three sentences: the target sentence containing the MWE and the two adjacent sentences. Annotators where explicitly instructed to select high quality examples, where neither of the two adjacent sentences were empty and, preferably, from the same paragraph. They were additionally required to flag examples containing novel meanings, so such new meanings of MWEs could be incorporated into the dataset. Sentences containing MWEs in Galician were directly obtained from the Wikipedia and the CC-100 corpora due to the sparsity of Galician data on the web. During this annotation step, we follow the method introduced by Tayyar Madabushi et al. (2021), and add two additional labels: 'Proper Noun' and 'Meta Usage'. 'Meta Usage' represents cases wherein a MWE is used literally, but within a metaphor (e.g. *life vest* in "Let the Word of God be our life vest to keep us afloat, so as not to drown.").

In the third phase, across all three languages, each possible meaning of each MWE was assigned a paraphrase by a language expert. For example, the compositional MWE *mailing list* had the associated paraphrase 'address list' added, whereas the idiomatic MWE *elbow room* had the associated paraphrases 'joint room', 'freedom' and 'space' added to correspond to each of its possible meanings. Language experts focused on ensuring that these paraphrases were as short as possible, so the resultant adversarial paraphrases could be used to evaluate the extent to which models capture nuanced differences in each of the meanings.

The final phase of the process involved the annotation of each example with the correct paraphrase of the relevant MWE. This was carried out by two annotators, and any disagreements were discussed (in the case of Galician, in the presence of a language expert) and cases where annotators were not able to agree were discarded.

3.1 The Competition Dataset

We use the training and development splits from Tayyar Madabushi et al. (2021) with the addition of Galician data, and use the test split released by them as the evaluation split during the initial practice phase of the competition. We create an independent test set consisting of examples with new MWEs, and this set was used to determine the teams' final rankings. The labels for the evaluation and test sets are not released. We note that the competition is still active (in the 'post-evaluation' phase), and open for submissions from anyone[5].

Since one of the goals of this task is to measure the ability of models to perform on previously unseen MWEs (Zero Shot) and on those for which they have very little training data (One Shot), we extract, where available, exactly one idiomatic and one compositional example associated with each MWE in the test data, which is released as associated One Shot training data.

The final dataset consisted of 8,683 entries and the breakdown of the dataset is shown in Table 1. For further details on the training, development and practice evaluation splits, we direct readers to the work by Tayyar Madabushi et al. (2021). It should be noted that this original dataset does not contain data from Galician and so the only training data available in Galician was the One Shot training data. This was to evaluate the ability of models to transfer their learning across languages, especially to one that is low resourced.

	Language			
Split	English	Portuguese	Galician	All
train	3487	1290	63	4840
dev	466	273	0	739
eval	483	279	0	762
test	916	713	713	2342
All	5352	2555	776	8683

Table 1: Breakdown of the full dataset by language and data split.

4 Task Description and Evaluation Metrics

SemEval-2022 Task 2 aims to stimulate research into a difficult area of NLP, that of handling non-compositional, or idiomatic, expressions. Since this is an area of difficulty for existing language

[5]https://competitions.codalab.org/competitions/34710

models, we introduce two Subtasks; the first Subtask relates to idiomaticity detection, whilst the second relates to idiomaticity representation, success in which will require models to correctly encode idiomaticity. It is hoped that these tasks will motivate the development of language models better able to handle idiomaticity. Since we wish to promote multilingual models, we require all participants to submit results across all three languages. Both Subtasks are available in two settings, and participants are given the flexibility to choose which settings they wish to take part in.

4.1 Subtask A: Idiomaticity Detection

The first Subtask is a binary classification task, where sentences must be correctly classified into 'idiomatic' (including 'Meta Usage') or 'non-idiomatic' / literal (including 'Proper Noun'). Each example consists of the target sentence and two context sentences (sourced from either side of the target sentence) along with the relevant MWE. Some examples from this Subtask are shown in Table 2.

This Subtask is available in two settings: Zero Shot and One Shot. In the Zero Shot setting, the MWEs in the training set are disjoint from those in the development and test sets. Success in this setting will require models to generalise to unseen MWEs at inference time. In the One Shot setting, we include in the training set one idiomatic and one non-idiomatic example for each MWE in the development and test sets. This breakdown is shown in Table 3.

We use macro F1 score between the gold labels and predictions as the evaluation metric for this Subtask, due to the imbalanced datasets.

4.2 Subtask B: Idiomaticity Representation

The second Subtask is a novel idiomatic semantic textual similarity (STS) task, introduced by Tayyar Madabushi et al. (2021), where, given two input sentences, models must return an STS score between 0 (least similar) and 1 (most similar), indicating the similarity of the sentences. This requires models to correctly encode the meaning of non-compositional MWEs (idioms) such that the encoding of a sentence containing an idiomatic phrase (e.g. "I initially feared that taking it would make me a **guinea pig**.") and the same sentence with the idiomatic phrase replaced by a (literal) paraphrase (e.g. "I initially feared that taking it would make me a **test subject**.") are semantically similar to each other. Notice also that these two sentences, which mean the same thing, must necessarily be equally similar to any other third sentence. We choose this third sentence to be the sentence with the idiomatic phrase replaced by an *incorrect* literal paraphrase (e.g. "I initially feared that taking it would make me a **pig**."). Such a sentence is the ideal adversarial example, and ensures that we test if models are making use of an incorrect meaning of the MWE in constructing a sentence representation.

Data for this Subtask is generated in the following manner: MWEs in sentences are replaced by the literal paraphrase of one of its associated meanings. For example, the MWE 'guinea pig' in the sentence "I initially feared that taking it would make me a *guinea pig*." is replaced by one of the literal paraphrases 'test subject' or 'pig' (see Table 4). Crucially, these replacements can either be with the correct paraphrase, or one that is incorrect. As such, there are two cases:

- The MWE has been replaced by its correct paraphrase. In this case, the similarity should be 1.
  $sim(E, E_{\rightarrow \text{c}}) = 1$
- The MWE has been replaced by its incorrect paraphrase. In this case, we require the model to give equivalent semantic similarities between this and the sentence where the MWE has been replaced by its correct paraphrase, and this and the original sentence.
  $sim(E, E_{\rightarrow \text{i}}) = sim(E_{\rightarrow \text{c}}, E_{\rightarrow \text{i}})$

Importantly, the task requires models to be *consistent*. Concretely, the STS score for the similarity between a sentence containing an idiomatic MWE and that same sentence with the MWE replaced by the correct paraphrase must be equal to *one* as this would imply that the model has correctly interpreted the meaning of the MWE. In the case where we consider the incorrect paraphrase, we check for consistency by requiring that the STS between the sentence containing the MWE and a sentence where the MWE is replaced by the incorrect paraphrase is equal to the STS between the sentence where the MWE is replaced by the correct paraphrase and one where it is replaced by the incorrect one. Notice, that all this does, is to require the model to, once again, interpret the meaning of the MWE to be the same (or very similar) to the correct literal paraphrase of that MWE. More formally, we require models to output STS scores for each example E such that:

Language	MWE	Sentence	Label
English	old hat	Serve our favorite bourbon whiskeys in an **old hat** and we'd still probably take a sip or two.	1
English	old hat	But not all of the accouterments of power are **old hat** for the president.	0
Portuguese	força bruta	**Força Bruta** vai reunir alguns dos homens mais fortes do mundo.	1
Portuguese	força bruta	Gardner é conhecido por ser impulsivo e usar os poderes com grande impacto, de forma instintiva, com **força bruta**.	0
Galician	porta grande	Á esquerda da **porta grande**, en terra, observamos a tumba de "Don Manuel López Vizcaíno.	1
Galician	porta grande	Os dous dominadores da Copa Galicia 2017 regresaron pola **porta grande** ao certame autonómico na súa quinta xornada.	0

Table 2: Examples for Subtask A. Note that the label 1 is assigned to non-idiomatic usage, which includes proper nouns, as in the Portuguese example.

		Language			
Train Split	MWEs	English	Portuguese	Galician	All
Zero Shot	236	3327	1164	0	4491
One Shot	250	160	126	63	349
Total	486	3487	1290	63	4840

Table 3: Breakdown of the training data into zero shot and one shot. Note that the MWEs in the zero shot and one shot data are disjoint.

$$\forall_{i \in I} \Big(sim(E, E_{\rightarrow \mathrm{c}}) = 1; \\ sim(E, E_{\rightarrow \mathrm{i}}) = sim(E_{\rightarrow \mathrm{c}}, E_{\rightarrow \mathrm{i}}) \Big) \quad (1)$$

In Equation 1 above, $E_{\rightarrow \mathrm{c}}$ represents an example containing the MWE E, wherein that MWE is replaced by its *correct* contextual paraphrase. $E_{\rightarrow \mathrm{i}}$ on the other hand, represents the example wherein the MWE E is replaced by one of its *incorrect* contextual paraphrases. Examples for this Subtask are shown in Table 4.

Since this task relies on models' ability to correctly assign STS scores for sentences with do not contain idiomatic MWEs, we additionally include standard STS data in our test data. This has the added benefit of preventing models from overfitting on the MWE dataset. We include this STS evaluation data from the STS Benchmark dataset (Cer et al., 2017) in English and the ASSIN2 STS dataset (Real et al., 2020) in Portuguese. There is no available STS data for Galician, so none is included. We use the Spearman's rank correlation coefficient between the two sets of STS scores generated by models as the evaluation metric in this Subtask. We do not use Pearson correlation as it has been shown to be a poor indicator of performance on STS tasks (Reimers et al., 2016).

This Subtask is also available in two settings: the Pre Train setting and the Fine Tune setting. In the Pre Train setting, we require that models are *not* trained on idiomatic STS data. However, models can be trained (including "fine-tuned") on any other training objective (such as during the pre-training of language models). The Fine Tune setting, on the other hand, allows all training regimes, including the fine-tuning on any idiomatic STS dataset.

4.3 Baselines

In order to generate baseline results, we used pre-trained transformer-based (Vaswani et al., 2017) language models. We use multilingual BERT (Devlin et al., 2019) to benefit from cross-lingual transfer. For both settings in Subtask A, we simply Fine Tune the pre-trained model on the training data provided. For the Zero Shot setting, we include the context sentences, whereas in the One Shot setting, we exclude the context sentences but add the MWE as a second sentence. This is based on the best-performing approaches found by Tayyar Madabushi et al. (2021).

For Subtask B Pre Train, we introduce single tokens for each MWE in the data. This is motivated by the 'idiom principle' (Sinclair and Sinclair, 1991), which hypothesises that humans process idioms by treating them as a single unit. Since BERT embeddings cannot be directly used for STS, we create a sentence transformer model (Reimers and Gurevych, 2019) using multilingual BERT with these added tokens, and train it on the English and Portuguese STS data. Importantly, the new tokens introduced for MWEs are randomly initialised and no continued pre-training is performed. As such, they serve to 'break compositionality' rather than to create more effective representations of MWEs. This breaking of compositionality has been shown to be effective by Tayyar Madabushi et al. (2021).

For the Fine Tune setting, the same approach is taken, although no training is done on the STS

Sentence (E)	Correct Replacement ($E_{\text{MWE}\rightarrow\text{c}}$)	Wrong Replacement ($E_{\text{MWE}\rightarrow\text{i}}$)	Expected
And finally, the snow falls again, this time in a thick, **wet blanket** that encapsulates everything.	And finally, the snow falls again, this time in a thick, **damp blanket** that encapsulates everything.	And finally, the snow falls again, this time in a thick, **killjoy** that encapsulates everything.	$sim(E, E_{\rightarrow\text{c}}) = 1$ $sim(E, E_{\rightarrow\text{i}}) = sim(E_{\rightarrow\text{c}}, E_{\rightarrow\text{i}})$
I initially feared that taking it would make me a **guinea pig**.	I initially feared that taking it would make me a **test subject**.	I initially feared that taking it would make me a **pig**.	$sim(E, E_{\rightarrow\text{c}}) = 1$ $sim(E, E_{\rightarrow\text{i}}) = sim(E_{\rightarrow\text{c}}, E_{\rightarrow\text{i}})$

Table 4: Examples for Subtask B. For brevity we only include examples in English.

data, and instead we Fine Tune on the training data provided. This lack of training on the STS data is intentional as we intend to establish the effectiveness of the MWE based training data, and are reflected by the comparatively lower scores on the STS subsection of the test data (Table 8).

It should be noted that these baseline methods that make use of multilingual BERT are particularly strong when compared to typical 'baselines'. This is intentional as we aim to promote the development of models that are comparable to the current state-of-the-art.

5 Participating Systems and Results

Twenty five teams in total participated, with the most participants to Subtask A Zero Shot (20). The results for the individual Subtasks are given in Table 5, Table 6, Table 7 and Table 8. Here we discuss the methods used by the best-performing teams as well as some interesting approaches. Full details of methods used by participants is given in Appendix A.

5.1 Subtask A Zero-Shot

Of the twenty teams that submitted to this setting, 12 reported using transformer-based approaches. The best-performing team (clay) used different masking strategies during pretraining, and performed finetuning with data augmentation (including back-translation, Edunov et al., 2018) as well as using soft-label finetuning (a knowledge distillation approach). The team in second (yxb) used a multilingual T5 model (Xue et al., 2021) with various data augmentation techniques including: back-translation; synonym replacement; random insertion, swap, and deletion. They also used an alternative loss function for unbalanced data, called focal loss (Lin et al., 2017). The third team (NER4ID; Tedeschi and Navigli, 2022) used a dual-encoder architecture to encode the MWE and its context, then predicted idiomaticity by looking at the similarity score. This approach has a precedent in previous work that hypothesises the semantic similarity between a MWE and its context to be a good indicator of idiomaticity (Liu and Hwa, 2018). They also implemented named entity recognition as an intermediate step which they found provided great improvements. Interestingly, two teams (UAlberta; Hauer et al., 2022, and Unimelb_AIP) used unsupervised approaches, i.e. not using any of the provided training data. UAlberta were able to beat the baseline using translation information from resources such as Open Multilingual Wordnet (Bond and Foster, 2013) and BabelNet (Navigli and Ponzetto, 2010). They hypothesised that for idiomatic MWEs, the individual words are less likely to share mult-synsets with their translations. They also used a POS tagger for identifying proper nouns.

5.2 Subtask A One Shot

The best-performing team (HIT; Chu et al., 2022) used XLM-R (Conneau et al., 2020), and added '[SEP]' tokens around the relevant MWE in the target sentence, unless it was capitalised, in which case they excluded these tokens. This is an alternative approach to that of Tayyar Madabushi et al. (2021), where the MWEs were added as a second sentence. They also used R-Drop (Wu et al., 2021) as a regularisation method. The second best team (kpfriends; Sik Oh, 2022) used an ensemble of checkpoints with soft-voting. They also started with XLM-RoBERTa (large) trained on CoNLL. Interestingly, this team had the largest difference in performance across the two settings of Subtask A (coming in 16th in the Zero Shot setting). The third best team (UAlberta; Hauer et al., 2022) used a transformer-based classifier with additional features of glosses for the individual words of the relevant MWE. They hypothesised that this would help for determining compositionality, since the meaning of compositional MWEs could be deduced from the glosses of the individual words. An interesting approach was taken by MaChAmp (van der Goot, 2022), who used multi-task learning across multiple SemEval tasks (2, 3, 4, 6, 10, 11, 12), pretrain-

ing a Rebalanced mBERT (RemBERT) (Chung et al., 2020) model across all of the tasks, then retraining a model for each specific task. Since for this task we do not allow the use of additional data, we do not include this team in the ranking, but their score is reported for reference.

5.3 Subtask B Pre Train

No teams reported using non-transformer-based approaches for this setting. The best-performing team (drsphelps; Phelps, 2022) used a modification of the baseline with BERT for Attentive Mimicking (BERTRAM) (Schick and Schütze, 2020) to generate embeddings as replacements for the randomly-initialised one token embeddings used by the baseline. This method takes both form and context into account, thus not assuming total non-compositionality as the one-token method does. It should be noted that every team in this setting improved upon the baseline result.

5.4 Subtask B Fine Tune

No teams reported using non-transformer-based approaches for this setting. The best-performing team (YNU-HPCC; Liu et al., 2022) used a pre-trained Sentence-BERT (Reimers and Gurevych, 2019) model, then finetuned using multiple negatives ranking loss (Henderson et al., 2017) and triplet loss. The second best team (drsphelps; Phelps, 2022) used an identical approach to that in Subtask B Pre Train, using BERTRAM (Schick and Schütze, 2020), with additional finetuning on the training data provided. The third best team (Eat Fish) used a multilingual model pretrained with knowledge distillation, as well as data augmentation.

[6]Not ranked due to only submitting to the 'post-evaluation' phase.

5.5 Overview of Submissions

In Figure 1 we show the models that were mentioned in the submissions.

The majority of participants used transformer-based approaches, although in both settings for Subtask A there were three teams using other approaches. In Subtask B, as mentioned previously, no non-transformer approaches were mentioned, which is expected since this task was designed for the pretrain-finetune paradigm.

In Figure 2 we show the methods mentioned in more than one submission. Data augmentation approaches were popular, the most frequently-mentioned being back-translation (Edunov et al., 2018). Equally as popular were approaches using

alternative loss functions.

6 Methods

The primary goal of this shared task was to provide a platform for the evaluation of a variety of methods for the identification and represention of MWEs. This section gives an overview of the methods that have been successful in each of the Subtasks. In particular, we attempt to identify the combination of methods across submissions that have significant potential for future development.

6.1 Subtask A

Subtask A, the identification of MWEs, comprised two settings: Zero Shot and One Shot. Crucially, the results from the task show that *methods that are successful in the Zero Shot setting, fail to be*

[7]Not ranked due to using a multi-task learning approach.

[8]Not ranked due to only submitting to the 'post-evaluation' phase.

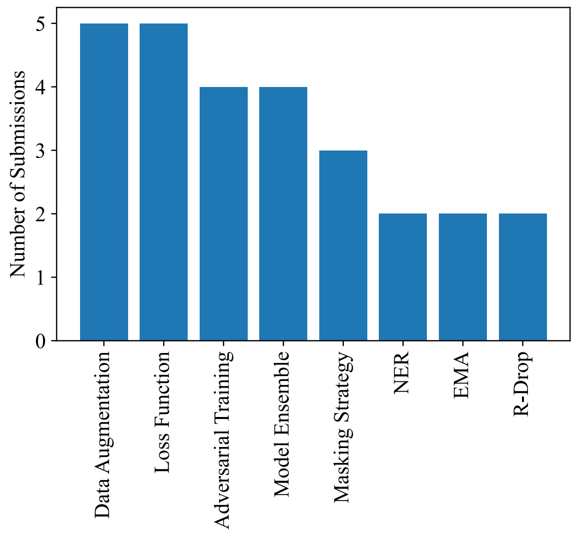

Figure 2: Methods mentioned in more than one submission.

successful in the One Shot setting and vice versa. The two problems seem to require capabilities that are quite distinct. This seems intuitive when translated into the kind of thinking that one might use in identifying idioms: When one hears an idiom for the first time, we are likely to recognise that it sounds 'idiom-like' based on our prior understanding of idioms, whereas when we come across an idiom that we are familiar with, we link our existing knowledge of that idiom with the current instance of it.

This seems to play out in the successful models in this Subtask, as the general trend amongst the methods that were successful in the Zero Shot setting, with one exception, is the generalisation of models using regularisation, data augmentation or dropout. While regularisation did feature in the top performing model in the One Shot setting, it seems to have been less important to generalise models when they had access to as little as one training example associated with each model. The best performing linguistically motivated method – which compares the semantic similarity between the MWE span and that of the surrounding context – ranked third in the Zero Shot setting, although it performed 11 points below the best performing method. This is of particular interest as this method has previously been shown to be extremely powerful in detecting idiomaticity in non-contextual models.

Models successful in the One Shot setting, again with one exception, seem to be those which are more powerful at extracting cues from the minimal training examples and tended to be larger, ensembled or trained to a larger extent using adversarial training. The best performing method which incorporated elements based on linguistic theory also ranked third in this setting and incorporated the gloss of each individual word in the target MWE to aid in models' ability to detect compositionality.

Interestingly, the use of the idiom principle in creating single token representations for MWEs is absent amongst the methods used for this Subtask. While such a comparison would have been interesting, it is hardly surprising that this method is not amongst those used, given that the cost of pre-training with new MWE tokens is rather high.

6.2 Subtask B

Subtask B, the novel task of creating contextual representations of MWEs which are consistent with the paraphrased version of that MWE as measured by Spearman's rank correlation, coefficient also had two settings: the first without associated training examples (Pre Train) and the second with (Fine Tune). Since the sentence embeddings generated by pre-trained language models cannot be directly compared for similarity, such models must be altered so as to be used for this Subtask. Additionally, as pointed out by Tayyar Madabushi et al. (2021), the MWEs contained within sentences can be represented using single tokens even without pre-training, as the 'breaking' of compositionality itself produces more accurate representations of sentences containing MWEs.

As such, models that perform the best on the Pre Train setting focus on the creation of more accurate single token representations of MWEs, while the top performing models on the Fine Tune setting, in general, focus on optimising sentence similarity. This seems to be consistent with the observation by Tayyar Madabushi et al. (2021) that fine-tuning is indeed a reasonable way of learning the representation of MWEs. It should be noted that these trends are less certain since there are fewer participants on this Subtask, some of whom do not share their methods, and the one team that we know used a method of learning new representations of MWEs is ranked first in the Pre Train setting but ranked second in the Fine Tune setting.

7 Conclusions and Future work

We present, in this paper, 'SemEval 2022 Task2: Multilingual Idiomaticity Detection and Sentence Embedding', consisting of two Subtasks: i) Subtask A, to test a language model's ability to detect idiom usage, and ii) Subtask B, to test a model's ability to generate representations of sentences containing idioms. This task, aimed at boosting research into the detection and representation of idiomatic expressions, had submissions from 25 teams consisting of close to 100 participants.

We additionally provide an overview and analysis of the methods used by participants, which we believe will help future research in this field. In particular, we highlight the need for distinct methods when detecting MWEs that have been previously seen and when detecting ones that have not. In representing idiomatic expressions, we show, through the novel idiomatic STS task presented here, that models are rather effective when they have training data available, but, as demonstrated in the Pre Train setting, more methods of encoding MWEs are required when training data is not available.

While the top performing methods across this task have been driven by deep neural models independent of linguistic features, we highlight that this does not imply that the addition of linguistically motivated features does not lead to improvements on the task. Instead, it points to the possibility of integrating these methods into the more powerful neural models in future work where an ablation study might shed more light on the impact of each feature.

A Full Breakdown of Methods

All participants were invited to submit a short description of their methods, as well as to submit a paper. In Table 9, Table 10, Table 11, and Table 12 we give all the method descriptions that were submitted.

Ranking	Team	Method
1	clay	"domain pretraining with different masking strategies finetuning with data augmentation such as back-translation finetuning with soft label from former checkpoint"
2	yxb	"use mT5-Base use Easy Data Augmentation techniques include back-translation, synonym replacement, random insertion, random swap, random deletion include label unbalanced loss function：focal loss use model ensemble"
3	NER4ID	"Dual-encoder (Transformer-based) architecture that encodes both the potentially idiomatic expression and its context, and predicts idiomaticity by looking at their similarity score: high similarity -> compositional, low similarity -> idiomatic. Another core contribution of our method is the use of Named Entity Recognition as an intermediate step to pre-identify some non-idiomatic expressions; this provides great improvements."
4	HIT	"1. we use the big pre-trained model, XLM-R-large. Compared with multilingual-BERT and XLM-R-base, XLM-R-large is obviously improved. 2. Separate the exact same phrases as MWE in the target sentence with the sep token. If the phrase in the sentence is capitalized, It is more likely to be named entities that the model can distinguish, so the sep tokens are not added around the capitalized phrases. 3. Using Regularized Dropout(r-drop) as regularization."
5	Hitachi	"Our approach is built on top of multilingual pre-trained language models, which include InfoXLM and XLM-R. We solve the task of multilingual idiomaticity detection as a binary classification task and follow the standard fine-tuning method except not using a special [CLS] representation for classification. Instead, we first take an average over MWE's span representations and subsequently feed the averaged representation into a linear layer for classification."
6	OCHADAI	"our model relies on pre-trained contextual representations from different multilingual state-of-the-art transformer-based language models (i.e., multilingual BERT and XLM-RoBERTa), and on adversarial training, a training method for further enhancing model generalization and robustness."
7	yjs	"For each input sentence in the training set, if the MWE is idiomatic then its corresponding tokens are labeled as "idiomatic" and the remaining tokens are labeled as "literal"; if the MWE is literal then all the tokens in the sequence are labeled as "literal". Method 1: We apply a Bi-Directional Attention Flow (BiDAF) network (Seo et al., 2017), while we use mBERT as the contextualised embedding, and we use pos tag embedding as its query input."
8	CardiffNLP-m	"CardiffNLP-metaphors submitted the results of two methods in total, applied both for Task A Zero Shot and one-shot. The first method uses xlm-roberta-large and the second uses several monolingual bert language models for English, Portuguese and Galician. For the Zero Shot settings, bert-multilingual-base is used to label the Galician sentences, because no Galician examples were included in the training set. The embedding of the three sentences and the embeddings of the isolated target are input of the models. We optimized the models over different training parameters on the development set."
9	Mirs	-
10	Amobee	-
11	HYU	"We devise four features ((i), (ii), (iii), and (iv) in the following) as input for a simple yet effective idiomaticity classifier that is a multi-layer perceptron with one hidden layer. First, to consider the contextualized semantics of a target sentence when influenced by its surrounding context, we concatenate the target sentence with its (i) previous and (ii) next sentences respectively and inject the two chunks into our feature extractor (XLM-R; a bidirectional multilingual language model) independently to generate two distinct ((i) and (ii)) features. While constructing the aforementioned features, we also introduce two techniques to clarify the presence of a MWE in the sequence: the first highlights the location of the MWE with a new, dedicated positional encoding, and the second appends the MWE once again at the end of the sequence. In addition, we focus on the way of better utilizing the information existing solely in the target sentence, regarding a MWE and its context (i.e., phrases in the target sentence except for the MWE) as separate ones. Specifically, we derive (iii) the "context-only" representation of the target sentence by using a variant of the target sentence where the MWE is masked, while we compute (iv) the "MWE-only" representation, which corresponds to the intrinsic meaning of the MWE irrespective of context, by inserting only the MWE into the feature extractor."
12	Zhichun Road	"1. We use InfoXLM-Base as text encoder. (performance: infoxlm > XLM-R > Mbert) 2.We use exponential moving average (EMA) method. 3.We use adversarial attack strategy(performance: Smart > freeLb > PGD = FGM). Finally，our approach ranked 12th."
13	海鲛NLP	-
14	UAlberta	"Our unsupervised translation-based approach leverages translation information in multilingual resources such as OMW and BabelNet. The hypothesis is that the translations of idiomatic MWEs tend to be non-compositional, and therefore the individual words of an MWE are less likely to share mult-synsets with their translations. In addition, since MWEs that are named entities are usually literal, we use a part-of-speech tagger to identify proper nouns."
15	Helsinki-NLP	"The system utilizes linguistically motivated features that typically characterize idiomatic expressions: non-substitutability, non-compositionality and affectiveness. This feature model is based on pre-trained models and classification pipelines that have been integrated into the transformers library provided by HuggingFace. The final classification combines the feature model with either sentence-transformers or a base BERT model. The system also adds a back-translation feature and applies simple post-correction rules based on boolean features."
16	daminglu123	"We used the same model as baseline but added one more LSTM layer at last."
17	kpfriends	"We experimented with various inductive training methods only using Zero Shot data provided. We are still experimenting various schemes, including novel MWE ideas. We will share the findings in our paper."
18	Unimelb_AIP	"We tackled this task in an unsupervised way (i.e. without using any portion of the training data). First, we trained a standard CBOW word2vec model on unlabelled data and used it to predict the top-500 words that would fit into the surrounding context of the target MWE (as performed during the training of the CBOW model). Then, we calculated the maximum cosine similarities between the predicted words and each MWE component word, and regarded the MWE as "literal" ("non-idiomatic") if they are higher than the mean cosine similarity between the component words and their 500 closest words. Finally, we ensembled five CBOW models trained with different window sizes (5, 10, 15, 20, and 30) to incorporate different levels of contextual information. One limitation of this approach is that it often classifies proper-noun and idiomatic usages into the same class ("non-literal"; as their surrounding contexts differ a lot from the literal usage ones), and to mitigate this problem, we always regarded MWEs as "non-idiomatic" if they contained any capital letter."
19	YNU-HPCC	"As for methods of the best submission results, we added a linear layer so as to choose effective information from all of output layer that were extracted by pre-trained model, XLM-RoBERTa, and then fine-tuned it to classify."
20	Ryan Wang	"CNN-bidirectional LSTM classifier with jointly trained word embeddings trained on full passages (target and context) from Zero Shot data"
N/A	JARVix	"we fine-tune a pretrained XLNet on the task dataset (after evaluating multiple large language models and their majority-voting ensemble)."

Table 9: Methods used in Subtask A Zero Shot. Note: CardiffNLP-m is short for CardiffNLP-metaphors.

Ranking	Team	Method
1	HIT	"Mostly the same as the zero-shot. We train the One Shot model initialized from the best Zero Shot checkpoint. We additionally post-processed the predictions based on the distribution of the labels in the One Shot train file."
2	kpfriends	"More than 10 checkpoints were created per "English" and "Spanish / Galician" and inferred separately, later ensembled using soft-voting. To stabilize training of xlm-roberta-large, we started with pre-trained models provided by Huggingface which were xlm-roberta-large trained on CoNLL. We also had some good results with xlm-roberta-base. We will deep dive into methodology and interesting observations / error analysis in our paper."
3	UAlberta	"Our method uses a transformer-based sequence classifier that takes as an input the context sentence and the glosses of each individual word in the target multi-word expression. The intuition is that the addition of the glosses to the input might help the classifier to detect if the meaning of the target multi-word expression can be deduced from the definitions of the individual words, i.e., if it is compositional. Note that this method is applicable to both settings."
4	Zhichun Road	"1. We use InfoXLM-Base as text encoder. (performance: infoxlm > XLM-R > Mbert) 2.We use exponential moving average (EMA) method. 3.We use adversarial attack strategy(performance: freeLB > Smart > PGD = FGM). Finally，our approach ranked 4th."
5	clay	"same as Zero Shot setting, but with more data include Zero Shot data and One Shot data"
6	YNU-HPCC	"As for methods of the best submission results, we simply concated sentence and MWE and input into pre-trained model, XLM-RoBERTa. CLS from last layer was extracted to classify."
7	CardiffNLP-m	"CardiffNLP-metaphors submitted the results of two methods in total, applied both for Task A Zero Shot and one-shot. The first method uses xlm-roberta-large and the second uses several monolingual bert language models for English, Portuguese and Galician. For the Zero Shot settings, bert-multilingual-base is used to label the Galician sentences, because no Galician examples were included in the training set. The embedding of the three sentences and the embeddings of the isolated target are input of the models. We optimized the models over different training parameters on the development set. xlm-roberta-large significantly ouperforms the monolingual experimental settings on the one shot track. "
8	yxb	"use mT5-Base use Easy Data Augmentation techniques include back-translation, synonym replacement, random insertion, random swap, random deletion include label unbalanced loss function：focal loss use model ensemble"
9	NER4ID	"Same as zero-shot"
10	HYU	"In One Shot setting, we used the same method as in a Zero Shot setting."
11	yjs	"Method 2: We used the BiDAF-based DISC architecture by (Zeng and Bhat, 2021). DISC firstly combine GLOVE embeddings and POS embeddings with a BiDAF layer, which is then infused with mBERT by another BiDAF layer. We use both methods in the two settings, Method 1 performs better than Method 2. In the submissions, the different results is caused by different random seeds, with/without previous and next sentences, and with/without MWE."
12	Mirs	-

Abstract

This paper describes the University of Helsinki submission to the SemEval 2022 task on multilingual idiomaticity detection. Our system utilizes several models made available by HuggingFace, along with the baseline BERT model for the task. We focus on feature engineering based on properties that characterize idiomatic expressions. The additional features lead to improvements over the baseline and the final submission achieves 15th place out of 20 submissions. The paper provides an error analysis of our model including visualisations of the contributions of individual features.

1 Introduction

We participated in the SemEval 2022 Task 2 (Tayyar Madabushi et al., 2022) Subtask A, zero-shot[1] setting: classification of a sentence containing a potentially idiomatic two-word multiword expression (MWE) as idiomatic or literal. The task provided four data sets[2] for English, Portuguese and Galician. Each MWE was represented by multiple example sentences, accompanied by the context (previous and next sentences). Each MWE could be always idiomatic, always literal or anything in between. Table 1 shows examples for both idiomatic (0) and literal (1) cases. Expanded examples (with context) are shown in Table 6 in the Appendix.

[1]The MWEs in the test data do not appear in the training data.

[2]Training, development, evaluation and test sets, with Galician only appearing in the final test set.

The motivation for our approach is testing linguistically motivated features that reflect important properties of idioms, such as non-compositionality, non-substitutability, non-literal-translatability and affectiveness (see chapter 2) and to see whether pre-trained models can be helpful for capturing these features. Our system uses a combination of models: BERT fine-tuning (Tayyar Madabushi et al., 2021), sentence embeddings (Reimers and Gurevych, 2019) and a feature model based on the above idiomatic properties.

2 Background and Related Work

The detection and analysis of idiomaticity has a rich history in the literature. An important property of idioms is non-compositionality (that is, the meaning of the expression does not correspond to the combination of the meaning of its components). (Peng et al., 2014; Constant et al., 2017; Gantar et al., 2018) Related to it are non-substitutability (components cannot be substituted with their synonyms) (Farahmand and Henderson, 2016; Senaldi et al., 2016; Constant et al., 2017) and non-literal-translatability (Constant et al., 2017).

Idioms tend to be semantic outliers (Feldman and Peng, 2013; Peng et al., 2014; Salton et al., 2016) in the sense that they violate the lexical cohesion of the surrounding discourse. They are also known to be more affective (either positive or negative) (Peng et al., 2014) than literal expressions.

In addition to being relatively fixed lexically (non-substitutability), idioms often exhibit lack of

Label	Target
0	He was not a *blue blood* jurist issuing judicial decisions that nobody understood affecting people and corporations that nobody knew.
1	The *blue blood* of the fossil-like creature is the only natural source of limulus amoebocyte lysate, a clotting agent that is used to test batches of injectable drugs for bacterial contamination that could cause fever, organ damage and even death.

Table 1: Idiomatic (0) and literal (1) examples from the zero_shot setting of training set for English MWE *blue blood*, which can be interpreted as either idiomatic or literal.

syntactic and/or morphological variability (Peng et al., 2014; Constant et al., 2017). In general, quantifying any variability has traditionally required obtaining frequencies of the variants from a full corpus, as done by Inurrieta et al. (2020). However, as we only have a small number of examples for each idiom, these properties are not modeled in our approach.

Compositionality and substitutability are often tested with techniques like backtranslation and mask filling tasks. **Backtranslation** involves translating text to another (i.e. pivot) language and translating it back (Sennrich et al., 2016; Edunov et al., 2018), and it has often been used for paraphrasing and data augmentation. Backtranslations have also been used for idioms in related work, see, e.g., Moirón and Tiedemann (2006); Bahar Salehi and Baldwin (2018).

Mask filling (Zhu et al., 2019; Donahue et al., 2020) is closely related to the cloze task (Taylor, 1953), where the objective is to predict a word missing from an expression. Mask filling has lately been made easier as modern languages models such as BERT (Devlin et al., 2019) and its derivatives are themselves so-called Masked Language Models (MLM). Mask filling can be useful for testing substitutability in context (Karidi et al., 2021; Zhu and Bhat, 2021).

3 System Description

Our submission[3] considers three models: the baseline BERT model provided by the task authors (Tayyar Madabushi et al., 2021), sentence embeddings with sentence-transformers (Reimers and Gurevych, 2019) and a feature model based on idiomaticity features. All our components rely on existing models and tools that have been integrated into the transformers library provided by HuggingFace (Wolf et al., 2020).

The final classification combines information from two components (either fine-tuned BERT + feature model or sentence embeddings + feature model). The result will be taken from the model which has the higher label probability[4]. See Figure 1 for an overview.

We compare different variants of the system with the performance of individual features and various baselines.

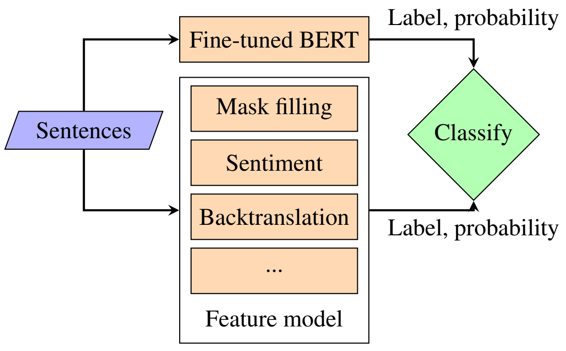

Figure 1: Basic classification procedure for the fine-tuned BERT + feature model combination. The feature model combines information from a number of HuggingFace models. Each model independently produces a label and associated probability. The label is by default taken from the model that has a higher probability. See Chapter 3.4 for the detailed classification procedure.

3.1 Fine-tuned BERT

The baseline model provided by the task organisers (Tayyar Madabushi et al., 2021) is based on BERT (Devlin et al., 2019). We build three variants: a) multilingual model (*bert-base-multilingual-cased*) for all languages (equivalent to the provided baseline), b) English model (*bert-base-cased*) for English data and multilingual model for non-English (trained with all data, including English) and c) same as case b, but multilingual model trained only with non-English data. The BERT model was fine-tuned with the training data, with the development set used for validation.

3.2 Sentence Embeddings (sbert)

Sentence embeddings can be used as an alternative baseline. We apply the *distiluse-base-multilingual-cased-v1*[5] model provided by HuggingFace and use the *sentence-transformers* python module[6]. The training procedure adopts the approach used by Tayyar Madabushi et al. (2021) by appending the MWE to the target sentence before training, as they found it to improve performance[7]. Logistic regression is used to train a classifier on top of the sentence embedding that we obtain from sbert.

[3]Implementation and details are available at https://github.com/dustedmtl/semeval2022.

[4]While both logistic regression and BERT models produce probabilities, the values aren't necessarily consummerate as BERT seems a lot more confident about the results.

[5]https://huggingface.co/sentence-transformers/distiluse-base-multilingual-cased-v1

[6]https://www.sbert.net

[7]This is not, however, equivalent to their methodology where the MWE is treated as a single token according to the "idiomatic principle" (i.e. stored as a single token in the mental lexicon) (Hashempour and Villavicencio, 2020).

Target	Label	Top terms	Top score	Hassub	Short	Found Idx	Found Score
There are several theories behind the origin of the term "*Double Dutch*."	0	., -, ..., s, *man*	0.008	False	3	10	-1.000
Além de ter sido um fracasso de bilheteria e crítica, o filme acabou marcado pelos seus *efeitos especiais*, principalmente ao antropomorfizar os gatos, que, bem, ficam um pouco bisonhos.	0	*erros*, personagens, **efeitos**, problemas, animais	0.540	True	0	3	0.092

Table 2: Training set substitution examples. In the first row, most of the suggestions are too short and no valid lexical substitute is found. The second example finds a component of *efeito especial* in plural form. The *Top terms* column shows the entry corresponding to *Top score* in *italics* and the one for *FoundIdx/Score* (if found) in **bold**. The above-zero scores represent the output from the mask-filling pipeline.

Note that we do not use the context sentences in this approach in any way.

3.3 Idiomaticity Features

Idiomaticity features are extracted using a number of HuggingFace pipelines and pre-trained models (see details below) for lexical substitution, sentiment analysis and backtranslation. Additionally, semantic outliers and surface-form-based boolean features are calculated. The training and classification with the feature model is done with logistic regression again, with boolean values converted to integers (True = 1 / literal, False = 0 / idiomatic).

3.3.1 Lexical Substitution

Because of the limited lexical variability and non-compositional nature of idiomatic expressions, it should be more difficult to find lexical substitutes for them, or their parts, than for literal expressions.

Our lexical substitution model utilizes the huggingface *fill-mask*[8] pipeline with the *xlm-roberta-base*[9] model. The pipeline will output a ranked list of top substitutions along with their scores[10]. Three different masks are used: one for masking the whole MWE (e.g. the expression *panda car* is replaced with <*mask*>)[11]), another for masking the first term (<*mask*> *car*) and a third one for masking the second term (*panda* <*mask*>)[12].

We obtain the top five candidates (individual words) from the pipeline. We are interested in two things: 1) how difficult it is to get a substitute in general, and 2) how difficult it is to get the *correct* substitute. The former reflects non-substitutability and the latter non-compositionality. A valid general substitute must only contain word characters and be at least three characters long. No other checks are made (such as whether the word class is correct or that the candidate is a synonym). A valid lexical substitute will additionally need to (case-insensitively) match either component of the MWE as it appears in the Target sentence. Inflected forms of the components are found by progressively stemming the component(s) with a regular expression- Additional tweaks are required for Portuguese because of orthographic variation (see Table 7 in the Appendix for examples).

The features that are generated are described below. Substitutions from masking individual terms are only used for the *Top score 1/2* and *FS/SS* features; all other features are derived from replacing the whole expression. Table 2 shows two examples for the features, with more examples in Table 8 in the Appendix.

Hassub Boolean feature: True when a valid lexical substitute is found, False otherwise.

Top score, Top score 1, Top score 2 The score of the top candidate, from replacing the whole expression, first term and second term, respectively. These features are a proxy for general (non-)substitutability.

Short, FS, SS The number of candidates that are too short (less than three characters) from masking the whole expression, first term and second term. The reasoning is that a lack of good suggestions is another proxy for non-substitutability.

FoundScore The score of the first valid lexical substitute [0-1], -1 otherwise. This one re-

[8]https://huggingface.co/tasks/fill-mask

[9]https://huggingface.co/xlm-roberta-base

[10]The mask-filling pipeline documentation doesn't explicitly state what the scores represent, but it's likely to be probability.

[11]The mask token is taken from the underlying model, which in this case is <*mask*>.

[12]The pipeline (by default) does not support using multiple mask tokens, so replacing the MWE with <*mask*> <*mask*> is not possible.

flects non-compositionality: replacement of the MWE with one of its components.

FoundIdx The index [1-5] of the first valid lexical substitute, 10 otherwise.

Note that the *FoundScore* and *FoundIdx* features essentially mix categorical and numeric values, which may reduce their usefulness. Additionally, *Top terms*, *Top terms 1* and *Top terms 2* are recorded from the mask filling process.

3.3.2 Sentiment Analysis

The affection feature is based on sentiment classification using the *cardiffnlp/twitter-xlm-roberta-base-sentiment*[13] model for predicting positive, negative or neutral sentiment. The neutral probability [0-1] is used as the value for the feature **Sentiment**.

3.3.3 Backtranslation

The target sentence is translated to another language (Portuguese for English, English for Portuguese and Galician) and then back-translated to the original language with the OPUS-MT (Tiedemann and Thottingal, 2020) models *opus-mt-en-roa* and *opus-mt-roa-en*[14]. The rationale is that idiomatic expressions exhibit non-compositionality and as such are less likely to be backtranslated correctly. The logic for locating the expression is the same that was used for lexical substitution: the exact form is required, with allowances for variations in Portuguese orthography. The value for the feature **Trans** is True if it is found and False otherwise. Table 7 in the Appendix shows a number of backtranslated examples.

3.3.4 Semantic Outliers

To measure semantic coherence, sentence embeddings are retrieved from sentence-transformers for the sentences/expressions. The value of the feature is the cosine similarity between the two.

Prevdiff Cosine similarity between the Previous and Target sentences.

Nextdiff Cosine similarity between the Next and Target sentences.

MWEdiff Cosine similarity between the MWE and the Target sentence.

3.3.5 Surface-form features

Based on data exploration, two additional surface features are used:

Quotes True if the MWE is enclosed in quotes, in which case it is more likely to be idiomatic.

Caps True if the MWE is capitalized (Camel Case). This is more likely to be a Proper Noun.

Table 9 in the Appendix shows examples for these features.

3.4 Final Classification

With the exception of simple baselines and majority voting classifier, the final classification is done by combining two components. For each prediction, the result will be taken from the model which has the higher probability. A number of ablation tests were run for the feature model with the development set to select the best set of features. In the end, all features except *Top score 1*, *FS* and *MWEdiff* were retained (where *features* means the bolded items in Chapters 3.3.1 through 3.3.5).

We also added a final post-correction step based on the results observed during development: the boolean features may (potentially) override the label. There are two modes for this: the first one will force the label unconditionally, the second one will force it only if the models disagree (*agree*).

The potential idiomatic features are *Quotes* and *!Trans* (*Trans* == False, that is, a mistranslation). Potential literal features are *Hassub* and *Caps*. Literal features take precedence, so if an expression is both quoted and capitalized, it is considered literal.

4 Results

4.1 Experimental Setup

Four data sets were released by the task administrators: training and developments sets, for which gold labels were provided; an evaluation set without gold labels (for which classification results could be obtained from the competition website) and a blind test set. The training set had more idiomatic (56%) and the development set more literal (54%) sentences.

The label is overwhelmingly likely to be 1 (literal) when the surface feature *Caps* == True (see

[13] `https://huggingface.co/cardiffnlp/twitter-xlm-roberta-base-sentiment`

[14] `https://huggingface.co/Helsinki-NLP/opus-mt-en-roa` and `https://huggingface.co/Helsinki-NLP/opus-mt-roa-en`. The models were chosen out of convenience, as only two models are required for translating between the languages to either direction.

Total	0.663

Table 5: Official results for the test set.

Figure 3 in the Appendix). We also found the features *Hassub* and *Quotes* to be useful, so they are used in all cases involving the feature model.

4.2 Development and Evaluation Sets

Results for the development set are shown in Table 3 for various baselines, sentence-transformers-based models and BERT-based models. Baselines for the boolean *Hassub* and *Trans* are taken directly from the feature: True=1, False=0, while for *Sentiment* above-mean scores are considered literal. *Majority class* assigns the majority label (literal) for all sentences.

The sentence embeddings + feature model yields better results than the base BERT model, but in general fine-tuning BERT is much better than using sentence embeddings as a fixed feature. For the BERT-based models[15], using an English-only model for English improves results, as does using the *!Trans* boolean feature. Using the boolean features only when the models disagree (*agree*) does not seem to have much impact. As Figure 4 in the Appendix shows, the BERT-based models are more likely to label a sentence as literal. Finally, the majority voting classifier (using the majority label from all three classifiers) fares worse than BERT+feature models.

The results for the evaluation set (in Table 4 are largely similar to those for the development set, except for two things: 1) the *!Trans* feature is detrimental to English and somewhat helpful for Portuguese and 2) boolean features should be used only when the underlying models disagree. In the end, using the feature model with BERT only slightly improves the result (0.725 > 0.723). Additionally, sentence embeddings + feature model approach outperforms BERT-based models for Portuguese.

4.3 Test Set

The test predictions were generated with the setup that produced the best overall results for the evaluation set: different BERT models for English and non-English combined with the feature model with boolean features *Hassub*, *Quotes* and *Caps* (only when the models disagree about the label). The official test results in Table 5 show that the results for Galician are not great - roughly on the level of random chance[16]. The official baseline isn't much better[17], likely due Galician being a low-resource language and lacking training data for the pre-trained models that were used. For English

[15]The baseline, multilingual 1 and 2 (ml1 and ml2) configurations refer to variants a-c in section 3.1.

[16]Without knowing the true labels, we assume a 50/50 split.

[17]`https://sites.google.com/view/semeval2022task2-idiomaticity/baselines`

and Portuguese, the results are similar to the best results for the development set.

Regarding specific features, the results lend support to the idea that idioms are more affective, thus sentiment analysis can be useful for detecting idiomaticity (see Figure 2 and Figure 6 in the Appendix). The exception here seems to be Galician, which is probably because the sentiment model is based on tweets. However, it is easier to get a lexical replacement for Galician (see Figure 5a in the Appendix). It may be possible that the Galician test sentences use simpler language - relatively speaking.

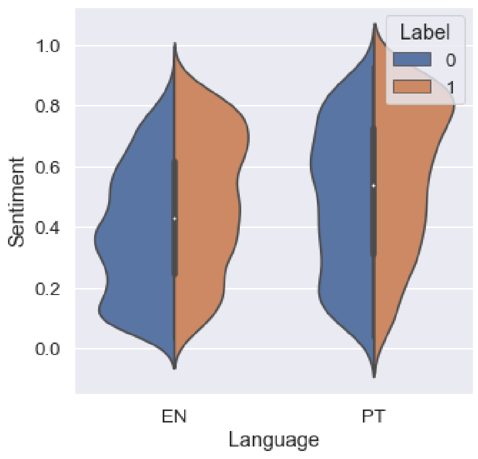

Figure 2: Violin plot for sentiment per language for the training set. The skewed sentiment distribution shows that the label is more likely to be literal (on average) for both English and Portuguese, if the sentiment score is higher (neutral sentiment). However, this feature alone is not sufficient for good performance.

Using the boolean features on top of the classifier models can be a bit of a hit-and-miss: what works with one dataset may be detrimental with another. Specifically, the *!Trans* feature worked well on the development set, but not on the evaluation set, and the *Hassub* feature worked on both of these sets, but not on the test set. In other words, the boolean features may make the model less robust.

Ablation studies performed after the official end of the competition confirm that using the *Hassub* feature for the test set was not a good strategy. Furthermore, a feature-only model (without sentence embeddings or BERT) outperformed the combined model, with the best results achieved by using the combined model for English and feature-only model for Portuguese and Galician. Nevertheless, even these results do not come close to the best models of the competition.

For detecting semantic outliers, the approach used in this paper (similarity based on sentence-transformers embeddings) appears to be too simple. More refined methods, such as those measuring lexical cohesion (Sporleder and Li, 2009) would be required.

5 Conclusions

Our system combines a feature model based on a number of idiomaticity features with a BERT transformer classifier. The feature model achieves competitive results compared to the reportedly strong baseline (Tayyar Madabushi et al., 2022), although it does not fare nearly as well as the best systems that competed in the subtask. Unsurprisingly, most of the features work best for English, whether or not the underlying BERT model is multilingual or not.

The work shows that a classification system utilizing idiomatic properties such as non-compositionality, non-substitutability and affectiveness can be implemented with readily available transformer APIs.

Another idea for future work is to improve the back-translation test by combining a "good" forward translation model (i.e. one that tends to properly treat idiomatic expressions) with a "bad" back-translation model (i.e. one that tends to produce literal translations). The latter could also be done by forcing component-wise translations in the back-translation step to reveal non-compositionality of the expression.

A Appendix

A number of tables and figures are presented here.

Table 6 shows samples from the training data. Tables 7, 8 and 9 list feature examples for substitution, backtranslation and Quotes/Caps surface features.

Figure 3 plots the boolean features *Hassub*, *Quotes*, *Caps* and *Trans* against the literal and idiomatic labels for the training set. Figure 4 demonstrates the differences in the labeling done by fine-tuned BERT and the feature model.

Figure 5 shows counts for boolean features for each language and data set. Illustrations for sentiment scores for all languages and datasets are shown in Figure 6.

Label	**Previous**	**Target**	**Next**
0	Heading outside (even just for a couple of minutes) or doing mundane things like brushing your teeth and making the bed can help your mind accept the fact that yes, alas, you are awake now.	Whether you're a *night owl* or early bird, though, try to make sure you're not diving right onto your phone.	Your morning will start calmer if you don't dive right into work emails and scrolling.
1	LCG asks that Monday customers put garbage and recycling carts at the curb for collection Tuesday morning.	In addition, the Lafayette Transit System office will be closed Monday, and there will be no Daytime, *Night Owl* or Paratransit bus service Monday.	Bus and paratransit services will resume regular schedules Tuesday.
0	I practiced before him in court and stood beside him on Canal Street during Endymion.	He was not a *blue blood* jurist issuing judicial decisions that nobody understood affecting people and corporations that nobody knew.	His blood was red with a little Irish green thrown in.
1	The American horseshoe crab has outlived the dinosaurs and survived four mass extinction events, but its population has been devastated in recent years, partly due to harvesting for biomedical production.	The *blue blood* of the fossil-like creature is the only natural source of limulus amoebocyte lysate, a clotting agent that is used to test batches of injectable drugs for bacterial contamination that could cause fever, organ damage and even death.	The crabs are fished from the oceans, taken to a lab to have about 30% of their blood harvested, then released back into the wild.

Table 6: Idiomatic (0) and literal (1) examples from the training set for English MWEs *night owl* and *blue blood* in the zero_shot setting. For *night owl*, the second example is considered literal as the MWE refers to a company name (Proper Noun).

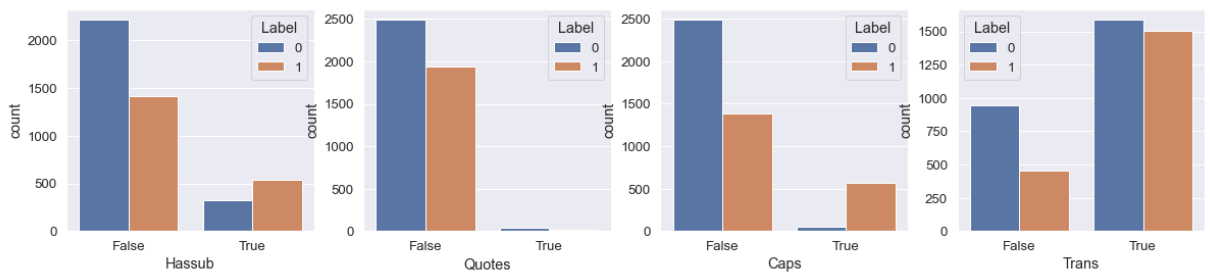
Table 7: Backtranslation examples for the training set; *Target* is the original sentence, *BT* is the backtranslated one. The matching process occasionally requires some tweaks for Portuguese. In the third row, the Target contains the expression *círculo virtuoso* without an accent, while the last row shows the translation of *amor-próprio* separated with a space instead of a dash.

Target	Label	Top terms	Top score	Hassub	Short	Found Idx	Found Score
There are several theories behind the origin of the term "*Double Dutch*."	0	., -, ..., s, *man*	0.008	False	3	10	-1.000
Double Dutch also derives from the same era, Dutch seeming a strange and convoluted language hence Double Dutch meaning indescernible, mad and generally all round not on foreign speak.	0	It, *English*, This, **Dutch**, German	0.385	True	1	4	0.062
No vídeo divulgado nas redes sociais, é possível perceber que um som faz o casal olhar para o prédio da frente e ver o *efeito especial* da fumaça.	0	*som*, **efeito**, tamanho, aumento, ar	0.214	True	1	2	0.120
Os *efeitos especiais* são necessários em cenas de batalha, porém, a DC costuma abusar da técnica.	0	***efeitos***, equipamentos, personagens, dados, filmes	0.158	True	0	1	0.158

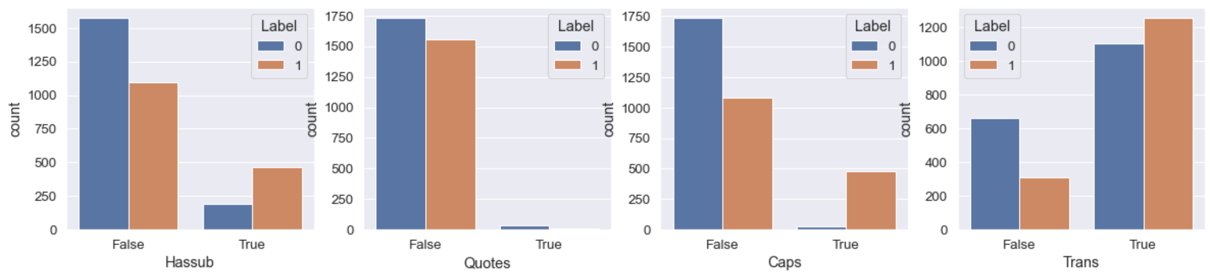
Table 8: Abbreviated substitution examples for the training set. The first two examples are for the English MWE *double dutch*, the last two for the Portuguese MWE *efeito especial*. In the first row, a substitution is not found and most of the suggested substitutions are too short, leading to a *Short* value of 3. In the second row, the fourth suggestion matches the MWE. For Portuguese, the expression *efeito especial* is found in singular form in the first example and in plural form in the second; the substitute suggestions must match the expression. The *Top terms* column shows the entry corresponding to *Top score* in *italics* and the one for *FoundIdx* and *FoundScore* (if found) in **bold**. The scores represent the output from the mask-filling pipeline.

MWE	Target	Label	Quotes	Caps
double dutch	*Double Dutch* also derives from the same era, Dutch seeming a strange and convoluted language hence Double Dutch meaning indescernible, mad and generally all round not on foreign speak.	0	False	True
double dutch	Since 1977 we have had a plethora of Foreign Ministers, to whom the subject of foreign affairs was *double Dutch*.	0	False	False
double dutch	At 6,400gns, Auldhouseburn sold another by the same sire, and again in lamb to *Double Dutch*, to Northern Irish buyer, J. Cubbitt of Ballymena.	1	False	True
night owl	The researchers said experience shows *"night owl"* patients with depression are less likely to recover and are more likely to commit suicide.	0	True	False

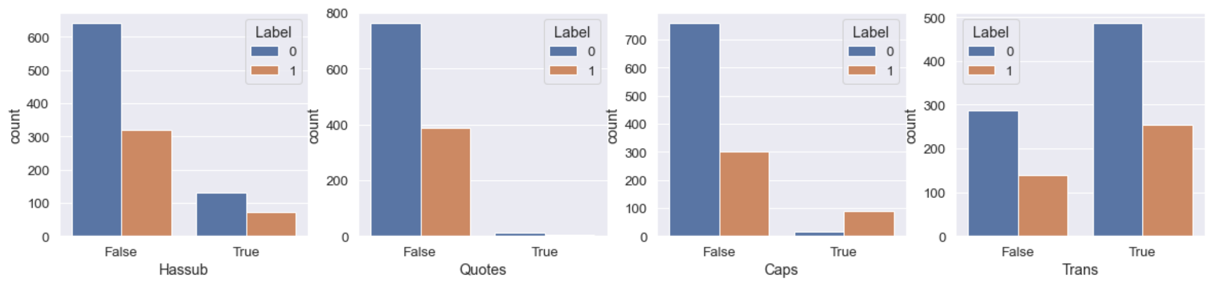
Table 9: Quotes/Caps examples for the training set. In the second row, *Caps* == False as both components of *double dutch* are not capitalized.



(a) All

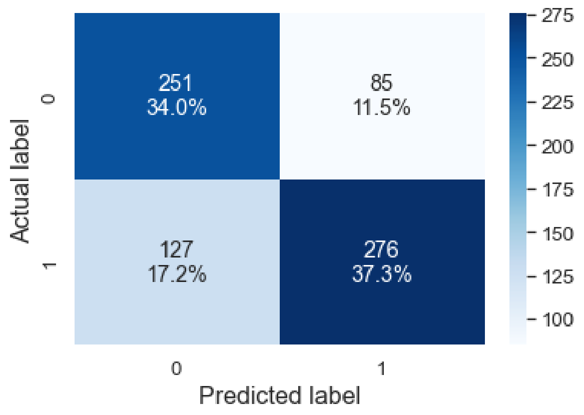


(b) English

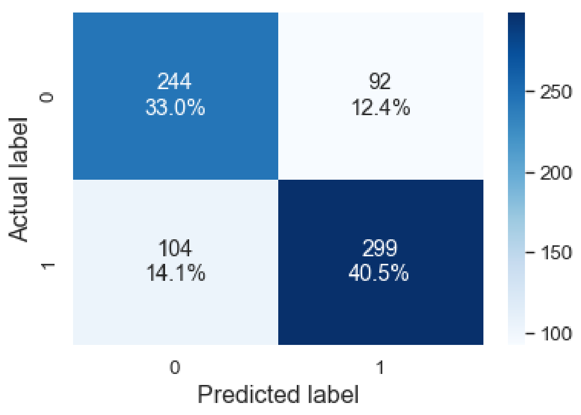


(c) Portuguese

Figure 3: Boolean features vs label for the training set. The label is overwhelmingly likely to be literal if the MWE is Capitalized (*Caps* == True), while idiomatic label is more likely if the MWE is mistranslated (*Trans* == False). It is generally difficult to get a valid lexical substitute (*Hassub* == True).

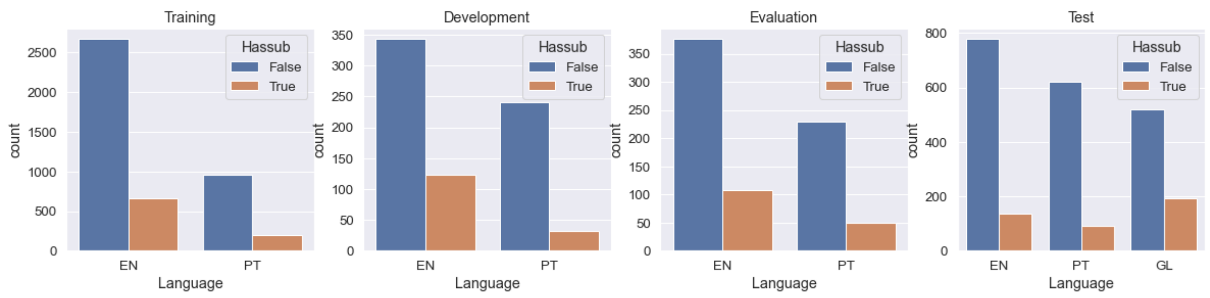


(a) Confusion matrix for the sbert+feature model.

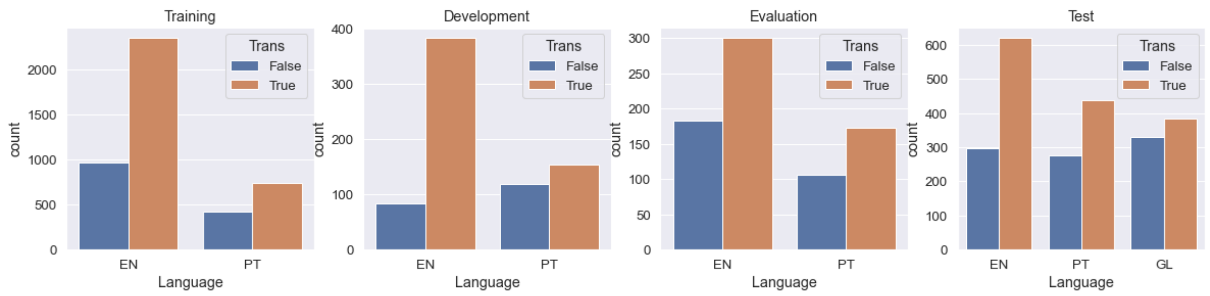


(b) Confusion matrix for the BERT+feature model.

Figure 4: Confusion matrices for the development set. The fine-tuned BERT model is more likely to classify the sentence as literal than the feature model.

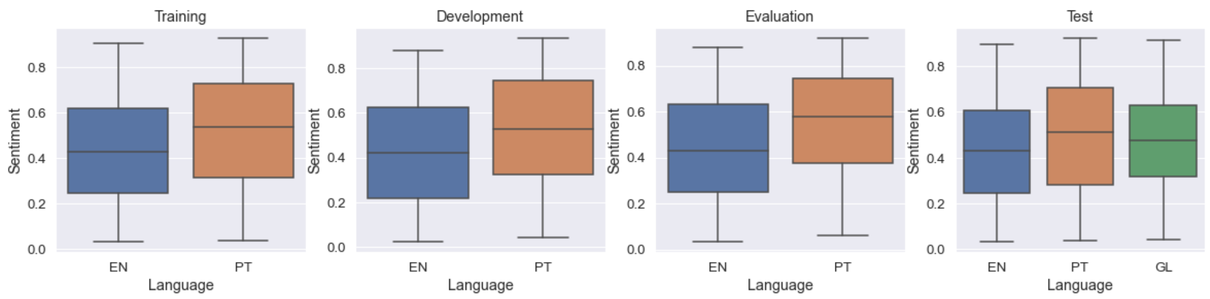


(a) Hassub

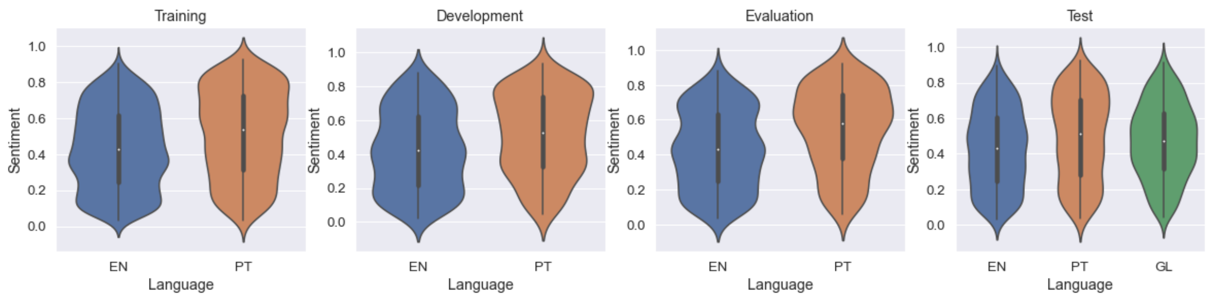


(b) Trans

Figure 5: Counts per feature, set and language. It is relatively easier to get a valid lexical substitute for Galician. Getting a correct backtranslation is harder for Portuguese than English, and harder still for Galician.



(a) Box plot



(b) Violin plot

Figure 6: Sentiment scores per set and language. The distributions are skewed for English and Portuguese, while the sentiment scores seem uninformative for Galician. Portuguese scores are generally higher - it is more difficult for the sentiment classifier to classify sentences as affective (either positive or negative).

Hitachi at SemEval-2022 Task 2: On the Effectiveness of Span-based Classification Approaches for Multilingual Idiomaticity Detection

Abstract

In this paper, we describe our system for SemEval-2022 Task 2: *Multilingual Idiomaticity Detection and Sentence Embedding*. The task aims at detecting idiomaticity in an input sequence (Subtask A) and modeling representation of sentences that contain potential idiomatic multiword expressions (MWEs) (Subtask B) in three languages. We focus on the zero-shot setting of Subtask A and propose two span-based idiomaticity classification methods: MWE span-based classification and *idiomatic* MWE span prediction-based classification. We use several cross-lingual pre-trained language models (InfoXLM, XLM-R, and others) as our backbone network. Our best-performing system, fine-tuned with the span-based idiomaticity classification, ranked fifth in the zero-shot setting of Subtask A and exhibited a macro F_1 score of 0.7466.

1 Introduction

SemEval-2022 Task 2 (Tayyar Madabushi et al., 2022) involves detecting idiomaticity in a given sentence (Subtask A) and learning effective representations of sentences that may contain idiomatic multiword expressions (MWEs) (Subtask B) in three languages: English, Portuguese, and Galician. Processing idiomaticity in a sequence correctly is an essential task in natural language processing (NLP), as idiomatic expressions are a key component of natural languages. Its high performance will contribute to various downstream tasks, such as sentiment analysis, information retrieval, and machine translation (Hashempour and Villavicencio, 2020; Tayyar Madabushi et al., 2021).

In this work, we propose two different approaches for multilingual idiomaticity detection (Subtask A) that take advantage of MWE span-based features. We use several cross-lingual pre-trained language models (InfoXLM (Chi et al., 2021a), XLM-R (Conneau et al., 2020), and others) and exploit their MWE span representations for classification, instead of using a special classification token (`[CLS]`), which typically corresponds to the first input token. Our concept is that these models should be able to focus more on the idiomaticity of an MWE in a given sequence by using its span representation rather than using the `[CLS]` token for classification, potentially resulting in a better detection performance.

Our main findings in the shared task are in three-fold.

1. The span-based idiomaticity classification method is highly effective compared to the standard `[CLS]`-based sequence classification approach adopted in various BERT (Devlin et al., 2019)-like models (Liu et al., 2019; Lan et al., 2020; Clark et al., 2020).

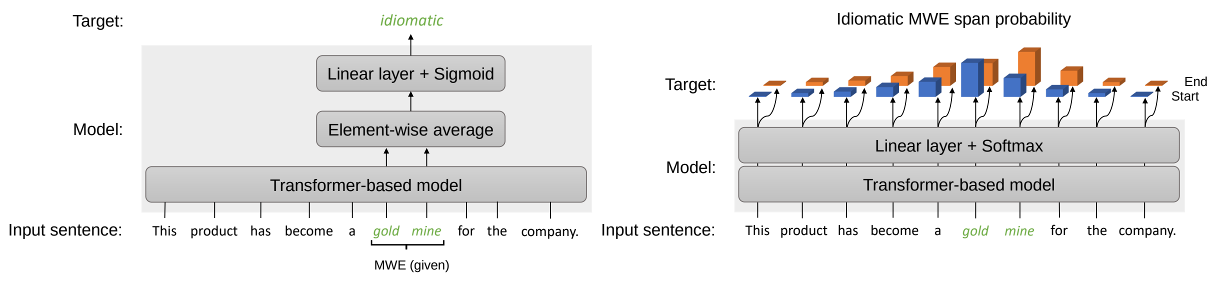
2. Detecting idiomaticity in Galician with no training data available is challenging even with state-of-the-art cross-lingual pre-trained language models.

3. Utilizing adjacent contexts with a target sentence is not always the best option for idiomaticity detection, even though it improves the baseline performance.

Consequently, our best-performing system, using the span-based classification, ranked fifth among 20 systems in the zero-shot setting of Subtask A and showed a macro F_1 score of 0.7466 on the test set.

2 Background

Idiomaticity Detection While the task of idiomaticity detection with respect to MWEs is not new, it is still considered challenging because state-of-the-art language representation models heavily depend on the principle of compositionality (Pelletier, 1994), which idioms do not follow, due to their tokenization methods (Kudo, 2018; Sennrich



(a) Span-based idiomaticity classification

(b) Span prediction-based idiomaticity classification

Figure 1: Overview of two proposed approaches for detecting idiomaticity.

et al., 2016). To overcome this problem, some studies (Hashempour and Villavicencio, 2020; Garcia et al., 2021) have regarded an MWE as a single token motivated by the assumption that people recognize an idiom as a single token (Sinclair et al., 1991). Alternatively, others have tried to utilize the adjacent contexts of MWEs as inputs and have demonstrated the effectiveness of this against tasks targeting verb-noun constructions (Sporleder and Li, 2009; Salton et al., 2016; King and Cook, 2018) and noun compounds (Tayyar Madabushi et al., 2021). This paper also utilizes adjacent contexts for classification but proposes new idiomaticity detection approaches in which the span information of an MWE plays an important role.

Cross-lingual Pre-trained Language Models Cross-lingual pre-trained language models have shown promising results in multilingual NLP tasks since the emergence of multilingual BERT (mBERT) (Devlin et al., 2019). In general, they are pre-trained with either multilingual masked language modeling (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020; Chung et al., 2021) or translation language modeling (Conneau and Lample, 2019). The difference between the two is that the former uses monolingual sentences while the latter utilizes concatenated parallel sentences for inputs. The state-of-the-art InfoXLM (Chi et al., 2021a) further utilized contrastive learning, where a model needs to distinguish a correct translated sample from negative ones. Our approach uses several cross-lingual pre-trained language models, including InfoXLM, XLM-R, XLM-Align (Chi et al., 2021b), and RemBERT (Chung et al., 2021), to utilize multilingual idiomaticity data efficiently.

3 Task Description

We briefly describe a multilingual idiomaticity detection task (Subtask A). Given a sentence composed of n words $\mathcal{S}_{\text{target}} = [w_1, \ldots, w_n]$ that contains an m-word MWE $\mathcal{W} = [w_1^{\text{MWE}}, \ldots, w_m^{\text{MWE}}]$, $\mathcal{S}$'s preceding sentence $\mathcal{S}_{\text{prev}}$, and succeeding sentence $\mathcal{S}_{\text{next}}$, the task is to classify if $\mathcal{W}$ is *idiomatic* (0) or not (1). The task dataset is based on Tayyar Madabushi et al. (2021) and contains *Galician* in addition to English and Portuguese. Each sample consists of $\mathcal{S} = [\mathcal{S}_{\text{prev}}; \mathcal{S}_{\text{target}}; \mathcal{S}_{\text{next}}]$, $\mathcal{W}$, a language type $lang \in \{\text{“EN”}, \text{“PT”}, \text{“GL”}\}$, and an idiomaticity label $y_{\text{MWE}} \in \{0, 1\}$. In the zero-shot setting, participants do not have any training samples for Galician and are only allowed to use the officially provided training and development sets for training. They must also use the same approach for all samples except language and can submit up to five systems for evaluation.

4 System Overview

Our system relies on cross-lingual pre-trained language models (InfoXLM and XLM-R and others) and classifies samples using either span-based classification or span prediction-based classification. We fine-tune several pre-trained language models and obtain final predictions by using an ensemble method. Figure 1 visualizes our approach for multilingual idiomaticity detection.[1]

4.1 Span-based Classification

There have been several attempts to utilize span hidden representations from a Transformer (Vaswani et al., 2017)-based pre-trained language model in various NLP tasks that can be formulated as span classification, including named entity recognition

[1]Appendix A describes our approaches in detail using equations.

(Yamada et al., 2020; Eberts and Ulges, 2020), relation classification (Baldini Soares et al., 2019) and propaganda technique classification (Da San Martino et al., 2020; Dimov et al., 2020; Jurkiewicz et al., 2020). These studies have all demonstrated the effectiveness of the span representations.

Here, we utilize this approach to solve the task of idiomaticity detection. We first pick up the span hidden representations of an MWE from the Transformer-based model, take their average, and feed the resulting vector into a linear layer for final classification (Figure 1 (a)).

Our concept with this approach is that the model should be able to focus more on the usage of an MWE in terms of idiomaticity in context rather than using a special `[CLS]` token for classification. Although we do not regard an MWE as a single token to encode, it is true that our approach is inspired by the idiom principle (Sinclair et al., 1991) in the sense that our model classifies a single averaged MWE span hidden representation for final classification.

4.2 Span Prediction-based Classification

For the second approach, we propose span prediction-based idiomaticity classification, inspired by BERT (Devlin et al., 2019)'s fine-tuning approach against the SQuAD v2.0 dataset (Rajpurkar et al., 2016, 2018), which contains some unanswerable questions. In BERT's approach, the answer text span in a given text for answerable questions is predicted, and the position of a `[CLS]` token for questions that do not have an answer is output. In our case, the task is to predict the MWE span in a given sequence for idiomatic MWEs and to output the position of a `[CLS]` token for non-idiomatic MWEs. This approach is illustrated in Figure 1 (b).

Our concept with this approach lies in the generalizability over unseen data. Predicting an idiomatic MWE span requires a model to differentiate non-idiomatic MWEs from idiomatic ones. This should force the model to learn semantic knowledge on MWEs in terms of idiomaticity and subsequently help the model to deliver a better performance on the test data.

5 Experimental Setup

Models We mainly utilized InfoXLM and XLM-R for our system submission, but we also tested several other cross-lingual pre-trained language models. Table 1 shows the list of models tested in this paper.[2] We selected these models because they are easy-to-use thanks to their availability on the HuggingFace Hub.[3]

Model	**Identifier**
InfoXLM (Chi et al., 2021a)	microsoft/infoxlm-large
XLM-R (Conneau et al., 2020)	xlm-roberta-large
XLM-Align (Chi et al., 2021b)	microsoft/xlm-align-base
RemBERT (Chung et al., 2021)	google/rembert
mBERT (Devlin et al., 2019)	bert-base-multilingual-cased

Table 1: List of cross-lingual pre-trained language models tested in this paper. Each identifier corresponds to the model name in the `transformers` library.

Data and Preprocessing We utilized the official training and development sets[4] for training, and no additional data was used, as stipulated by the competition rules. We tokenized samples using pre-trained tokenizers provided by the `transformers` library (Wolf et al., 2020) and set the sequence length to 256. When using an MWE as an additional input feature, we added it to the second sentence following Tayyar Madabushi et al. (2021).

Evaluation Metrics The evaluation metric for Subtask A is a macro F_1 score with respect to idiomaticity labels.

Fine-tuning We implemented our approaches using PyTorch (Paszke et al., 2019) and the `transformers` library. We fine-tuned all models for ten epochs each using one NVIDIA Tesla V100 (SXM2 - 32GB) with a batch size of 16 and automatic mixed precision applied. We used an Adam optimizer (Kingma and Ba, 2014) and saved a checkpoint of each model every ten steps. To minimize the effect of random seeds, we trained all models for ten times each with different random seeds. We then selected the best-performing models on the basis of the macro F_1 scores on the development set.[5]

Ensemble We fused the outputs of the fine-tuned pre-trained language models to further boost perfor-

[2]We provide a brief explanation of the five cross-lingual pre-trained language models in Appendix B and the performance comparison in Appendix E.

[3]`https://huggingface.co/models`

[4]`https://github.com/H-TayyarMadabushi/SemEval_2022_Task2-idiomaticity`

[5]For more details on hyperparameters, please refer to Appendix C.

System	Ensemble Method	Models Used
System 1	No Ensemble	InfoXLM for EN, XLM-R for PT & GL
System 2	Stacking	InfoXLM $\times$ 4, XLM-R $\times$ 1
System 3	Majority Vote	InfoXLM $\times$ 5, XLM-R $\times$ 1
System 4	Stacking	InfoXLM $\times$ 5, XLM-R $\times$ 1
System 5	Majority Vote	InfoXLM $\times$ 5, XLM-R $\times$ 1

Table 2: Configurations of our submitted systems. For ensemble methods, we used predicted labels from pre-trained language models as an input feature. For systems with stacked generalization, we trained a logistic regression model as a meta estimator.

mance on unseen data. For submission, we use either stacked generalization (Wolpert, 1992), where we train a machine learning model using predictions from pre-trained language models and corresponding idiomaticity labels and then make a final decision with it, or naïve majority voting on predicted labels. We implemented stacked generalization using scikit-learn (Pedregosa et al., 2011). Prediction labels on the development set were used as training data for a meta estimator. To train the estimator, we first divided the training data into 90% for training and 10% for hold-out. We then trained the estimator using three-fold cross-validation (CV). We tested both a ridge classifier and a logistic regression and chose the best-performing model based on the average CV score over the three validation folds. We subsequently picked up the best estimator from the resulting three models using the hold-out set. Finally, the best estimator predicted labels for the test set using the predictions of the pre-trained language models.

Submitted Systems We submitted the five models listed in Table 2 to the evaluation phase.[6] Note that all models were fine-tuned with the span-based classification approach following our preliminary experiments on the development and evaluation sets.

6 Results

Table 3 shows the official test set results for the zero-shot setting of Subtask A. Our best-performing model (System 2), using four InfoXLM models and one XLM-R model with stacked generalization, achieved a macro F_1 score of 0.7466 and was ranked fifth among 20 teams.

Ensemble We utilized ensemble methods in four out of five submissions, of which two use stacked generalization and the others adopt a naïve majority voting approach. Table 4 lists the results of our five submissions on the test set. The results indicate the effectiveness of the ensemble methods, which outperform the model with no ensemble methods by 0.0112 for the best-performing model using stacked generalization. Even for the naïve majority voting approach, the performance improved or did not fall below the result without ensembling.

Classification Approaches We verified the efficacy of three idiomaticity classification approaches—span-based classification, span prediction-based classification, and conventional `[CLS]`-based classification—using the same pre-trained model (InfoXLM). We can see in Table 5 that the span-based classification approach exhibited by far the best average macro F_1 score of 0.7303 on the test set, compared to average

Rank	Team	Macro F_1
1	clay	0.8895
2	yxb	0.8498
3	NER4ID	0.7740
4	HIT	0.7715
5	**Hitachi** (Ours)	0.7466
	Baseline	0.6540

Table 3: Top five macro F_1 scores on test set in zero-shot setting of Subtask A. Baseline uses mBERT following Tayyar Madabushi et al. (2021).

Approach		Macro F_1
No Ensemble	System 1	0.7354
Majority Vote	System 3	0.7354
	System 5	0.7448
Stacking	System 2	**0.7466**
	System 4	0.7452

Table 4: Macro F_1 test scores for our five submitted systems. All models were trained with the span-based classification approach. **Bold** indicates the best result.

[6]For the detailed configurations of each model, please see Appendix D.

Approach	Macro F$_1$ Development	Macro F$_1$ Test
Span-based	**0.7898** (.0138)	**0.7303** (.0211)
Span prediction-based	0.7514 (.0086)	0.6245 (.0255)
`[CLS]`-based	0.7166 (.0675)	0.6333 (.0371)

Table 5: Average macro F$_1$ development and test scores of three classification approaches with standard deviations over ten runs in parentheses. We fine-tuned InfoXLM and used the same hyperparameter settings and input features for all models.

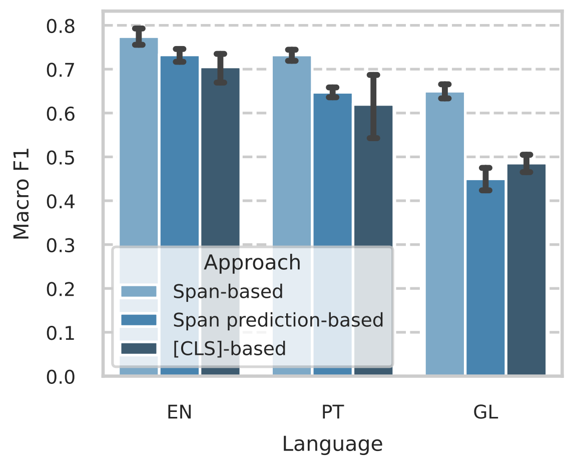


Figure 2: Average macro F$_1$ scores of three idiomaticity classification approaches on the test set grouped by language. Error bars denote 95% confidence interval.

macro F$_1$ scores of 0.6245 and 0.6333 for the span prediction-based and the `[CLS]`-based approaches, respectively. This huge difference stems partly from the Galician classification performance, since we have no associated training or development sets for Galician.

Figure 2 shows the average macro F$_1$ scores on the test set grouped by language. The span-based classification approach produced the highest performance across the three languages, and the performance variations among languages were relatively small, with the maximum difference of 0.1245 between English and Galician. In contrast, the span prediction-based and `[CLS]`-based approaches did not perform well on Galician samples, exhibiting average macro F$_1$ scores of 0.4499 and 0.4858, respectively. We assume that because idioms are generally language- and culture-specific[7] (Aldahesh, 2013; Al-kadi, 2015), it is difficult for models fine-tuned on English and Portuguese data to detect idiomaticity in unseen Galician samples without letting them know where they should be mainly looking, as in the span-based approach.

[7]Although Portuguese and Galician have strong historical ties, they are categorized as two different languages (Ramallo and Rei-Doval, 2015; Garcia, 2021).

Feature	Macro F$_1$ Development	Macro F$_1$ Test
Plain	0.7859 (.0131)	0.7131 (.0196)
Plain + MWE	0.7835 (.0078)	**0.7315** (.0179)
Plain + Context	0.7898 (.0138)	0.7303 (.0211)
Plain + MWE + Context	**0.7918** (.0141)	0.7280 (.0212)

Table 6: Average macro F$_1$ development and test scores with standard deviations over ten runs in parentheses. "Plain" denotes a target sentence, while "Context" represents the previous and next sentences. We fine-tuned InfoXLM using the span-based classification approach and used the same hyperparameter settings for all models.

Input Features Tayyar Madabushi et al. (2021) reported that encoding a target sentence along with its adjacent contexts showed the best classification performance in the zero-shot setting among the four possible input feature combinations: (i) a target sentence, (ii) a target sentence with its MWE as a second sentence, (iii) a target sentence with its adjacent contexts, and (iv) a target sentence, its MWE and adjacent contexts. Here, we also investigated these combinations using the span-based classification approach (Table 6). The results indicate that considering a target sentence and its adjacent contexts is not always the best option. In our experiments, utilizing a target sentence and its target MWE as inputs (Plain + MWE) achieved the best average macro F$_1$ score of 0.7315, followed by Plain + Context with a macro F$_1$ score of 0.7303. While using only a target sentence showed comparable performance to the other approaches on the development set, it ended up producing the worst result on the test set. These results suggest that using an additional feature along with a target sentence is likely to boost detection performance, but it is not clear which combination of input features yields the best performance given the standard deviations.

7 Conclusion

In this paper, we have proposed two approaches for detecting idiomaticity in a given sequence: span-based classification and span prediction-based classification. While the performance of the latter was almost on par with that of the well-known standard sequence classification approach using a `[CLS]` hidden representation, the former outperformed it and showed the best macro F_1 score of 0.7466, which ranked fifth in the zero-shot setting of Subtask A. We also found that it is essential to guide a model on which tokens to look at when no training data is available for a particular language. In future work, we will investigate a more effective idiomaticity detection approach against unseen language data.

Appendices

A Approaches

Here, we describe our two approaches in detail using mathematical notations.

A.1 Span-based Classification

Given $\mathcal{S}$, $\mathcal{W}$, and y_{MWE}, we first tokenize $\mathcal{S}$ and $\mathcal{W}_{\text{MWE}}$ using a pre-trained tokenizer and obtain their token-level representations: $\mathcal{S}' = [t_1, \ldots, t_{n' \in \mathbb{N}}]$ and $\mathcal{W}' = [t_1^{\text{MWE}}, \ldots, t_{m' \in \mathbb{N}}^{\text{MWE}}]$. We then feed $\mathcal{S}'$ into a Transformer-based pre-trained language model and obtain the output hidden representation $\mathbf{H} = [\mathbf{h}_1, \ldots, \mathbf{h}_n']$. We pick up only the hidden representation of $\mathcal{W}'$ and compute their average as $\mathbf{h}_{\text{MWE}} = \frac{1}{|\mathcal{W}'|}\left(\mathbf{h}_1^{\text{MWE}} + \cdots + \mathbf{h}_{m'}^{\text{MWE}}\right)$. Finally, we put $\mathbf{h}_{\text{MWE}}$ into an output linear layer and obtain the prediction. The training objective in this task is the binary cross-entropy loss.

A.2 Span Prediction-based Classification

Given $\mathcal{S}'$, a start position of $\mathcal{W}'$ and an end position of $\mathcal{W}'$, we first feed $\mathcal{S}$ into a Transformer-based model and then put the output representation $\mathbf{H}$ to a linear classifier for classification, yielding $\mathbf{O} \in \mathbb{R}^{n' \times 2} = [\mathbf{o}_{\text{start}}; \mathbf{o}_{\text{end}}]$. We finally apply the softmax function to $\mathbf{o}_{\text{start}}$ and $\mathbf{o}_{\text{end}}$ in order to obtain the idiomatic MWE span probabilities. For prediction, we first calculate the maximum scoring span and obtain its score as $s = o_i^{\text{start}} + o_j^{\text{end}}$, where j must be greater than i, and o_i^{start} and o_j^{end} are the i-th and j-th values of $\mathbf{o}_{\text{start}}$ and $\mathbf{o}_{\text{end}}$, respectively. We also calculate the non-idiomatic score as $\overline{s} = o_1^{\text{start}} + o_1^{\text{end}}$, where index 1 refers to the index of the `[CLS]` token. If $s \geq \overline{s}$, $\mathcal{W}$ is regarded as *idiomatic*. Otherwise, $\mathcal{W}$ is predicted as a non-idiomatic MWE. This task is trained with an average of the log-likelihoods of the correct start $\mathcal{L}_{\text{start}}$ and end $\mathcal{L}_{\text{end}}$ positions: $\mathcal{L}_{\text{span}} = \frac{1}{2}\left(\mathcal{L}_{\text{start}} + \mathcal{L}_{\text{end}}\right)$.

B Cross-lingual Pre-trained Language Models

We briefly explain the five cross-lingual pre-trained language models tested in this paper.

- mBERT (Devlin et al., 2019): Pre-trained with multilingual masked language modeling using Wikipedia. Its architecture follows that of BERT-BASE.

- XLM-R (Conneau et al., 2020): Pre-trained with multilingual masked language modeling using CommomCrawl, which is much larger than Wikipedia. The architecture generally follows that of BERT-LARGE.

- InfoXLM (Chi et al., 2021a): Pre-trained with multilingual masked language modeling, translation language modeling, and the newly proposed cross-lingual contrastive learning, using CommonCrawl. The architecture follows that of XLM-R.

- XLM-Align (Chi et al., 2021b): Pre-trained with multilingual masked language modeling, translation language modeling and denoising word alignment, using CommonCrawl and

Wikipedia. The architecture generally follows that of BERT-BASE.

- RemBERT (Chung et al., 2021): Pre-trained with multilingual masked language modeling using both CommonCrawl and Wikipedia. The architecture is completely different from that of XLM-R, though it has the same number of parameters (559M). It consists of 32 hidden layers, 18 attention heads and $Dim_{\text{hidden}} = 1152$.

Note that all models can accommodate the three target languages (English, Portuguese, and Galician).

C Hyperparameter Settings

Table 8 shows the hyperparameter settings. We explored various hyperparameter combinations with respect to a pre-trained language model, a peak learning rate, and an input feature and selected the models with a macro F_1 score of 0.795 or above on the development set. Note that we also tested XLM-Align, RemBERT, and mBERT in our preliminary experiments, but these did not perform well on the development set (see Appendix E); therefore, we did not use them in our submissions.

D Model Configurations

Table 9 lists the models used for our submissions, while Table 10 shows the configurations of our five submitted systems. For System 1, we used the two different best-performing models for English and Portuguese.[8] For Galician, because we did not have any training samples provided in the zero-shot setting, we used the same model as Portuguese, as both Galician and Portuguese have grammatical and lexical similarities due to their shared historical background (Ramallo and Rei-Doval, 2015; Cascallar-Fuentes et al., 2018; Garcia, 2021).

E Performance Comparison of Five Cross-lingual Pre-trained Language Models

Table 7 compares average macro F_1 scores of five cross-lingual pre-trained language models on the development and test sets. Interestingly, RemBERT produced the best result on the test set with an average macro F_1 score of 0.7452, though it ranked third for the development set. This is presumably because the Galician and English classification performances of RemBERT are better than any other cross-lingual pre-trained language models that we tested (Figure 3).

[8] We selected the best-performing models based on macro F_1 scores on the evaluation set.

Model	**Macro F_1**	
	Development	Test
InfoXLM	0.7898 (.0139)	0.7304 (.0211)
XLM-R	**0.7959** (.0110)	0.7116 (.0125)
XLM-Align	0.7600 (.0096)	0.7015 (.0119)
RemBERT	0.7833 (.0090)	**0.7452** (.0192)
mBERT	0.7440 (.0125)	0.7014 (.0125)

Table 7: Average macro F_1 development and test scores of five cross-lingual pre-trained language models with standard deviations over ten runs in parentheses. We use the same hyperparameter settings for all models.

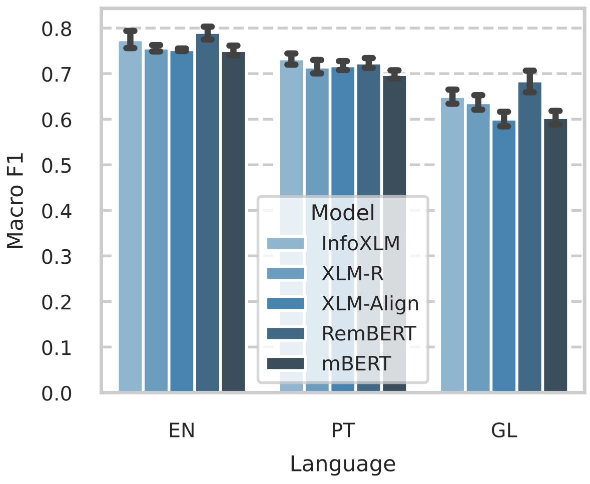

Figure 3: Average macro F_1 scores of five cross-lingual pre-trained language models on the test set grouped by language. Error bars denote 95% confidence interval.

Hyperparameter	**Candidate**
Batch size	16
Epochs	10
Model	(InfoXLM, XLM-R)
Peak learning rate	(0.5e-5, 1e-5, 1.5e-5, 2e-5, 2.5e-5, 3e-5)
Input feature	(Plain + MWE, Plain + Context, Plain + MWE + Context)
Warmup steps	5% of steps
Weight decay	0.01
Adam ϵ	1e-8
Adam β_1	0.9
Adam β_2	0.999
Sequence length	256
Attention Dropout	0.1
Dropout	0.1

UAlberta at SemEval 2022 Task 2: Leveraging Glosses and Translations for Multilingual Idiomaticity Detection

Bradley Hauer, Seeratpal Jaura, Talgat Omarov, Grzegorz Kondrak
Alberta Machine Intelligence Institute, Department of Computing Science
University of Alberta, Edmonton, Canada
{bmhauer,seeratpa,omarov,gkondrak}@ualberta.ca

Abstract

We describe the University of Alberta systems for the SemEval-2022 Task 2 on multilingual idiomaticity detection. Working under the assumption that idiomatic expressions are non-compositional, our first method integrates information on the meanings of the individual words of an expression into a binary classifier. Further hypothesizing that literal and idiomatic expressions translate differently, our second method translates an expression in context, and uses a lexical knowledge base to determine if the translation is literal. Our approaches are grounded in linguistic phenomena, and leverage existing sources of lexical knowledge. Our results offer support for both approaches, particularly the former.

1 Introduction

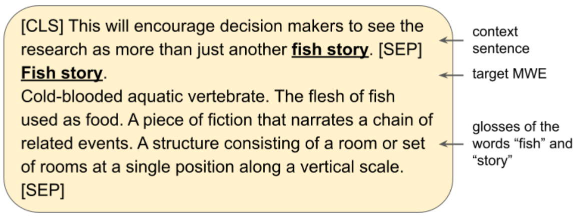
In this paper, we describe the University of Alberta systems for the task of classifying multi-word expressions (MWEs) in context as either *idiomatic* or *literal* (Tayyar Madabushi et al., 2022). Each instance in the data includes a MWE (e.g., *closed book*), its language, and its context, composed of the three surrounding sentences. We participate in both the zero-shot and one-shot settings.

While the exact definitions of the two key terms are not stated explicitly in the task description[1], it is suggested that *idiomatic* is synonymous with *non-compositional*. The Pocket Oxford Dictionary defines *idiomatic* as "not immediately comprehensible from the words used," and *literal* as "taking words in their basic sense." Therefore, we adopt the following MWE *compositionality criterion*

$$\text{literal} \equiv \text{compositional} \equiv \neg\,\text{idiomatic}$$

where the three terms are considered to be Boolean variables. In addition, the shared task considers all proper noun MWEs (e.g., *Eager Beaver*) as literal.

[1]https://sites.google.com/view/semeval2022task2-idiomaticity



[CLS] This will encourage decision makers to see the research as more than just another **fish story**. [SEP]
Fish story.
Cold-blooded aquatic vertebrate. The flesh of fish used as food. A piece of fiction that narrates a chain of related events. A structure consisting of a room or set of rooms at a single position along a vertical scale.
[SEP]
context sentence
target MWE
glosses of the words "fish" and "story"

Figure 1: An example of defBERT input.

Our goal is to explore the idea that glosses and translations of word senses can help decide whether the meaning of a given MWE occurrence is compositional. Based on the above-stated compositionality criterion, this in turn could facilitate idiomaticity detection. In particular, we hypothesize that at least one of the words in any idiomatic expression is used in a non-standard sense. Following the intuition that a traditional word sense disambiguation (WSD) system can only identify senses that are included in a given sense inventory, we propose two methods that indirectly detect non-standard senses by leveraging either glosses or translations of senses from such an inventory.

Our gloss-based method follows from the intuition that the meaning of a given MWE occurrence is related to any of the existing sense glosses of its component words *only if the expression is compositional*. Therefore, the addition of the glosses to the context of the expression should help the classifier in deciding whether the MWE is used in a literal or idiomatic sense. We implement this method by adding the glosses of each sense of each individual word, retrieved from a lexical knowledge base, to the input to a neural classifier which fine-tunes multilingual BERT (mBERT; Devlin et al., 2019) for the idiomaticity detection task. We refer to this method as defBERT (Figure 1).

Our translation-based method follows from the observation that compositional expressions are typically translated word-for-word ("literally"), which implies that each content word and its translation should have the same meaning. Therefore, each such multilingual word pair should share a multi-synset in a multi-wordnet (Hauer and Kondrak, 2020b). The procedure is as follows: (1) translate the MWE in context; (2) word-align the source and target sentences; (3) lemmatize and POS-tag the source MWE; and (4) for each lemma in the MWE, search for a multi-synset that contains both the lemma and its translation. This method is unsupervised, and we refer to it as MT.

Our results provide evidence that leveraging lexical resources is beneficial for idiomaticity detection. In particular, our gloss-based method, when combined with a type-based UNATT heuristic, is among the top-scoring submissions in the one-shot setting. The heuristic is based on the observation that some MWEs are inherently idiomatic or literal, regardless of their context, which is confirmed by our analysis of the development set annotations.

2 Related Work

Early attempts to represent idiomatic MWEs involve treating idiomatic phrases as individual tokens and learning corresponding static embeddings (Mikolov et al., 2013). However, Cordeiro et al. (2016) show that the effectiveness of this method is limited by data sparsity for longer idiomatic expressions. Furthermore, Shwartz and Dagan (2019) and Garcia et al. (2021) conclude that idiomaticity is not yet accurately represented even by contextual embedding models. Tayyar Madabushi et al. (2021) create a new manually labeled dataset containing idiomatic and literal MWEs, and propose a method based on a pre-trained neural language model.

Regarding using lexical translations for idiomaticity detection, Moirón and Tiedemann (2006) measure semantic entropy in bitext alignment statistics, while Salehi et al. (2014) predict compositionality by presenting an unsupervised method that uses Wiktionary translation, synonyms, and definition information. We extend these ideas by applying machine translation, and consulting a multilingual lexical knowledge base.

Our prior work has already demonstrated the utility of lexical translations for various semantic tasks, including prior SemEval tasks on predicting cross-lingual entailment (Hauer et al., 2020) and contextual synonymy detection (Hauer et al., 2021), as well as word sense disambiguation (Luan et al., 2020), and homonymy detection (Hauer and Kondrak, 2020a; Habibi et al., 2021).

3 Methods

In this section, we describe our methods for idiomaticity detection.

3.1 Baseline mBERT

We re-implemented the mBERT classifier baseline (Devlin et al., 2019) following the methodology of Tayyar Madabushi et al. (2021). The model takes the context sentence and the relevant MWE as an input, and outputs a binary label indicating the idiomaticity of the target MWE. The input sequence is constructed by concatenating the MWE to the end of the context sentence after the special [SEP] token.

It is important to note the differences between our re-implementation and the official baseline provided by the task organizers. In the official baseline, the organizers add the target MWE as an additional feature in the one-shot setting but not in the zero-shot setting. Furthermore, the organizers include the sentences preceding and succeeding the target sentence only in the zero-shot setting. In our re-implementation, we add the target MWE and exclude the preceding and succeeding sentences in both zero-shot and one-shot settings.

3.2 Gloss-based Method

Our first method, defBERT, extends the baseline model by adding the glosses of all possible senses of each individual word in the target MWE to the classifier's input. The intuition is that the addition of the glosses to the input should help the classifier decide if the meaning of the target MWE can be deduced from the definitions of the individual words, i.e., if it is compositional. In the example in Figure 1, the disparity between the context in which *fish story* appears, and the glosses of the various senses of the words *fish* and *story* indicates that the MWE is idiomatic in this context.

The intuition for this method is that non-native speakers can identify idiomatic expressions, provided they understand the standard meanings of the words which comprise them. Suppose that the vocabulary of a non-native speaker covers most of the essential words necessary to understand a language, but not idiomatic expressions. Even if the speaker cannot deduce the meaning of an idiomatic expression in context, they can guess that the expression was used in an idiomatic sense because individual words of this expression do not make sense in the given context.

3.3 Translation-based Method

Our MT method is based on translating the target MWE in context, and leverages multilingual semantic resources. The intuition behind this method is that idioms are generally specific to a particular language, and, being non-compositional, their meanings cannot be conveyed simply by translating the individual words.

Under this hypothesis, to classify an MWE as literal or idiomatic, we need only determine whether the words in the MWE are translated literally. We do this by first identifying the translation of each word via alignment. We then consult a multilingual wordnet, or *multi-wordnet*, a lexical knowledge-base which organizes words in two or more languages into multilingual synonym sets, or *multi-synsets*. Each multi-synset corresponds to a unique concept, and contains the words which express that concept. Given a word in context, and a translation of that word in that context, we consider the word to be literally translated if it shares at least one multi-synset with its translation.

For example, consider an instance in which the MWE *wedding anniversary* is translated into Italian as *anniversario di matrimonio*. Our method checks if either of the translation pairs (*wedding*, *matrimonio*) and (*anniversary*, *anniversario*) share a multi-synset in a multi-wordnet. We test two versions of this method: in MT(all), this condition must be satisfied for all content words in the MWE; in MT(one), detecting a literal translation for one word is sufficient to classify the MWE as literal. In addition, multiple languages of translation may be considered.

3.4 Additional Heuristics

The annotation methodology for this shared task includes proper nouns in the literal class. We therefore use a part-of-speech tagger to detect proper nouns; if any word in the MWE is tagged as a proper noun, MT automatically classifies it as literal without further consideration.

In the one-shot setting, we also use a type-based heuristic which we refer to as UNATT. The intuition behind this heuristic is that certain MWEs are inherently idiomatic or literal, regardless of the context that they appear in. If the training data has no example of an MWE in a particular class, the heuristic exploits this fact as evidence that the MWE should always be classified as the opposite, attested class. For example, this heuristic always classifies *life vest* as idiomatic and *economic aid* as literal, as these are the only classes in which these MWEs appear in the training data. In practice, since UNATT returns no classification if the training set contains instances that belong to either class, this heuristic must be used in combination with another method.

3.5 Combination

Our defBERT and MT methods take different views of the data, with the former using a neural language model and gloss information, and the latter using translation and a lexical knowledge base. We therefore consider combining the two methods. In this approach, we independently apply defBERT and MT to a given instance. If the two methods agree, we return the agreed-upon classification; if they disagree, we return a default class, which is a tunable parameter. As with the other methods, we can combine this method with the UNATT heuristic in the one-shot setting.

4 Experiments

We now describe our experiments, including the tools and resources, the experimental setup, the results, and a discussion of our findings.

4.1 Lexical Resources

As lexical resources for sense translations and glosses, we use two different multi-wordnets: BabelNet (BN; Navigli and Ponzetto, 2010, 2012), and Open Multilingual WordNet (OMW; Bond and Foster, 2013). The defBERT method and the alignment tool access BN 4.0 via the provided Java API[2]. For the MT method, we access the BN 5.0 via the HTTP API. We access OMW via the NLTK interface (Bird et al., 2009). For the MT method, we consider the translation of a word to be literal if it shares a multi-synset with the word in either BN or OMW. For lemmatization and POS tagging, we use TreeTagger[3] (Schmid, 2013).

Both BN and OMW contain English glosses for most concepts, but the availability of glosses in other languages varies. In particular, OMW contains no Portuguese or Galician glosses. With BabelNet, we experimented with two techniques: using English glosses for all languages, and using glosses from the language of the instance, i.e. the

[2]`https://babelnet.org/guide`

[3]We use the pre-trained models for English, Portuguese, and Galician from `https://cis.uni-muenchen.de/~schmid/tools/TreeTagger.`

source language, when available. We refer to these variants as defBERT-BN-en and defBERT-BN-src, respectively. Since defBERT uses a multilingual pre-trained language model, it can seamlessly handle input from multiple languages. Furthermore, because of the relatively poor coverage of Galician in the lexical resources (only 54% of glosses are available in this language), we attempt to leverage its close relationship to Portuguese by processing Galician as if it was Portuguese.

4.2 Translation and Word Alignment

We translate the context sentence of each MWE with Google Translate API[4]. We translated English instances into Italian, and Portuguese/Galician instances into English, because of the good coverage of these languages in our resources. We also conducted development experiments with translation into less related languages, as well as with combining translation information from multiple languages, but we observed no consistent improvements.

We align each input sentence with its translation using BabAlign (Luan et al., 2020), which consults BabelNet to refine the alignments generated by a base aligner, FastAlign (Dyer et al., 2013). To further improve the alignment quality, we augment the set of sentence-translation pairs with additional parallel data from the OpenSubtitles parallel corpus (Lison and Tiedemann, 2016). We note that the English-Galician bitext is less than 1% of the size of the other two bitexts.

4.3 mBERT and defBERT

We fine-tune the mBERT-based models using the binary classification objective on the labeled training dataset. In the zero-shot setting, the MWEs in the training data are disjoint from those in the development and test splits, while in the one-shot setting, all MWEs in the development and test splits have at least one example in the training data. In the zero-shot setting, we trained the models only on the zero-shot training set, while in the one-shot setting, we trained the models on both training sets. In particular, we fine-tuned the models for 20 epochs with a maximum sequence length of 256, a learning rate of 2e-5, and a per device batch size of 16, using the HuggingFace Transformers library.[5]

[4]`https://cloud.google.com/translate`
[5]`https://huggingface.co`

4.4 Development experiments

Table 1 contains the results of the following models: the official mBERT-based baseline (row 0) as reported by the shared task organizers, our reimplementation of the official baseline (row 1), three variants of defBERT method which is based on mBERT (rows 2-4), defBERT combined with the UNATT heuristic (row 5), and the MT method combined with defBERT (rows 6-7)[6]. For rows 1-5 we average the macro F1 score obtained over five runs with random initializations.

Our experiments with defBERT explored the impact of adding glosses to the mBERT model, including the source and language of the glosses. With English glosses retrieved from BabelNet, defBERT improves the total score over the mBERT model in the zero-shot setting, especially on Portuguese. The results also suggest that the English glosses may be preferable to glosses in the source language, a finding which could simplify work on lower-resourced languages, where glosses may not be available.

Combining the predictions of the mBERT-based models with the UNATT heuristic improves the one-shot F1 scores in all cases (row 5 vs. row 4).

The MT methods achieve the best results when combined with defBERT on the development set in the zero-shot setting: MT(one) for English (row 6), and MT(all) for Portuguese (row 7). This demonstrates the utility of using lexical translation information for idiomaticity detection when annotated training data is not available.

4.5 Error Analysis

We found that the defBERT method performs slightly better, by about 1% F1, on literal instances as compared to idiomatic instances in the one-shot setting. In other words, the method is less likely to make an error when given a literal instance. We speculate that this is explained by the model's consistent classification of proper nouns as literal expressions. Indeed, a proper noun is identified incorrectly in only one instance. The fraction of idiomatic vs. literal instances is 39% in English and 56% in Portuguese.

For the MT method, a large number of of errors were caused by a literal translation of an idiomatic expression by Google Translate, even though the

[6]After the test output submission deadline, we discovered errors in our implementation of the MT methods. We report our original results for consistency with the official results.

7	MT(all) + defBERT	66.4	**69.2**	73.7	78.0	65.4	62.5	54.3	62.1	80.3	73.8	73.9	77.3

Table 1: The macro F1 scores on the development and test datasets. Our official submissions are in rows 4-7. Where not otherwise specified, defBERT is in the OMW-en configuration.

corresponding expression is not meaningful in the target language. For example, "she was different, like a closed book" is translated into Italian as "era diversa, come un libro chiuso" even though the Italian translation does not carry the meaning of a person being secretive. In a few cases, the translation would simply copy the source language expression, yielding output which is not fully translated. In addition, some correct lexical translations are not in our lexical resources. Finally, a number of incorrect idiomatic predictions could be traced to word alignment errors, especially in cases of many-to-one alignments (e.g., *bow tie* correctly translated as *papillon*).

Manual analysis performed on the development set corroborates our hypothesis that most multi-word expressions are inherently idiomatic (e.g., *home run*) or literal (e.g., *insurance company*). Only about one-third of the expressions are ambiguous in the sense that they can be classified as either class depending on the context (e.g. *closed book*). Our judgements are generally corroborated by the gold labels, with the exception of proper nouns, which are consistently marked as literal. The UNATT heuristic (Section 3.4), which is based on this observation, obtains a remarkable 98.3% precision and 55.8% recall on the set of 739 instances in the development set.

4.6 Test set results

The results on the test set are shown in Table 1. Our best results are produced by defBERT-BN-en in the zero-shot setting, and the combination of defBERT with the UNATT heuristic in the one-shot setting. The latter also obtains the best result on Galician, which demonstrates its applicability to low-resource languages, as this method only requires English glosses.

The results of combining defBERT with MT are well below the baseline, which may be due to a different balance of classes in the test set, omissions in lexical resources, and/or errors in our initial implementation. Another possible reason is that modern idiomatic expressions are often translated word-for-word ("calqued"), especially from English into other European languages. Examples from the development set include *flower child, banana republic*, and *sex bomb*.

5 Conclusion

Our top result ranks third overall in the one-shot setting. The corresponding method is applicable to a wide variety of languages. It takes advantage of the ability of neural language models to seamlessly incorporate textual information such as glosses, even if it is expressed in a different language. These results strongly support our hypothesis that the gloss information of individual words can improve idiomaticity detection. Moreover, our development results support the hypothesis that non-compositional expressions can be identified through their translations. These findings conform with our prior work on leveraging translation for various semantic tasks (Section 2). We hope that this work will motivate further investigation into the role of multilinguality in semantics.

Abstract

We propose a unified framework that enables us to consider various aspects of contextualization at different levels to better identify the idiomaticity of multi-word expressions. Through extensive experiments, we demonstrate that our approach based on the inter- and inner-sentence context of a target MWE is effective in improving the performance of related models. We also share our experience in detail on the task of SemEval-2022 Task 2 such that future work on the same task can be benefited from this.

1 Introduction

Multi-word expressions (MWEs) are a group of linguistic components containing two or more words with outstanding collocation (Baldwin and Kim, 2010; Constant et al., 2017). MWEs are valuable in that they contribute to enriching the expressiveness of a language, allowing diverse interpretations of their meaning according to the context in which they are located. That is, the semantics of an MWE can be originated from either (i) the direct composition of the literal definitions of its constituents (i.e., compositional meaning) or (ii) its conventional usage in the language (i.e., idiomatic meaning). For instance, given an expression called *wet blanket*, its compositional meaning is ‘a piece of cloth soaked in liquid’, whereas its idiomatic meaning is ‘a person who spoils the mood’ (see Table 1).

While MWEs function as an effective means of improving the abundance of a language, they are also one of the main obstacles that complicate natural language processing (NLP), from the perspective that an NLP model should be able to precisely identify their mode. In addition, the current trend where the goal of most NLP models is chiefly focused on capturing compositionality raises the question of how properly to deal with idiomatic aspects of linguistic expressions (Garcia et al., 2021a,b; Zeng and Bhat, 2021).

Category	**Meaning**	**Example**
Compositional (Non-idiomatic)	A piece of cloth soaked in liquid.	And finally, the snow falls again, this time in a thick, *wet blanket* that encapsulates everything.
Idiomatic	A person who spoils the mood.	When Marie brings him down to earth, it’s not clear if she’s being a passive-aggressive *wet blanket* or if she might have a point.

Table 1: Comparison between the compositional and idiomatic meanings of the expression *wet blanket*.

An intuitive solution for mitigating the aforementioned problem is an introduction of a sophisticated method designed to estimate the idiomaticity of a given expression, which enables the separate processing of the expression according to its category. In a similar vein, we propose a series of techniques for better detecting the idiomaticity of a target MWE by actively exploiting its surrounding context in addition to considering the relationship between metaphors and the notion of idiomaticity.

Participating in SemEval-2022 Task 2, we focus on classifying two-noun compounds into idiomatic and non-idiomatic. The task provides two configurations. In the zero-shot setting, a model’s performance is evaluated on the set of sequences that include MWEs never appeared in the training phase. Meanwhile, in the one-shot setting, our model is exposed to a pair of instances per each MWE during training, one of which shows the idiomatic use of the MWE while the other is an example for the non-idiomatic case.[1] We present a unified framework that can be used in both kinds, paying slightly more attention to the one-shot setting. In extensive experiments, we show that most of our considerations lead to improvement in performance. We also present discourse on the task specification to promote a fair comparison between related models.

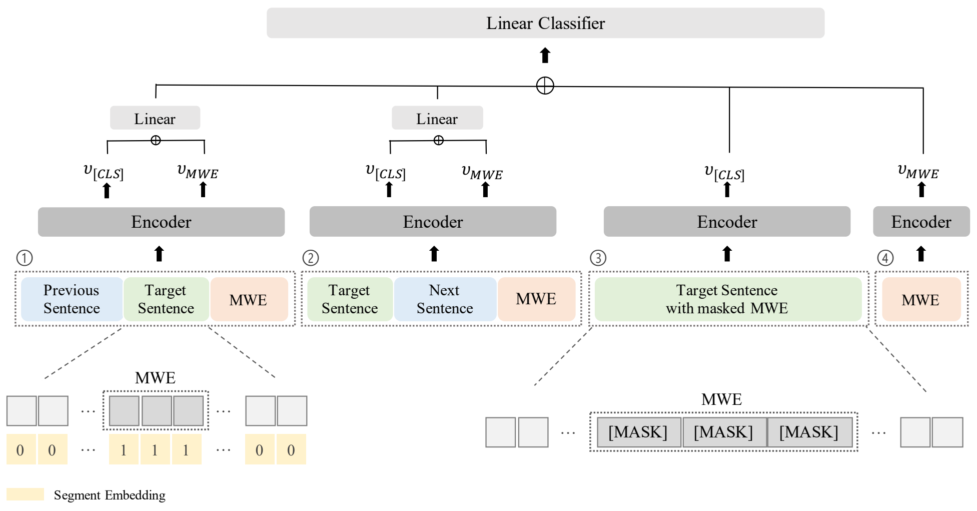

Figure 1: Proposed framework. Two features on the left (① and ②) are based on the surrounding context (Section 3.1), while the remaining two (③ and ④) are originated from considering the inner-sentence context (Section 3.2).

2 Related Work

Idiomaticity detection has been widely studied in the literature (Reddy et al., 2011; Liu and Hwa, 2019; Garcia et al., 2021a,b; Zeng and Bhat, 2021). Above all, Tayyar Madabushi et al. (2021) present a dataset that is the foundation of SemEval 2022 Task 2. This dataset consists of sentences that contain potential idiomatic MWEs with two surrounding sentences and annotations about the fine-grained set of meanings. The authors also evaluate a model's ability to detect idiomatic usage depending on whether context and MWE are included. They report that reflecting the context in the way of simply concatenating surrounding sentences is not generally helpful, and that adding the corresponding MWE at the end of the input sequence improves performance. In the following sections, we re-examine their findings and present our own revision.

On the other hand, we investigate the viability of applying techniques for metaphor detection (Gao et al., 2018; Mao et al., 2019; Lin et al., 2021) into idiomaticity classification, inspired by the resemblance of the two tasks. A metaphor is a form of figurative expression used to implicitly compare two things seemingly unrelated on the surface at the attribute level (Baldwin and Kim, 2010). Not all metaphors have the property of idiomaticity, but some idioms rely on metaphorical composition.

In practice, Choi et al. (2021) introduce two metaphor identification theories (Metaphor Identification Procedure (MIP; Group (2007), Steen (2010)) and Selectional Preference Violation (SPV; Wilks (1975)) into their model to better capture metaphors, which we expect also might be helpful for the procedure of identifying idiomatic expressions. The basic ideas of MIP and SPV are that a metaphor can be identified when we discover the difference between its literal and contextual meaning, and that it can also be detected when its semantics is distinguishable from that of its context. To realize the concepts, for MIP, Choi et al. (2021) employ a target word's contextualized and isolated representations, while for SPV, they utilize the contextualized representations of the target word and the sentence including the word. We adopt some of their ideas and customize them for our purpose, i.e., modeling features for idiomaticity detection.

3 Proposed Method

As a participant of SemEval-2022 Task 2, we propose a framework powered on four features devised to facilitate the detection of idiomatic expressions. These features are computed by the same foundation model,[2] but distinguished from each other by what is inserted into the model as input to compute the features. A simple linear classifier is introduced on top of the concatenation of the four features to finally gauge the idiomaticity of an MWE in an input sequence. Figure 1 presents the overall picture of our method.

3.1 Features Based on Surrounding Context

We first focus on the fact reported by Tayyar Madabushi et al. (2021) that the *surrounding context*

[2]In this work, a 'foundation model' refers to a Transformer *encoder* pre-trained on large corpora, e.g., BERT and XLM-R.

(a.k.a. inter-sentence context), which we define as sentences located right before and after a target sentence, is uninformative in predicting idiomaticity. We hypothesize that this disappointing outcome is partly due to the way such context was exploited.

To be specific, given a sentence containing an MWE and its previous and following sentences, Tayyar Madabushi et al. (2021) propose simply putting all the three together in order. Despite its simplicity, this approach has an explicit drawback that a model should automatically learn how to distinguish the target sentence from its surrounding context. Moreover, when combined with context without caution, the input sequence becomes much (approximately $3\times$) longer than its original form, which might cause a negative effect on performance by merely intensifying the complexity of the problem rather than providing additional information.

To alleviate the aforementioned problems, we suggest a new approach of combining a target sentence with its context. Concretely, we first concatenate the target sentence with its ① previous and ② next sentences *respectively* (i.e., previous-target & target-next), and then inject each chunk into our encoder to derive $v_{\text{[CLS]}}$ and v_{MWE}. By doing so, we expect that the target sentence can be relatively more emphasized than its context, as the target sentence naturally appears twice while its context is exposed only once. Plus, by dividing the whole sequence into two parts, it is anticipated that the encoder struggles less to extract useful information from the input. Note that $v_{\text{[CLS]}}$ is the representation for the entire chunk, which is obtained by taking the [CLS] embedding from the last layer of the encoder, and that v_{MWE} is the average of the representations of the subwords that constitute the target MWE. Lastly, the final context-sensitive feature is computed by conducting a linear transformation of the concatenation of $v_{\text{[CLS]}}$ and v_{MWE}.

On the other hand, we propose two extra techniques in order to provide a clue on the location of MWEs. While constructing token-level representations for our encoder, we employ trainable segment embeddings that draw the line between tokens for the target MWE and others. Moreover, the target MWE is repeated at the end of each chunk, following Tayyar Madabushi et al. (2021).

3.2 Features Based on Inner-Sentence Context

Second, we consider adding features dedicated to more effectively leveraging the information embedded in the target sentence, regarding the MWE and its neighboring words as separate objects. We import some ideas from prior work for metaphor detection (Mao et al., 2019; Choi et al., 2021), exploiting the conceptual relationship between metaphors and idiomatic expressions.

Initially, we assume that similar to Metaphor Identification Procedure (MIP), whose core idea is that a metaphoric word's semantics become distinct from its lexical meaning when it is contextualized, we consider an MWE as idiomatic when its static and contextualized embeddings are heterogeneous. While the contextualized representation of the target MWE is already available from the features provided in Section 3.1, we have not yet introduced the MWE's static representations. To implement this, we again make use of the same encoder, however, only the MWE itself (removed from its context) is presented as input to the model. We call the output of this procedure the ④ *MWE-exclusive* representation, which becomes an ingredient for realizing the 'idiomatic' version of MIP. Note also that according to Garcia et al. (2021b), static models have been considered as competitive or even better to/than contextualized models for idiomaticity detection. Therefore, we aim to reinforce our framework by employing both the options.

Meanwhile, Choi et al. (2021) use Selectional Preference Violation (SPV) for metaphor detection, assuming that the semantics of a metaphoric word should be distinctive from that of its context.[3] We basically adopt their idea, but revise its implementation, arguing that their implementation might be somewhat defective. In detail, Choi et al. (2021) compute the embeddings of a target and its context exactly as we do when computing $v_{\text{[CLS]}}$ and v_{MWE} in Section 3.1. However, it is highly probable that $v_{\text{[CLS]}}$ and v_{MWE} contain similar information as they are intertwined with each other by the attention mechanism, which is undesirable when estimating separate semantics of the target and context. We thus introduce the ③ *context-exclusive* representation of the target sentence by providing our encoder with a variant of the sentence where the target MWE is masked. When combined with the features from the previous section, we expect that the inner-sentence context independent from the target MWE at all can be useful for applying the concept of SPV into idiomaticity detection.

[3]This time, we limit the scope of the context as the sentence emcompassing a target expression (i.e., inner-sentence context), following Choi et al. (2021).

Model / Lang.	English	Portuguese	Galician	Overall
Zero-shot setting				
Baseline (BERT)	70.70	68.03	50.65	65.40

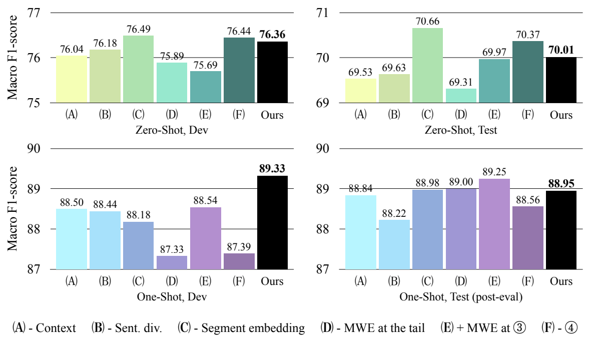

Figure 2: Ablation study.

4 Experiments

4.1 Experimental Setup

For all experiments, we present five instances per each model with the corresponding random seeds (42, 360, 2578, 5925, 9463). Each instance is trained for 10 epochs, and its best checkpoint which shows the top performance on the development set in terms of the macro F1-score is chosen for the inference of the test set. We use a max sequence length of 300, a learning rate of 3e-5 for the AdamW (Loshchilov and Hutter, 2019) optimizer, and a batch size of 16 for the training set and 8 for the validation and test sets. The vectors of each representation ($v_{\text{[CLS]}}$ and v_{MWE}) have 768 dimensions respectively and the learning rate is scheduled to linearly decrease after the second epoch. We leverage XLM-R(-base) (Conneau et al., 2020) as our foundation model.

4.2 Main Results

We compare the results of our method (submitted) against those of the baseline offered by the task organizers (Tayyar Madabushi et al., 2022). Although the original baseline is powered on Multilingual BERT(-base), for a comparison, we also report the performance of the baseline equipped with XLM-R(-base). Evaluation is conducted on the test set, and each model's performance is reported according to the language on which it is tested (English, Portuguese, and Galician) and the setting it is trained (zero- and one-shot).

From Table 2, we can see that both in the zero- and one-shot settings, our model largely outperforms baselines. Notice that in the zero-shot setting, our model outperforms the baseline powered on the same foundation model (XLM-R) by more than 16% in Galician. Considering that Galician was not included in the training data, this result confirms that our model is more generalizable than the baselines from the perspective of input language.

4.3 Ablation Study

We perform an ablation study to confirm whether the elements of our framework are significant. Note that all the results used for comparison are the average of the scores of different instances with five random seeds. Overall, when tested on the validation set, the final version of our approach succeed in outperforming most of the variations, especially in the one-shot setting where our decisions for selecting the final model were made. We present more detailed analysis in the following.

First, we compare our method with the variation (A) which uses only target sentences without surrounding context and the variation (B) which reflects the context by concatenating three sentences. Tayyar Madabushi et al. (2021), where the authors employ the variation (B), previously reported that it is not helpful for idiomaticity detection to consider the surrounding context of a target MWE. However, as shown in Figure 2, we find that taking the context into account following our approach (i.e., separating the context into two chunks) is in fact advantageous in all experimental settings. Furthermore, we observe that the deviation of the scores of our method is much smaller and more stable than that of not considering context. This implies that if there exists a data instance not having much information available from its target sentence, the surrounding context of the target sentence can complements the lack of information.

Contrary to our expectation, it is shown that our method is not always better than the three variations (C), (D) and (E). The variation (C) removes segment embeddings, the variation (D) stops the repetition of MWEs at the tails of ① and ②, and in the variation (E) the target MWE is recovered (not masked) in the computation of '*context-exclusive*' representation (③). We leave a detailed examination regarding these as a follow-up study.

Lastly, it turns out that the variation (F) which removes the '*MWE-exclusive*' representation (④), is more favored in the zero-shot setting. Unlike the one-shot setting, where a pair of positive and negative examples for a particular MWEs can be provided, the zero-shot setting requires the evaluation of MWEs not presented in the training set, which is a more harsher condition for idiomaticity detection models. Therefore, we conjecture that static representations for the MWEs unseen during training become a little bit noisy in the zero-shot setting, failing to function following our intention.

5 Discussion

5.1 Issue on Validation Set in One-shot Setting

In the one-shot setting, we expect that a pair of data instances (one for idiomatic and the other for non-idiomatic) per every MWE in the test set should be provided to the model we train. Likewise, if one wants to confirm that the validation set is rigorous enough to be a substitute for the test set in the procedure of selecting hyperparameters, every MWE in the validation set should have two corresponding instances in the training set. During the competition for SemEval 2022 Task 2, we have discovered that the necessary condition holds for the validation set in the practice phase, while **it does not hold in the evaluation phase**. In other words, the training set provided in the practice phase incorporated data instances that correspond to MWEs in the validation set. However, as the training set has been substituted with a new version, a problem has arisen where MWEs in the newly released training set do not match with those in the validation set. We conjecture that this discrepancy prevents one's optimal actions in choosing the best models.

To prove our hypothesis, we test a variant whose performance on the validation set is not optimal, but has the potential of working well when evaluated on the test set. Specifically, we replicate our experiments, but do not choose the best instance based on validation performance. Instead, we simply choose the model instance trained until 9 epochs and compare it to baselines. As shown in Table 2, we find that the instance chosen based on the validation set (i.e., ours (submitted)) is worse than the randomly selected one (i.e., ours (post-eval)), implying that the inappropriateness of the validation set in the evaluation phase might hinder correct comparisons between submitted models.

Form of MWEs	Validation	Test
Zero-shot setting		
Original form	76.34	**71.72**
Inflectional form	**76.36**	70.01
One-shot setting		
Original form	88.14	**89.80**
Inflectional form	**89.33**	88.95

Table 3: Performance gap with form changes in MWEs.

5.2 Impact of Form Changes in MWEs

When MWEs are repeated at the end of input sequences in ① and ② and embedded solely in ④ in our implementation, we copy them from target sentences so that we can preserve their inflectional form appearing in the sentences, rather than adopting their original form. To confirm the effectiveness of this approach, we conduct an experiment where we replace the MWEs with their original form.

From Table 3, we observe that unlike the case on the validation set where applying inflectional form is always helpful, it turns out that when evaluated on the test set, employing inflectional form is not beneficial for performance improvement, contrary to our expectation. The idea of having utilized the inflectional form of MWEs is from our conjecture that compositional and static representations of MWEs should be computed from the same form for a fair comparison between them. However, it seems that it is more effective to provide a model with a MWE's original form in addition to its inflectional form such that the model can extract more information from the both sides. We leave thorough analysis on this phenomenon as future work.

6 Conclusion

In this work, we investigate the method of implementing better idiomaticity detection models by considering different levels of contextualization. We propose four features grounded on the surrounding and inner-sentence context of a target MWE, showing that these features are effective in improving performance. Moreover, we present a discussion on the issue related to the validation set in the one-shot setting and the impact of the form of MWEs. As future work, we plan to develop a method of designing the interaction between related features in a more sophisticated fashion, instead of simply concatenating them.

Abstract

This paper describes our system for SemEval-2022 Task 2 Multilingual Idiomaticity Detection and Sentence Embedding sub-task B. We modify a standard BERT sentence transformer by adding embeddings for each idioms, which are created using BERTRAM and a small number of contexts. We show that this technique increases the quality of idiom representations and leads to better performance on the task. We also perform analysis on our final results and show that the quality of the produced idiom embeddings is highly sensitive to the quality of the input contexts.

1 Introduction

Idiomatic expressions present a challenge to Large Language Models (LLMs) as their meaning cannot necessarily be derived from the composition of their component tokens, a trait that LLMs often exploit to create representations of multi-word expressions. The lack of compositionality leads to poor representations for idiomatic expressions and in turn poor performance in downstream tasks whose data includes them.

SemEval-2022 task 2b (Tayyar Madabushi et al., 2022) encourages the creation of better representations of idiomatic expressions across multiple languages by presenting a **Semantic Text Similarity (STS)** task in which correct STS scores are required whether or not either sentence contains an idiomatic expression. The sub-task requires the creation of a self-consistent model in which a sentence including an idiomatic expression and one containing its literal meaning ('*swan song*' and '*final performance*') are exactly similar to each other and equally similar to any other sentence.

To achieve this goal, we investigate whether due to the similarity between idioms and rare-words Schick and Schütze's BERT for Attentive Mimicking (Schick and Schütze, 2020) (BERTRAM) model, which was designed for use with rare-words, can be used to explicitly learn high-quality embeddings for idiomatic expressions. We also investigate how many examples of each idiom are required to create embeddings that perform well on the task, as well as how the quality of contexts fed to the BERTRAM model effects the representations and performance on the task.

Evaluating our model on the task shows that externally trained idiom embeddings significantly increase the performance on STS data containing idioms while maintaining high performance on general STS data. This improved performance gained an overall spearman rank score of 0.6402 and first place (of six entries) on the pre-train setting, and an overall spearman rank score of 0.6504 and second place (of five entries) on the fine-tune setting.[1]

2 Background

Adopting the idiom principle (Sinclair, 1991) to produce a single token representation for MWEs has been used widely within static embedding distributional semantic models (Mikolov et al., 2013; Cordeiro et al., 2019). Within contextualised representation models, Hashempour and Villavicencio, 2020 show that the contextualised representations produced by context2vec (Melamud et al., 2016) and BERT (Devlin et al., 2019) models can be used to differentiate between idiomatic and literal uses of MWEs. However, the MWEs are only represented by one token in the input, before being broken into many tokens using BERTs word piece tokenizer. Tayyar Madabushi et al., 2021 add a token to the BERT embedding matrix and shows that this method improves representations through increased performance on their proposed STS task. The embeddings they add to BERT are randomly initialised, however, and only trained during the fine-tun step on limited data.

[1]The code for creating the embeddings and the modified baseline system code can be found on GitHub: https://github.com/drsphelps/semeval-task-2.

Usage	Example in Sentence
Idiomatic	Blockchains, fundamentally, are banking because what they're doing is allowing the transaction of value across networks … they're doing it in an orthogonally different way," he said Wednesday in what may be his **swan song** in public office.
Literal	Blockchains, fundamentally, are banking because what they're doing is allowing the transaction of value across networks … they're doing it in an orthogonally different way," he said Wednesday in what may be his **bird song** in public office.
Semantically Similar	Blockchains, fundamentally, are banking because what they're doing is allowing the transaction of value across networks … they're doing it in an orthogonally different way," he said Wednesday in what may be his **final performance** in public office.

Table 1: Example sentences for the Idiomatic STS data. Idiomatic and Semantically similar should be given an STS score of 1, and be given the same score when compared to the literal use.

2.1 BERTRAM

BERT for Attentive Mimicking (BERTRAM) (Schick and Schütze, 2020), originally developed to improve representations of rare words, builds upon attentive mimicking (Schick and Schütze, 2019) to create embeddings, within existing embedding spaces, for tokens that incorporate both form and context information from a small number of example contexts. During training the model attempt to recreate embeddings for common words with the existing embedding in the model treated as the 'gold embedding', a process known as mimicking. Form embeddings are then learnt using trained n-gram character embeddings, before being passed with a context into a BERT model. The output of the BERT model forms the embedding for that specific context. To incorporate knowledge from many contexts an attention layer is applied over the outputs for each context to get the final embedding. There exist other models to produce effective embeddings from a small number of contexts (Zhao et al., 2018; Pinter et al., 2017), however, BERTRAM is the only model that is non-bag-of-words and incorporates both form and context information when creating the embedding.

Rare words are unsurprisingly defined by how uncommon they are within datasets. This leads to problems when using LLMs on tasks involving rare words as the word pieces they are broken down into have not been influenced enough during pre-training to accurately represent them. Similarly, idiomatic phrases represent a small proportion of the usage of their constituent words, the idioms in the development set for this task represent an average of 4.9% of the usage of their constituent words. Therefore, the embeddings for constituent words are not significantly effected by the usage of idioms in the training data, leading to the model failing to understand the idiomatic expressions. Further similarities between idioms and rare-words include the variance in compositionality, for example, *unicycle* can be partially understood from its word pieces, whereas *kumquat* cannot.

3 Methodology

3.1 Embedding Creation

Due to the similarities between rare words and idioms, we use BERTRAM to create representations for idiomatic expressions. A separate BERTRAM model is used for each nof the tasks languages. For English, we use the pre-trained model provided with the original paper. For Portuguese and Galician we train BERTRAM models with BERTimbau Base (Souza et al., 2020) and Bertinho-Base (Vilares et al., 2021) respectively used as the base transformers. The Portuguese and Galician BERTRAM models that we train are trained using almost the same training regime outlined for the English model in the original paper, 3 epochs of context only training, 10 epochs of form only training and 3 epochs of combined training. Due to time and compute restrictions, we do not use One-Token Approximation to expand the number of gold standard representations that can be used for attentive mimicking. The Portuguese and Galician splits of the cc100 dataset (Conneau et al., 2020; Wenzek et al., 2020) are used to train the models, with the entire split being used for Galician, and a 10GB subset used for Portuguese.

Contexts for each of the idioms found in the task data can then be created using these models. Examples are retrieved from the relevant split in the cc100 dataset using a grep command [2] that retrieves the entire line that the instance of the idiom is found on. We investigate how changing the number of contexts used to create each embeddings

[2] *grep -i " $val" -m250 en.txt > $val.data*, where $val is the idiom of interest

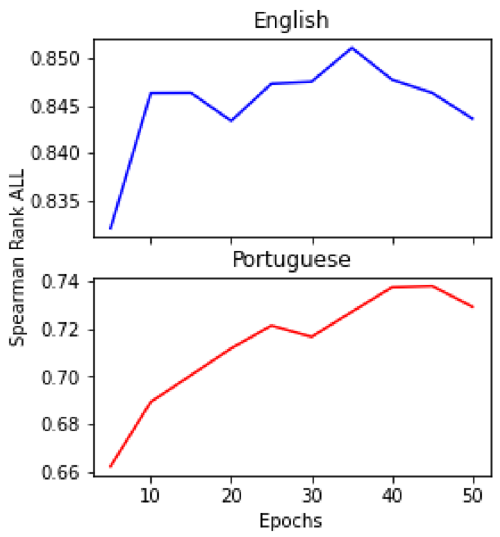

Figure 1: Overall Spearman Rank performance on the development set for the English and Portuguese models at different epochs during pretraining

changes our performance on the task by creating embeddings for each idiom with between 1-250 examples in intervals.

3.2 Model Architecture

For predicting the similarity scores, a separate model is used for each of the languages BERT-Base (Devlin et al., 2019) for English, BERTimbau for Portuguese, and Bertinho-Base for Galician. The created BERTRAM embeddings for each of the idioms found within the task are added into the embedding matrix of the relevant model. These models are used within a Sentence BERT (Reimers and Gurevych, 2019) setup, implemented using the SentenceTransformers library, which consists of a siamese network structure that uses mean squared error over the cosine similarities of the input sentences as it's loss function. This allows us to use the contextualised embedding outputs of our BERT networks to find cosine similarity between a given pair of sentences.

3.3 Data

This sub-task uses data in English, Portuguese and Galician. Data is also split into general STS data which does not necessarily contain idioms and idiom STS data which specifically contains idioms and phrases which are semantically similar or literally similar. An example of idiom STS data taken from the task description can be seen in Table 1.

English and Portuguese are the primary languages and general STS data, from STSBenchmark

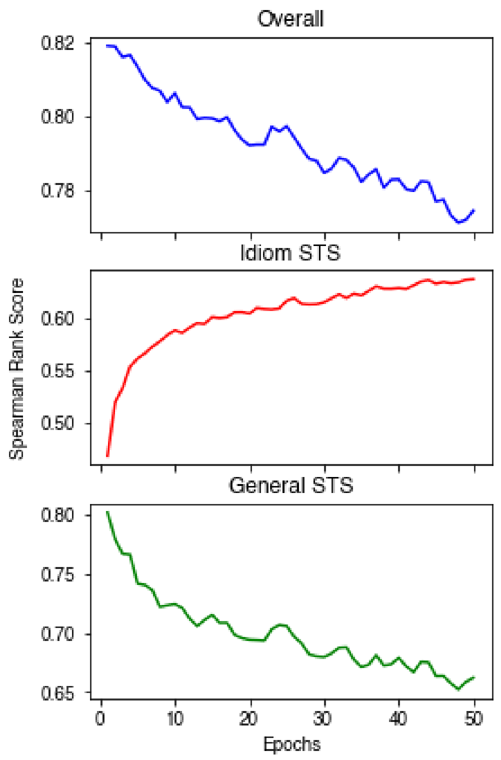

Figure 2: Overall and Idiom STS Only Spearman Rank on the development set whilst training on the Idiom STS data

(Cer et al., 2017) and ASSIN2 (Real et al., 2020) for English and Portuguese respectively, and idiom STS data for both languages are included in the train, dev, eval and test sets. A very small amount (50 examples) of Galician data, comprised of idiom STS data, is also included in the test set.

The task is split into two settings, pre-train and fine-tune. The pre-train setting does not allow for the use of STS score annotated data which includes idioms, whereas any data can be used in the fine-tune setting.

The evaluation metric used in this task is the correlation between the predicted similarities and the gold standard ones, calculated using Spearman's Rank Correlation Coefficient. The Spearman's Rank is calculated for the general STS data and the idiom STS data separately, however, the Spearman's Rank for the entire dataset is used in the final evaluation.

3.4 Pre-train Setting

For the pre-train setting, we use the general STS data in English and Portuguese to train the respective models. Due to a lack of available STS data for Galician, it is trained on the Portuguese data, as

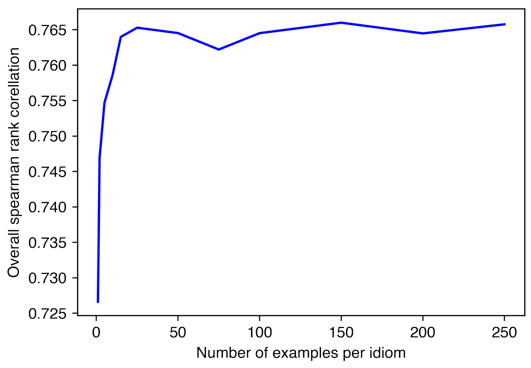

Figure 3: Overall Spearman Rank corellation score on the development set with different numbers of examples used to create the idiom embeddings.

there is a high level of similarity between the two languages.

Evaluating the models on the dev split, we investigate the optimal number of epochs for the English and Portuguese models. The results (shown in figure 1) show that 45 epochs are optimal for Portuguese and 35 for English. Due to a lack of dev split data for Galician we use the result from the Portuguese model as they are trained on the same data.

3.5 Fine-tune Setting

For the fine-tune setting we start with the models from the pre-train setting, and further train them on the Idiom STS data provided as part of the task.

Again we investigate the optimal number of epochs of training on this data (results shown in figure 2). We find that the overall spearman rank is highest after just a single epoch of training, with further training considerably reducing the performance on the general STS data, and thus on the overall STS score. However, further training, up to 50 epochs, continues to increase the performance of the model on Idiom STS data. Therefore, depending on the application and required trade-off, the model can be tuned to either perform better on general STS data or idiom STS data.

3.6 Number of Examples

We also tune the number of examples given for each idiom on the development data. Using BERTRAM we train embeddings for each of the idioms using a range of different numbers of examples from 1-250. The performance of each set of embeddings is evaluated by training the whole system for 10 epochs followed by evaluation on the dev set. Figure 3 shows the results of this experiment. The performance increases quickly from 1-15 examples before flattening out. The absolute highest performance is achieved at 150 examples, and so this is the value we use going forward.

4 Results

The final results for our system on the test data can be seen in Table 2. These scores show significant improvement over the baseline system and led to our system being placed first for the pre-train setting, and second for the fine-tune setting.

Fine-tuning has a much lower effect on the performance of the system when evaluated on the test set than compared with the dev and evaluation sets, with only a small, but significant, rise in overall correlation. Performance rises by only 0.0198 and 0.022 for English and Portuguese respectively, and unlike on dev data we do not see a uniform increase on the SR Idiom score.

4.1 Galician Performance

The performance we achieve on the Galician idiom data is much lower than what is seen on the English and Portuguese data. As we didn't have access to any development data for Galician further investigation will be needed to identify the causes of this discrepancy. Due to the smaller amount of Galician data in the cc100 corpus, some idioms did not have the full 150 examples that were used to create the embeddings for the English and Portuguese idioms. Additionally, there was no Galician STS data to train the final model on, and even though Portuguese and Galician are very similar, the small difference may lead to differences in the performance.

4.2 Error Analysis and Data Issues

To perform analysis on the quality of the created representations we calculate the Spearman's Rank Correlation for each of the idioms in the development set individually. Any idioms with less than 5 occurrences in the development data are removed, as significant correlation scores cannot be achieved with such a low sample size.

When evaluating the performance of the idioms individually, we can see that some of the idiomatic expressions perform much worse than average. For example the spearman rank for score for 'fish story' is just 0.190 when the embedding is trained on 10

random examples.

Analysis of these errors shows that the lower performance can, at least in part, be attributed to different phrase senses in the automatically collected examples. Taking our above example '*fish story*', 3 different phrase senses can be observed in the original randomly selected examples: a tall tale, a literal story about fish, and as a proper noun in the title of the film 'A Fish Story'. This leads to a divergence in the contexts in the examples, and the contexts for the idiomatic uses, leading to worse embeddings for the idiomatic phrases.

We can explore this further by producing a manually collected gold standard example set, for the English language subset of the MWEs. Taking the original 250 examples for each idiom, we select 10 gold standard examples. To avoid overfitting our embeddings to this task, we only manually remove examples where the MWE is being used as a proper noun (e.g. the film 'A Fish Story'), or the idiom is being misused, leaving in correct literal and idiomatic uses of the phrase. After removing the proper noun and misused cases, 10 random examples are selected to form our 'gold standard' example set.

We then compare the spearman scores achieved when the embeddings are trained with the gold standard examples, to scores when the representations are produced using 10 random examples when both models are evaluated on the English split of development set. The results for selected MWEs with the randomly selected (auto) and manually chosen (manual) contexts can be seen in table 3.

The manually selected examples lead to an increase in performance on the Idiom STS data split from 0.406 to 0.450. A small increase from 0.841 to 0.848 overall on the English split can also be observed, however this performance is limited by the general STS score which is unaffected by our manual selection. Particularly large improvements in spearman rank coefficient can be seen on MWEs with multiple meanings (panda car, banana republic, fish story, etc.). Surprisingly, we actually see the performance on some MWEs fall, however this can likely be attributed to the random selection of examples, and variance in the contexts used for each idiom, especially on the MWEs which did not have many usages removed as they are only used in the idiomatic form (eager beaver, chain reaction, etc.).

5 Conclusion

We build our system by augmenting BERT models for each language with single token embeddings learnt using BERTRAM. BERTRAM is used due to its high performance on rare words, which share many properties with idioms such as non-compositionality and being rare examples of com-

ponent pieces. Our results, and subsequent ranking at first place (of six entries) in the pre-train setting and second place (of five entries) in the fine-tune setting, show that BERTRAM can learn high-quality word embeddings for idioms and that this leads to better performance on downstream tasks. Our error analysis shows that BERTRAM is sensitive to the quality of examples it is shown, and that performance can be improved even further by manually selecting a gold set of contexts for each idiom. Future work could look at the differences in performance between the Portuguese and Galician models with the goal of increasing performance on Galician, and perform more analysis to explore the discrepancy in performance between individual idioms further.

Abstract

Large Language Models have been successful in a wide variety of Natural Language Processing tasks by capturing the compositionality of the text representations. In spite of their great success, these vector representations fail to capture meaning of idiomatic multi-word expressions (MWEs). In this paper, we focus on the detection of idiomatic expressions by using binary classification, based on Subtask A of SemEval-2022 Task 2 (Tayyar Madabushi et al., 2022). Thereafter, we perform the classification in two different settings: zero-shot and one-shot, to determine if a given sentence contains an idiom or not. N shot classification for this task is defined by N number of common idioms between the training and testing sets. In this paper, we train multiple Large Language Models in both the settings and achieve an F1 score (macro) of 0.73 for the zero-shot setting and an F1 score (macro) of 0.85 for the one-shot setting. An implementation of our work can be found at https://github.com/ashwinpathak20/Idiomaticity_Detection_Using_Few_Shot_Learning.

1 Introduction

Transformer-based Large Language Models (LLMs)(Kant et al., 2018) like BERT, DistilBERT, RoBERTa and their variants show state of art performance on a large number of NLP tasks, yet, they fail to capture multi-word expressions such as idioms. This is because contextualized pre-trained models learn compositional representations of text at sub-word and word level to reduce the vocabulary size.

Therefore, we evaluate how well do LLMs identify idiomatcity by formulating the problem as a classification task.

In this paper, we propose an approach for Subtask A of SemEval-2022 Task 2 (Tayyar Madabushi et al., 2022). We treat the development data as held-out development data, and report our performance on the test data. To evaluate how well LLMs identify idiomaticity, we use two different settings to determine the generalizability of the LLMs: zero-shot and one-shot setting. The zero-shot setting is defined such that the MWEs in the train set are mutually exclusive of the MWEs found in the test set. For the one-shot setting, there is only one Idiomatic and/or one Literal training example for one MWE in the development set. This is different from traditional definitions of zero-shot and one-shot classification.

The rest of the paper describes the related works in section II and the dataset used in Section III. Section IV gives the methodology used in zero-shot and one-shot learning. Section V describes the performed experiments and Section VI discusses the results. Section VII concludes the paper with a discussion on future research prospects and directions.

2 Related Work

Idiomaticity identification for MWEs has been widely studied for single token representation using statistical and semantic methods (Lin, 1999; Baldwin and Villavicencio, 2002).

Recent works use contextual representations without any token representation for idiomaticity identification for MWEs (Hashempour and Villavicencio, 2020). (Tayyar Madabushi et al., 2021) introduces new tokens for MWEs into a contextual pre-trained language model. However, they do not explore the relationship of potential MWEs in a sentence.

To this end, we present a contextual and compositional network incorporating latent semantic

[*] Equal contribution
[†] Corresponding author

significance of MWEs in a sentence. Using word embeddings for semantic similarity have been explored before (Katz and Giesbrecht, 2006). However, the challenge for the semantic usage identifcation of MWEs lies in the ambiguity in meanings of MWEs. Additionally, low frequency occurrences of MWEs inhibit the models to effectively learn the contextual representations as well.

Siamese Networks have been widely used for similarity detection and difference tracking. We propose to carry forward this idea for identification of idioms in MWEs by comparing the literal usage of MWEs from their idiomatic usage. This enables our approach to learn a contextual and compositional structure within a sentence.

3 Method

SemEval 2022 task 2 Subtask A (Tayyar Madabushi et al., 2021, 2022) is a task to evaluate the extent to which models can identify idiomaticity in text through a coarse-grained classification into an "Idiomatic" or "Non-idiomatic" class. To better evaluate a model's ability to generalise and learn in a sample efficient fashion, the scores are reported in the zero-shot and one-shot setups.

Data

The dataset used in this report is the one provided by (Tayyar Madabushi et al., 2021). Each of the train and development splits of this dataset consists of samples containing a target sentence, it's language information, a multiword expression (MWE), two contextual sentences that occur before and after the target sentence, and a label associated with the target. The label represents whether the multiword expression was used in an idiomatic sense or not.

The train split is further divided into zero-shot and one-shot data, containing 4491 and 140 samples each, consisting of 236 and 100 distinct MWEs respectively. Similarly, the development data contains 739 samples made from 50 different MWEs. One-shot MWEs have no overlap with zero-shot ones. However, development data MWEs are a proper subset, as can be expected in a one-shot classification scenario.

Zero-shot learning

For the zero-shot learning task, we use the train data to build a classifier using large language models like BERT-multilingual-uncased, DistilBERT-multilingual-uncased, XLM-RoBERTa-large and XLM-net. This task is "zero-shot" in nature as the idioms used in the train set and the development set are distinct. Therefore, we capture the discrepancy in the contextual meaning for idiomaticity, that is, we aim that our classifier distinguishes on the basis of lack of semantic correctness of literal meaning in the presence of an idiom in a sentence.
To make sure that idioms are not used explicitly while pre-training in large language models, we run a natural language inference task on BART-Large-MNLI and RoBERTa-Large-MNLI with the hypothesis as "idiom". The macro F1 score for both approaches is 0.51 and 0.50 respectively, which proves that there is no semantically learnt concept of "idiomaticity" by the model. No training data was used for this step.

We therefore use multilingual LLMs to build classifiers for this setting. We need multilingual classifiers as the data consists of idioms in three languages: English, Portuguese and Galician. We further analyse the majority voting approach on the predictions of trained classifiers (inference based ensembling).

Figure 1: One-shot learning framework

One-shot learning

In the one-shot setting, we use the only positive and/or the only negative training example, as available for each MWE in the development set. Note that the actual examples in the training data are different from those in the development set in both settings.

As shown in Fig 1, our model relies on finding similarity or relation scores between two input sentences. We first train this model on the pretext task of predicting whether two sentences with the same MWE belong to the same class. To achieve this goal, we employ contextual word embeddings to encode two sentences into feature vectors via an embedding function f_θ. The feature vectors are then combined with an operator $\mathcal{O}(.,.)$ to output $\mathcal{O}(f_\theta(x_i), f_\theta(x_j))$ on two inputs x_i and x_j. This is finally passed to a similarity/relation function g_ϕ to give score $s_{i,j}$ as,

$$s_{i,j} = g_\phi(\mathcal{O}(f_\theta(x_i), f_\theta(x_j)))$$

We test this framework with two underlying models - a Siamese Neural Network (Koch et al., 2015) and a Relation Network (Sung et al., 2018). With the Siamese Network, the operator $\mathcal{O}(.,.)$ is the element-wise difference between the two input feature vectors. The function g_ϕ is a fully connected layer followed by sigmoid activation. The loss in this case can be defined as, $L(s_{i,j}) = \Sigma_{i,j} 1_{y_i=y_j} \log(s_{i,j}) + (1 - 1_{y_i=y_j}) \log(1 - s_{i,j})$, where y_i and y_j are the labels associated with x_i and x_j. Similarly, for the Relation Network, $\mathcal{O}(.,.)$ becomes the concatenation operator, g_ϕ becomes three fully connected layers with non linear activations followed by a sigmoid activation function. The loss in this case is the MSE loss, $L(s_{i,j}) = \frac{1}{n}\Sigma_{i,j}(s_{i,j} - 1(y_i == y_j))^2$. In both of the models, x_i, x_j pairs are samples with matching MWEs.

We propose a novel inference methodology for our binary classification problem, where we also consider a dissimilarity score $1 - s_{i,j}$, with x_i, x_j belonging to support and query sets respectively. Support set is defined to be all samples with the same MWE as the query. We find the maximum of similarity and dissimilarity scores for all examples in the support set, and assign the same label or the opposite depending on whether the maximum was the similarity or the dissimilarity score. This helps us with (Tayyar Madabushi et al., 2021) dataset where one-shot training data doesn't have samples for both the classes (idiomatic and non-idiomatic) for all MWEs.

4 Experiments

Zero-shot learning

We run our experiments on pre-trained models for zero-shot classification. We use Multilingual BERT, Multilingual DistilBERT, BERT-Portuguese, XL-Net and XLM-RoBERTa for exhaustive comparison and evaluation. We ensemble XL-NET, XLM-RoBERTa, and Multilingual DistilBERT in a majority vote based setting. As per the SemEval task, our baseline is Multilingual BERT for classification.

One-shot learning

For the contextual embeddings, we run our experiments on pre-trained compositional multilingual base models BERT, DistilBERT and XLM-RoBERTa for exhaustive comparison and evaluation. We run Siamese networks with cross entropy loss and Relation Networks with an MSE loss.

Our hyperparameter search pointed towards a dropout rate of 0.5, a learning rate of 2e-5 and we found AdamW to be the best performing optimizer.

5 Results

LN	Model	Dev F1
EN	BERT	0.65
EN	DistilBERT	0.70
EN	XLM-RoBERTa	**0.73**
EN	XL-NET	**0.73**
EN	Ensemble	0.71
PT	BERT	**0.64**
PT	DistilBERT	0.58
PT	XLM-RoBERTa	0.63
PT	XL-NET	0.62
PT	Ensemble	0.53
EN-PT	BERT	0.67
EN-PT	DistilBERT	0.70
EN-PT	XLM-RoBERTa	0.71
EN-PT	XL-NET	**0.73**
EN-PT	Ensemble	0.68

Table 1: Zero-shot evaluation results

LN	Emb Model	Siamese F1	Relation F1
EN	BERT	0.79	**0.85**
EN	DistilBERT	0.79	0.83
EN	XLM-RoBERTa	0.83	**0.85**
PT	BERT	0.81	0.84
PT	DistilBERT	0.80	**0.85**
PT	XLM-RoBERTa	0.85	**0.85**

EN-PT	DistilBERT	0.79	0.84
EN-PT	XLM-RoBERTa	0.84	**0.85**

Table 2: One-shot evaluation results

Zero-shot learning

Table 1 shows F1-scores for different configurations, both ensemble and individual language models, with the baseline model being Multilingual BERT. We observe that the ensemble model performs better than the baseline in case of EN (0.71 F1 score) and EN-PT (0.68 F1 score) as compared to PT (0.53 F1 score) data. We further observe that

Setting	Language	Test F1
Zero-shot	EN	0.7869
Zero-shot	PT	0.7201
Zero-shot	GL	0.5588
Zero-shot	EN,PT,GL	0.7235
One-shot	EN	0.8410
One-shot	PT	0.8162
One-shot	GL	0.7918
One-shot	EN,PT,GL	0.8243

Table 3: Test evaluation results

XL-NET outperforms other models in case of English and Portuguese inputs. Our best performing zero-shot setting results in a 0.72 F1 score on the test split of the dataset,, which is a significant boost from the 0.65 F1 score in the baseline provided by (Tayyar Madabushi et al., 2021).

One-shot learning
Table 2 reports F-1 scores for one-shot learning. We found the best results of our Siamese and Relation network with XLM-RoBERTa (0.85 F1-score). We also observed a better score for Portuguese dataset as compared to English dataset on all of our models. Our best performing relation networks get 0.82 F1 score on the test split, which is competitive with (Tayyar Madabushi et al., 2021).

Table 3 breaks down our test set evaluation results by language. GL in the table stands for Galician, which had data only in the test split.

6 Analysis and Conclusion

In this paper we analyzed the effectiveness of large Language Models towards identifying idiomaticity in a given phrase using zero-shot and one-shot classification tasks.

In zero-shot classification, we use inference-level ensembling of different language models and observe that it outperforms BERT baseline in cases where the input language consists of English. This highlights a high degree of disagreement amongst the language models w.r.t Portuguese input, highlighting their brittleness.

For one-shot classification, through Siamese and Relation Networks, we are able to represent the latent semantic relationship among MWEs leading to a much better F1 score than zero-shot classification and competitive with prior work. We believe that the improvement in performance of the relation network comes due to the learn-able nature of the distance function used between query and support data sample, as well as our novel inference methodology which also takes into account the dissimilarity score. Future work for one-shot classification could aim at breaking the barrier of 0.85 F1 score we seem to have hit on the dev set with all embedding base models.

CardiffNLP-Metaphor at SemEval-2022 Task 2: Targeted Fine-tuning of Transformer-based Language Models for Idiomaticity Detection

Joanne Boisson and **Luis Espinosa Anke** and **Jose Camacho Collados**
School of Computer Science and Informatics
Cardiff University
`BoissonJC@cardiff.ac.uk`

Abstract

This paper describes the experiments ran for SemEval-2022 Task 2, subtask A, zero-shot and one-shot settings for idiomaticity detection. Our main approach is based on fine-tuning transformer-based language models as a baseline to perform binary classification. Our system, CardiffNLP-Metaphor, ranked 8th and 7th (respectively on zero- and one-shot settings on this task. Our main contribution lies in the extensive evaluation of transformer-based language models and various configurations, showing, among others, the potential of large multilingual models over base monolingual models. Moreover, we analyse the impact of various input parameters, which offer interesting insights on how language models work in practice.

1 Introduction

Idiomatic language identification is an important task for language understanding. Recent language models are surprisingly accurate at distinguishing literal and figurative use of language, but very little work has been done on measuring their ability to generalize across languages. Even for mainstream languages such as English, there is still little understanding on the way language models process idiomatic expressions (IE's). This SemEval task (Tayyar Madabushi et al., 2022) focuses, in particular, on multi-word expressions (MWE), adding the challenge of representing such expressions in models.

The Subtask A of SemEval Task 2 invited participants to extend the range of existing experiments for multilingual idiomatic language detection. Data were provided in English, Portuguese, and Galician. The task is framed as a binary classification of MWE between an idiomatic and a literal usage. In the zero-shot setting, no Galician example is provided in the training and development set. The MWE of the development, evaluation and test sets are unseen in the training set. In the one-shot setting, exactly one example of the MWE encountered respectively in the practicing and test phase is added to the training data. Therefore, these settings provide a challenging framework in which language models have to learn from few or no examples.

As part of the CardiffNLP-Metaphor team, we used a simple strategy similar to the method employed in the original paper releasing the dataset Tayyar Madabushi et al. (2021). In particular, we assessed the performance of monolingual and multilingual language models on the task. To this end, we compared the performance of these models using different input formats and training parameters. The best results are obtained with a XLM-RoBERTa large (Lample and Conneau, 2019) with 7 epochs, 8 instances per batch, a maximum sequence length of 350, the longest three-sentence context, and including target information (i.e., the embedding and the position of the target in the sentence). Our submitted model was based on the best performance in the development set across both tasks, using a wide range of different inputs and parameters.

Our system ranked 8th with a best f1-macro score of 0.7378 for the zero-shot competition and 7th with a score of 0.8934 for the one-shot competition.[1] The main contributions of this paper are the following:

- We show that the multilingual large RoBERTa model (Liu et al., 2019) performs better than monolingual and base models on the one-shot track, which differs from what was found in the original paper (Tayyar Madabushi et al., 2021).
- We found that XLM-RoBERTa base and large can be unstable, also in comparison with simi-

Table 1: Dataset description. Number of example for each language and percentage of idiomatic MWE expressions. The labels of the evaluation and test sets are unknown.

lar models. This could also explain the difference in our conclusion and that of Tayyar Madabushi et al. (2021) after exploratory runs with large models.

- We confirm the importance of providing the embeddings of the MWE separately to the model, and running a relatively large amount of epochs (up to 9 leads to improvements). Our best model is obtained with seven epochs.

- We test various input formats, including maximum sequence length and context length, and the impact of shuffling the training data on the results, allowing us to discuss the results obtained in previous experiments with this dataset.

2 Related Work

In this task, idiomatic expressions are either frozen (well-known) metaphors, or frozen noun compounds involved in longer metaphors. This dataset relates to other datasets labelled for metaphorical usage of words such as the VU Amsterdam corpus (VUAC) (Steen, 2010) used in a SemEval 2020 task (Leong et al., 2020). However, such datasets are not restricted to idioms or compounds. All the words occurring in texts are labeled. This could ultimately lead to a design of NLP tasks focusing on idioms, but has in the main been used for the predictions of metaphors at the word level. Other metaphor datasets built for NLP such as the LCC corpus (Mohler et al., 2016) may contain some MWE but are not focusing on the specific issues posed by idioms, and also include creative metaphors in their scope.

To the best of our knowledge, there are other five datasets particularly designed for the study of the compositionality of MWE in context in English. The idioms in context (IDIX) corpus (Sporleder et al., 2010) includes idiomatic constructions with non consecutive words (e.g. *raise* one's *eyebrows*) and the phrasal verb corpus (Tu and Roth, 2012) is restricted to *V+PRP* constructions. The SemEval 2013 Task 5b on phrasal semantics is very similar to the task addressed this year, with a division between *known phrases* and *unknown phrases* settings within the binary classification task, but restricted to English. More recently, the MAGPIE corpus (Haagsma et al., 2020), a large repository of 56,622 sentences containing potential idiomatic expressions has been shared with the NLP community. The selection of its initial list of idioms differ from our dataset: after a semi automatic selection of idiomatic expressions, a crowdsourced annotation approach is adopted to determine whether the expression is used metaphorically or literally. In a similar design than the dataset used for Subtask B, Zhou et al. (2021) constructed a curated dataset of sentences pairs: one element containing an idiomatic expression and the second element being the same sentences with the IEs replaced by its literal paraphrase.

As for its connection with language models, Garcia et al. (2021) compared various language models for probing idiomaticity in vector space models. In this work, we go beyond the capabilities of vector space models and test the capabilities of finetuning multilingual language models on the task. The most related work to our analysis is perhaps that done by Zeng and Bhat (2021). They proposed a neural architecture that uses attention flow, designed for the task of detecting whether a sentence has an idiomatic expression and localizing it when it occurs in a figurative sense.

3 Data

Our team participated in Subtask A (zero and one-shot tracks) of the SemEval-2022, Task 2 on Idiomaticity Detection (Tayyar Madabushi et al., 2022). The tasks tackles binary classifiation of MWE in three languages, with variable amount and type of data seen in the training set by the model. Table 1 summarizes the distribution of the instances per language and label. The MWE are all noun compounds, sourced from the Noun Coumpound Senses dataset (Cordeiro et al., 2019).The examples consists of excerpts of text of the Web.

As shown in Table 2, literal instances in our task

Table 2: Examples of labelled instances with their original four labels in Tayyar Madabushi et al. (2021) and grouping to two labels idiomatic/non-idiomatic for the SemEval binary classifiation Subtask A.

include *non-idiomatic* use of MWE and *proper nouns*. Idiomatic instances gathers *idiomatic* use and *literal use within a longer metaphor*.

The experiments are organized along six splits of the data (c.f. Table 1) : training zero-shot, training one shot for evaluation phase, training one shot for test phase, development, evaluation and test sets. Labels were provided to the participants for the training and development sets. The practice and test phase were run on Codalab.

4 System overview and experiments

4.1 System configurations

We test two different configurations to address this binary classification task: one multilingual classifier trained on all the training data at once, and one monolingual classifier per language. For the zero-shot setting in the monolingual classification configuration, we do not have any training examples of Galician. Therefore, we replace the Galician model by a multilingual model trained on the English and Portuguese examples.

We use well-known transformer-based language models: English, Portuguese BERT and Multilingual BERT (Devlin et al., 2019), XLM-RoBERTa base and large (Conneau et al., 2020). For the monolingual models of Galician, we use Bertinho Vilares et al. (2021) model[3], trained on Wikipedia. The cased version of the language models is used in all our experiments, following Tayyar Madabushi et al. (2021) and because the target MWE contain proper nouns.

4.2 Preprocessing

The data are preprocessed to find all the occurrences of the expressions and record their positions in the three sentences provided for each instance of the datasets.

We search for lower case and upper case occurrences, with words separated by a space or a hyphen. Only in the cases where an exact match cannot be found, we also rely on their lemmata to identify MWEs in plural form. For this, we relied on Stanza[4], which covers the three languages of the experiments including Galician.

We find 80% instances with only one occurrence, and 20% with multiple occurrences in the training and development sets. We considered contexts of one or three sentences (the previous and following sentence in the latter case). The positions of the target are recorded for both contexts length. We then generate two versions of tagged sentences, one where only the first occurrence of the target in the core sentence is marked and one with all the occurrences are marked, using special tokens.

4.3 Experiments

All the experiments are done using the Simple Transformers library[5] with a Quadro RTX 8000 GPU. In order to analyse the effect of several variables in the performance, we performed the following experiments on the development set.

Experiment 1: Shuffling the training set. We study the variation of the performances for three seeds (1,2,3), after three shuffles of the training set (A, B, C), for different batch sizes (8, 16, 32, 64). Our goal is to distinguish the variations in the performances due to various parameters modifications from the variation induced by the order in which instances are fed into the model during training.

Experiment 2: Context and input format. A context limited to the core sentence provided for each example (noted *core-sent* in Table 4) is compared to the concatenation of this core sentence with its previous and following sentence (noted *3-sent*). Different maximum sequence lengths (128, 300, 350, 400, 512) are also tested.

We further test the various ways to encode information about the target and its position in the

[3]Huggingface ID: dvilares/bertinho-gl-base-cased

[4]`https://stanfordnlp.github.io/stanza/`

[5]Version 0.62.0, `https://simpletransformers.ai/`

sentence: tagging only the first occurrence of the target in the core sentence (*first*) is compared to tagging all the occurrences of the target within the input text (*multiple*); one option allows the embedding of the target expression to be passed to the model independently from the sentence (*pair*).[6]

When the *tagged* and the *pair* parameters are both set to *False*, the sentence is provided to the model without any indication concerning the target. This baseline configuration is very interesting in order to evaluate the impact of the topic of the text on idiom detection. For example, in the training data, all the occurrences of *blood bath* are idiomatic except for one occurrence of a proper noun (c.f. Table 2). *Blood bath* is more likely to be used idiomatically than literately in many corpora, as long as they are not rare domain-specific archives on vampires relaxing habits. On the contrary, all 21 occurrences of *marketing consultant* are literal.

Experiment 3: Monolingual and multilingual models. Monolingual and multilingual language models are compared with the two configurations introduced in Section 4.1. In this experiment, we measure the ability of the multilingual models to transfer knowledge across English and Portuguese with a comparison between two additional training methods, bringing the experiment to a comparison between three configurations:

1. Fine-tuning monolingual BERT models for English and Portuguese, and Galician for the one-shot setting. Data are split by language, three classifiers are trained.

2. Fine-tuning three multilingual models using the same settings as in 1.

3. Fine-tuning one single monolingual model, with all the data in the two languages for the zero-shot track and three languages for the one-shot track

Experiment 4: Language models size. Previous initial experiments from Tayyar Madabushi et al. (2021) concluded that large models were not performing better than base models, after a few attempts. We explore further the performance of large models in comparison with base ones under various classifier parameters and for different shuffles of the training set.

[6]Table 7 in the Appendix includes more details about the input formats.

Zero-shot					
train set	seed	Batch size			
		8	16	32	64

Table 3: Experiment 1. Results of XLM-RoBERTa base with 1 epoch, max-seq-length=128, for 3 data shuffles and 3 random seeds. A context of 1 sentence is used, with multiple occurrences of the target tagged, and the MWE embedding provided separately to the classifier (pair). Displayed scores are F1-macro for the development set, aggregated for both English and Portuguese.

5 Results

During the exploratory phase, we tested 111 different parameter configurations, shuffling the data before each run. The twenty best models (sorted according to their performances in the one-shot setting) are shown in Table 8 in the Appendix[7]. These results are used in complement to the following experiments for drawing our conclusions.

Experiment 1: Shuffling the training set. With XLM-RoBERTa-base, Table 3 shows that the classifier is very sensitive to the order in which the input data are passed to the model. When the model does not attribute the same label to all instances of the development set, it may vary by 2 points for a given random seed. The model fails to converge for

[7]The complete results are available in the GitHub repository of this paper `https://github.com/Mionies/CardiffNLP-SemEval-2022-Task2/blob/main/param_optimization_shuffe/data.csv`.

Table 4: Experiment 2. Contextual and input format parameters. This experiment is run with XLM-RoBERTa-base, 3 epochs, a batch size=8, max-seq-length=512, a lr=4e-05, on 3 seeds with training set shuffle A (c.f. Experiment 1). The results obtained with the best seed is displayed. An average over the three seeds was impossible because the model often does not converge. The metric used is F1 macro, computed on the development set.

Languages		Zero-shot		
Pre-train	Fine-tune	EN	PT	EN,PT
mono	mono	0.786	0.645	0.747
multi	mono	**0.793**	0.664	**0.764**
multi	multi	0.76	**0.686**	0.748
Languages		One-shot		
Pre-train	Fine-tune	EN	EN	EN,PT
mono	mono	**0.897**	**0.873**	**0.892**
multi	mono	0.835	0.783	0.829
multi	multi	0.851	0.809	0.843

Table 5: Experiment 3. Mono and multilingual training data configurations for pretrained models and fine-tuning. XLM-RoBERTa base is used. The experiment ran with 4 epochs, a batch size=8, a lr=2e-05 using one seed [3] and training set shuffle A. The metric used is F1 macro, computed on the development set.

some seeds and shuffle combinations. The problem arises more often with a small batch size of 8, but it also fails to converge once with batch sizes as large as 64 in our experiment. The issue does not disappear for a larger number of epochs. In the exploratory phase, we tried a broad range of training hyper-parameters, and encountered this issue for models trained with 6, 7 and 8 epochs, both with XLM-RoBERTa base and XLM-RoBERTa large.

The multilingual BERT language model shows more stability. With the same datasets and parameters as those used in Table 3, it always obtains a f-score >0.70 in the zero-shot track, and >0.72 in the one shot track. BERT and XLM-RoBERTa perform comparably in the zero-shot experiment but XLM-RoBERTa obtains the best performance in the one-shot setting.

Experiment 2: Context and input format. The results are presented in Table 4. With the experimental settings chosen, it is difficult to draw any conclusion on which context window (*core-sentence* or *3-sentences*) or tagging scheme (*first* or *multiple*) is better for the task. Both Table 8 in the Appendix and the results obtained by Tayyar Madabushi et al. (2021) suggest that providing the embedding of the target MWE separately to the model (*pair*) improves the performance.

Among the two configurations which input the sentences (*core-sentence* or *three-sentences* contexts) to the model without giving any information about the target, one performs consistently better than random for English examples in the development set zero-shot, with F1-scores of 75.3. It suggests that performances of the model may not mainly be due to the discrimination between compositional and non compositional interaction between the target and the context. The topic of the sentence may also have an important influence, which we did not fully analyze in this work.

Experiment 3: Monolingual and multilingual models. The base monolingual and multilingual settings show similar performance, in preliminary experiments (Table 8) and Experiment 3 (Table

Training parameters				Zero-shot			One-shot

Table 6: Experiment 4. Base and Large XLM-RoBERTa models comparison. The results are averaged over three seeds. All the models are trained with 7 epochs. The input parameters are set to pair=True, multiple=True, context=paragraph, lr.=2e-05. The metric used is F1 macro, computed on the development set.

5). Experiment 3 is a comparison of the models, for one fixed set of parameters and one fixed shuffle of the training set. In this case, monolingual pre-training or fine-tuning with BERT outperforms the exclusive usage of the multilingual XLM-RoBERTa configuration. Overall, XLM-RoBERTa large obtains higher scores than monolingual BERT models, base and large[8], for the two settings and languages. In conclusion, XLM-RoBERTa base is outperformed by monolingual BERT models for some parameters and shuffles, but XLM-RoBERTa large attains 7 of the 10 best overall scores in the one-shot settings, and of 5 of the 10 best results in the zero-shot settings.

Experiment 4: Language Model Size. Table 6 and Table 8 in Appendix A both show that the best performances reached are obtained by XLM-RoBERTa large. The gap between the models is clear with the one-shot track, and unclear for the zero-shot. The pairwise comparison of the base and large models for the zero-shot track shows that the base model often outperforms the large one.

In the one-shot setting, a closest look at the results per seed reveals base and large models show similar results only when a large standard deviation between seeds affect the overall performance of the large model [9].

Tracks and optimal number of epochs. The evolution of the scores between Table 3 and Table 6 shows that the one-shot setting needs more epochs to reach its highest performances than than the zero-shot setting. The F1-macro score increases by 2 points in the Zero-shot between 1 and 7 epochs when it gains 10 points in the one-shot training configuration.

6 Conclusion

In this system description paper, we explained our method to fine-tune transformer-based language models for the task of idiomaticity detection. Beyond the implementation, we also attempted to answer a few practical questions on how these models learn the task, and particularly their optimal parameters and input settings.

As future work, we would like to explore unsupervised approaches (e.g. sentence embeddings especially tuned on in-domain data such as news corpora of English, Portuguese and Galician). We are also planning to explore various methods to input the three contextual sentences, beyond simple concatenation as explored in this paper. Another interesting topic for further research would be to explore the complex compositionality relations occurring also withing the idiomatic expression, as exemplified sometimes in the examples labelled *meta-usage* in this dataset.

[8]Large and base models are both tested for the English classifier during the preliminary experiments (c.f. Table 8).

[9]The F1-macro for EN and PT and seed [1,2,3] in shuffle C are 0.907, 0.764 and 0.9, the standard deviation is 0.081.

kpfriends at SemEval-2022 Task 2: NEAMER - Named Entity Augmented Multi-word Expression Recognizer

Min Sik Oh
Alexa AI[*]
ohtrent@amazon.com

Abstract

We present NEAMER - Named Entity Augmented Multi-word Expression Recognizer. This system is inspired by non-compositionality characteristics shared between Named Entity and Idiomatic Expressions. We utilize transfer learning and locality features to enhance idiom classification task. This system is our submission for SemEval Task 2: Multilingual Idiomaticity Detection and Sentence Embedding Subtask A OneShot shared task. We achieve SOTA with F1 0.9395 during post-evaluation phase. We also observe improvement in training stability. Lastly, we experiment with non-compositionality knowledge transfer, cross-lingual fine-tuning and locality features, which we also introduce in this paper.

1 Introduction

Multi-Word Expressions (MWEs) are defined as "idiosyncratic interpretations that cross word boundaries (or spaces)" (Sag et al., 2002). Recent advances in pre-trained language models such as BERT (Devlin et al., 2019) have enhanced performance of Sentence Classification task, however tasks that specifically identify Multi-Word Expressions (MWE) remain unsolved due to its specific idiomatic properties (Garcia et al., 2021; Yu and Ettinger, 2020). This SemEval shared task (Tayyar Madabushi et al., 2022) aims to understand Multi-Word Expressions better by novel classification and sentence similarity tasks.

Named Entity Recognition (NER) is a task to identify Named Entities (People, Organizations etc.) in a sentence. Multiple datasets exist that specifically perform this task, including CoNLL-02/03 Shared Tasks for English, German, Spanish and Dutch (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003). Multi-Word Expressions and Named Entities are similar in a way that they consist of more than one word but they form a single semantic unit. Thus, Named Entities could be seen as a specific type of Multi-Word Expressions (Jackendoff, 1997; Vincze et al., 2011). However they are different from idiomatic expressions.

MWE	Target	Label
gold mine	This means that search data is a **gold mine** for marketing strategy.	0 (Idiomatic)
gold mine	The hashtag “Qixia **gold mine** incident” has been viewed many million of times on the social media site Weibo.	1 (Non-idiomatic)
gold mine	The **Gold Mine**’s plain frontage & sparse, white-walled dining room suggest that it’s a quick-fix refuelling stop rather than a place to linger.	1 (Non-idiomatic)

Table 1: Dataset samples, table from (Tayyar Madabushi et al., 2021). Note that 3rd example is a named entity (The Gold Mine referring to a restaurant).

We propose **NEAMER - Named Entity Augmented Multi-word Expression Recognizer** that aim to utilize non-compositionality shared between two streams of NLP research. We explore transfer learning between NER and idiom classification tasks. We also experiment with "locality features" to augment representations of text.

We have participated in Subtask A which is a multilingual classification task to determine if a given sentence has correct idiomatic usage or not. We have focused our efforts on the OneShot setting, where the goal is to classify the target sentence utilizing the ZeroShot dataset consisting of idioms not found in test set and the OneShot dataset consisting of 1 idiom-label pair for all idioms in test set.

[*]Research unrelated to work

The dataset has been provided by task organizers (Tayyar Madabushi et al., 2021).

Contributions of this paper are :

- NEAMER system which utilizes transfer learning, NER and other locality features to improve performance and stability of MWE classification task.
- Investigation into transfer learning between NER and idiom classification task.
- Performance and error analysis to understand capabilities of transfer learning, cross-lingual fine-tuning and locality features.

2 Methodology

2.1 Idiom and Named Entity

Idioms and named entities are similar in the way that when they are comprised of multiple words, collocated words encode extra semantics while individual words lose their semantics partially or completely. This property is referred as non-compositionality (Baldwin and Kim, 2010). "In a nutshell" means "very briefly, giving only the main points" (Cambridge, 2022) as an idiom; individual words lose their concrete semantics and only the combination specifies intended meaning. Similarly, "Papa John's" refers to "an American pizza restaurant chain" (Wikipedia, 2022) when used as a named entity; in this case, even grammatical functions of individual words are mostly ignored. This similarity is the basis for the transfer learning experiments we performed.

We have discussed similarities, but what about differences? Idioms and named entities refer to completely different usage of MWEs. Idioms are utilized to improve fluency and understandability, or make language more colloquial (Baldwin and Kim, 2010). Named entities are utilized to specify name of persons, organizations and locations (Tjong Kim Sang and De Meulder, 2003) and do not have such social purpose. Correspondingly we can expect certain knowledge to be easily transferable between two tasks, while it may take more epochs to obtain best final performance due to fundamental difference between tasks leading to necessity for "unlearning" the previous fine-tuned task. We explore the ideas in the experiments.

2.2 Transfer Learning and Stability

As discussed in Section 2.1, idioms and named entities show similar non-compositionality. Thus this is the basis for our transfer-learning experiments, where large language models finetuned on NER task are further trained on idiomatic expression classification task. We investigate following ideas in the experiments:

1. We hypothesize that disparity between task types can bring instability. Large language models are known to be unstable during training (McCoy et al., 2019; Zhou et al., 2020). Language models are trained using Masked LM pre-training task. The aim of the Masked LM task is to classify every masked word to original word, which results in classification of each tokens to 30,000 possible labels. In contrast, the task at hand is much simpler, with the aim being to classify whole sentence into 2 labels according to usage of relevant MWE. NER task can bridge this task complexity gap since the aim is to classify each tokens to 9 labels.

2. We hypothesize that non-compositionality understanding of the model can be shared between tasks. NER systems need to understand non-compositionality to correctly predict B-XXX tags. It also predicts multiple named entities per sentence. Thus we assert that enough non-compositionality understanding is learnt during the NER fine-tuning process compared to Masked LM task where each token is predicted independently.

We additionally hypothesize that language-specific knowledge could be improved for the model through fine-tuning with similar language data, which we perform experiments on.

2.3 Locality Features

We design 5 features that are closely related to MWE usage types. Those are the following:

1. Entity - Whether an MWE contains an NER output span, or an NER output span contains an MWE.

2. Capitalization - Whether any word in the MWE is intentionally capitalized (excluding the first word in a sentence and the case where MWE itself is explicitly capitalized in the dataset).

3. "Be a *" - Whether the MWE starts with a be-verb and the article 'a/an'. Same for Portuguese.

4. "The *" - Whether the MWE starts with "the".

5. Quotation - Whether the MWE is surrounded by quotation marks (" or ').

We name them "locality features" because they expand upon specific position of an MWE by looking at adjacent characters. We encode locality features using a deep neural network to give enough

Feature	Total	0 (Idiomatic)	1 (Not-idiomatic)
All	4491	2535	1956
"The *"	720	**366**	**354**
Entity	650	94	**556**
Capitalized	634	50	**584**
Quotation	165	**124**	41
"Be a *"	80	**68**	12
Parenthesis	6	**5**	1

Table 2: Label statistics in ZeroShot data

Model	ENG F1

significance to the features during training / inference while enabling them to learn complex relationships between the text. This is further informed by label imbalance (excluding "The *" label, which is balanced) shown in Table 2. We perform experiments on whether or not locality features improve the performance on the idiom classification task.

3 Experiment Setup

3.1 Model Selection

Experimental results on English ZeroShot (shown in Table 3) were used to determine pre-trained checkpoints with best performance. We thus selected XLM-Roberta-Large (Conneau et al., 2020) as a starting point for training OneShot models.

The list of checkpoints is: xlm-roberta-base, xlm-roberta-large, xlm-roberta-large-finetuned-conll03-english, xlm-roberta-large-finetuned-conll02-spanish, xlm-roberta-large-finetune-conll03-german, Davlan/xlm-roberta-base-ner-hrl, Davlan/xlm-roberta-large-ner-hrl.

3.2 Model Architecture

Our model training scheme and architecture is presented in Figure 1. We fine-tune the model on NER task with selected language. For the experiments, we utilize NER fine-tuned checkpoints as described in Section 3.1 instead of actually performing NER fine-tuning. Then, we train the NER fine-tuned model with text and idiom (MWE) data for the idiom classification task along with selected locality features. We use two layers of fully connected network to encode locality features that are concatenated to the text representation. Locality features used are described in Section 4.5 and implemented in Python to obtain one-hot vectors which are fed into the fully connected network. The feature encoding and hidden layers of FCN are of size 200. In comparision, LM text encoding is 768 as originally used by XLMRobertaForSequenceClassification class in HuggingFace. The size of encoder feature representation is selected to enhance importance of locality features in comparison to LM representation. We use the classification head provided by the same XLMRobertaForSequenceClassification class.

3.3 Training Procedure

We mostly focus on OneShot setting, using both ZeroShot and OneShot data provided. We used a learning rate of 2×10^{-5} and a batch size of 16 for training our models. Models were trained for 24 epochs and the best checkpoints on the evaluation data were selected. Random seeds of 0, 1, 3, 5, 42 are used for initial experiments. If any of the seeds exhibit training failures due to instability (F1 < 0.5), we perform additional experiments with random seeds 49, 81, 100, 121. This resulted in at least 5 checkpoints for our experiments. All provided training data was used for training the models. We picked checkpoints that perform best on respective languages (EN / PT) for evaluation and submission.

Model	Success
XLM-R	55.6%
XLM-R-EngNER	100%
XLM-R-GermanNER	88.9%
XLM-R-EngNER, Augmented	100%

Table 4: Model training success percentage.

Phase	ALL	EN	PT	GL
Baseline	87.7	88.1	87.0	85.4
Evaluation	93.5	**96.1**	89.9	92.1
Post-Evaluation[3]	**94.0**	**96.1**	**91.1**	**92.8**

Table 5: Best submissions.

[1] We implemented our models in HuggingFace (Wolf et al., 2019) and Pytorch (Paszke et al., 2019). We utilize Tesla V100 NVIDIA GPU for training.

4 Results

4.1 Model Stability

We present observed training success rate for each of the models in Table 4. We define training failure as an observance where F1 of the checkpoint is smaller than 0.5. We observe a very high training failure rate for the XLM-R$_{\text{large}}$ model (44.4%). We assert that this is due to discrepancy between the pre-training task of MaskedLM and the idiom classification task (more discussion in Section 2.2.)

4.2 Best Submissions

We show our best submissions in Table 5. Our best official submission during evaluation phase is ensemble of 3 checkpoints per language consisting of XLM-R$_{\text{large}}$-EngNER & SpaNER, with exception of one XLM-R$_{\text{base}}$-EngNER checkpoint[2]. Best post-evaluation submission is ensemble of 5 checkpoints per language consisting of XLM-R$_{\text{large}}$-EngNER & SpaNER, selected via process described in Section 3.3. We achieved top 2 during the competition (Section 7). We are currently first place in the post-competition leaderboard (4/15/2022).

4.3 Ensemble Model Performance

We submit our models based on the ensemble model performance shown in Table 6. Checkpoints for ensemble were selected via the process described in Section 3.3. XLM-R$_{\text{large}}$ + NER models (xlm-roberta-large-finetuned-conll03-english, xlm-roberta-large-finetuned-conll02-spanish) that represent transfer learning characteristics perform best, with high F1 score across all languages. Interestingly, locality feature augmentation does not seem to enhance the final output compared to the transfer learning only method. This could be due to model checkpoints not having enough variance between them caused by over-reliance on label imbalance. (More discussion in Section 4.5)

Model	ALL	EN	PT	GL
XLM-R	92.7	94.5	89.5	92.3
XLM-R$_{\text{NER}_{\text{HRL, 36}}}$	92.5	**96.1**	88.4	90.3
XLM-R$_{\text{NER}_{\text{ENG, SPA}}}$	**94.0**	**96.1**	**91.1**	**92.8**
XLM-R$_{\text{NER}}{}^{\text{Aug}}$	92.8	95.6	89.4	90.8

Table 6: Test data F1 performance for ensemble models. All XLM-R models are large variant.

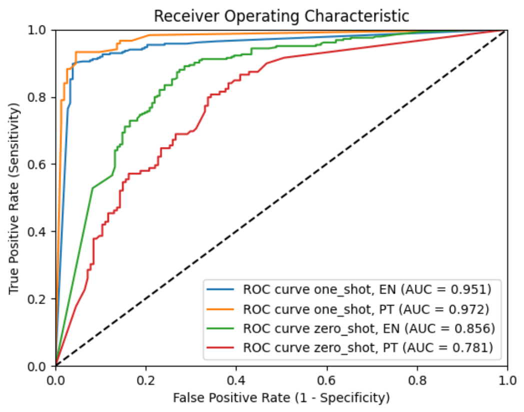

Figure 2: ROC curve of XLM-R$_{\text{NER}}$ on validation data for all tasks. We observe very strong prediction ranking capability for both EN and PT (AUC > 0.950) for OneShot task.

4.4 Average Model Performance

The average F1 scores are presented in Table 7. We observe that additional finetuning on English NER data results in higher performance compared to the baseline XLM-R$_{\text{large}}$ model. Augmentation of the model using locality features results in a slight performance increase. Results suggest that NER fine-tuning assists in the idiom classification task, while locality features help relatively less. NER fine-tuning is helpful due to the language model adapting to the non-compositionality expressed in both tasks (more discussion in Section 2.2.)

[1]Galician test data was inferred by Portuguese model for submission.

[2]The checkpoints were selected according to best performance on validation set.

[3]Experiment performed after end of competition.

Model	Average	Ensemble
XLM-R$_{large}$	93.0	94.5
XLM-R$_{large}$-Eng	**94.0**	**96.1**
XLM-R$_{large}$-Eng, Aug	**94.2**	95.6
XLM-R$_{base}$-HRL	91.1	-
XLM-R$_{large}$-HRL	92.9	-
XLM-R$_{large}$-HRL, 36	**94.2**	**96.1**

Table 7: English test data F1

Model	ALL	EN	PT	GL
XLM-R$_{NER}$	62.3	70.8	67.7	44.4
XLM-R$_{NER}{}^{Aug}$	**64.9**	**72.6**	67.4	**49.2**

Table 8: ZeroShot ensemble test data F1 performance. We note comparatively higher performance for locality feature augmented model on English and Galician data.

4.5 Locality Features

Effect of locality features seem to be marginal, since average F1 (Table 7) only slightly improves in comparison with transfer-learning only model. We also observe lower ensemble performance (Table 6). An enhanced architecture (attention layer in which features explicitly interact with each other) with layer-wise learning rate tuning (to lessen the adverse impact of a cold-start of the feature encoding layers) and dropout (to randomize model training for ensemble enhancement) might be beneficial. We leave it to future work.

We hypothesize that while locality features may be a promising feature to utilize for enhanced architectures, using it by itself may be a relatively too simple indicator. Locality features only require looking at 1~2 specific tokens[4], thus non-compositionality expressed between the tokens themselves is very simple compared to complexity of MWE. An explicit NER feature may also be already encoded in the model via NER fine-tuning step such that no new information is provided during training.

Lastly, we note that we achieve the best ZeroShot setting performance in our experiments with XLM$_{NER}{}^{Aug}$ model which is an ensemble of 3 checkpoints (Table 8). Thus, the locality features could be more promising in the ZeroShot setting where there is less information regarding specific MWE usage. We leave a thorough evaluation to future work.

[4]i.e. Capitalization - first letter of words in MWE, Quotation - ' or " before and after MWE. Parenthesis - (or) before and after MWE.

Model	EN	PT	GL
XLM-R$_{large}$-Eng, Spa	94.0	87.5	88.5
XLM-R$_{large}$-German	93.6	87.2	84.2
XLM-R$_{base}$-HRL	91.1	83.6	83.2
XLM-R$_{large}$-HRL	92.9	84.0	83.7
XLM-R$_{large}$-HRL, 36	**94.2**	85.9	87.2

Table 9: Test data average F1 performance for HRL model variants and English, Spanish and German NER fine-tuned model.

4.6 Crosslingual NER Transfer Learning

XLM-R$_{large}$-HRL is an XLM-R$_{large}$ model trained on NER tasks for 10 languages (Arabic, German, English, Spanish, French, Italian, Latvian, Dutch, Portuguese and Chinese). Rationale for fine-tuning this model is to observe the following :

1. Impact of fine-tuning on a model from a pre-trained model trained on NER data from multiple languages. This model has been trained on all CONLL02 / 03 datasets for English, Spanish, Dutch and German, as well as 8 language specific datasets.

2. Impact of fine-tuning on a model which has been pre-trained with capability to perform Portuguese NER task. This model has been trained on Paramopama and Second Harem (Freitas et al., 2010) Portuguese NER datasets.

We show the results in Table 9. We observe that while XLM-R$_{large}$-HRL performs worse on EN F1 than the similarly fine-tuned XLM-R$_{large}$-English and German, training for 36 epochs (50% epoch increase) yields comparable performance. This aligns with our hypothesis that task-to-task training requires "unlearning" partial aspects of the previous task and thus may take longer to train (more discussion in Section 2.1). XLM-R$_{large}$-English was only trained on CoNLL03 English NER task, while HRL models were trained on NER datasets corresponding to 10 languages - this may result in a higher amount of NER task and language specific knowledge that needs to be removed for the model to train properly.

Similarly, we observe worse performance on Portuguese and Galician results for HRL models compared to Spanish fine-tuned model. Portuguese and Galician seem to require more training epochs than English to achieve comparable performance. This may be due to the difference in dataset size per language in both the ZeroShot and OneShot training data for idiom classification task

Feature	LM	NER	Aug
Capitalized (137)	94.2	94.2	91.2
Entity (131)	93.1	93.1	90.8
"The *" (52)	86.5	**92.3**	**92.3**
"Be a *" (13)	100.0	100.0	100.0
Quoted (12)	90.5	90.5	90.5

Table 10: Micro F1 Metrics (validation data) for each locality feature tagged samples corresponding to XLM-R, XLM-R$_{NER}$ and XLM-R$_{NER}{}^{Aug}$. We observe that transfer learning has improved the performance for "The *" feature. More discussion in Section 5.1.

	Pred 0	Pred 1
Label 0 (Idiomatic)	5	9
Label 1 (Non-idiomatic)	0	117

	Pred 0	Pred 1
Label 0 (Idiomatic)	2	12
Label 1 (Non-idiomatic)	0	117

Table 11: Confusion matrix for Entity in non-augmented models(XLM-R, XLM-R$_{NER}$) vs augmented model (XLM-R$_{NER}{}^{Aug}$).

(English:Portuguese = 2.9:1). We leave training the models on more Portuguese idiom classification datasets and longer epochs to future work.

We also experiment with a model fine-tuned on CoNLL 03 German NER task. We note slightly worse performance for German fine-tuned model compared to models fine-tuned on highly similar languages (English and Spanish NER fine-tuned models). This result seems to suggest that fine-tuning the model on same language for both NER task and Idiom Classification task achieves best performance. More experiments with many languages from other parts of the world could be performed.

5 Error Analysis

5.1 Categorical Performance

We show the F1 metrics for the validation data per each feature in Table 10. We find that the F1 score of "The *" locality feature has increased by 5.8 points after transfer learning is introduced. This locality feature does not directly correspond to NER, and is the only sample-balanced locality feature as shown in Table 2. Thus, we argue that this is further proof of NER transfer learning teaching general non-compositionality to LM that is transferred to MWE classification task.

We also find that Capitalized and Entity F1 scores have stayed the same after the introduction of NER transfer learning, and it has actually decreased by 2~3 points after locality feature augmentation. We also observe a recall decrease of 0.214 (0.357 -> 0.143) as shown in Table 11. As discussed in Section 4.5, this is due to over-reliance on training data label imbalance.

5.2 Sample Analysis

We list the prediction improvements between base XLM-R$_{large}$ model and NER transfer-learning based models in Appendix A. Interestingly, we observe that 6 out of 9 sample prediction improvements for English model are also observed with HRL, German[5] models. This strongly suggests that shared characteristics are present between NER transfer-learning based models. We also observe that the model output changes are not associated with named entities, strengthening our hypothesis of general non-compositionality knowledge transfer between tasks.

6 Conclusion

We present NEAMER - Named Entity Augmented Multi-word Expression Recognizer. This system explores how we can utilize non-compositionality shared between Named Entity and Idiomatic Expressions. We find that the NER transfer learning variant achieves the best MWE classification OneShot performance. We also observe high training stability. We investigate non-compositionality knowledge transfer between tasks and obtain promising results across experiments.

7 Rank Information

During the official evaluation phase, we were top 2 in Subtask A (One-Shot) leaderboard with F1 score of 0.9346 (Table 5). We trained 50 checkpoints and measured F1 on English and Portuguese separately. Checkpoints were generated via process described in 3.3. Best English performing checkpoints inferred on English test submission data, while best Portuguese performing checkpoints inferred on Galician as well as Portuguese test submission data. Finally, we ensembled best performing models on each language using different strategies (including top 3, top 5, top 10) to optimize generalization performance.

[5]German model is not trained on CoNLL03 English data, making the result more interesting.

8 Acknowledgements

We'd like to sincerely thank SemEval Task 2 Organizers, especially Harish Tayyar Madabushi, for organizing the Shared Task and providing valuable correspondence during review. We also thank Young Sun Yoon for sharing his knowledge of Ibero-Romance languages.

A Prediction Improvements

We list the classification improvements[6] in validation dataset observed across NER transfer learning models in comparison to base XLM-R$_{\text{large}}$ model. The NER transfer learning models we compare are English, German, and HRL (10 languages). We find 6 samples that prediction have improved consistently across all 3 models, which is 66.7% of prediction improvements in English model.

MWE	**Sentence**	**Feature**
high life	"This is the story of “Memo Fantasma” or “Will the Ghost,” who started life in the Medellín Cartel, funded the bloody rise of a paramilitary army, and today lives the high life in Madrid."	"The *"

daming.lu@bytedance.com

Abstract

Multiword expressions (MWEs) or idiomaticity are a common phenomenon in natural languages. Current pre-trained language models cannot effectively capture the meaning of these MWEs. The reason is that two single words, after combined together, could have an abruptly different meaning than the compositionality of the meanings of each word, whereas pre-trained language models reply on words' compositionality. We propose an improved method of adding an LSTM layer to the mBERT model to get better results on a text classification task (Subtask A). Our result is slightly better than the baseline. We also tried adding TextCNN to mBERT and adding both LSTM and TextCNN to mBERT. We participate in SubTask A and find that adding only LSTM gives the best performance.

1 Introduction

Machine learning has made deep impacts on various areas, such as computer vision (He et al., 2015, 2017; Lu, 2018), computational biology (Jumper et al., 2021; Huang et al., 2019; Lu, 2010, 2009), and natural language processing (Yang et al., 2019b; Lewis et al., 2019; Madabushi et al., 2020) . In natural language processing, large pre-trained models are prevailing and have achieved great successes. Models such as BERT (Devlin et al., 2018), RoBERTA (Liu et al., 2019), XLNet (Yang et al., 2019a), ALBERT (Lan et al., 2020), Ernie (Sun et al., 2019), etc. performed pretty well in tasks such as sentiment analysis, commonsense reasoning (Lin et al., 2019; Lu, 2020), QA system (Chen and Yih, 2020; Yu et al., 2015) and many other tasks. However, these models are not good at certain tasks such as assessing humor and capturing idiomaticity. This shortcoming is largely due to natural languages' flexibility.

In this paper, we focus on how to use large pre-trained language models to determine whether a multiword expression (MWE) has a trivial meaning (Tayyar Madabushi et al., 2022), a.k.a, the compositionality of each word's meaning, or it is an idiomatic usage. We use the dataset provided in (Tayyar Madabushi et al., 2021). In the training set, the target MWE is given. The previous sentence, the target sentence and the next sentence are also given. We need to decide if the MWE has an idiomatic meaning or its meaning is trivial. This task then can be treated as a text classification problem.

The rest part of this paper is organized as follows:

- We first introduce the dataset and the task with details.
- Then we describe how we built up our pipeline with BERT, LSTM and TextCNN.
- We give our results in section 4.
- Lastly, we provide our discussion in section 5.

2 Dataset and Task

As mentioned in (Tayyar Madabushi et al., 2021), the dataset for Subtask A consists of naturally occurring (target) sentences, previous sentences and next sentences. The target sentence contains potentially idiomatic MWEs annotated with a fine-grained set of meanings: compositional meaning and idiomatic meaning(s). Table 1 shows two samples from the training data. One has an idiomatic expression, and the other not.

3 Methods

Our core pre-trained language model is mBERT (Wolf et al., 2020). We chose mBERT over BERT hoping that it could better fit the task's multi-language specification. In traditional methods, n-gram was used to detect and group the MWEs. In

Table 1: Sample data for Subtask A.

previous sentence	target sentence	next sentence	target MWE	label (0 means idiomatic)
"The job has traditionally been non-political, but Mrs. Trump's decision to hire a Trump Organization employee added partisanship to the role, even though Mr. Harleth tried to frame his work there as one stop in a long career in the hospitality industry."	"The White House job was well compensated — former chief ushers say salaries run in the $200,000 range — but the days are long, particularly if the president is an early riser or a night owl; Mr. Trump was both."	Mr. Biden is not a morning person, people familiar with his schedule say.)	night owl	0
Demography expert Piotr Szukalski told Dziennik Gazeta Prawna he thinks that deep concerns about the spread of the coronavirus are to blame.	Minister of Family and Social Policy Marlena Malag ascribed the high death rate to the pandemic and said it would take a long time for the current government program of family benefits intended to boost the birth rate to reverse the negative trend.	"Commenting on data the state agency Statistics Poland released in December for 11 months of 2020, economist Rafal Mundry said the number of deaths was the highest since World War II, and the number of births the lowest in 15 years."	birth rate	1

our methods, we tried to use either LSTM (Hochreiter and Schmidhuber, 1997) or TextCNN (Kim, 2014) to capture the MWEs. We concatenate LSTM or TextCNN to mBERT in order to increase the performance.

3.1 LSTM

Unlike RNN (Jordan, 1997), LSTM is good at remembering only the important parts of a sentence. We hope it can help us group up the MWEs and improve the performance. We add a bidirectional LSTM layer at the output of the sequential transformers. The bidirectional LSTM layer was initialized as 1-layer and bidirectional, with a dropout of 0.1.

3.2 TextCNN

Similar to traditional CNN (Schmidhuber, 2015) in computer vision, TextCNN (Kim, 2014) extracts features from a small area of text. We suppose this layer can help us detect the span of the MWEs so that performance can be improved.

4 Results

We use the mBERT with 12 hidden layers. We did experiments on dropouts with 0.1 and 0.2. As mentioned in Section 3, we explored of adding either a LSTM or a CNN to the final fully connected layer of the transformer from mBERT. Table 2 provides our experiments and results. We were expecting that mBERT + TextCNN could give us the best results. But it turned out that mBERT + LSTM performs best for Subtask A among our experiments. The author has put the code for this paper on GitHub[1].

[1]`https://github.com/daming-lu/semeval_2022_task2_sub_a`

Table 2: Subtask A Experiment Results

Method	Zero-Shot	One-Shot
mBERT	0.6448	0.6987
+LSTM, dp=0.1	0.6546	0.6998
+LSTM, dp=0.2	0.6333	0.6613
+TextCNN, dp=0.1	0.6501	0.6827
+TextCNN, dp=0.2	0.6254	0.6309
+TextCNN+LSTM	0.6502	0.6977
+LSTM, dp=0.1(**test**)	0.654	0.704

5 Discussion

One reason that our method does not boost the performance a lot might be that we add the LSTM or TextCNN to the end, whose effect is limited to the whole pipeline. Another new method, according to (Gao et al., 2021), is that we can turn this classification problem into a masked word problem. In PROMPT, it claims the integration is more genuine, but choosing the prompt could be technical.

Another important reason is overfitting. We tried to increase dropout from 0.1 to 0.2 in order to get rid of overfitting. But the effect was opposite. According to (Tan et al., 2015), adding LSTM could boost question answering tasks, whereas our task is in fact a text classification. This might be the reason of the tiny improvement.

HiJoNLP at SemEval-2022 Task 2: Detecting Idiomaticity of Multiword Expressions using Multilingual Pretrained Language Models

Minghuan Tan
School of Computing and Information Systems
Singapore Management University
mhtan.2017@phdcs.smu.edu.sg

Abstract

This paper describes an approach to detect idiomaticity only from the contextualized representation of a MWE over multilingual pretrained language models. Our experiments find that larger models are usually more effective in idiomaticity detection. However, using a higher layer of the model may not guarantee a better performance. In multilingual scenarios, the convergence of different languages are not consistent and rich-resource languages have big advantages over other languages.

1 Introduction

In the past several years, there have been breakthroughs in a variety of natural language processing tasks with the power of pretrained language models. These include but are not limit to question answering (Devlin et al., 2019), language generation (Radford et al., 2018, 2019) and machine translation (Liu et al., 2020). However, it's still not clear whether pretrained language models have the ability in capturing the meanings of multiword expressions (MWEs), especially idioms. Given the prevalent usage of idioms in different languages, identifying the correct meaning of a phrase in a certain context is crucial for many downstream tasks including sentiment analysis (Williams et al., 2015), automatic spelling correction (Horbach et al., 2016) and machine translation (Isabelle et al., 2017).

In literature, idiomaticity detection has been a research topic drawing much attention from the NLP community. MWEs which have both an idiomatic interpretation and a literal interpretation are also referred as Potentially Idiomatic Expressions (PIEs), for example, *spill the beans*. There has been both supervised (Sporleder and Li, 2009) and unsupervised (Haagsma et al., 2018; Kurfalı and Östling, 2020) approaches to solve this problem. For example, Feldman and Peng (2013) treated idiom recognition as outlier detection, which does not rely on costly annotated training data. Peng et al. (2014) incorporated the affective hypothesis of idioms to facilitate the identification of idiomatic operations.

Due to the limited understanding of how pretrained language models may handle representation of phrases, a series of works are proposed to investigate phrase composition from their contextualized representations. Yu and Ettinger (2020) conduct analysis of phrasal representations in state-of-the-art pre-trained transformers and find that phrase representation in these models still relies heavily on word content, showing little evidence of nuanced composition. Shwartz and Dagan (2019) confirm that contextualized word representations perform better than static word embeddings, more so on detecting meaning shift than in recovering implicit information. Therefore, it remains a challenging problem to resolve the idiomaticity of phrases.

Specifically on idiomaticity, recent approaches are trying to further diagnose pretrained language models using new metrics and datasets. Garcia et al. (2021a) analyse different levels of contextualisation to check to what extent models are able to detect idiomaticity at type and token level. Garcia et al. (2021b) propose probing measures to assess Noun Compound (NC) idiomaticity and conclude that idiomaticity is not yet accurately represented by contextualised models. AStitchInLanguageModels (Tayyar Madabushi et al., 2021) design two tasks to first test a language model's ability to detect idiom usage, and the effectiveness of a language model in generating representations of sentences containing idioms. Tan and Jiang (2021) conduct two probing tasks, PIE usage classification and idiom paraphrase identification, suggesting that BERT indeed is able to separate the literal and idiomatic usages of a PIE with high accuracy and is also able to encode the idiomatic meaning of a PIE to some extent. However, there's still much more to explore in idiomaticity.

Based upon AStitchInLanguageModels (Tayyar Madabushi et al., 2021), SemEval-2022

Proceedings of the 16th International Workshop on Semantic Evaluation (SemEval-2022), pages 190 - 196
July 14-15, 2022 ©2022 Association for Computational Linguistics

Task2 (Tayyar Madabushi et al., 2022) is proposed with a focus on multilingual idiomaticity. The task is arranged consisting the two subtasks:

1. Subtask A: A binary classification task aimed at determining whether a sentence contains an idiomatic expression.

2. Subtask B: Pretrain or finetune a model which is expected to output the correct Semantic Text Similarity (STS) scores between sentence pairs, whether or not either sentence contains an idiomatic expression.

In this paper, we focus on Subtask A and investigate how the span representation of a MWE can tell about its idiomaticity. We extend one of the monolingual idiomaticity probing method (Tan and Jiang, 2021) to multilingual scenario and compare multiple settings using multi-lingual BERT (mBERT) (Devlin et al., 2019) and XLM-R (Conneau et al., 2020). Following Yu and Ettinger (2020), we also consider variations of phrase representations across models, layers, and representation types. Different from them, we use more representation types to conduct the experiments.

Our main conclusion from these experiments are two folds:

1. Larger models are usually more effective in idiomaticity detection. However, a higher layer may not contribute more to the idiomaticity detection task, or more contextualization does not guarantee a better performance.

2. For multilingual scenario, the convergence of different languages are not consistent. Rich resource languages have initiative advantages over other languages.

2 System Overview

2.1 Subtask A

For Subtask A, to test models' ability to generalise, both zero-shot and one-shot settings are considered.

1. zero-shot: PIEs in the training set are completely disjoint from those in the test and development sets.

2. one-shot: one positive and one negative training examples for each MWE in the test and development sets

Note that the actual examples in the training data are different from those in the test and development sets in both settings.

Data Each row of the data of Subtask A has attributes like language and the potentially idiomatic MWE. The "Target" is the sentence that contains this MWE. The previous and next sentences for context are also provided. The label provides the annotation of that row, and a label of 0 indicates "Idiomatic" and a label of 1 indicates "non-idiomatic", including proper nouns.

Baseline The baseline model (Tayyar Madabushi et al., 2022) is based on mBERT. In the zero-shot setting, the model uses the context (the sentences preceding and succeeding the one containing the idioms) and does not add the idiom as an additional feature (in the "second input sentence"). In the one shot setting, the model is trained on both the zero-shot and one-shot data, but exclude the context (the sentences preceding and succeeding the one containing the idioms) and add the idiom as an additional feature in the "second sentence".

2.2 Span-based Model

While the common practice for classification tasks using pretrained language models usually needs concatenation of text sequences, this does not tell us enough information how representations of MWEs may lead to the change of performance. Therefore, in this work, we focus on the contextualized representations of MWEs to predict its idiomaticity.

Problem Formulation Consisting with the definition in (Tan and Jiang, 2021) , given a sentence denoted as $(w_1, w_2, \ldots, w_n)$, which contains a MWE with m words denoted as $(w_i, \ldots, w_{i+m-1})$, The task is to decide whether the MWE is used with its *literal* meaning or its *idiomatic* meaning, or if a sentence contains an idiomatic expression as describe in the task.

Span Identification In this work, our method requires a pair of span indices of the target MWE to extract their hidden representation from the encoded sequence. However, in this task, no such indices is offered explicitly from the dataset. We empirically find these indices by using editing distances in characters between the MWE and the sentence. This method works for most of the cases.

Span Representation For each MWE, we have a pair of span offsets in the original context. We use an L-layer BERT to process the tokenized context by prepending `[CLS]` to the beginning and append-

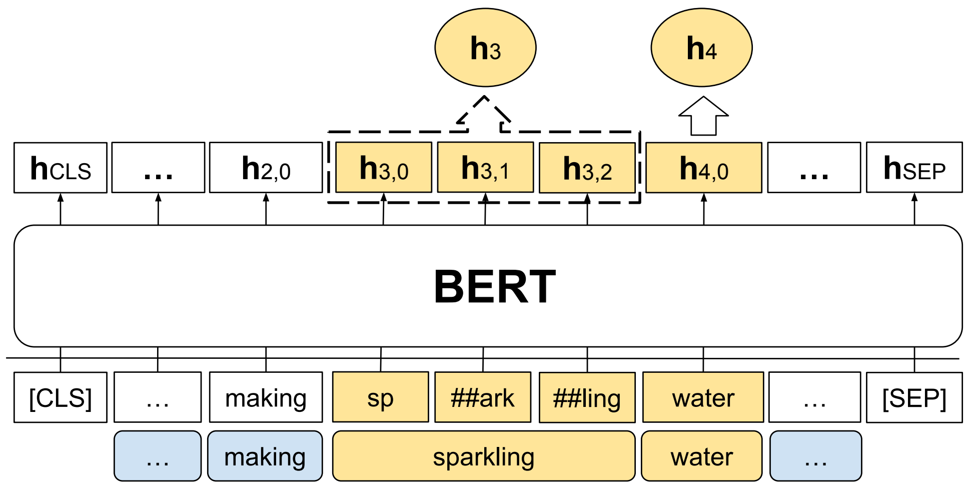

Figure 1: Mismatched transformer-based span representation.

ing `[SEP]` to the end. Let $\mathbf{h}_i^k \in \mathbb{R}^d$ denote the hidden vector produced by the kth layer of BERT representing w_i. We extract the hidden representations of the span to get its contextualized representations. For each MWE, we get a sequence of hidden vectors at the k-th layer for the m tokens inside this MWE as follows: $\mathbf{p}^k = (\mathbf{h}_i^k, \mathbf{h}_{i+1}^k, \ldots, \mathbf{h}_{i+m-1}^k)$.

In transformer-based models, a word might be tokenized into several pieces. We adopt the mismatched tokenization trick offered by Allennlp [1] to reconstruct its hidden vector. The hidden vector will be the average embeddings of constituent pieces. The mismatched encoding is illustrated in Figure 1.

We represent the target MWE using the span by six different kinds of combinations of the span's words. The first four of them are only using their endpoints. We use $\mathbf{x} = \mathbf{h}_i^k$ to denote the start of the span and $\mathbf{y} = \mathbf{h}_{i+m-1}^k$ to denote the end of the span.

1. **x,y** The span is represented by a direct concatenation of two endpoints.
2. **x,y,x-y** The span is represented by a direct concatenation of two endpoints and the difference of them.
3. **x,y,x*y** The span is represented by a direct concatenation of two endpoints and the elementwise product of them.
4. **x,y,x*y,x-y** The span is represented by a direct concatenation of two endpoints, the elementwise product and the difference of them.
5. **SelfAttentive** We firstly compute an unnormalized attention score for each word in the document. Then we compute spans representations with respect to these scores by normalising the attention scores for words inside the span.
6. **MaxPooling** A span is represented through a dimension-wise max-pooling operation. Given a span, the resulting value of a dimension is using the maximum value of this dimension across all the span tokens.

Span Classification We use a binary linear classifier upon the span representation.

3 Experiments

In this paper, we want to test how the pretrained model, the transformer layer and the representation type, affect performance of idiomaticity detection.

3.1 Settings

This subtask is evaluated using the Macro F1 score between the gold labels and model predictions (see the details in the evaluation script).

All the multilingual pretrained langauge models are hold by Huggingface, including mBERT[2], XLM-R[3] and XLM-R-L[4].

Since we are focusing on comparison of span representation across different layers and representation types, we conduct experiments with the 4-th,

8-th and 12-th layer of mBERT and XLM-R and the 8-th, 12-th and 24-th layer of XLM-R-L. All six representation types are considered for each layer-based models.

We run most of our experiments with an NVIDIA 1080ti GPU with 11GB memory, and use a NVIDIA A100 for XLM-R-L-based experiments. We finetune each experiment for 10 epochs with the learning rate set to 5e-5. We notice that the training process converges with training accuracy 1 in a short period. To reduce the effect of overfitting, we use a dropout probability of 0.5 before the classification layer. Our code is built over Allennlp2 and will be released on Github[5].

3.2 Results and Analyses for Subtask A

We list the overall experiment results in Table 3 in the Appendix. The table contains three main parts with each part showing the detailed experiment results for a multilingual pretrained language model. In each part, we test all six combinations of span representations using encoded sequences from different layers. To better illustrate our major conclusions, we select the best settings for each multilingual model from Table 3, and rearrange the zero-shot results to Table 1 and one-shot results to Table 2.

Table 1 shows us that using only endpoints of the span can be effective in predicting its idiomaticity and representation type **x,y,x-y** is a good choice for the zero-shot setting. We think representation using only endpoints is working well might due to most of the MWEs in current dataset consist of two words.

Table 2 shows us that representation type **MaxPooling** is a good choice for the one-shot setting and the best performance may be achieved using middle layers.

Combining both zero-shot setting and one-shot setting, we find that larger models are usually more effective in idiomaticity detection. For a specific pretrained model, using contextualized representation from a higher layer may not guarantee a better performance. For example, from the perspective of overall score for the One Shot scenario, the highest scores are all reached at the 8-th layer. However, we didn't observe a consistent advantage of using a specific representation type across different models and layers.

From the perspective of language, span-based models are achieving relative larger gains in both settings for GL. On one hand, the corpus used for training pretrained language models is not balanced across different languages. For example, in XLM-R, data from EN is several times than that of PT and hundrands times than that of GL. The data for GL may just surpass a minimal size for learning a BERT model and restricts performance in both settings for GL compared with PT and EN. On the other hand, this tells us that better span representation still help in detection of idiomaticity.

3.3 Endpoints-based Representation

This work focuses on the contextualized representation of the span of a target MWE. As pointed out by

[5]https://github.com/VisualJoyce/CiYi

others, phrase representations, especially idioms, are not always compositional and rely more than the constituent words in the span. Not to mention, it is a much easier case which only uses the endpoints of the span. However, in both zero-shot setting and one-shot setting, we notice that endpoints-based methods works almost as well. We suspect this may due to the following reasons: (1) Endpoints of MWEs are highly correlated with these MWEs and can be very indicative about their representation. (2) Most of the MWEs covered in this dataset contain two words.

4 Conclusion

In conclusion, our experiments find that larger models are usually more effective in idiomaticity detection. And for a specific pretrained model, using contetualized representation from a higher layer may not guarantee a better performance. As the data used for multilingual pretrained language models is not well-balanced, rich resource languages have significant advantages over other languages. In the future, with the community contributing stronger language models with more balanced language distribution and more multilingual idiom-annotated datasets, idiomaticity detection still has large potentials to be explored from more angles.

Abstract

This paper presents our contribution to the SemEval-2022 Task 2: Multilingual Idiomaticity Detection and Sentence Embedding. We explore the impact of three different pre-trained multilingual language models in the SubTaskA. By enhancing the model generalization and robustness, we use the exponential moving average (EMA) method and the adversarial attack strategy. In SubTaskB, we add an effective cross-attention module for modeling the relationships of two sentences. We jointly train the model with a contrastive learning objective and employ a momentum contrast to enlarge the number of negative pairs. Additionally, we use the alignment and uniformity properties to measure the quality of sentence embeddings. Our approach obtained competitive results in both subtasks.

1 Introduction

In recent years, the pre-trained models have been widely used and play a vital role in the natural language processing tasks. The success of language models relies on huge amounts of unlabeled data and the useful representation layers that are designed to draw on information from the surrounding context (Devlin et al., 2018;Nedumpozhimana and Kelleher, 2021). However, more recent studies show that even state-of-the-art pre-trained contextual models (e.g. BERT) can't accurately represent idiomatic expressions (Yu and Ettinger, 2020;Garcia et al., 2021). One reason for this is that many expressions can be used both literally and idiomatically.

Specifically, the size of vocabulary can't increase indefinitely, which makes representing idiomatic phrases particularly challenging (Shwartz, 2021;Tayyar Madabushi et al., 2021). Idioms occur in almost all languages, to distinguish whether an expression has an idiomatic sense would leverage both cross-lingual models and multiword expressions (MWEs). The SemEval 2022 Task 2(Tayyar Madabushi et al., 2022) is aimed at detecting and representing MWEs and presents a novel multilingual dataset across English, Portuguese and Galician. And this task consists of two different subtasks to evaluate the model's ability to identify and capture idiomaticity.

SubTask	Train	Dev	Test	Desc
zero-shot	4492	740	763	binary classification
one-shot	4492	740	763	
pre-train	24498	2000	3827	semantic similarity
fine-tune	6573	2182	2263	

Table 1: The statistics of datasets.

Our contributions can be summarized as follows: 1) We choose three transformer-based language models from the XTREME LeaderBoard (Hu et al., 2020), and compare the effectiveness of mBERT$_{base}$ (Devlin et al., 2018), XLM-R$_{base}$(Conneau et al., 2020), and InfoXLM$_{base}$(Chi et al., 2021). 2) We adopt the exponential moving average method (EMA) and adversarial training strategy to improve the model's generalization and robustness. We achieved considerably performance gain of 2.91%, 3.87% over the baseline solution, and ranked 12th in the zero-shot settings and 4th in the one-shot settings. 3) With finetuning on the supervised target datasets, we use cross-attention module and jointly train the model with an extra contrastive loss layer on top of the BERT encoder. Our approach achieved an 8.22%, 4.5% improvement compared to the baseline solution, and ranked top-4 in the pre-train and fine-tune settings. We release the source code and pre-trained models associated with this work. [1]

Moreover, we find that adversarial training can

[1] https://github.com/cuixuage/SemEval2022-Task2

achieve good performance by setting the appropriate batch size. In the SubTaskB, we show that joint training regularizes the sentence embeddings' anisotropic space to be more uniform but also suffers a degeneration in alignment slightly. The trade-off between the alignment and uniformity (Wang and Isola, 2020) indicates that perfect alignment and perfect uniformity are likely hard to simultaneously achieve in practice.

2 Background

SemEval-2022 Task 2(Tayyar Madabushi et al., 2022) provides two subtasks. Subtask A consists of a binary classification task aimed at determining whether a sentence contains an idiomatic expression. The sample of the dataset consists of the previous sentence, target sentence, next sentence, and MWE. The target sentence contains the potentially idiomatic MWE, and the label of 0 indicates "Idiomatic" and the label of 1 indicates "non-idiomatic". Our model receives the context sentences as input in the zero-shot setting, and receives the target sentence by adding the MWE as an additional feature in the one-shot setting. This is based on the results presented in the dataset paper (Tayyar Madabushi et al., 2021).

SubtaskB consists of a novel task which requires the model to output the correct Semantic Text Similarity (STS) scores. The task is designed to test a model's ability to generate sentence embeddings that accurately represent sentences regardless of whether or not they contain idiomatic expressions. When evaluating the trained model, we first obtain the sentence embeddings, then we calculate the Spearman correlation between the cosine similarity scores of sentence embeddings and the gold labels. The statistics of the corpus are shown in Table 1. Our team participated in both subtasks, and the next section will introduce an overview of our system.

3 System Overview

We focus on comparing the impact of different training techniques adopted in our system. In this section, we first present the BERT-like text encoder, then we introduce several strategies for improving models' robustness. Finally, we talk about the design of the cross-attention module and the jointly training way of incorporating supervised signals and unsupervised signals.

3.1 Transformer-based Models

In the zero-shot and one-shot settings, we compare several pre-trained multilingual language models from the XTREME Leaderboard[2] as the text encoder . The models shown below are also available on the hugging-face website[3].

mBert$_{base}$,the bert-base-multilingual-cased model is pre-trained on the top 104 languages with the Wikipedia dataset, and consists of 12-layer, 768-hidden, 12-heads, 109M parameters and a shared vocabulary size of 110000 (Devlin et al., 2018).

XLM-R$_{base}$,the xlm-roberta-base model consists of 100 languages and pre-trained with filtered CommonCrawl dataset, and consists of 12-layer, 768-hidden, 12-heads, $\tilde{2}$70M parameters and a shared vocabulary size of 250002 (Conneau et al., 2020).

InfoXLM$_{base}$,we use the "microsoft/infoxlm-base" model containing 94 languages and pre-trained with CCNet dataset, and has the same configurations of XLM-R and a shared vocabulary size of 250002 (Chi et al., 2021).

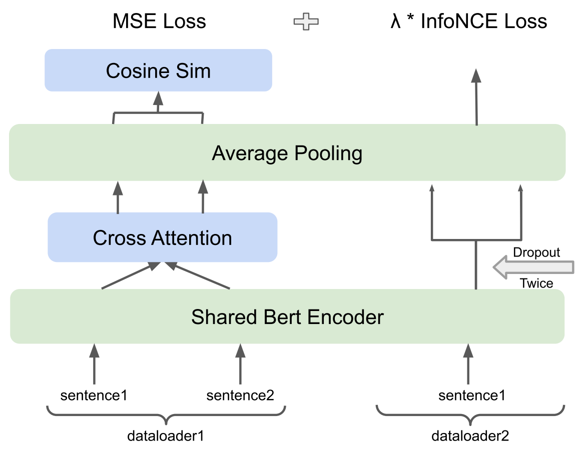

Figure 1: Incorporating supervised and unsupervised signals. MSE Loss: the mean squared error, InfoNCE Loss: the contrastive objective.

3.2 Training Procedures

There are two ways of enhancing the model generalization and robustness.

Exponential Moving Average Our model uses EMA to smooth the trained parameters. Evaluations that use averaged parameters sometimes produce significantly better results than the final trained values. Formally, we define the smoothed

[2]https://sites.research.google/xtreme
[3]https://huggingface.co/models

SubTaskB	Model	ALL Data	Idiom Data	STS Data
pre-train	mBert$_{base}$	53.90	21.87	80.82
	mBert$^{\diamondsuit}_{base}$	55.58	27.18	82.09
	mBert$^{\clubsuit}_{base}$	56.32	28.26	83.59
fine-tune	mBert$_{base}$	62.29	34.59	52.29
	mBert$^{\diamondsuit}_{base}$	63.16	36.95	53.49
	mBert$^{\clubsuit}_{base}$	64.01	39.56	56.15

Table 2: Performance of Our Approach on the Sentence Representation Task. We report the Spearman correlation $\times$ 100 on the test sets, $\diamondsuit$: jointly train the model with the contrastive objective, $\clubsuit$: jointly train the model with the cross-attention module and the contrastive objective.

variables and trained variables as θ_s and θ_t, EMA decay weight as: η. After each training step, we update θ_s by:

$$\theta_s \leftarrow \eta\theta_s + (1-\eta)\theta_t \tag{1}$$

Adversarial Training Recently, adversarial attack has been widely applied in computer vision and natural language processing (Yan et al., 2021). Many works use it during fine-tuning, because computing adversarial perturbations relies on supervised signals. We explore the influence of adversarial training strategies with different batch size, and compare the FGSM (Goodfellow et al., 2015), PGD (Madry et al., 2019), FREELB (Zhu et al., 2020) and SMART (Jiang et al., 2020) methods in the zero-shot and one-shot settings. It works by augmenting the input with a small perturbation that maximizes the adversarial loss:

$$\min_{\theta} \mathbb{E}_{(x,y)\sim\mathcal{D}}\left[\max_{\Delta x\in\Omega} L(x+\Delta x, y; \theta)\right] \tag{2}$$

where the $\mathcal{D}$ is dataset, x is input, y is the gold label, θ is the model parameters, $L(x, y; \theta)$ is the loss function and Δx is the perturbation. In our experiments, we adopt SMART method in zero-shot setting, and FREELB method in one-shot setting. These choices are based on actual performance.

3.3 Sentence Representation

Reimers and Gurevych (2019) propose a siamese architecture with a shared BERT encoder to compute the sentence representations for each input text. By making use of unlabeled texts, SimCSE (Gao et al., 2021) proposes an unsupervised contrastive learning method to alleviate the collapse issue of BERT. Compared to unsupervised SimCSE, we use extra supervised signals during training. Our approach is mainly inspired by ConSERT (Yan et al., 2021) and EsimCSE (Wu et al., 2021). As shown in Figure 1, there are two major objectives and an extra cross-attention module to exchange information with the token-wise embeddings.

$$\mathcal{L}_{\text{joint}} = \mathcal{L}_{\text{mse}} + \lambda\mathcal{L}_{\text{con}} \tag{3}$$

the λ is a hyperparameter to balance two objectives. $\mathcal{L}_{\text{mse}}$ is Mean Squared Error, $\mathcal{L}_{\text{con}}$ is Contrastive Loss.

During training, each data point is trained to find out its counterpart among $(N-1)$ from in-batch negative samples and the queue of data samples. The samples in the queue are progressively replaced (He et al., 2020).

$$-\log \frac{e^{\text{sim}\left(\mathbf{h}_i,\mathbf{h}_i^{+}\right)/\tau}}{\sum_{j=1}^{N} e^{\text{sim}\left(\mathbf{h}_i,\mathbf{h}_j^{+}\right)/\tau} + \sum_{q=1}^{Q} e^{\text{sim}\left(\mathbf{h}_i,\mathbf{h}_q^{+}\right)/\tau}} \tag{4}$$

The h_* is the sentence representation, where h_i and h_i^+ are semantically related. The h_q^+ is denotes a sentence embedding in the momentum-updated queue. And the Q is the size of the queue, $sim(h1, h2)$ is the cosine similarity scores of sentence representations, τ is a temperature hyperparameter. In the end, we average the all N Li losses to calculate the contrastive loss $\mathcal{C}_{\text{con}}$.

4 Experiments

4.1 Settings

We use InfoXLM$_{base}$ (Chi et al., 2021) as the text encoder, the EMA decay weight is set to 0.999, the learning rate is set to 2e-5 with warmup ratio over 10% in the SubTaskA. We compare the impact of batch size $\in$ 16, 32, 64 with different adversarial training strategies. By default, We set ε to 1.0 in FGM, set K steps to 3 in PGD, FREELB and SMART. That means calculate 3 steps in the adversarial attack. We adopt λ as 0.5 and μ as 0.2 to smooth the logits and embeddings in the SMART method (Jiang et al., 2020). We use SMART method and batches of size 16 in zero-shot setting, FREELB method and batches of size 32 in one-shot setting.

SubTask	Model	Practice	Post-Eval
zero-shot	mBert$_{base}$	68.71	-
	infoxlm$^{\diamondsuit}_{base}$	76.21	68.31
one-shot	mBert$_{base}$	84.77	-
	infoxlm$^{\clubsuit}_{base}$	94.07	90.33

Table 3: Performance of Our Approach on the Idiomaticity Detection Task. We report the F1 Score × 100 on the dev and test sets, $\diamondsuit$: set bath size to 16 and use SMART, $\clubsuit$: set bath size to 32 and use FREELB.

Method	Practice	Post-Eval
mBert$_{base}$	68.71	-
InfoXLM$_{base}$	73.10	65.2
+EMA	75.75	67.85
+EMA+SMART	76.21	68.31

Table 4: The effect of different strategies and keep accumulating from top to bottom. We report the dev-F1 Score × 100 in zero-shot setting.

In the SubTaskB, we use mBERT$_{base}$ (Devlin et al., 2018) as the text encoder, set batch size to 32 and set warmup ratio to 10%. During the jointly training, λ is set to 0.15 and τ is set to 0.05 that used in the $\mathcal{L}_{\text{con}}$. We use the dev set of STS-B and ASSIN2 to tune the hyperparameter and evaluate the model every 250 steps during training. The best checkpoint is saved for testing, we further discuss the results of our experiments in the subsequent section.

4.2 Main Results

Our submitted results were evaluated on F1 Score in SubTaskA, and Spearman correlation in SubTaskB. We jointly train the model with contrastive objective and the supervised signals on the Semantic Text Similarity dataset, including STSBenchmark and ASSIN2 datasets. We compare several models as the text encoder and different training methods, as described in Section 3. The main results shown in Table 2 and Table 3. As shown in Table 3, we achieve a performance gain of 2.91%, 3.87% over the baseline solution by finetuning the InfoXLM$_{base}$ model with using EMA method and adversarial training. In the Table 2, our approach achieves a 8.22%, 4.5% improvement compared to the baseline solution that indicates the usefulness of the cross-attention module and jointly training way. In the next section, we study the effect of different strategies.

5 Ablation Studies

5.1 Effect of Pre-trained Models

We investigate the impact of adopting different multi-lingual models in the zero-shot setting. In Figure 2, we show the results of different language models fine-tuning in 50 epochs. We find that the best f1 score on validation dataset is provided by InfoXLM$_{base}$ (Chi et al., 2021).

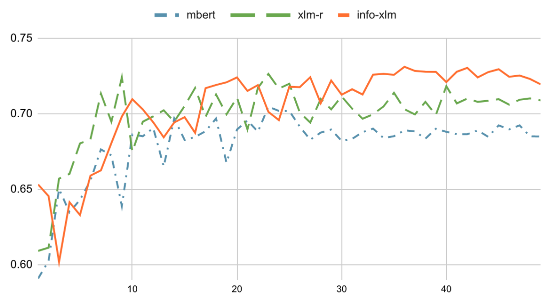

Figure 2: The fine-tuning of multi-lingual language models. We report the dev-F1 Score in zero-shot setting.

5.2 Effect of Training Techniques

As shown in Figure 3, we set bath size to 16 and use 0.999 as the EMA decay weight to obtain the best score. In the zero-shot and one-shot settings, we find that the performance is extremely sensitive to the batch size. And with the benefit of smoothing performance, using the EMA method can improve the model robustness when evaluating the trained model.

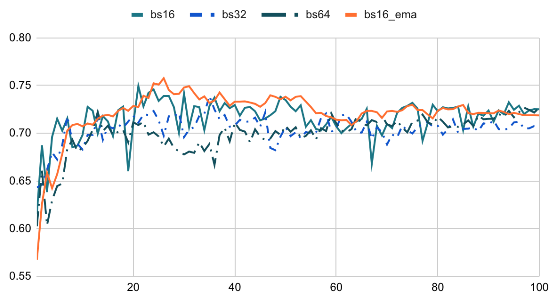

Figure 3: The batch size with EMA method. We report the dev-F1 Score in zero-shot setting.

The experimental results of adversarial training are presented in Figure 4. We set the size of mini-batch to 16 and use SMART in the zero-shot setting, and the batch size is set to 32 and use FREELB as adversarial attack in one-shot setting. We observe that the SMART and FREELB strategies have better performance than FGM and PGD strategies.

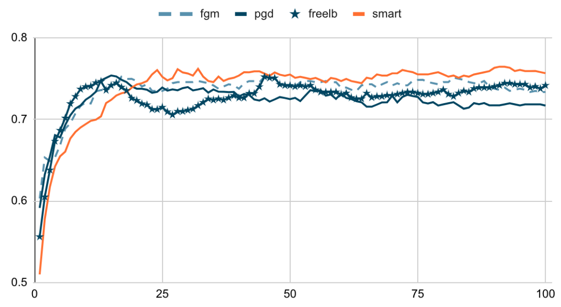

Figure 4: The performance of different adversarial attack strategies. We report the dev-F1 Score in zero-shot setting.

As presented in Table 5, we explore the impact of InfoXLM$_{base}$ model, smaller batch size, EMA method and adversarial training. These strategies can effectively improve the performance of our approach.

5.3 Effect of Contrastive Learning

In this section, we investigate the contrastive learning how to further improve the performance of sentence representations. As shown in Table 5, we use contrastive learning as unsupervised signals which yields a substantial improvement on the STS-Test dataset. We also use an extra cross-attention layer to achieve a 0.8%, 1.2% improvement in the pre-train and fine-tune settings. The cross attention idea is inspired by Reimers and Gurevych (2019), the paper shows that the Cross-Encoder achieves better performances than Bi-Encoders.

Method	Practice	Post-Eval
mBert$_{base}$	70.33	-
+CrossAttention	70.96	55.94
+ + InfoNCE	71.11	56.09
+ + + MoCo	71.34	56.32

Table 5: The effect of different strategies on the STSTest dataset. We report the Spearman correlation × 100 in pre-train setting.

In general, models which have both better alignment and uniformity obtain better sentence representations, confirming the findings in Wang and Isola (2020). We also evaluate these metrics to measure the quality of learned embeddings, including alignment of the positive pairs and uniformity of the whole representation space. We calculate uniformity on the STS-B and ASSIN2 datasets, and alignment from the positive pairs that have the gold label more than or equal to the number 4.

As shown in Figure 5, we also find that: 1) Though pre-trained embeddings have good alignment, their uniformity is poor, e.g. mBert$_{base}$. 2) Unsupervised SimCSE$_{base}$ (Gao et al., 2021) has better uniformity of pre-trained embeddings than mBert$_{base}$. 3) Jointly training regularizes the sentence embeddings' anisotropic space to be more uniform than others, but also suffers a degeneration in alignment slightly. 4) The trade off between the alignment and uniformity indicates that perfect alignment and perfect uniformity are likely hard to simultaneously achieve in practice.

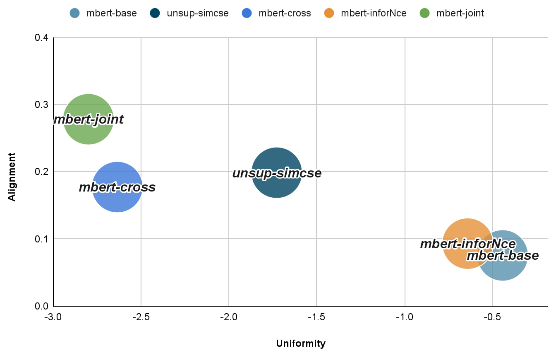

Figure 5: The alignment and uniformity of different pre-trained models. The closer to the origin of the coordinate axis, the better sentence representations.

6 Conclusion and Future Work

In this work, we provide an overview of the combined approach to detect and represent multiword expressions. We use InfoXLM$_{base}$ model as the text encoder and enhance the model generalization and robustness with exponential moving average (EMA) method and the adversarial attack strategy in the SubTaskA. In the SubTaskB, experimental results show that the cross-attention module and the contrastive learning task can considerably improve the performance. Finally, we analyze the alignment and uniformity properties to measure the quality of sentence embeddings. Future work of our system includes: 1) Using the larger pre-trained language models, such as mBert$_{large}$, InfoXLM$_{large}$. 2) Adopting other data augmentation, including Token-Shuffle, Token-Cutoff and Mix-Up.

Roberto Navigli
Sapienza University of Rome
navigli@diag.uniroma1.it

Abstract

Idioms are lexically-complex phrases whose meaning cannot be derived by compositionally interpreting their components. Although the automatic identification and understanding of idioms is essential for a wide range of Natural Language Understanding tasks, they are still largely under-investigated. This motivated the organization of the SemEval-2022 Task 2, which is divided into two multilingual subtasks: one about idiomaticity detection, and the other about sentence embeddings. In this work, we focus on the first subtask and propose a Transformer-based dual-encoder architecture to compute the semantic similarity between a potentially-idiomatic expression and its context and, based on this, predict idiomaticity. Then, we show how and to what extent Named Entity Recognition can be exploited to reduce the degree of confusion of idiom identification systems and, therefore, improve performance. Our model achieves 92.1 F_1 in the one-shot setting and shows strong robustness towards unseen idioms achieving 77.4 F_1 in the zero-shot setting. We release our code at https://github.com/Babelscape/ner4id.

1 Introduction

One of the main challenges in Natural Language Processing (NLP) is to embed the meaning of a piece of raw text (e.g. a word or a sentence) in a low-dimensional dense vector. With the advent of pretrained language models, which exploit contextual information and assume compositionality of word representations, significant improvements have been made in this direction (Peters et al., 2018; Devlin et al., 2019). On the other hand, very little attention has been paid to idiomatic expressions, i.e. multi-word expressions (MWEs) with an established meaning unrelated to the meanings of the individual constituents. However, since idiomaticity is a frequent phenomenon that can be observed in all languages, idiomatic expressions should play an important role in NLP. Indeed, their identification and understanding is crucial not only for Natural Language Understanding tasks such as Word Sense Disambiguation (Bevilacqua et al., 2021b), Semantic Role Labeling (Conia et al., 2021) and Semantic Parsing (Bevilacqua et al., 2021a), but also for Machine Translation (Edunov et al., 2018; Liu et al., 2020), Question Answering (Mishra and Jain, 2016) and Text Summarization (Chu and Wang, 2018), *inter alia*.

In the SemEval-2022 Task 2: *Multilingual Idiomaticity Detection and Sentence Embedding* (Tayyar Madabushi et al., 2022), research on idioms has been promoted by adapting datasets and tasks from the work carried out by Tayyar Madabushi et al. (2021). Specifically, the organizers propose two subtasks:

- **Subtask A**: a binary classification task in which potentially-idiomatic expressions (PIEs) must be labeled as either "Idiomatic" or "Literal", based on the context they appear in. To better test models' generalization capabilities, two different settings are provided: *zero-shot* and *one-shot*;

- **Subtask B**: requires models to output the correct Semantic Text Similarity (STS) scores between sentence pairs based on whether or not each sentence contains an idiomatic expression. Subtask B is also available in two settings: *pre-train* and *fine-tune*.

Both subtasks cover three languages: English, Portuguese and Galician[1]. In addition, the organizers provide strong baseline systems to compare with.

In this paper, we present the NER4ID submission to the SemEval-2022 Task 2 which focuses on Subtask A. Specifically, we successfully tackle

[1]Galician is included only in the test sets to test transfer-learning abilities of the models.

the idiom identification task by introducing a two-step system that: i) uses Named Entity Recognition (NER) to pre-identify non-idiomatic expressions, and ii) exploits a novel Transformer-based dual-encoder architecture to compute the semantic similarities between the remaining potentially-idiomatic expressions and their contexts and, based on these, predict idiomaticity. Finally, we extensively evaluate our system on both one-shot and zero-shot settings. We release our code at `https://github.com/Babelscape/ner4id`.

2 Related Work

Approaches to idiom identification were initially built on the notion that idiomatic expressions, like other MWEs, are less syntactically and lexically flexible than non-idiomatic and compositional ones. Indeed, initial studies focused on specific syntactic constructions. Fazly and Stevenson (2006) focused on verb/noun idioms, e.g. *shoot the breeze*, and used the Pointwise Mutual Information (PMI, Church et al., 1991) measure to quantify the degree of lexical, syntactic, and overall fixedness of a given verb+noun combination. Cook et al. (2007) and Diab and Bhutada (2009) also focused on verb/noun idioms using similar strategies. Other studies, instead, focused on verb/particle idioms, e.g. *call off* (Ramisch et al., 2008), or on idioms satisfying specific restrictions, i.e. subject/verb, such as *tension mounted*, and verb/direct-object, e.g. *break the ice* (Shutova et al., 2010).

The following generation of approaches exploited semantic idiosyncrasy, i.e. the linguistic property in which the meaning of an idiomatic expression cannot be completely derived from the meaning of its individual constituents. This property causes idioms to appear in contexts typically unrelated to the meaning of their individual components, hence it provides a key aspect to be exploited in an automatic approach. In particular, Muzny and Zettlemoyer (2013) introduced new lexical and graph-based features that use WordNet[2] and Wiktionary[3], and proposed a simple yet efficient binary Perceptron classifier to distinguish idiomatic and literal expressions by exploiting their components and dictionary definitions. A similar, but unsupervised approach that relied on the dictionary definitions of each component of a given idiom was adopted by Verma and Vuppuluri (2015).

[2]`https://wordnet.princeton.edu/`
[3]`https://www.wiktionary.org/`

Finally, these latter methods have been superseded by approaches making use of distributional similarity in the form of both static and contextualized word embeddings (Gharbieh et al., 2016; Ehren, 2017; Senaldi et al., 2019; Liu and Hwa, 2019; Hashempour and Villavicencio, 2020; Kurfalı and Östling, 2020; Fakharian, 2021; Garcia et al., 2021; Nedumpozhimana and Kelleher, 2021), while keeping the underlying assumption unchanged, that is, the vector representation of the component words should be distant from the vector representation of the context, or of the expression as a whole.

Although efforts have been made in this direction, most of the studies to date have focused on the English language. Additionally, the low performance of current idiomaticity detection systems makes them not very reliable, and therefore such systems tend not to be included in downstream applications. In this work, instead, we propose a high-performance multilingual system for idiomaticity identification.

3 NER4ID

We first describe our architecture for idiomaticity detection (Section 3.1), and then we show how Named Entity Recognition can be included to obtain a more robust idiom identification system (Section 3.2). Figure 1 provides a graphical representation of the overall idiom identification system.

3.1 Dual-Encoder Architecture

In order to distinguish between compositional and idiomatic phrases, we exploit the semantic idiosyncrasy property of idiomatic expressions. This property often implies that when a MWE occurs with its idiomatic meaning, then the meaning of its individual components is unrelated to the surrounding context. On the other hand, when the expression has a compositional meaning, individual words are related to the context. To better explain, consider the following two alternatives in which the potentially idiomatic expression *piece of cake* occurs:

a) Decryption is a <u>*piece of cake*</u> if you know the override codes;

b) Tom ate the last <u>*piece of cake*</u>, but if you want, I'm making another dessert.

In the first case, where *piece of cake* has an idiomatic meaning (i.e. it means *straightforward*),

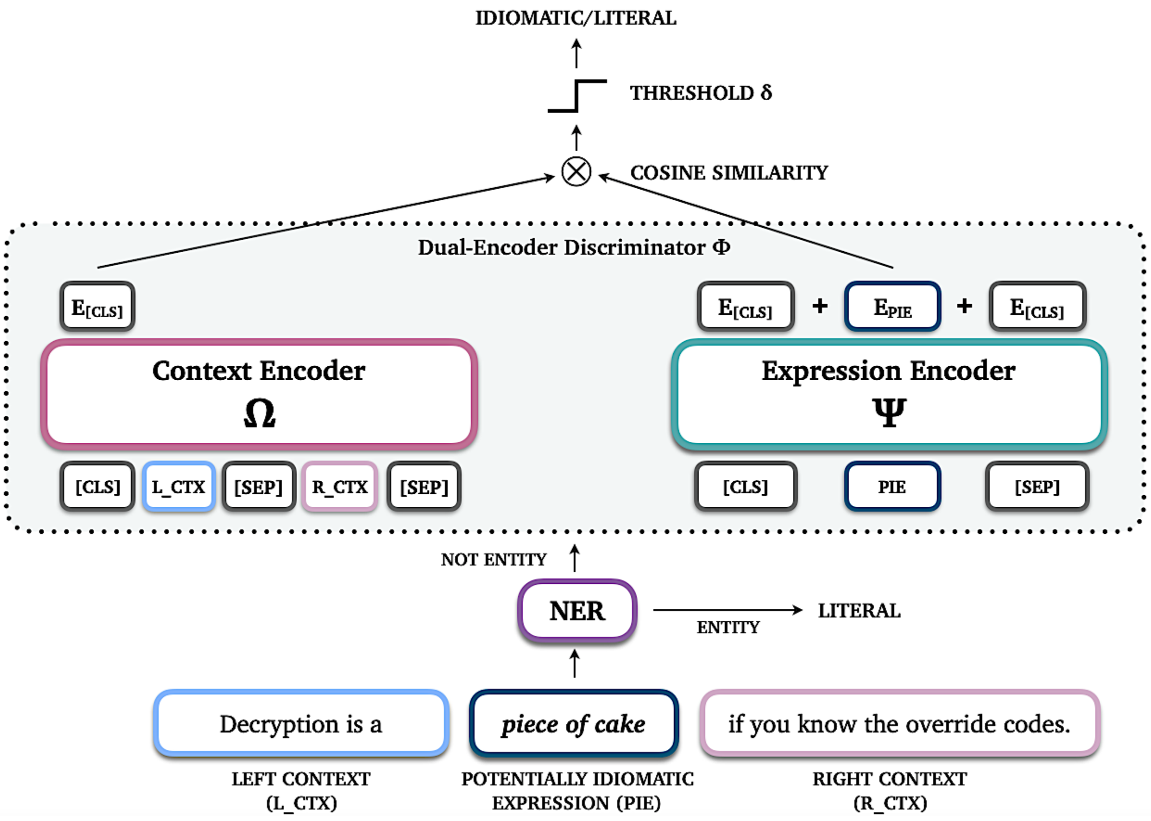

Figure 1: Graphical representation of our architecture for idiomaticity detection. “E" stands for Embedding. A potentially idiomatic expression e is labeled as idiomatic when: i) e is not an entity, and ii) the cosine similarity score between the representations $\Omega(c)$ and $\Psi(e)$, where c is the surrounding context, is lower than the threshold δ.

the word *cake* has nothing to do with the surrounding context. In the second case, instead, we find multiple words whose meaning is related to the meaning of *cake*, i.e. *ate* and *dessert*.

Following the above described intuition, and taking inspiration from recent advances in the main disambiguation tasks (Blevins and Zettlemoyer, 2020; Botha et al., 2020; Tedeschi et al., 2021a), we design a dual-encoder architecture to produce a vector representation for both the expression and its context, and then, based on their cosine similarity, we label the expression as either idiomatic or literal. More formally, let us define an expression encoder Ψ and a context encoder Ω. Then, given an expression-context pair $\langle e, c\rangle$, the output of the dual-encoder architecture Φ is defined as follows:

$$\Phi(e,c) = \begin{cases} 0, & \text{if } \dfrac{\Psi(e)^T\Omega(c)}{\|\Psi(e)\|\,\|\Omega(c)\|} \leq \delta \\ 1, & \text{otherwise} \end{cases} \quad (1)$$

where $\Phi(e,c) = 0$ means that e is idiomatic in c, while $\Phi(e,c) = 1$ if e has a literal meaning in c. δ is a manually-tuned threshold. Both encoders are BERT-based architectures that take as input the tokenized versions of expressions and their contexts, respectively, surrounded by the special tokens [CLS] and [SEP]. To encode an expression, we take the sum of the individual representations of all its subwords. Instead, for the context we take the representation of the [CLS] token.

3.2 Entity or Idiom?

As we discussed in the previous Section, semantic idiosyncrasy is essential for discriminating between idiomatic and literal expressions. However, there are cases in which the individual constituents of a potentially idiomatic expression are unrelated to the context, but the expression as used in that particular context is not idiomatic. Many of these cases correspond to named entities. Table 1 provides a selection of examples – extracted from the Subtask A datasets – in which PIEs are named entities. For instance, in the first example, *Blood Bath* is a movie and, therefore, it does not have an idiomatic meaning. Nevertheless, its constituents (i.e. *blood* and *bath*) are unrelated to the context, hence misleading our dual-encoder architecture (Section 3.1) to classify it as idiomatic.

PIE	Context
blood bath	Deborah Loomis is an actress, known for Hercules in New York (1970), Foreplay (1975) and ***Blood Bath*** (1976).
fine line	***Fine Line*** received generally positive reviews from music critics, particularly towards its production and stylistic influences.
monkey business	***Monkey Business*** is an Action, Adventure, Comedy, Crime movie that was released in 1998 and has a run time of 1 hr 29 min.
rocket science	After finishing "Confrontation", the band shifted to "***Rocket Science***".
night owl	Andrew Gonzalez, owner, ***Night Owl*** Cookies: "Nobody believed in me except for Deco Drive.","They got me on air very quickly!"
silver spoon	Not only is it endorsed by the UK's biggest food brands – Weetabix, Shredded Wheat, ***Silver Spoon***, Carling lager, Marriage's flour – but being Red Tractor also means you can supply different retailers without lots of different requirements.

Table 1: Examples of sentences where potentially idiomatic expressions (PIEs) are named entities.

In order to cope with this issue, we exploit Named Entity Recognition, i.e. the task of identifying specific words as belonging to predefined semantic types, such as Person, Location and Organization (Nadeau and Sekine, 2007). Specifically, we introduce an auxiliary NER module in our classification pipeline that, given as input a raw text sequence of n tokens $X = x_1, \ldots, x_n$ containing a potentially idiomatic expression p, predicts all the entities $E = e_1, \ldots, e_m$ in X. Then, if $p \in E$, p is labeled as literal, otherwise p is provided to the dual encoder, together with its context. To detect further entities, we also exploit capitalization.

4 Experiments

In this Section, we describe our experimental setup (Section 4.1), the datasets we use to train and evaluate our idiom identification system (Section 4.2), and the obtained results (Section 4.3).

4.1 Experimental Setup

We implement our dual-encoder architecture (Section 3.1) with PyTorch (Paszke et al., 2019), using the Transformers library (Wolf et al., 2019) to load the weights of `BERT-base-cased` for English and of `BERT-base-portuguese-cased` for Portuguese and Galician. We fine-tune our idiom identification system for 100 epochs with a Mean-Squared Error loss criterion, adopting an early stopping strategy with a patience value of 20, Adam (Kingma and Ba, 2015) optimizer, and a learning rate of 10^{-5}. Additionally, we set $\delta = 0$[4], and use 32 as batch size, with 4 steps of gradient accumulation. To identify entities, instead, we employ `wikineural-multilingual-ner`[5], a Multilingual BERT (mBERT) model fine-tuned on the WikiNEuRal dataset (Tedeschi et al., 2021b). We compare systems by means of their Macro F_1 scores, as specified by the competition rules. Our final scores are obtained by ensembling the predictions of $N = 9$ model checkpoints[6] and taking the class with the highest number of votes.

Model training was carried out on a NVIDIA GeForce RTX 3090. Each training (i.e. for each model configuration) required ∼1min/epoch on average, for a mean of ∼30 epochs.

4.2 Training, Validation and Test Data

The training, validation and test sets we use in our experiments are those provided for SubTask A[7]. Data statistics are provided in Table 2.

[4]We train our system to produce a cosine similarity score s between a MWE e and its context c, which is $s = -1$ when e is idiomatic in c, or $s = 1$ otherwise. Therefore, in Eq. 1, $\delta = 0$ means that negative similarity scores are mapped to 0 (*Idiomatic*), while positive scores are mapped to 1 (*Literal*).

[5]`https://huggingface.co/Babelscape/wikineural-multilingual-ner`

[6]We use the dev set to search for the optimal value of N by choosing from $N = \{1, 3, 5, 7, 9, 11, 13\}$.

[7]`https://github.com/H-TayyarMadabushi/SemEval_2022_Task2-idiomaticity`

Split	EN	PT	GL	Total
`train-one-shot`	73	73	63	209
`train-zero-shot`	3327	1164	0	4491
`dev`	466	273	0	739
`test`	916	713	713	2342

Table 2: Number of examples in the training, validation and test sets for each of the covered languages: English (EN), Portuguese (PT) and Galician (GL).

	System	EN	PT	GL	ALL
zero-shot	Baseline	70.1	68.0	50.7	65.4
	Our System w/o NER	76.4	63.5	59.7	69.9
	Our System	**86.8**	**70.4**	**65.5**	**77.4**
one-shot	Baseline	88.6	86.4	81.6	86.5
	Our System w/o NER	91.0	86.8	83.9	88.8
	Our System	**95.8**	**88.9**	**87.4**	**92.1**

Table 3: Results of our system with and without the inclusion of the NER module on English (EN), Portuguese (PT) and Galician (GL) languages using the Macro-F_1 score metric. The ALL column reports the overall results. The baselines are provided by task organizers.

In the *zero-shot* setting, potentially idiomatic expressions in the training set are completely disjoint from those in the validation and test sets. In the *one-shot* setting, instead, one positive and one negative example are included for each MWE in the test and validation sets. Finally, note that the zero-shot training set and the validation set cover only English and Portuguese languages, while the test set also contains the Galician language, hence further increasing the difficulty of the zero-shot setting.

4.3 Results

In preliminary experiments, we measure the impact that context inclusion (i.e., the sentences preceding and following the one containing the PIEs) has on our system's performance. Similar to Tayyar Madabushi et al. (2021), we observe a slight drop in performance (i.e., -0.3 F_1 points, on average on the zero-shot and one-shot settings) and longer training times, hence we do not include context in our experiments. Then, in order to show the effectiveness of our dual-encoder architecture (Section 3.1) and of our entire idiomaticity detection system that includes the NER module (Section 3.2), we compare them with the strong mBERT-based baselines provided by the task organizers (Tayyar Madabushi et al., 2022): for the zero-shot setting, their model takes as input the context, while for the one-shot setting, they exclude the context and provide as input only the sentence containing the PIE, where the latter is separated from the rest of the input by using the "[SEP]" special token.

In both zero-shot and one-shot settings, our system far exceeds the performance of the competitive baselines. Specifically, in the zero-shot setting we observe an average improvement of 12 F_1 points for the complete system (Figure 1), and of 4.5 F_1 points using only the dual-encoder architecture (Section 3.1). Likewise, in the one-shot setting we point out an average improvement of 5.6 F_1 points for the overall architecture, and of 2.3 F_1 points for the dual encoder. Therefore, the findings are twofold: i) dual encoders that exploit semantic idiosyncrasy discriminate well between idiomatic and literal expressions, and ii) an idiomaticity detection system can greatly benefit from the inclusion of a NER module in the classification pipeline to manage such ambiguous cases (cf. the examples in Table 1, extracted by using our NER classifier).

5 Conclusions

In this paper, we presented our NER4ID submission to SemEval-2022 Task 2 focusing on the Multilingual Idiomaticity Detection subtask. We started by exploiting the semantic idiosyncrasy property of idiomatic expressions and introduced a novel dual-encoder Transformer-based architecture that encodes both the potentially idiomatic expression (PIE) and its context, and based on their similarity predicts idiomaticity. Further, by manually inspecting our system's errors we discovered critical cases in which, although the individual constituents of a PIE were unrelated to the context, the expressions were not idiomatic in that particular context in which they were used. In most of these cases, the PIEs were part of a named entity. Hence, our second main contribution was devoted to the inclusion of an auxiliary NER module in the idiomaticity detection pipeline in order to avoid these errors. Our experiments showed that: i) our dual-encoder architecture was able to successfully solve the idiom identification task by consistently outperforming the strong baselines provided by the task organizers, and ii) the inclusion of NER in the pipeline provided further improvements of up to 7.5 F_1 points.

As future work, we plan to follow the research line proposed by Tedeschi et al. (2022), and explore the identification of idioms directly on raw texts, i.e., without pre-identified potentially idiomatic expressions, and study a broader set of languages.

Abstract

This paper will present the methods[1] we use as the YNU-HPCC team in the SemEval-2022 Task 2, Multilingual Idiomaticity Detection and Sentence Embedding. We are involved in two subtasks, including four settings. In subtask B of sentence representation, we used novel approaches with ideas of contrastive learning to optimize model, where method of CoSENT was used in the pre-train setting, and triplet loss and multiple negatives ranking loss functions in fine-tune setting. We had achieved very competitive results on the final released test datasets. However, for subtask A of idiomaticity detection, we simply did a few explorations and experiments based on the xlm-RoBERTa model. Sentence concatenated with additional MWE as inputs did well in a one-shot setting. Sentences containing context had a poor performance on final released test data in zero-shot setting even if we attempted to extract effective information from CLS tokens of hidden layers.

1 Introduction

Meaning of sentence could be captured by compositionality of word representations. However, there widely exists potentially idiomatic phrases in different languages, which are multiword expressions (MWEs) with idiomatic and literal meanings. Therefore, representation of idiomatic phrases is not directly compositional. A previous study has shown that the representation of idiomatic phrases by contextual models, such as ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and some of its variants, are not accurate(Garcia et al., 2021). It will be challenging to represent the MWEs correctly in the downstream tasks (Tayyar Madabushi et al., 2021). SemEval-2022 Task 2, Multilingual Idiomaticity Detection and Sentence Embedding (Tayyar Madabushi et al., 2022), involves English (EN), Portuguese (PT), and Galician (GL). This task includes two subtasks and each subtask contains two settings:

- Subtask A: Determining whether a sentence contains an idiomatic expression. This is a binary classification task with two settings of zero-shot and one-shot. Zero-shot setting means that idiomatic phrases (MWEs) in training examples are completely disjoint to those in development, evaluation, and test sets. In a one-shot setting, MWEs appearing in development and test sets include in the training sentences.

- Subtask B: Outputing the correct Semantic Text Similarity (STS) scores between sentence pairs whether or not either sentence contains an idiomatic expression. The STS scores represent semantical similarity between two sentences ranging from 0 (least similar) to 1 (most similar). This is a regressive task with two setting of pre-train and fine-tune. In the pre-train setting, models require to be trained on any semantic text similarity dataset without idiom. The fine-tune setting should use provided training sets included MWEs.

The remainder of this paper is organized as follows. In Section 2, we describe the structures of model and system. The details about data and implementation and comparative results are presented in Section 3. Finally, a conclusion is drawn in Section 4.

2 System Overview

2.1 Subtask A: Idiomaticity Detection

This is a binary classification task that requires classifying sentences into either *Idiomatic* or *Non-idiomatic*. mBERT (BERT multilingual base model) was used as a pre-trained model in the baseline method. It is a masked language models pre-

[1]The code of this paper is available at: https://github.com/lkh-meredith/SemEval2022_Task2_YNU-HPCC

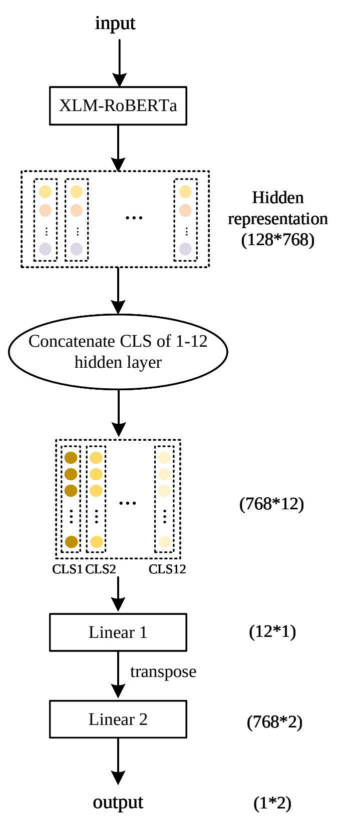

Figure 1: Model architecture of zero-shot setting

trained on the top 104 languages with Wikipedia, which is able to map multilingual representation to the same semantic space, but unable to master cross-lingual information. XLM-RoBERTa (Conneau et al., 2020) was a cross-lingual language model used for our experiment in this subtask, which combined XLM (CONNEAU and Lample, 2019) and RoBERTa (Liu et al., 2019) pre-trained on the 2.5TB of filtered CommonCrawl data containing 100 languages. It is good for the scarce language corpus that could use information learned from larger corpus of other languages. Figure 1 is process of zero-shot setting. Linear 1 layer extracted effective information from concatenated CLS tokens from 1-12 hidden layer of model's output. In the one-shot setting, we simply extracted CLS from the last hidden layer of model's output to classify.

2.2 Subtask B: Sentence Representation

In the pre-train setting , the methodology of baseline was that a sentence transformer model was created by mBERT model adding MWE tokens and training it. As shown in Figure 2 (a), it based SBERT (Reimers and Gurevych, 2019) architecture with the regression objective function, which is a good way of breaking compositionality of idiomatic phrase (Tayyar Madabushi et al., 2021). Figure 2 (b) illustrated one of the methods that we took, which was a siamese network structure of SBERT with classification objective function. Vectors $u, v, \parallel u - v \parallel$ was concatenated as a feature, and $\parallel u - v \parallel$ could play a crucial role in determining if two sentences were similar. Figure 2 (c) illustrates a new method of optimizing cosine similarity, CoSENT (Cosine Sentence), which was proposed by Jianlin Su in his blog post[2]. In the method (c), sentences in a batch are composed of sentences pairs, where two sentences that belong to one sentence pair are adjacent, so they can not be shuffled. The most important part of it was that a loss function based on contrastive learning was designed to maintain training and prediction consistency. CoSENT loss function defined as follows,

$$\log\left[1+\sum_{\mathrm{sim(i,j)>sim(m,n)}} e^{\lambda(\cos(\mathrm{u_m,u_n})-\cos(\mathrm{u_i,u_j}))}\right] \quad (1)$$

where (i, j) and (m, n) are sentence pairs, u_i, u_j, u_m, u_n are sentence embeddings. λ is a hyper-parameter of 20 in our experiment. $e^{\lambda(\cos(u_m,u_n)-\cos(u_i,u_j))}$ is added when label of (i, j) is greater than (m, n), so $\cos(u_i, u_j) > \cos(u_m, u_n)$ is expected in the loss function.

The methodology of baseline used for the fine-tune setting is similar to the pre-train setting: create a sentence transformer model with mBERT adding MWE tokens. This sentence transformer firstly output scores for some of fine-tune data that had no scores (details about data in section 3.1) and trained on them. The questions about the method is that: 1) It is not good to calculate similarity directly between sentence vectors generated by pre-trained model without fine-tuing, which generate static labels and may not accurate. 2) mBERT are not trained on the parallel data, so their vector space across languages are not aligned, which may result in poor results on other languanges. We chose a sentence transformer, distiluse-base-mutilingual-cased (Reimers and Gurevych, 2019), provided in Hugging Face models hub[3], which had been demonstrated to generate good sentence embeddings in

multilingual language and been evaluated in task of multilingual sematic textual similarity. The the difference of its two version, v1 and v2, is that mUSE sentence encoder supports 15 languages and v2 supports 50 including GL respectively. The training approach was achieved by using knowledge distillation. It is able to extend sentence embedding from source language to target ones by sentence pairs of translation (Reimers and Gurevych, 2020). The training procedure of this pre-trained model is shown in Figure 3 using mUSE (Yang et al., 2020) as teacher model and distilmBERT (a distilled version of the mBERT) as student model. Mean pooling of outputs are as sentence vector and minimize the mean-squared loss. Therefore, this model applies to semantic similarity task, and it will be removed last dense layer was as extractor of feature in our experiment.

Triplet loss and multiple negatives ranking loss functions were used to fine-tune. Triplet loss function was used to fine-tune model so that the distance of correct sentence pairs should be closer than incorrect sentence pairs. It computed as follows:

$$\max(\| anchor - pos \| - \| anchor - neg \| \\ + margin, 0) \tag{2}$$

The multiple negatives ranking loss (Henderson et al., 2017) was used to implement and optimize, as shown in Figure 4. $(S_1, S_1') \dots (S_n, S_n')$ were positive pairs. The matrix X represented cosine similarity between sentence pairs in a batch. For a batch of size n, there would be n targets ($y = (0, 1, \dots, n-1)$) treated as labels to represent position of positive pairs in the matrix. With increasing batch sizes, the performance usually is better. The approximated mean negative log probability of data was realized to calculated by cross entropy loss in Pytorch:

$$\begin{aligned} & -\frac{1}{n}\sum_{i=0}^{n-1} \log \frac{e^{X_{i,y_i}}}{\sum_{j=0}^{n-1} e^{X_{i,y_j}}} \\ & = -\frac{1}{n}\sum_{i=0}^{n-1}\left[X_{i,y_i} - \log\left(\sum_{j=0}^{n-1} e^{X_{i,y_j}}\right)\right] \end{aligned} \tag{3}$$

3 Experiments

3.1 Dataset

There includes EN, PT, and GL in datasets. GL is only provided in test dataset and one-shot training data, aiming to test models' ability to transfer learning across languages. Besides, Modern Galician (GL) is part of the West Iberian languages group, which belongs to a family of Romance languages including the Portuguese. A brief intro-

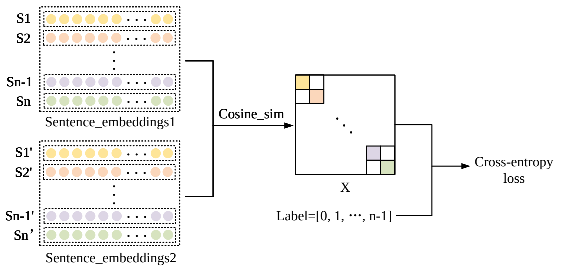

Figure 4: Multiple negatives ranking loss used for positive pairs

duction about datasets describes as follows, and more details are in the task description paper (Tayyar Madabushi et al., 2022).

In the subtask A, training data provided includes zero-shot and one-shot data. A label of 0 indicates *Idiomatic* and a label of 1 indicates *Non-idiomatic*. Zero-shot training data combined with the context, sentences preceding and succeeding the one containing the idioms, are used as training sentences in the zero-shot setting. In the one-shot setting, both the zero-shot and one-shot data are used to train, which exclude the context but add the MWEs as an additional feature. Sentence was concatenated to MWE and separated them by SEP.

Train split of STSBenchmark datasets in English and ASSIN2 datasets in Portuguese are as training dataset in the subtask B pre-train setting. Development and test datasets consist of sentence pairs, some of whom contains idiomaticity and other has no idiomaticity, which replaced by non-idiomatic paraphrases. They will be computed a score (cosine similarity) after model's outputing.

In the subtask B fine-tune setting, development and test datasets are the same as the pre-train setting. Train datasets provided contain EN and PT training examples with type of one-shot and zero-shot totally, and also contain some GL training one-shot examples. For integrity of idiom tokens, MWEs in datasets were added into the tokenizer of model. Training data have positive and negative types. The positive examples mean that sentence with an idiom (S_{MWE}) is the same as the sentence in which the idiom has been replaced by a phrase that correctly represents the meaning of the idiom in context (S_c). So their STS score are equal to 1 ($sim(S_{MWE}, S_c) = 1$). For the negative examples, a sentence with an idiom and the same sentence in which the idiom has been replaced by a phrase that incorrectly represents the meaning of the idiom in context (S_i) should have a low STS score. The score is approximately equal to the STS score between a sentence where the idiom has been replaced by a phrase that correctly represents its meaning and one wherein it incorrectly represents the meaning ($sim(S_{MWE}, S_i) = sim(S_c, S_i)$).

3.2 Evaluation Metrics

Subtask A is evaluated by the Macro F1 score between the gold labels and predictions. F1 score is defined as follows:

$$F1\ score = 2 \times \frac{precision \times recall}{precision + recall} \tag{4}$$

Macro F1 score will calculate average of the precision and recall for all classes firstly, and does not take label imbalance into account.

The metric of subtask B is the Spearman Rank correlation to evaluate outputing STS scores, which is defined as follows:

$$\rho_s = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \tag{5}$$

$$d_i = rank(X_i) - rank(Y_i) \tag{6}$$

where n and d_i denote amount of data and difference between position of variate X and Y after sort, respectively. It computes Pearson correlation coefficient using rank of data sets. This metric uses to evaluate correlation between STS of model's output and gold label.

3.3 Implementation Details

Herein all experiments, we set seed of 4 and AdamW optimizer (Loshchilov and Hutter, 2019) with learning rate 2e-5. Besides, batch-size was set as 32, 4, 16 in zero-shot , one-shot setting and subtask B respectively. A linear learning rate warm-up was 5% and 10% in subtask A and subtask B respectively. A max sequence length of 128 was in subtask A and pre-train setting, 512 in fine-tune setting. Each model was fine-tuned for 10 epochs, where the model exhibiting the best performance on the dev set was used to predict the test set in the competition.

For subtask A of binary classification, cross-entropy loss function was used. The methods of Figure 2 were experimented in the pre-train setting. We set our default pooling strategy was mean, and method (c) used mean pooling of last hidden layer and first-last hidden layer respectively.

In the fine-tune setting, a sentence transformer based on the pre-training model was created. The

* *0.5602*, *0.2628*, and *0.7990* are the revised results, which are different from the results had been submitted on the evaluation. Because we found out later that there existed something wrong in our former data processing. It had be trained after correcting and used the same method and parameters as before.

Table 2: Results of subtask B

sentence transformer we chose, distiluse-base-multilingual-cased, was extended the vocabulary of MWEs and removed last dense layer was as extractor of feature. Then, mean pooling was applied to output, which generated sentence representation of 768 dimension. Besides, training data were divided into two datasets and used two loss function to fine-tune model. According to negative training data, S_{MWE}, S_c, and S_i constituted a triplet of $(anchor, pos, neg)$. Triplet loss function was used, and we set margin as 0.1 in our experiment. The positive training data only had S_{MWE} and S_c, which composed positive pairs $(anchor_i, pos_i)$. Similar to the training process of unsupervised SimCSE (Gao et al., 2021), $(anchor_i, pos_j) for (i \neq j)$ were as negative pairs. So multiple negatives ranking loss function were used in this part.

3.4 Comparative Results

All of Experimental results are listed in Tables 1 and 2. The reason for results of development and test set difference may be the inconsistent data distribution of them that GL was added in test data. However, the difference of them in zero-shot setting appeared that the sentences including of contiguous context did not make the model learn strong ability of generalization so that all the results on the test set were below the baseline. The results of one-shot setting indicated that classify the sentence and MWE by splicing them together as one texts could be integrated and obtained a better results and xlm-RoBERTa performed better.

In the results of pre-train setting, in comparative to method (a), while method (b) grasped better semantic information of idiom, it could not output good semantic similarity on STS dataset because of training method. It could be found that method (c) could ease their problem and achieved a better result compared with method (a) and (b). The results of fine-tune setting show that these two loss functions play a important role, and the model's understanding of idioms can be improved to some extent by contrastive learning. The distiluse-base-multilingual-cased also used baseline method based on $sim(S_{MWE}, S_i) = sim(S_c, S_i)$. Besides, although v2 supported more languages including GL than v1, it performed a bit poorer instead, which explains further that the model training on more languages appear loss of performance for the information that has been learned.

4 Conclusions

Herein, we discuss and experiment the methods we used in SemEval-2022 Task 2. We participated in two subtasks, idiomaticity detection and representation of idiomaticity. Each of subtasks including two settings, achieved the 19th, 6th, 5th, and 1th places in the final test sets, respectively. Our results showed that the idea introduced contrastive learning in representation of idiomaticity achieved good results, but methods of zero-shot setting in idiomaticity detection did not well and were lack of ability of generalization. We intended to explore and improve the performance of zero-shot and few-shot learning further in future work.

Abstract

We propose a multilingual adversarial training model for determining whether a sentence contains an idiomatic expression. Given that a key challenge with this task is the limited size of annotated data, our model relies on pre-trained contextual representations from different multilingual state-of-the-art transformer-based language models (i.e., multilingual BERT and XLM-RoBERTa), and on adversarial training, a training method for further enhancing model generalization and robustness. Without relying on any human-crafted features, knowledge bases, or additional datasets other than the target datasets, our model achieved competitive results and ranked 6th place in SubTask A (zero-shot) setting and 15th place in SubTask A (one-shot) setting.

1 Introduction

Large-scale pre-trained language models such as BERT (Devlin et al., 2019) have achieved great success in a wide range of natural language processing (NLP) tasks. However, more recent studies show that even such contextual models have a limited ability to capture idiomaticity (Garcia et al., 2021). Idiomatic expressions denote a group of words that behave as single words to some extent. Their linguistic behavior cannot be inferred from the characteristics of their components, and still pose a challenge to natural language processing (NLP) systems.

This paper describes the system developed by the OCHADAI team for SemEval-2022 Task 2 - Multilingual Idiomaticity Detection and Sentence Embedding (Tayyar Madabushi et al., 2022). Given that a key challenge in this task is the limited size of annotated data, we follow best practices from recent work on enhancing model generalization and robustness and propose a model ensemble that leverages multilingual pre-trained representations and adversarial training. Our model ranked 6th on SubTask A (zero-shot), and 15th on SubTask A (one-shot).

Setting	Language	Train	Dev	Eval	Test
zero-shot	English	3,327	-	-	-
	Portuguese	1,164	-	-	-
	Galician	0	-	-	-
one-shot	English	87	466	483	916
	Portuguese	53	273	279	713
	Galician	0	0	0	713

Table 1: Summary of the SemEval 2022 Task 2 Subtask A dataset. Note that the dev, eval and test sets are used in both settings.

2 Task Description

SemEval-2021 Task 2 SubTask A consists of a binary classification task that requires classifying sentences with a target multiword expression (MWE) into either "Idiomatic" or "Literal" across English, Portuguese and Galician (Tayyar Madabushi et al., 2021). Further, it is subdivided into two settings to better test models' ability to generalize: zero-shot and one-shot. In the zero-shot" setting, multiword expressions (potentially idiomatic phrases), in the training set are completely disjoint from those in the test and development sets. In the "one-shot" setting, one positive and one negative training examples are included for each MWE in the test and development sets. Note that the actual examples in the training data are different from those in the test and development sets in both settings. Only the datasets provided by the organizers are allowed to train the models. Participants can use only the data provided for the zero-shot setting to train the zero-shot model. However, participants were allowed to use data provided for both settings to train models in the one-shot setting. The statistics of the corpus are presented in Table 1. Our team submitted results for both settings, and the next section outlines the overview of our model.

Setting	Language	Sentence	Target MWE	Label
zero-shot	English	This song is about unconditionally supporting someone you love. This is a **love song**. Let's be there for each other.	love song	1
one-shot	Portuguese	Estamos honrando o teto e construindo as paredes", afirmou. Em outro momento, voltando ao tema do impasse do Orçamento, ele reforçou que a busca é por uma solução, que a briga tem "mérito" e que "sempre, em grande rebanho, tem uma **ovelha negra**"."Mas não é o Congresso nem o grosso do ministério", completou.	ovelha negra	0
one-shot	Galician	Non podemos abandonalos á súa sorte, porque sen mozos e mozas no campo e sen a súa actividade agraria suporía, entre outras cousas, a deslocalización da produción e a dependencia alimentaria Máis alá das políticas comunitarias, ¿cres que poden desenvolverse alternativas para a **xente nova** a partir de medidas municipais, autonómicas ou estatais? Estase a facer?	xente nova	0

Table 2: Example sentences and labels for Subtask A. Note that "Idiomatic" is assigned the label 0 in the dataset and "non-idiomatic" (including proper nouns) are assigned the label 1.

3 System Overview

We focus on exploring different training techniques using BERT and RoBERTa, given their superior performance on a wide range of NLP tasks. Each text encoder and training method used in our model are detailed below.

3.1 Text Encoders

M-BERT (Devlin et al., 2019): We use the M-BERT$_{\text{BASE}}$ model released by the authors. It is pre-trained on the top 104 languages with the largest Wikipedia using a masked language modeling (MLM) objective. This model is case sensitive: it makes a difference between english and English.
XLM-R (Conneau et al., 2019): XLM-RoBERTa (XLM-R) is a multilingual version of RoBERTa. It is pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages. XLM-R has been shown to perform particularly well on low-resource languages, such as Swahili and Urdu. We use the XLM-R$_{\text{LARGE}}$ model released by the authors.

3.2 Training Procedures

Standard fine-tuning: This is the standard fine-tuning procedure where we fine-tune BERT and RoBERTa on each training setting-specific data.
Adversarial training (ADV): Adversarial training has proven effective in improving model generalization and robustness in computer vision (Madry et al., 2017; Goodfellow et al., 2014) and more recently in NLP (Zhu et al., 2019; Jiang et al., 2019; Cheng et al., 2019; Liu et al., 2020a; Pereira et al., 2020). It works by augmenting the input with a small perturbation that maximizes the adversarial loss:

$$\min_{\theta} \mathbb{E}_{(x,y)\sim D}[\max_{\delta} l(f(x+\delta;\theta), y)] \tag{1}$$

where the inner maximization can be solved by projected gradient descent (Madry et al., 2017). Recently, adversarial training has been successfully applied to NLP as well (Zhu et al., 2019; Jiang et al., 2019; Pereira et al., 2020). In our experiments, we use SMART (Jiang et al., 2019), which instead regularizes the standard training objective using *virtual adversarial training* (Miyato et al., 2018):

$$\begin{aligned}\min_{\theta} \mathbb{E}_{(x,y)\sim D}[l(f(x;\theta), y)+ \\ \alpha \max_{\delta} l(f(x+\delta;\theta), f(x;\theta))]\end{aligned} \tag{2}$$

Effectively, the adversarial term encourages smoothness in the input neighborhood, and α is a hyperparameter that controls the trade-off between standard errors and adversarial errors.

4 Experiments

4.1 Implementation Details

Our model implementation is based on the MT-DNN framework (Liu et al., 2019a, 2020b). We use BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2019) as the text encoders. We used ADAM (Kingma and Ba, 2015) as our optimizer with a learning rate in the range $\in \{8\times10^{-6}, 9\times10^{-6}, 1\times10^{-5}\}$ and a batch size $\in \{8, 16, 32\}$. The maximum number of epochs was set to 10. A linear learning rate decay schedule with warm-up over 0.1 was used, unless stated otherwise. To avoid gradient exploding, we clipped the gradient norm within 1. All the texts were tokenized using wordpieces and were chopped to spans no longer than 512 tokens. During adversarial training, we follow (Jiang et al., 2019) and set the perturbation size to 1×10^{-5}, the step size to 1×10^{-3}, and to 1×10^{-5} the variance for initializing the perturbation. The number of projected gradient steps and the α parameter (Equation 2) were both set to 1.

We follow (Devlin et al., 2019) and (Liu et al., 2019b), and set the first token as the [CLS] token and the <s> token, respectively, when encoding the input on BERT and RoBERTa, respectively. We separate the input sentence and the target expression with the special token [SEP] and </s> for BERT and RoBERTa, respectively. e.g. [CLS] Ben Salmon is a committed *night owl* with an undying devotion to discovering new music.,"He lives in the great state of Oregon, where he hosts a killerradio show and obsesses about Kentucky basketball from afar. [SEP] *night owl* [SEP].

For both settings (zero-shot and one-shot), we used the dev dataset released by organizers to fine-tune the model's hyperparameters.

4.2 Main Results

Submitted systems were evaluated in terms of F1-score. The systems were ranked from highest F1-score score to lowest. We built several models that use different text encoders and different training methods, as described in Section 3. See Table 3 for the results.

First, we observe that models that use adversarial training obtained better performance overall, without using any additional knowledge source, and without using any additional dataset other than the target task datasets. These results suggest that adversarial training leads to a more robust model and helps generalize better on unseen data. For the zero-shot setting, the model that uses XLM-R as the text encoder and adversarial training performed better than M-BERT on the development set. Thus, we decided to submit this model's results on the test set. It obtained a test set F1-score of 0.7457, and ranked 6th among all participating systems. On the other hand, on the one-shot setting, M-BERT performed better than XLM-R on the development set. Again, M-BERT with adversarial training performed better than vanilla fine-tuning. This model obtained an F1-score of 0.6573 on the test set, and ranked 15th among all participating systems.

5 Conclusion

We proposed a simple and efficient model for multilingual idiomaticity detection. Our experiments demonstrated that it achieves competitive results on both zero-shot and one-shot settings, without relying on any additional resource other than the target task dataset. Although in this paper we focused on the multilingual idiomaticity detection task, our model can be generalized to solve other downstream tasks as well, and we will explore this direction as future work.

Method	**zero-shot** F1	**one-shot** F1
	Dev	
Standard$_{\text{XLM-R}_{\text{LARGE}}}$	0.7076	0.7769
SMART$_{\text{XLM-R}_{\text{LARGE}}}$	0.7378	0.7958
Standard$_{\text{M-BERT}_{\text{BASE}}}$	0.5540	0.8462
SMART$_{\text{M-BERT}_{\text{BASE}}}$	0.6200	0.8568
	Test	
SMART$_{\text{XLM-R}_{\text{LARGE}}}$	0.7457	-
SMART$_{\text{M-BERT}_{\text{BASE}}}$	-	0.6573

Abstract

The same multi-word expressions may have different meanings in different sentences. They can be mainly divided into two categories, which are literal meaning and idiomatic meaning. Non-contextual-based methods perform poorly on this problem, and we need contextual embedding to understand the idiomatic meaning of multi-word expressions correctly. We use a pre-trained language model, which can provide a context-aware sentence embedding, to detect whether multi-word expression in the sentence is idiomatic usage.

1 Introduction

The goal of the SemEval-2022 Task2 (Tayyar Madabushi et al., 2022) SubtaskA is to detect whether a multi-word expression in a sentence is idiomatic in usage. It is a multilingual task and consists of three languages: English, Portuguese and Galician.

Multi-word expressions (MWEs) are expressions that consist of at least two words and are syntactically or semantically specific. The semantics of MWEs are usually divided into two types, (i) the combination of literal meanings of each word in the phrase or (ii) inherent usages (e.g., idiomatic meaning). Understanding the semantic meaning of a sentence requires the correct identification of the MWE in the sentence. Table 1 contains one case for each of the two usages.

Literal	When removing a **big fish** from a net, it should be held in a manner that suports the girth.
Idiomatic	It was still a respectable finish for both Fadol and Nayre, who were ranked outside the top 500 in the world but caught some **big fish** along the way

Table 1: Examples of idiomatic and non-idiomatic usage

Traditional non-contextual word embedding models, such as word2vec (Mikolov et al., 2013), perform poorly at this task. Simple superposition of non-contextually word embeddings does not correctly express the semantics of idiomatic phrases. Therefore, contextual embedding models (Conneau et al., 2020; Devlin et al., 2019) are required to correctly understand the meaning of multi-word expressions in idiomatic usage.

We used large-scale cross-lingual pre-trained language models, multilingual BERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020), with a softmax classifier on top of the pre-trained LM to train a binary classification model. The training data are processed before training, and regularization dropout (Liang et al., 2021), adversarial training (Miyato et al., 2017; Madry et al., 2018) are used in the training process. In addition, we observed the training data and found an interesting phenomenon that we can get better results by post-processing after the training using heuristic rule.

2 Background

2.1 Task Description

Task 2 contains two subtasks, SubtaskA is idiom detection, and SubtaskB is similarity scoring of texts containing idioms. This article focus on SubtaskA. SubtaskA contains two settings, zero-shot and one-shot.

- Zero-shot: Multi-word expressions that appear in test data do not appear in training data.
- One-shot: Every multi-word expressions that appeared in the test data appeared in training data at least once.
- Data Restriction: Under zero-shot setting, we can only use zero-shot training data, and we can use both zero-shot and one-shot training data under one-shot setting. Test data is same for both settings.

2.2 Data Details

In this section, we will describe the characteristics of the training data and test data. The official data includes eight columns, which are DataID, Language, MWE, Setting, Previous, Target, Next, Label.

2.2.1 Language

The test data includes 916, 713, 713 entries in English, Portuguese and Galician, respectively.

There are only English and Portuguese examples in the training data of zero-shot setting, which means that in the testing phase, the model requires zero-shot transfer of Galician with the learned knowledge on other two languages. Any MWE in zero-shot training data will not appear in the test data.

In one-shot training data, there are 73 entries in each of the three languages, which is relatively small compared to zero-shot training data. Any MWE in the one-shot training data will appear in the test data.

2.2.2 Data Length

We counted the average length of the data to facilitate appropriate truncation when using a pre-trained model.

The average, median, max length of target sentences after tokenizer corresponding to the pre-train model are 42.6, 195, 40, respectively. Over 90% of sentences are 64 or less in length.

The average, median, max position that MWE occurs in sentences after tokenizer is 18.9, 89, 15, respectively, and over 90% of sentences are 37 or less in position.

2.3 Related Work

So far, there has been extensive research about idioms detection. (Zeng and Bhat, 2021) propose a multi-stage neural architecture with attention flow. (Garcia et al., 2021a,b) probs idiomaticity in vector space and propose NCTTI dataset. (Do Dinh et al., 2018) propose a multi-task learning method. (Tayyar Madabushi et al., 2021) present a multilingual idiom detection dataset, which will be used as this SemEval-2022 idioms detection track.

Pre-trained word embedding can capture syntactic and semantic information from large amounts of unlabeled data, which has been a standard part of natural language processing task (Mikolov et al., 2013; Pennington et al., 2014). However, each of these methods can only obtain a fixed, non-contextual vector representation for each word which makes it difficult to convey the correct meaning of polysemous words. Due to the disadvantages of non-contextual embedding, recent work has begun to focus on contextual embedding, typical cases are context2vec (Melamud et al., 2016), ELMo (Peters et al., 2018), BERT (Devlin et al., 2019).

The most commonly used in contextual embedding is the pre-trained language model (Devlin et al., 2019; Conneau et al., 2020). These models perform self-supervised training through mask language modeling, next sentence predicting, and other objectives in hundreds of millions of unlabeled datas. Benefiting from multilingual training data, these models have cross-language capabilities. Pre-trained models are gradually taking the place of pre-trained word embeddings as the new paradigm for natural language processing.

3 System Overview

Figure 1 depicts the flow chart of the whole system. We first preprocess the data, tokenizing and then feed into a pre-trained model to get hidden states. Apply some pooling method to get fixed length sentence representation to train a softmax binary classifier. After that, the prediction results of the model are post-processed. In the training process, contrastive learning, adversarial training, regularized dropout, etc. are used. Table 2 is then used as an example to introduce the data preprocessing process of the system.

3.1 Baseline

The baseline method below refers to the method in paper (Tayyar Madabushi et al., 2021).

- In the zero-shot setting, Multilingual BERT is trained on zero-shot data, using the context without idiom as an additional feature.
- In the one-shot setting, Multilingual BERT is trained on combination of the zero-shot and one-shot data, excluding the context and adding the idiom as an additional feature.

3.2 Data Preprocessing

3.2.1 Truncation

The data provides the context of the target sentence. We only use target sentences for training because we found that if we concatenate previous, target,

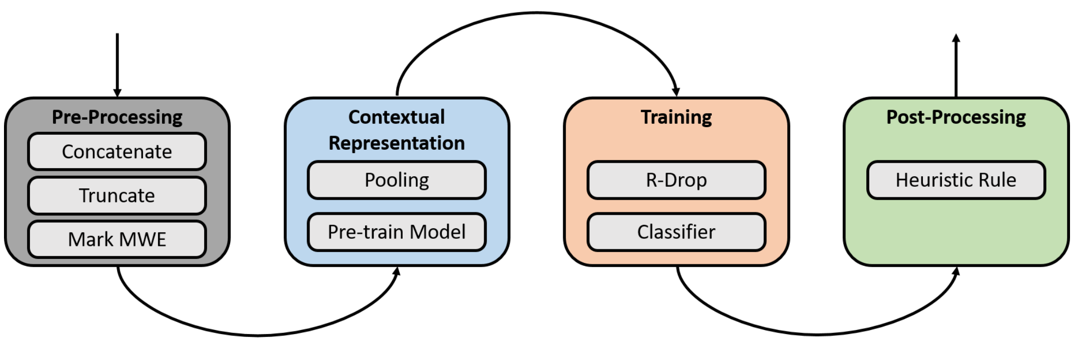

Figure 1: System flow diagram

and next together, the sentence length will be too long, which slows down training and harms performance. We guess that to distinguish whether the MWE is an idiomatic usage, we only need to focus on words near the MWE, too long sentences will introduce unnecessary distractions.

According to the length statistics in the previous chapter, 128 is used as the maximum truncation length of the pre-trained model, which can ensure that most sentences will not be truncated and keep the sentence length as small as possible.

3.2.2 MWE Marking

Following the baseline method, we use the tokenizer's [SEP] token to mark the MWE in the sentence. Unlike the baseline method, we only mark MWEs without deformation. Proper nouns are usually non-idiomatic usage, and are often deformed. Pre-trained models can recognize proper nouns well, so we do not mark the deformed MWEs. The results also show that this gives better performance.

Example in Table 2, MWE 'milk tooth' in sentence "Her latest pamphlet **Milk Tooth**, published by Rough Trade Books, is a collection of thwarted escape plans for a too-heavy world" is capitalized, according to our rules, the MWE in this sentence is not marked. If the MWE in the sentence is not deformed, the [SEP] token will be used to mark the MWE, just like [SEP]**milk tooth**[SEP].

3.3 Model

3.3.1 Pre-trained Model

We tried different multilingual pre-trained models, including mBERT and XLM-RoBERTa, and XLM-RoBERTa consistently outperforms mBERT. In addition, we also try to use different size models, including mBERT-base-cased, XLM-RoBERTa-base, XLM-RoBERTa-large, and bigger models lead to better performance.

3.3.2 Classifier

Different pooling methods are used for hidden states of different layers, including mean pooling, max pooling, [CLS], and token-level pooling. The results show that different pooling methods have little effect on the results. For simplicity, [CLS] is used as the sentence representation.

For token-level pooling, we pool the vectors of MWE positions in hidden states to obtain the final sentence representation, which harms the performance.

After pooling on the pre-trained model, fixed-length sentence representation is obtained. This is followed by a full connection layer with dropout (Srivastava et al., 2014) and a softmax classifier.

3.3.3 Regularized Dropout

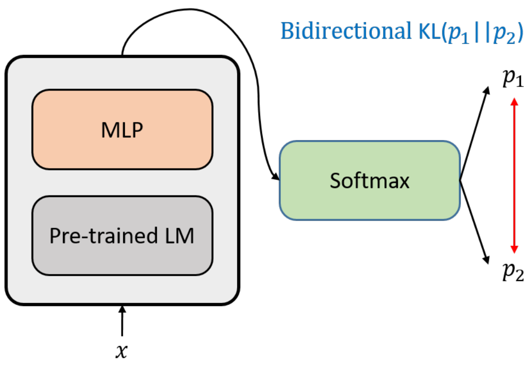

Figure 2: Regularized Dropout

Deep neural networks usually use dropout (Srivastava et al., 2014), but the use of dropout introduces inconsistency between train and inference. R-drop (Liang et al., 2021) is a means of regularization in the training process to mitigate this inconsistency.

A sample output through the pre-trained model, MLP and softmax can be regarded as a probability distribution. R-drop performs two independent

MWE	milk tooth

Target	Her latest pamphlet **Milk Tooth**, published by Rough Trade Books, is a collection of thwarted escape plans for a too-heavy world.
Next	In these poems of trauma and transformation, the present throbs with unfinished histories.
Label	1

Table 2: Training data example (useless columns have been removed)

forward calculations for each sample, obtaining two outputs probability distribution. Due to the dropout, these two outputs will be slightly different, introducing inconsistency. To mitigate this, the bi-directional KL-divergence is calculated as a penalty between these two outputs probability distributions. In the following equation, y_i represents the label, x_i represents the input, and the superscript represents two independent forward operations. p_i^1, p_i^2 represent probability distribution obtained from two independent forwards.

$$\mathcal{L}_{CE}^{i} = CE(x_i^1, y_i) \ + \ CE(x_i^2, y_i) \tag{1}$$

$$\mathcal{L}_{KL}^{i} = \frac{1}{2}(\mathcal{D}_{KL}(p_i^1||p_i^2) + \mathcal{D}_{KL}(p_i^2||p_i^1)) \tag{2}$$

$$\mathcal{L}^{i} = \mathcal{L}_{CE}^{i} + \alpha \cdot \mathcal{L}_{KL}^{i} \tag{3}$$

3.3.4 Post Processing

We found an interesting phenomenon in the training data. Some MWEs in one-shot training data have only one category label, and most of these MWEs corresponding to entries in the dev data have the same label as in the training data. Some proper nouns are labeled with idiomatic meanings, however some with literal meanings. These labeling inconsistencies may cause problems in the learning of the model, so we design a heuristic rule. On top of the model prediction results, if there is only one label for a certain MWE in the training set, then replace all the predictions for that MWE in the test set with whichever label appears in the training set.

4 Experiment

4.1 Hyperparameters

We use the Huggingface Transformers (Wolf et al., 2019) implementation of mBERT and XLM-RoBERTa. During the training, the learning rate schedule strategy is warmup of first 10% steps with cosine learning rate decay in rest steps. For zero-shot and one-shot, we use learning rates of 1e-5 and 3e-5, respectively, and one-shot is continued training on the well-performing zero-shot model. The mini-batch size is 32. The coefficient of R-drop is chosen from 0, 1, 2, 4. We train a total of 20 epochs and save the best-performing checkpoints on the development set. All models are trained on one single NVIDIA Tesla V100 GPU.

Model	Zero-shot	One-shot
mBERT$_{base}$ w/ C w/ I	74.90	84.78
mBERT$_{base}$ w/ C w/o I	70.59	76.98
mBERT$_{base}$ w/o C w/ I	**75.31**	**85.76**
mBERT$_{base}$ w/o C w/o I	70.76	82.59

Table 3: Context and idiom effects on the development set results. C: context. I: Idiom. (Macro F1 $\times$ 100)

Model	Max Len	Zero-shot	One-shot
mBERT$_{base}$	128	**76.31**	**87.97**
mBERT$_{base}$	192	75.62	87.96
mBERT$_{base}$	256	75.64	86.24

Table 4: Effect of different maximum sentence lengths on the development set results. (Macro F1 $\times$ 100)

4.2 Evaluation Metrics

SubtaskA is evaluated using the Macro F1 score between the gold labels and model predictions.

$$Macro\ F1 = 2 \cdot \frac{precision \times recall}{precision + recall} \tag{4}$$

4.3 Hyperparameters Selection

We compare different pre-trained models, max length, and whether to use MWE and contexts.

4.3.1 Context and Idiom

We compare the performance of the model with and without context in Table 3, the effect of marking idioms on the results. Moreover we conduct experiments on BERT$_{base}$, using [CLS] as pooling, with the max sentence length set to 128. The method of marking MWEs here follows the baseline.

Experiments show that ignoring context and mark idioms gives better results, and this setting will be continued for future experiments.

Model	Zero-shot	One-shot
mBERT$_{base}$	75.31	87.97
XLM-R$_{base}$	76.99	89.15
XLM-R$_{large}$	**78.17**	**91.84**

Table 5: Effect of different pre-trained models on the development set. (Macro F1 $\times$ 100)

4.3.2 Max Sentence Length

In this section, a comparison is made between the cases with different maximum sentence lengths. The model follows the previous setting, with idioms marked and context ignored, using first-last-avg as pooling for training.

Our original hypothesis is that performance and speed are a trade-off as the maximum sentence length increases. In contrast, Table 4 shows that a maximum sentence length of 128 is sufficient in terms of speed and performance. We do not test a smaller maximum sentence length because further reduction might cause parts of the sentence to be truncated, harming the performance.

4.3.3 Pre-trained Model

We compared mBERT$_{base}$, XLM-RoBERTa$_{base}$, and XLM-RoBERTa$_{large}$, and results in Table 5 demonstrated that XLM-RoBERTa outperformed mBERT, and the large model performed better than base model. In addition, our final submission results were obtained using XLM-R$_{large}$.

From the results, we found that the performance improvement is evident as the model size grows, and there is no bottleneck yet. Therefore, increasing the model size may be a simple and effective way.

5 Results

5.1 System Performance

Our final results use model fusion on thirteen models. The zero-shot model finished fourth with an F1 of 77.15, and the one-shot model finished first with an F1 of 93.85.

5.2 Ablation Study

Table 6 provides the results of the ablation study. The baseline of the ablation experiment follows the hyperparameters of the experiment chapter, except that the model is replaced with XLM-R$_{large}$.

Model	Zero-shot	One-shot
XLM-R$_{large}$	78.05	91.02
+mark MWE	78.17	91.84
+contrastive pre-train	-	89.95
+contrastive auxiliary	76.30	88.05
+AEDA	79.09	89.76
+AT	79.78	92.47
+R-drop	**80.34**	**92.91**
+post-processing	-	**93.73**

Table 6: Ablation experiments on the development set. (Macro F1 $\times$ 100)

5.2.1 Mark MWE

First, we change the method of marking MWE in the baseline. We use [SEP] token for tagging only if the MWE in the sentence is the same as the MWE provided in the data. The reason for this is that the organizer's rule is to label proper nouns as literal meaning, and proper nouns are usually deformed with initial capitalization. The pre-trained model can distinguish proper nouns well under the training of a large amount of corpus.

5.2.2 Adversarial Training

Adversarial training (Miyato et al., 2017; Madry et al., 2018) is a way to enhance the robustness of neural networks by adding small perturbations to the samples to interfere with the predictions of the model. In our experiments, the results in Table 6 show that adversarial training significantly improves performance.

5.2.3 R-drop

R-drop is a regularization tool that aims to maintain the consistency of model prediction and training while using dropout by adding bi-directional KL-divergence as a penalty term. After adding R-drop, the performance is significantly improved, exceeding the adversarial training. In Table 6, under zero-shot setting, the relative improvement is 2.17 and 0.56 compared to baseline and adversarial training, respectively, and this improvement is 1.07 and 0.44 under one-shot setting, respectively.

5.2.4 Heuristic Rule

We used the heuristic rule mentioned in 3.3.4 for replacement under the one-shot setting, and as shown in the Table 6, the relative improvement is 0.82 percentage points.

5.2.5 Negative Results

Contrastive Learning: Recently, contrastive learning has been a hot topic in NLP, especially in sentence representation learning. Inspired by SimCSE (Gao et al., 2021), we use contrastive learning before and during training classification, using the data from subtaskA for contrastive pre-train and apply contrastive loss during training as an auxiliary training objectives, respectively. Unfortunately, as shown in Table 6, both of these methods make the results much worse.

Data Augmentation: Due to lack of training data, we use data augmentation for expansion. We used AEDA (Karimi et al., 2021) as a means of data augmentation, which is a straightforward data augmentation, by adding punctuation marks to the sentences. The results showed that a particular improvement was achieved under zero-shot setting, but a decrease was achieved under one-shot setting.

6 Conclusion

We continuously improve the model performance by improving the MWE marking method, using larger pre-trained models, adding regularization terms and heuristic rules. Inspired by pre-trained models, we can find that future work needs to focus more on external data besides training data, especially data with specific idioms, such as idiom dictionaries, because the size of the external data is much larger than the training data, which has not been fully exploited.

Abstract

We report the results of the SemEval 2022 Task 3, PreTENS, on evaluation the acceptability of simple sentences containing constructions whose two arguments are presupposed to be or not to be in an ordered taxonomic relation. The task featured two sub-tasks articulated as: *(i)* binary prediction task and *(ii)* regression task, predicting the acceptability in a continuous scale. The sentences were artificially generated in three languages (English, Italian and French). 21 systems, with 8 system papers were submitted for the task, all based on various types of fine-tuned transformer systems, often with ensemble methods and various data augmentation techniques. The best systems reached an F1-macro score of 94.49 (sub-task1) and a Spearman correlation coefficient of 0.80 (sub-task2), with interesting variations in specific constructions and/or languages.

1 Introduction

A growing body of literature on the cognitive side of computational linguistics has tried to probe the ability of language models to recognize deviant linguistic structures. Recognizing linguistic ill-formedness requires some degree of metalinguistic awareness in adult humans (i.e. the ability to say not just that there is 'something wrong' in a sentence, but also where the problem lies or how the sentence could be improved), and it is not clear whether and to what extent artificial systems can induce this type of knowledge purely from exposure to raw linguistic data (Linzen and Baroni, 2020). Most of the previous investigations on this topic have focused on phenomena that are purely syntactic (agreement, Gulordava et al. 2018; dislocated arguments with island effects, Wilcox et al. (2018); Warstadt et al. (2019); Chowdhury and Zamparelli (2018), clause embedding, Futrell et al. 2019, etc.) or at the syntax/semantics interface (negative-polarity items, Jumelet and Hupkes 2018; argument structure, quantifier restrictions, Warstadt et al. 2019), mostly using LSTM architectures (but see Tran et al. 2018; Ettinger 2020). The fact that many purely semantic effects result in the (non) availability of certain readings (e.g. the scope of a quantifier over a higher negation, in "I didn't see some people") makes it of course harder to translated them into computationally testable paradigms.

The task we describe in this paper focuses on an area of purely semantic competence that, to the best of our knowledge, is unexplored in the computational literature, and one which gives rise to a robust intuition of deviance, triggered by the failure of a type of **presupposition**: the requirement for two nominal arguments to be (or not be) in an (ordered) **taxonomic relation**. These presuppositions are introduced by a wide variety of constructions, such as comparatives (1a), coordinations, verbs like *prefer*, modifiers headed by *type* or *except* (1b) etc. (see Table 1 for the full list).

(1) a. I hate guns more than {*weapons / social media}.
b. I like dogs, except {*birds / greyhounds}

Distinguishing the deviant from the acceptable cases requires the ability to (i) detect taxonomic relations and (ii) recognize those constructions which place restrictions on them. The first point is of course crucial for most tasks in Natural Language Inference (NLI) — an active and fast-growing field in the NLP community, with various datasets and benchmarks (e.g. GLUE Wang et al. 2018, SuperGLUE Wang et al. 2019). NLI datasets, however, normally assume that felicity conditions are satisfied. The present dataset, which we call PreTENS, takes a step back and aims to verify if a computational model can detect when this presupposition fails.

The task requires world knowledge, commonsense knowledge (in the sense discussed in Storks et al. 2019), but also linguistic knowledge, to catch

Construction (Variants)	**Example**	**Presup.**
EXCEPT (2)	I like [$_{A1}$ dogs] except [$_{A2}$ {*cats / pugs / *animals}]	**A1>A2**
PARTICULAR (2)	I like [$_{A1}$ dogs], and in particular [$_{A2}$ {*animals / *cats / pugs}].	**A1>A2**
IN GENERAL	I like [$_{A1}$ dogs], and [$_{A2}$ {animals / *cats / *pugs}] in general.	**A1<A2**
GENERALLY	I like [$_{A1}$ dogs], and more generally [$_{A2}$ {animals / *cats / *pugs}].	**A1<A2**
TYPE (2)	I like [$_{A1}$ dogs], an interesting type of [$_{A2}$ {animal / *cat / *pug}].	**A1<A2**
AND-TOO	I like [$_{A1}$ dogs], and [$_{A2}$ {cats / *pugs / *animals}] too.	**$A1 \not\lessgtr A2$**
COMPAR. (3)	I like [$_{A1}$ dogs] more than [$_{A2}$ {cats / *pugs / *animals}]	**$A1 \not\lessgtr A2$**
DRATHER	I would rather have [$_{A1}$ dogs] than [$_{A2}$ {cats / *pugs / *animals}]	**$A1 \not\lessgtr A2$**
PREFER	I don't like [$_{A1}$ dogs], I prefer [$_{A2}$ {cats / *pugs / *animals}]	**$A1 \not\lessgtr A2$**
UNLIKE	Unlike [$_{A1}$ dogs], [$_{A2}$ {*animals / cats / *pugs}] are often mentioned in this text .	**$A1 \not\lessgtr A2$**
BUT-NOT	I like [$_{A1}$ dogs], but not [$_{A2}$ {*animals / cats / pugs}]	**$A1 \not\lessgtr / > A2$**

Table 1: Distribution of taxonomic constructions and their presuppositions. $\not\lessgtr$ indicates no overlap; (*n*) indicates n variants on the construction (e.g. COMPAR. contains samples of majority, minority and equality comparatives). The BUT-NOT case is probably ambiguous, with one meaning close to EXCEPT; the same applies to GENERALLY, which draw uncertain results in the human evaluation and was excluded from sub-task 2 in favour of IN GENERAL.

the requirement of the specific presupposition-inducing constructions. In this respect, the present task is closer in spirit to SemEval-2020 task 4, sub-task A, on the validation of sentences for common-sense (Wang et al., 2020), than to SemEval 2016 task 3, where participants had to extract and identify the taxonomic relationships between two terms (Bordea et al., 2016).

Besides NLI practitioners, the task could be relevant for researchers interested in the potential of NNs as cognitive/linguistic models (see e.g. Warstadt et al. 2019). We believe that it is also a potentially useful addition to the toolbox of probes used to understand the inner working of current language models.

2 Dataset and Task description

2.1 Composition

The PreTENS contains 21,765 artificial sentences with 2-argument relations filled by nominals (the **argument nouns**). The sentences were designed to follow or flout the presuppositions that (i) the argument nouns should or should not be in a taxonomic relation (i.e. one a subset of the other: *dogs* < *animals*) and (ii) when a taxonomic relation was required, the order should be a specific one. (ii) differentiates *I like dogs, and in particular pitbulls* from **I like pitbulls, and in particular dogs*). The list of constructions used is in Table 1.

The data for this task was programmatically generated from a human-verified template, yielding sets of sentences that are extremely similar across constructions. The argument nouns (A1 and A2 in Table 1) are taken from the following semantic categories: *dogs, birds, animals, cars, motorcycles, cutlery, clothes, trees, plastics, furniture, wine, animals, sports, music, vegetables, fruits, pork-based food, desserts, seafood, apartments, movies, jewelry, pets, rain, nature, senses, emotions, books, workers* and *scientists*, and repeat across constructions. The elements not in taxonomic relations were chosen to maximize the plausibility of comparison (e.g. *dogs* if the semantic category was *birds*) and the verbs were chosen to be as semantically neutral as possible (often *like* or *have*, but e.g. *trust* in the semantic category of *senses*). The English template file was created and revised (using dictionaries and Wordnet) by the task proponents, all expert linguists, and double-checked by a native speaker.

PreTENS is a simplified, no-repetiton subset of a larger dataset, DuckRabbit, which also contains 5 semantic categories (*countries, cities, painters, politicians, actors*) examplified by well-known proper names (e.g. *Paris, Picasso, Obama*), which we decided not to use for the PreTENS task. The full DuckRabbit dataset (55,296 items) is arranged in a way that systematically tests all the possible orders of pairs of argument nouns taken from a super-category, a subcategory in the same taxonomic domain and a distractor (non taxonomically ordered with either, e.g. <*birds, parrots, dogs*>). This arrangement, however, creates a large number of repeated entries.

The fixed nature of the patterns used allowed us to propose the dataset in three languages (English, Italian and French), where the French and Italian versions are slightly adapted translations of the English dataset.[1] Adding more languages would

[1] A key difference was that the English bare plurals used in generic sentences were replaced by NPs introduced by definite

be relatively straightforward. The template and the scripts used to generate the data are publicly available under a CC BY 3.0 "Attribution" license.[2] As far as we can tell, the contents do not raise any issue w.r.t. ethics or privacy.

2.2 Definition of the Task

The task was articulated into the two sub-tasks:

- a **binary classification task** (hereafter referred to as *sub-task1*), which consisted in predicting the acceptability label assigned to each sentence of the test set on the basis of a theoretical linguistic model;
- a **regression task** (hereafter *sub-task2*), which consisted in predicting the average score on a 7 point Likert-scale assigned by human annotators to a subset of data evaluated via crowdsourcing (see Section 2.3).

For each task and each language, the dataset was split into training and test sets. The classification task was composed of 5,838 training samples and 14,560 testing samples; the regression task, of 524 sentences in training and 1,009 in test. Table 2 reports the internal composition of the training and test dataset of each sub-task. As it can be seen, not all the constructions contained in the test were provided in the training set. This choice was deliberate, to test the generalization abilities of the systems across unseen constructions. The sentences in training data were independently randomly ordered in the three languages, to discourage mapping the results obtained in one language to sentences with the same ID in the other languages.

2.3 Annotation with human judgments

The dataset released for *Sub-task2* is composed by a subset of 1,533 sentences taken from the whole dataset, corresponding to about 5% of the total and representative of the patterns considered, which were judged by human annotators via a crowdsourcing campaign.

The purpose of this evaluation was two-fold: (i) to provide a bottom-up assessment of the quality of

Constructions	sub-task1		sub-task2	
	Training	**Test**	**Training**	**Test**
and-too	835	525	131	88
but-not	831	526	131	88
comparatives	835	3,245	131	88
drather	–	1,360	–	–
except	831	1,887	–	–
in general	–	–	–	219
generally	–	1,360	–	–
particular	835	1,885	–	219
prefer	835	525	–	–
type	835	1,887	131	88
unlike	–	1,360	–	219
TOTAL	**5,838**	**14,560**	**524**	**1,009**

Table 2: Distribution of taxonomic constructions in terms of number of sentences in the dataset.

the linguistic categories that informed the creation of the dataset templates; (ii) to obtain more fine-grained judgments of semantic acceptability in the form of gradual, rather than categorical, scores.

The annotation was performed through the Prolific[3] platform. Specifically, for each language the annotation process was split into different tasks, each one consisting in the annotation of about 150 randomly mixed sentences for the typologies reported in Table 1. For all tasks, we recruited 12 native speakers, who were asked to read each sentence and answer the following question:

> *How acceptable is this sentence from 1 (completely unacceptable) to 7 (completely acceptable)?'*

As an example, we report below two sentences (with corresponding average score) from the English portion of the annotated dataset, which were rated as very poorly and very highly acceptable:

> *I like politicians, an interesting type of farmer* (1.42)
>
> *I like governors, an interesting type of politician* (6.16)

Table 3 provides the average value (μ) and standard deviation (σ) of acceptability labels for the whole dataset (first row) and for sentences classified according to the various constructions. As it can be noted, French sentences were evaluated on average as more acceptable than Italian and English ones but with a slightly higher standard deviation. While for all languages the maximum average score on the Likert scale was obtained by very few sentences (i.e. only one sentence for English and French and four for Italian), the number

determiners in Italian and French. This makes the latter sub-datasets systematically longer. In addition, certain English nouns required compounds or N+PPs to be rendered in the other languages.

Table 3: Statistics about the distribution of human judgments in the dataset collected for sub-task2. μ = average judgment; σ = standard deviation.

of sentences rated with the lowest score is higher for Italian and French (i.e. 42 and 45 respectively) than for English (i.e. 7). If we focus on the distribution of judgments across the distinct constructions, we observe that examples containing the TYPE construction were perceived on average as the less acceptable ones for all languages. Conversely, sentences belonging to the AND TOO and COMPARATIVES categories obtained the highest acceptability scores.

In order to see how consistent was the human perception of semantic acceptability across languages, we computed the Pearson's r between the average scores assigned to the whole set of sentences for each pair of languages. The correlation scores were very high, with the highest scores obtained between sentences in French and Italian (i.e. 0.86), followed by English and French (i.e. 0.80), and, lastly, by English and Italian (i.e. 0.77)[4].

Finally, an additional outcome that we want to highlight here is the strong connection between the theoretically-driven and the human-based semantic acceptability label, which was assessed by calculating the Spearman's rank correlation coefficient between the average human scores and the binary acceptability labels attributed to the same set of sentences, for all languages. In this case, too, we found a very high correlation, although weaker in English (ρ=.73) than in Italian and, especially, French (ρ =.78 and .83, respectively).

3 Shared Task Organisation

Shared Task Phases We ran the shared Task 3 in two phases. In the first phase, we released the baseline pipeline, along with the cross-validation results on the official training set and introduced the participants to the aforementioned task evaluation measure.

The second phase – the main Evaluation Phase – was conducted using codalab platforms for both sub-task1[5] and sub-task2.[6] During this phase, the participants were provided with the test sets and were allowed to submit their predictions to the system. The number of submissions of each participant was limited to three, but the participant could choose among them which runs/submission they want to display in the leader-board. During the evaluation phase, the leader-board was visible to all the participants.

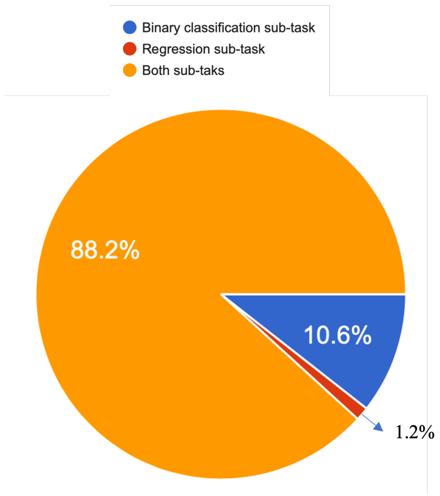

Figure 1: Statistics of participants' interest on Tasks based on initial registration.

Task	sub-task1	sub-task2
Team Participated	21	17
Total System Submissions	134	110
Total Accepted Submissions	108	84

Table 4: Statistics on participation

Baselines For each sub-task a separate baseline were defined: *i)* for Sub-task1 – the binary classification sub-task, a Linear Support Vector classifier using n-grams (up to three) as input features was used, and for the *ii)* Sub-task2 – the regression sub-task, a baseline using a Linear Support Vector regressor with the same n-grams features was provided.

We provided the starter code to all the participants, along with different cross-validation configurations that we encouraged participants to use to validate their methodology. Moreover, we provided

[4]All correlations are significant with p value< 0.01.

[6]https://codalab.lisn.upsaclay.fr/competitions/1290

information on how the performance in the validation task translated in the official test split (applying the baseline methods to the official test-set yielded results 10-20% lower than with the training set). We highlighted the importance of achieving maximal syntactic generality on this task and test different cross-validation configurations on the training set.

Official Evaluation Metrics Given the differences in the nature of the sub-tasks output, we defined two different sets of evaluation metrics. For sub-task1, systems are evaluated with respect to binary and macro F-measure. These measures were evaluated per languages, and the final ranking was based on the global ranking of each participant, calculated by averaging the macro F-measure score from all the three languages (this provided an incentive to give results for all languages). In addition to the official measure, we also gave the participants their precision and recall scores, per language.

As for sub-task2, a Spearman's rank correlation coefficient (ρ) between the task participants' scores and the test set scores was computed. To be consistent with sub-task1, the global ranking of this task was calculated by averaging the position of the participant's ρ per language.

At the end of the competition, we provided the participants with packages containing the results for each of their submissions, and publicly updated the leader-board with ranks listing all teams who competed in each sub-task.

Participation The task attracted nearly 83 teams. Among them, 43 teams actually registered for the evaluation phase; 21 teams (sub-task1) and 17 teams (sub-task2) submitted their system's predictions. The detailed statistics are shown in Table 4.

4 Participating Systems

We received six system description papers for both sub-tasks, plus two papers by teams that participated only in sub-task1, for a total of eight papers. As it can be observed in the following summaries of the approaches proposed, there were several points of methodological similarity, but also interesting differences. Many teams experimented data augmentation techniques devised to overcome the limited amount of training data, in particular for the solution of sub-task2. These techniques ranged from the use of external resources to the generation of new sentences (Zhou et al. (2022), Sarhan et al. (2022) and van den Berg et al. (2022)), to the automatic translations across the three languages considered (Sarhan et al. (2022) and Zhou et al. (2022)), to mapping the Likert scale results to the binary values. This was the strategy used by the first two teams classified (Xia et al. (2022) and Li et al. (2022)) according to the global scores.

As we can see by the description of the participating systems (see Section 4.1), the majority of teams chose monolingual instead of multilingual models, especially in the resolution of sub-task1. The exceptions are represented by Li et al. (2022), who obtained the second position in the global ranking of both sub-tasks, by Aziz et al. (2022), and by Sarhan et al. (2022) who (in the resolution of sub-task 2 only), used the multilingual version of the Universal Sentence Encoder, since it yielded better performance than the monolingual one. Interestingly enough, the top-ranked team in both sub-tasks (Xia et al. (2022)) found that, for all languages, the monolingual DeBERTa-v3 models always outperformed the multilingual version.

A further approach shared by the participating teams is represented by the adoption of ensemble methods. Two main ensemble strategies were suggested. In the first one, the training data used to fine-tune the adopted model was split, obtaining different models, each with its training and validation sets. This was the case with the second-ranked system (Li et al. (2022) and with Vetter et al. (2022), but only in sub-task2. A second main approach used the fusion of the acceptability scores predicted by two different models. As described in the following subsection, Aziz et al. (2022) combined the scores predicted by XLM-RoBERTa (Conneau et al., 2019) and mBERT (Devlin et al., 2019), while Zhou et al. (2022) merged the predictions made by ERNIE-M and DeBERTa-v3 (only in sub-task1).

4.1 Individual System Descriptions

Xia et al. (2022) (model LingJing), tackling sub-task1, experimented with different strategies to fine-tune DeBERTa-v3 (He et al., 2021), which ended up outperforming both the PreTENS baseline and three new baselines introduced by the authors, including a multilingual version of DeBERTa, i.e. mDeBERTa model. These strategies included the augmentation of the original training set with trans-

lations from the three languages, adversarial training and Child-Tuning (Xu et al., 2021). In addition, the authors performed experiments with different compositions of the original training, i.e. mixing the data for the three languages, and fine-tuning in one language, then expanding to the others. Each strategy achieved different results for each language. Due to the small size of the training set of sub-task2, the team transferred the knowledge of the classification model to the regression task, in terms of the model's parameters and in the idea of mapping the Likert scale results to the binary values.

Li et al. (2022) (HW-TSC), addressing both subtasks1 and 2, developed an ensemble classification and regression model by fine-tuning the multilingual XLM-RoBERTa model (Conneau et al., 2019) on different splits of the training data. To this end, they added a language tag to each training sentence with the same id across the three languages and divided the data in different folds to prevent the model from learning the translation information. To address the small size of the sub-task2 training data, they devised a data augmentation strategy to transform the binary values into the scalar human judgments.

Sarhan et al. (2022) (UU-TAX), experimented with different Neural Language Models and diverse training data compositions to test their generalization abilities against the PreTENS tasks. For sub-task1, their best performing model is represented by ELECTRA (Clark et al., 2020), which was fine-tuned using a two-stage strategy to augment the original training data. Firstly, the authors generated new sentences by making modifications to the original sentences using BERT-base (Devlin et al., 2019) to obtain the embeddings of the modified words. Secondly, for each language *l*, the original sentences of the other two languages were translated into *l* using the Google Translate API. For sub-task2, the best model uses the multilingual version of the Universal Sentence Encoder (Yang et al., 2020) followed by a different type of classifier for each language.

Aziz et al. (2022) (CSECU-DSG), for both subtasks, exploited an ensemble method of two multilingual Transformers, i.e. XLM-RoBERTa (Conneau et al., 2019) and mBERT (Devlin et al., 2019), which were fine-tuned with the PreTENS datasets. To enhance the performance of each individual model, the authors fused the predicted probability scores of the two models by computing their weighted arithmetic mean.

Vetter et al. (2022) (KaMiKla), for both subtasks, used monolingual versions of the BERT model (Devlin et al., 2019), i.e. BERT base for English, AlBERTo (Polignano et al., 2019) for Italian and CamemBERT (Martin et al., 2020) for French. For sub-task1, the authors fine-tuned the models on the distributed training data, while for sub-task2,

Table 6: Sub-task 2 results for each team/user ordered by overall ρ along with results for each language. Team/user names marked with $\star$ have submitted their system description.

they first normalized the scores to be between zero and one, then performed an inverse transformation to get the final output. In addition, for this second task, they trained 10 models per language (each with its one training split) and used the median result as their final prediction.

Zhou et al. (2022) (SPDB) participated only in sub-task1, using a different ensemble system for each language. For Italian and French, the system combines the results of 10 ERNIE-M models (Ouyang et al., 2021) obtained by applying a cross-validation process; for English, the authors combined the predictions made by ERNIE-M and DeBERTa-v3 (He et al., 2021). They also enlarged the distributed PreTENS training set using *i)* two different translators (Google and Baidu) to translate the English sentences into French and Italian, thus increasing the diversity of data, and *ii)* the English and French version of the XNLI dataset (Conneau et al., 2018).

van den Berg et al. (2022) (RUG-1-pegasussers) participated only in sub-task1 using English BERT base (Devlin et al., 2019) which they fine-tuned, experimenting with multiple approaches to expand the training data. In particular, they augmented the data by adding new English sentences that contained new category templates, new words instantiating the templates, new words previously used exclusively as hyponyms, inversions of the arguments involved in the taxonomical relation, paraphrases automatically generated. The acceptability labels of Italian and French sentences were predicted by translating the sentences into English, in order to process them with the English BERT.

Markchom et al. (2022) (UoR-NCL), for both sub-tasks, experimented with fine-tuning different monolingual versions of the BERT-based model (Devlin et al., 2019), i.e. DistilBERT-Base-Uncased for English (Sanh et al., 2019), BERT-Base-Italian-XXL-Uncased for Italian, FlauBERT-Base-Uncased for French. The authors relied on the distributed training data to fine-tune the models using specific loss functions, binary cross-entropy loss for sub-task1 and mean squared error loss for sub-task2.

5 Results and Discussion

Almost all teams submitted their runs for the three languages considered. Tables 5 and 6 show, for each sub-task, the top submissions received from each team, along with the baseline scores. Team names marked with $\star$ represent teams that have submitted system description papers. The *Rank* column reports the position of the team in the ranking for global and language-specific scores.

Task 1 evaluation: To better understand the performances per construction of the models submitted, we report the average F1-macro ($\pm std$) of the top-3 submissions per language, in Table 7.

Our results show that English — the most resource-rich language in terms of computational models and data — outperforms the Italian and French models for correctly predicting presuppositions in these constructions. However, the English model performed below French in the UNLIKE construction (e.g. "Unlike trees, {*oaks /

CONSTRUCTION	EN	FR	IT	Avg_lang
DRATHER	**94.9** (±0.04)	90.9 (±0.03)	89.3 (±0.03)	91.70

TYPE	**75.8** (±0.14)	66.8 (±0.08)	72.2 (±0.12)	71.60
GENERALLY	45.5 (±0.0)	**75.2** (±0.12)	46.7 (±0.01)	55.80

Table 7: Average macro F-measure of the top 3 participants per construction in sub-task 1 (binary classification). The standard deviation between the top 3 submission are in (.). Best results per construction are in bold.

animals} are often mentioned in this text", presupp. A1$\not\leq$A2), and does quite poorly in GENERALLY ("I like oaks, and more generally {trees / *animals}", presupp. A1<A2). Note that neither constructions were present in the training set. Italian is aligned with English, while interestingly the French model seems to be capable of more accurate generalizations in both cases.

Task 2 evaluation: To gain a better understanding of the models generalization abilities in this task, we computed the Root Mean Squared Error (RMSE) between the gold value and the average predicted value by the first three teams classified. This data is shown in Figure 2 for each construction and for each language, along with the average value across languages. As it can be seen, the resulting picture contrasts substantially with that of sub-task1. The TYPE and PARTICULAR constructions, among the worst in the first sub-task, have the lowest error in sub-task2. The second task sees a substantial drop of ANDTOO (now the worst case) and COMPARATIVES (one of the best constructions in sub-task1).

We also observe distinctions between languages across the two tasks. In particular, while the average performance for English across constructions is the highest in sub-task1, the French models obtained on average the best results in sub-task2. The success at predicting the presuppositional knowledge triggered by the same construction changes in the two sub-tasks (which are often demanded to different models in the various teams). For example, the French models are the best at classifying the acceptability label for the UNLIKE construction but are the worst in predicting the human score for the same construction. Conversely, COMPARATIVES turn out to be among the easiest constructions for the English models in sub-task1 but are the most mispredicted English type in sub-task2.

Quite interestingly, the presence of a construction in training doesn't always guarantee better performances. Two notable examples are represented by DRATHER and PARTICULAR. Despite being absent in the training set of the corresponding tasks, the first obtains the highest F1 score (for English and on average) and the second is among the top-predicted constructions in sub-task2. We leave a more thorough analysis of the systematicity of these trends to future work, where we will also consider the linguistic variants for each construction and the semantic categories of the nominal arguments involved.

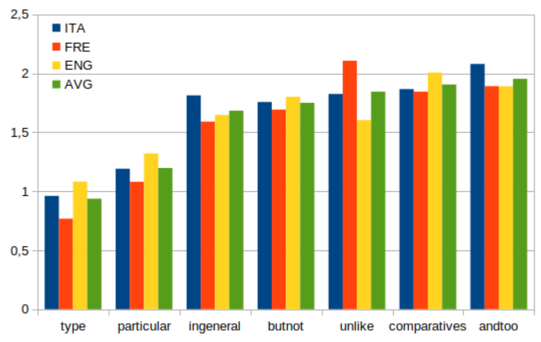

Figure 2: sub-task2: Root Mean Squared Error (RMSE) averaged across the top 3 participants per construction (lower is better). Constructions are ordered per average RMSE values across languages.

6 Conclusion

The SemEval2022 task3 – PreTENS offered two sub-tasks aiming to investigate the effectiveness of computational models to detect a certain type of presuppositional failures induced by specific constructions. The task attracted a total of 21 teams, from both academia and industry. The findings showcases the power and ubiquity of large self-supervised pre-trained models in mono- or multilingual settings. Despite this apparent uniformity, the participants chose to use and combine the models in very different and creative ways, giving rise to a range of scores from 70.54% to 94.49%.

The outcomes of the task highlights the ability of these transformer models to generalize to new/unknown construction in the test sets, but also the presence of intriguing differences in specific constructions and languages (e.g. in the binary task *A1 and more generally A2* reaches a 75.2 F-measure in French but a 46.7 in Italian). Also worth further investigation is the lower correlation between the binary judgments and the human ratings in English — probably reflected in the .05 drop seen in the sub-task2 global score for this language, compared to French.

The success of the task indicates a growing interest towards research on prediction models that can incorporate world knowledge and common sense, along with an understanding of the linguistic properties that condition the outcomes. We hope that this trend will continue and the PreTENS data will help researchers to probe future models for this ability. With this spirit, we make the dataset public.

Abstract

This paper presents the results and main findings of our system on SemEval-2022 Task 3 Presupposed Taxonomies: Evaluating Neural Network Semantics (PreTENS)[1]. This task aims at semantic competence with specific attention on the evaluation of language models, which is a task with respect to the recognition of appropriate taxonomic relations between two nominal arguments. Two sub-tasks including binary classification and regression are designed for the evaluation. For the classification sub-task, we adopt the DeBERTa-v3 pre-trained model for fine-tuning datasets of different languages. Due to the small size of the training datasets of the regression sub-task, we transfer the knowledge of classification model (i.e., model parameters) to the regression task. The experimental results show that the proposed method achieves the best results on both sub-tasks. Meanwhile, we also report negative results of multiple training strategies for further discussion. All the experimental codes are open-sourced at https://github.com/WENGSYX/Semeval.

1 Introduction

In order to dive into the capability of the current language models (Bengio et al., 2000; Howard and Ruder, 2018), we take part in and apply the pre-training language model on the SemEval-2022 Tasks 3: the Presupposed Taxonomies: Evaluating Neural Network Semantics (PreTENS) (Zamparelli et al., 2022). To evaluate the model performance comprehensively, two sub-tasks are designed in this PreTENS task:

Sub-task 1) Binary classification task[2], which consists in predicting the acceptability label assigned to each sentence of the test set. For example, "I like trees, and in particular birches" is acceptable while " I like oaks, and in particular trees" is unacceptable, so they are labeled 1 and 0, respectively.

Sub-task 2) Regression sub-task[3], which consists in predicting the average score assigned by human annotators on a seven-point Likert scale (Joshi et al., 2015) with respect to the subset of data evaluated via crowdsourcing. For example,"I like governors, an interesting type of politician" is more acceptable than "I like politicians, an interesting type of farmer", so the former will also have a higher score (6.16) than the latter (1.42).

It is noted that both sub-tasks comprise datasets in 3 languages: English, Italian, French, where French and Italian are slightly adapted translations of the English dataset. For each sub-task, every sample is formed as the arguments A and B, e.g., comparatives (I like A more than B), exemplifications (I like A, and in particular B), generalizations (I like A, and B in general), and others, where the argument nouns are taken from various semantic categories.

The most similar tasks are the Natural Language Inference (MacCartney, 2009; Bowman et al., 2015; Conneau et al., 2017) and Taxonomy Expansion & Enrichment (Zhang et al., 2018; Shen et al., 2018; Yu et al., 2020), where the former requires the model to differentiate the relationship between a premise sentence and a hypothetical sentence, while the latter shall identify the relationship between different concepts. There are many powerful language models for accomplishing these tasks (Devlin et al., 2018; He et al., 2020), and well-formed semantic representations can be obtained for the downstream tasks. However, it is a challenge for the model to decide the acceptance of the given sentence, as the semantic meaning is hard to be distinguished. Moreover, the performance of downstream tasks when fine-tuning is limited by the size of the training dataset (Xie et al., 2020).

To solve the above problems, we propose a

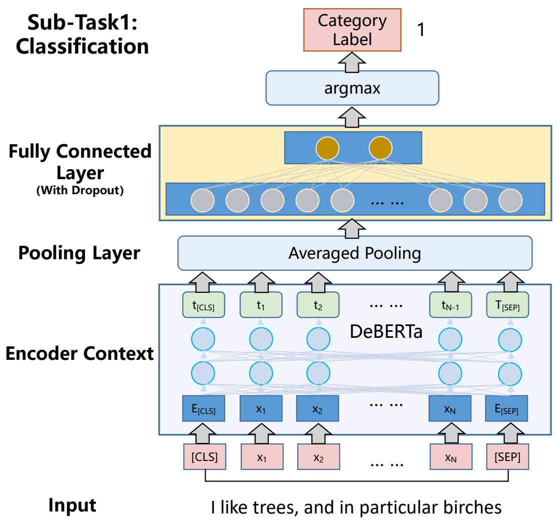
method that applies DeBERTa to lexical-level presupposed relation taxonomy with knowledge transfer. Specifically, the powerful DeBERTa-v3 pre-trained model (He et al., 2021) is fine-tuned with datasets of different languages in the classification task. For the regression task, due to the limited size of the training datasets, we fine-tune the trained model of the classification task in the regression task. As a result, the proposed method achieves a global top score of 94.173 in sub-task 1 and a global top score of 0.802 in sub-task 2. Our method wins on two sub-tasks. In addition, we present the negative results of multiple training strategies when fine-tuning and provide further discussions.

2 Main method

In this section, we will elaborate on the main methods for the two sub-tasks of the PreTENS task. The training strategies are included at the end of this section.

2.1 Sub-task 1 - Binary classification using DeBERTa

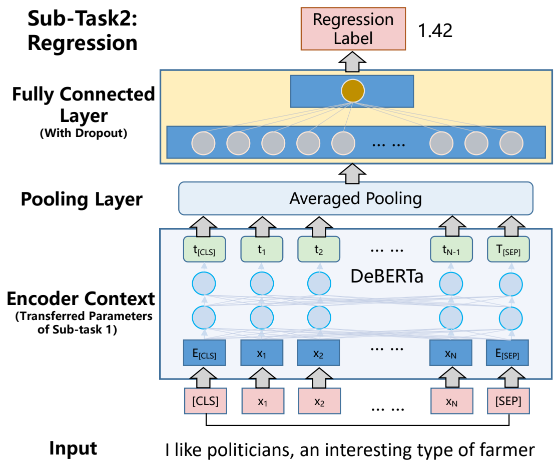


Sub-Task1: Classification
Category Label
1
argmax
Fully Connected Layer (With Dropout)
Pooling Layer
Averaged Pooling
Encoder Context
DeBERTa
Input
I like trees, and in particular birches

Figure 1: Main structure of the method in sub-task 1.

Sub-task 1 is a classic classification task, where two acceptability labels are required to be classified. We adopt the DeBERTa-v3 (He et al., 2021) model for processing this binary classification, where the main method structure is shown in Figure 1. The given sentence is separated into tokens and then sent to the pre-trained model as the input. To obtain the complete meaning of the whole sentence, we take the output embedding of each token to be averaged by the averaged pooling layer. The binary classification task is designed by sending the averaged encoding into the fully connected layer with dropout.

2.2 Sub-task 2 - Regression with knowledge transferring



Sub-Task2: Regression
Regression Label
1.42
Fully Connected Layer (With Dropout)
Pooling Layer
Averaged Pooling
Encoder Context (Transferred Parameters of Sub-task 1)
DeBERTa
Input
I like politicians, an interesting type of farmer

Figure 2: Main structure of the method in sub-task 2.

Sub-task 2 is a regression task, where a seven-point Likert-scale which ranges from 1 (not at all acceptable) to 7 (completely acceptable) is used to perform the regression. There is a subset of 1,533 sentences of the entire dataset for this regression task, where the total number is relatively small. It is a wise choice to transfer the knowledge from the pre-trained model of sub-task 1 into the regression task. The reason is that the fine-tuned model of sub-task 1 learns quite a few patterns of sentence acceptance that come from the extra knowledge. As shown in Figure 2, the DeBERTa-v3 model trained in sub-task 1 is designed to perform the regression task. The fully connected layer with dropout for obtaining the output logits is used for the regression task.

2.3 Multiple training strategies

In this section, we will introduce some training strategies used in the competition, which includes data augmentation with translation, adversarial training and child-tuning training.

2.3.1 Data augmentation with translation

When fine-tuning the English datasets, we translate the training sample of the Italian and the French to English one by one based on the M2M-1.2B model (Ott et al., 2019; Fan et al., 2020). It is a process that provides more useful datasets from the same

Example	Sample	Label
Classification	I like trees, and in particular birches	1
	I like oaks, and in particular trees	0
Regression	I like politicians, an interesting type of farmer	1.42
	I like governors, an interesting type of politician	6.16

Table 1: The dataset sample example.

resources. As a result, the DeBERTa model fine-tuned the datasets in English may achieve better results.

2.3.2 Adversarial training

The common method in adversarial training is the Fast Gradient Method (FGM). The idea of the FGM (Miyato et al., 2016) is straightforward[4]. The loss is to increase the gradient so that we can take

$$\Delta x = \epsilon \nabla_x L(x, y; \theta) \tag{1}$$

where x represents the input, y represents the label, θ is the model parameter, $L(x, y; \theta)$ is the loss of a single sample, Δx is the anti-disturbance. To prevent Δx from being too large, it is usually necessary to standardize $\nabla_x L(x, y; \theta)$. The more common way is

$$\Delta x = \epsilon \frac{\nabla_x L(x, y; \theta)}{\|\nabla_x L(x, y; \theta)\|}. \tag{2}$$

2.3.3 Child-tuning training

We use the Child-tuning (Xu et al., 2021) for fine-tuning the pre-trained model and only update the parameters of the Child network through gradients mask. For the two sub-tasks, the task-independent algorithm is used. In the process of fine-tuning, the gradients mask is obtained by sampling from the Bernoulli distribution (Chen and Liu, 1997) in each step of iterative update, which is equivalent to randomly dividing a part of the network parameters when updating. The equation of the above steps is shown as follows

$$\begin{aligned} \mathbf{w}_{t+1} &= \mathbf{w}_t - \eta \frac{\partial \mathcal{L}(\mathbf{w}_t)}{\partial \mathbf{w}_t} \odot M_t \\ \boldsymbol{M}_t &\sim \text{ Bernoulli } (p_F). \end{aligned} \tag{3}$$

3 Experimental setup

3.1 Data description

The PreTENS dataset not only needs to judge the classification relationship between two nouns

[4]https://spaces.ac.cn/archives/72

Datasets	Classification Task		Regression Task	
Language	Train	Test	Train	Test
English	5837	14560	524	1009
French	5837	14560	524	1009
Italian	5837	14560	524	1009

Table 2: Number statistics of task dataset samples.

(Wang et al., 2017), but also needs to identify whether the two nouns are in line with the actual situation in the artificially constructed natural sentences. The argument nouns are taken from 30 semantic categories (e.g., dogs, birds, mammals, cars, motorcycles...).

Specifically, PreTENS is articulated into the two following sub-tasks. The classification task requires judging the acceptability of the samples. The training set and test set contain 5838 and 14556 samples. Regression Sub-task obtains scores from 1 (not at all acceptable) to 7 (completely acceptable) through human crowdsourcing, which could be affected by usability considerations, argument order, and other factors. The data set of the regression sub-task is a small amount, 524 sentences will be provided for the training set and 1,009 for the test set. The example of two sub-task datasets is shown in Table 1, and the number statistics of each sub-task is shown in Table 2.

3.2 Evaluation metrics

For classification tasks, the official evaluation indicators include precision, recall, macro F1, and global score. The global score is the average value of macro F1.

$$Precision = \frac{TP}{TP + FP}$$

$$Recall = \frac{TP}{TP + FN}$$

$$F1 = \frac{2 Precision Recall}{Precision + Recall}$$

$$MacroF1 = \frac{\sum_{i=1}^{n} F1_i}{n}$$

$$Global = \frac{F1(En) + F1(Fr) + F1(It))}{3}$$

where n means that the higher the total number of categories, accuracy, recall rate, and macro F1. The higher F1 the method, the better the performance.[5]

For regression, it is mainly evaluated by MSE, RMSE and Spearman correlation (rho) (Wissler, 1905).

$$MSE = \frac{1}{n}\Sigma_{i=1}^{n}\left(\frac{R_i - Q_i}{\sigma_i}\right)^2$$

$$RMSE = \sqrt{MSE}$$

$$RHO = 1 - \frac{6\sum_{i=1}^{n}(R_i - Q_i)^2}{n(n^2-1)}$$

where the paired values of two variables are ranked from small to large (or from large to small). R_i represents the rank of x_i, Q_i represents the rank of y_i, and R_i - Q_i is the difference between the ranks of x_i and y_i.

3.3 Baselines introduction

3.3.1 Binary classification sub-task

N-gram method The original baseline provided by the organizers is based on the n-grams (Broder et al., 1997), where n=3. A Linear Support Vector (Tang, 2013) classifier using n-grams (set to 3) as input features is used for the binary classification.

mDeBERTa model The mDeBERTa (He et al., 2021) is a multilingual version of DeBERTa (He et al., 2020) which uses the same structure as DeBERTa and was trained with CC100 multilingual data (Wenzek et al., 2020; Conneau et al., 2020). The mDeBERTa model comes with 12 layers and a hidden size of 768. It has 86M backbone parameters with a vocabulary containing 250K tokens which introduce 190M parameters in the Embedding layer. This model was trained using the 2.5T CC100 data as XLM-R (Conneau et al., 2019).

3.3.2 Regression sub-task

N-gram method This method is provided by the organizers, where it uses a Linear Support Vector regressor with the 3-grams features is provided for the regression sub-task.

mDeBERTa model We adopt the mDeBERTa (He et al., 2021) for processing the sub-task 2. The architecture of this method is the same as Figure 2, where the linear layer over in the mDeBERTa is initialized before fine-tuning. A clamped step is performed for obtaining the final results of the regression.

3.4 Implementation details

We train the model based on the PyTorch (Paszke et al., 2019) and use the hugging-face (Wolf et al., 2020) framework. During training, we employ the AdamW optimizer (Loshchilov and Hutter, 2017). The default learning rate is set to 1e-5 with the warm-up (He et al., 2016). Four RTX3090 GPUs are implemented for all experiments. There are some variants of the DeBERTa-v3 model, i.e., base and large model. We adopt DeBERTa-v3-large models as our backbone, where the batch size is set to 24, and the max length of input is set to 64. We train our backbone for 6 epochs, and save the model parameters at the end of each round. We test the saved checkpoints in the evaluation phase, and select the highest score as the experimental result.

For the sub-task 1, we will implement the overall training (by mixing the datasets in different languages for training), and separate training (to fine-tune in one language and expand to the others), and conduct experiments on the training strategies such as FGM, data augmentation with translation and Child-tuning.

For the sub-task 2, we map the result of [1,7] in the label space to the minimum value of [0,1]. The results of the regression model are clamped so that the minimum value is 0 and the maximum value is 1. Moreover, we will compare the performance of models which use knowledge transfer or not.

4 Results and discussions

In this section, we studied the experimental results of the two sub-tasks and the impact of different strategies on the results, and further discussed the comparison with other participants to prove the effectiveness of the method. Finally, Studies analyze the deviation of language model and the future research direction.

4.1 Experimental results

4.1.1 Classification sub-task

Model Selection We first carry out experiments on three different models when fine-tuning, namely

[5]Below is the specific meaning of the formula. TP: The prediction is correct and the sample is correct. FP: The prediction is wrong and the sample is correct. FN: The prediction is correct and the sample is wrong.

Table 4: Main experimental results of the sub-task2.

mDeBERTa, DeBERTa-v3-base, DeBERTa-v3-large. It can be found in the Figure 3 that the DeBERTa-v3-large model beats the N-gram method and surpass mDeBERTa in French and Italian. It shows that the larger model can bring improvements in the classification task.

Datasets Choosing We are more curious about the generalization ability of the DeBERTa model to fine-tune one language and then transfer to other languages. As a result, we fine-tune the datasets of separate and overall training in different languages. Although the performance by fine-tuning a single language is not satisfactory, it can be better than overall training. It is because there will be large gaps between different languages, and forced dataset mixing will reduce the final performance.

Training strategies After that, we compare some commonly used training strategies and the experimental results in this task, including FGM, translation, and Child-tuning. The performance of the FGM is not good, which indicates that the task pays more attention to the semantic features at the lexical level than the semantic features of sentences. All languages are translated into English, even better than using the original language. We believe that this is because the error accumulation caused by inaccurate translation will interfere with the semantic representation information. The result of Child-tuning is positive, which shows that the catastrophic forgetting problem of the model can be alleviated by eliminating some unimportant weights in the large model.

4.1.2 Regression sub-task

In our experiments of sub-task 2 shown in the Figure 4, we select three different methods for the experiments and compare them with the same experimental settings. The "Original" is the original pre-training model, the "Fine-Tuned" represents the model that is fine-tuned by sub-task1 and re-initialized the linear layer. The experimental results of three different methods show that the performance of the model can be greatly improved through knowledge transfer.

4.2 Official results

As shown in Table 5 and Table 6, our method achieved first place in subtask 1and subtask 2 and

was substantially ahead of second place. Specifically, we earned first place in English, French and Italian in the subtask one classification task, with macroF1 values of 96.988%, 92.817% and 92.714%, respectively. Our global score of 94.173% was 1.863% above second place. For the Subtask 2 regression task, we also came first in English, French and Italian, with RHO scores of 0.758, 0.841 and 0.807, respectively. Our global rank score of Subtask 2 was 0.802, 0.045 above the second-place score.

4.3 Case studies

We counted and analyzed the mispredicted samples, and the distribution of error types is shown in Figures 3 and 4. For subtask 1, we select all the predicted error data for statistics. For subtask 2, we chose the top 100 samples with the most significant difference from the ground truth as the analysis object.

As we can see from Figure 3, the most mispredicted type in the classification task was “generally", with 57%, followed by“type" with 18% and “unlike" with 16%. Our analysis suggests that the reason for the incorrect predictions may be that “generally" sentences are less frequent in common usage and that our model did not have a large enough corpus of similar samples in the previous pre-training phase, thus leading to incorrect predictions.

From Figure 4, we can see that the top 100 data types with the greatest difference from the ground truth on the regression task are more evenly distributed, which means that the model migration is effective for subtask 2.

5 Conclusion

In this paper, we introduce the submitted system to the Semeval-22 task3 PreTENS. Based on the pre-training DeBERTa-v3, we carry out a simple and effective classification method in sub-task 1 and apply the method of knowledge transferring to sub-task 2. The proposed systems have won first place on both sub-tasks. The experimental results show that our proposed method has better performance than other methods. In addition, we also conducted a number of comparative experiments to further explore the difficulties of the PreTENS task. In the future, we will try to explore more effective methods to perform better semantic taxonomies.

Abstract

This paper describes our system created for the SemEval 2022 Task 3: Presupposed Taxonomies - Evaluating Neural-network Semantics. This task is focused on correctly recognizing taxonomic word relations in English, French and Italian. We develop various data generation techniques that expand the originally provided train set and show that all methods increase the performance of models trained on these expanded datasets. Our final system outperforms the baseline from the task organizers by achieving an average macro F1 score of 79.6 on all languages, compared to the baseline's 67.4.

1 Introduction

In this paper, we describe our system and approach for the SemEval 2022 PreTENS (Presupposed Taxonomies: Evaluating Neural Network Semantics) shared task (Zamparelli et al., 2022).[1] The aim of this task is to gain a better understanding of the ability of language models to recognize taxonomic relations between two words.

We focus on subtask 1, which is a binary classification task in which a system should predict whether a sentence is valid or not, depending on the taxonomic word relation in a given sentence. We formulate the following research question:

> What are effective data generation approaches in order to improve a language model's ability to recognize appropriate taxonomic word relations?

In our attempt to answer this question, we experiment with multiple approaches: adding new templates, adding new nouns from similar word lists, adding additional hyponyms, inverting templates and using a paraphrasing model to create sentence variations. We use the expanded training data to fine-tune a base English BERT (Devlin et al., 2019) model for the final classification task.

In our approach, we incorporate all three languages for this task: English, Italian and French. Instead of generating additional data for each language and training separate models, we opt to train an English model and translate the Italian and French sentences to English, before predicting the validity labels. We choose this approach in part because several of our data generation methods are not available for French or Italian. We make use of Google Translate, as this is a widely used state-of-the-art general-domain translation system. Our model, trained on the expanded dataset, scores an average F1 score across all languages of 79.6, which is an improvement over the 67.4 baseline score. We find that the best data expansion technique is to combine multiple approaches, where the output of one method is the input for the next. Our ablation experiments show that our paraphrasing method improves scores the most. All code, data and other related files can be found in our GitHub repository.[2]

2 Task description

For the binary classification subtask, the challenge was to predict the acceptability label assigned to each sentence of the test set. The participants were provided with a training set consisting of 5,838 sample sentences and their validity labels, while the test set contained 14,556 sentences. The splits were provided in English, Italian and French, the latter two being slightly adapted translations of the English dataset. These sentences exemplify constructions enforcing presuppositions on the taxonomic status of their arguments A and B, as can be seen in the following examples:

[*]Contributed equally

[1]`https://sites.google.com/view/semeval2022-pretens/home-page`

[2]`https://github.com/WPoelman/shared-task`

I like trees, and in particular birches.	1
I like oaks, and in particular trees.	0

A sentence will only get a validity label of 1 when the taxonomic relations are compatible with the sentence construction.

For this task, participants were free to use external resources, with the exception of lexical resources where semantic relationships (including taxonomic ones) are manually marked, such as WordNet (Miller, 1995) or BabelNet (Navigli and Ponzetto, 2012). However, using these lexical resources was allowed for the generation of data, which is part of our approach.

The task of detecting taxonomic word relations has been tried via various approaches. From purely rule-based (Hearst, 1992), to using semantic tree-like resources (Navigli et al., 2011), to adapting pre-trained language models (Atzori and Balloccu, 2020; Chen et al., 2021) or creating hybrid systems (Shwartz et al., 2016; Ravichander et al., 2020). Since this SemEval task is focused on *neural* (language) models, we opt to use BERT and focus mainly on different data generation techniques.

3 System overview

Our main research focus is to explore the effects of different data generation approaches to expand the English training data. This data is then used to train an English BERT model. The unseen Italian and French sentences (to predict) from the test set are first translated into English before we feed them to the model to get their final prediction. We describe these different stages in more detail below.

3.1 Development data split

In order to evaluate our experiments during the development of our system, we created a test set from the original training data. The aim of this set is to replicate the expected official test data characteristics as well as possible. The original training data, as published by the task organizers, consists of seven different templates, distinguished by the words used to describe the relation between two nouns (thus disregarding pronouns). We categorize these in three types of relations:

1. No hypernym relations possible: *I do not like pigs, I prefer animals*
2. Word A is a hypernym of word B: *I like animals, except pigs*
3. Word B cannot be a hypernym of word A: *I like animals, but not pigs*

The first two categories are seen in two templates, while the last category is only relevant to one template. In order to evaluate our techniques, we created our own test set which consists of all sentences with three templates: one for each defined relation. These templates are not present in the training set. Additionally, we filtered nouns that were used with the verbs 'use' and 'met', i.e. verbs that relate to the noun categories 'materials' and 'people'. These nouns were only present in our test set, to ensure that we also evaluate the system on unseen nouns. Additionally, adding the sentences with these nouns means that the test set contains all seven templates, so that there are four overlapping templates with the training set, as this also seems similar to the official test set, where we expected some overlap with training sentences.

3.2 Data generation methods

3.2.1 New templates

First, new templates were added. As described in the previous section, our initial training split consists of only four templates. However, since sentences occur in many different variations, we manually wrote templates in the three previously distinguished relation categories.[3] In total, we added 58 new templates: 22 for the first relation, 23 for the second and 13 for the third.

3.2.2 New words

Our next step was to add new words to the templates. In the task description it was mentioned that the nouns were divided into 30 semantic categories, such as dogs, mammals, motorcycles etc. Not all categories were given, so we tried to infer this from the training data. We extracted all unique nouns from the training data and divided these into lists of different categories. With these categories, we tried to approximate and expand the semantic categories given by the organizers. Certain changes were made, for example, splitting the 'entertainment' category, consisting of books, movies, games and music into separate categories, or combining mammals and dogs into an 'animals' category. Words that occurred together but did not fit into a category, which includes emotions and buildings among others, got assigned to a 'miscellaneous' category. Finally, 14 categories were identified. These categories were also tied to certain verbs in the provided training data. The verb

[3]The full criteria of writing these can be found in our data split description.

'like' was used in all categories, but 'use' was only paired with materials, for example.

The word lists were then enriched. This was mainly done manually, with the help of searching for all hyponyms for a word in WordNet. More verbs were added as well. All categories and their verbs can be found in Table 1. Moreover, we added additional pronouns, with their corresponding possessive pronouns. In addition to *I/my* and *he/his*, we added *she/her* and *they/their*. These lists were used to fill in the existing and new templates. The sentences were checked on their validity using WordNet in order to generate their labels. The generated data is balanced, meaning that each category gets an even amount of relation types, which, in turn, get an even amount of 1's and 0's.

Category	**Verbs**
Animals	like, **love**
People and professions	like, **love**, met
Materials	like, **love**, use
Games and sports	like, **love**, **enjoy**, **play**
Clothing and jewelry	like, **love**, **wear**
Drinks	like, **love**, **enjoy**, **drink**
Food	like, **love**, **enjoy**, **eat**
Transport	like, **love**, **enjoy**
Movies	like, **love**, **enjoy**, **watch**
Music	like, **love**, **enjoy**, **listen to**
Books	like, **love**, **enjoy**, **read**
Plants	like, **love**
Furniture and household items	like, **love**
Miscellaneous	like, **love**, **enjoy**, **feel**, trust

Table 1: Categories and their corresponding verbs. The bold verbs have been added to the data.

3.2.3 Hyponyms of hyponyms

We noticed that in the valid sentences containing appropriate taxonomic relations, the used arguments always have the same role throughout the data set. As an example, in the valid sentence *I like seafood, except salmon* the argument 'seafood' is a hypernym and the argument 'salmon' is a hyponym. In all other sentences of the training data, the word 'salmon' is also exclusively used as a hyponym, even though it can be a hypernym in a sentence such as *I like salmon, except redfish*.

In line with this example, we created additional sentences where words previously used exclusively as a hyponym, were now used as a hypernym. To do so, we extracted all the hyponyms occurring in the training data and searched WordNet for their direct hyponyms. We then used the first five returned results to generate both valid and invalid new sentences. In creating these additional sentences, we aim to challenge the language model to recognize appropriate taxonomic relations even when the role of an argument alternated between being a subcategory and a supercategory.

3.2.4 Inverting

As mentioned before, we categorized the training data into three possible template relations. For a sentence with the relation 'X is a hypernym of Y', e.g. *I like animals, except pigs*, we know that the sentence is valid because 'animal' is a hypernym of 'pig'. Following this logic, we also know that swapping the arguments to create *I like pigs, except animals*, invalidates the sentence. This process of swapping the arguments in a sentence and (possibly) changing the validity is what we call 'inverting'. Note that not every sentence's validity will change when inverted. When swapping the arguments in the valid sentence *I like jazz more than jewelry* to *I like jewelry more than jazz*, the sentence remains valid. Therefore, we carefully looked at the conditions that make a sentence valid or invalid.[4] We then swapped the two arguments of each sentence and changed the validity label when applicable to create additional data. The language model should learn that the validity also depends on the order of the arguments.

3.2.5 Paraphrasing

In addition to data generation, we also wanted to look at synthetic data. This led us to experiment with a neural paraphrasing model. Specifically we used a fine-tuned 'Pegasus' model from Google (Zhang et al., 2020), originally trained on the task of summarizing and fine-tuned on paraphrasing. We used this model as the final step in our data generation pipeline in order to generate paraphrases of all method combinations. The following is an example the paraphrasing outputs:

I do not like dogs, I prefer blackbirds.

- I prefer blackbirds, I don't like dogs.
- I don't like dogs and I like blackbirds.
- I don't like dogs and I prefer blackbirds.

As the example shows, the differences are not drastic, but do introduce some variation. In order to prevent the paraphrasing model from outputting unrelated sentences, we applied some filtering steps to restrain the output of the model. For instance,

[4] Valid and invalid relations for each template are described in our data split description.

we added length constraints, which ensures that the newly generated sentences were not too short, but neither too long. We allowed at most ten paraphrases per sentence.

3.3 Lemmatization

Since the generated sentences were not all grammatically correct (e.g. ‘He like’ instead of ‘He likes’) and because of the fact that the nouns in the original data were plural and the nouns extracted from WordNet were singular, we experimented with lemmatizing the nouns and verbs in the generated sentences. This might remedy the incorrect sentences by equally pre-processing all sentences.

3.4 Translation

By combining the output from our different generation methods, we created an English training set. We used this to fine-tune a pre-trained English language model, namely BERT base provided by Hugging Face.[5] Then, in order to predict the validity labels for Italian and French sentences, we translated these into English in order to process them with the English model. We opted for this approach since several of the data generation methods were not available for French or Italian. For instance, there were no paraphrasing models or easily accessible WordNet-like resources available.

For the translation system, we use Google Translate, as this general-domain transformer-based system is the state-of-the-art. Manual inspection revealed that translation quality seemed sufficient for our purposes.

3.5 System

We experiment with various combinations of the previously mentioned data generation techniques. The detailed results of these experiments are described in the Results section. Our final training dataset was created as follows:

1. Take the existing and new templates (not the ones included our test set)
2. Fill these in with new words from our word lists
3. From the resulting sentences, create additional sentences using the noun hyponyms

[5] https://huggingface.co/bert-base-uncased

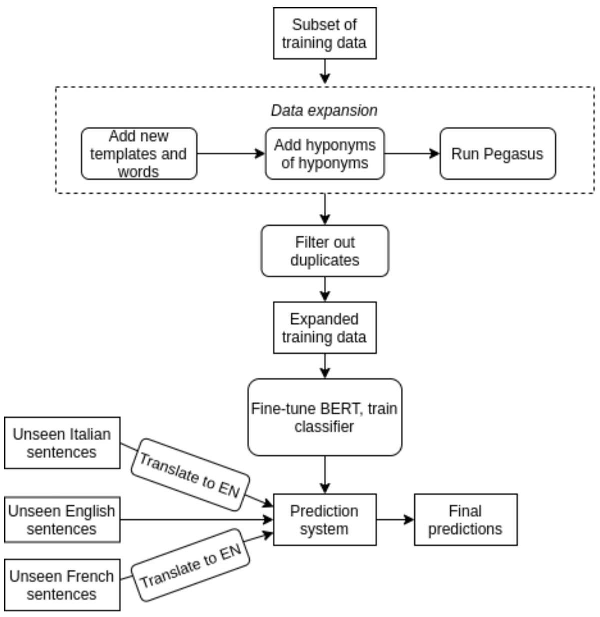

Figure 1: Overview of system and prediction pipeline.

4. Add paraphrases of all generated sentences
5. Finally, filter out duplicate sentences

This resulted in dataset of 211,354 sentences, which was used to train our final model. Figure 1 shows an overview of our entire system to get the final predictions.

4 Experimental setup

To run our experiments, we created various combinations of our data generation techniques. The full list of experiments can be seen in Table 3. The paraphrasing model we used comes from the Hugging Face model hub.[6]

We trained each system using the Hugging Face transformers library.[7] The exact hyperparameters and other settings can be found in Appendix A. The final model we used for generating our submission can be found in our GitHub repository.

As mentioned, all models were tested using our custom test set with special challenging characteristics.

5 Results

In this section, we discuss the results on both our custom test set and the official test set. We also provide an error analysis in order to gain insight into

[6] https://huggingface.co/tuner007/pegasus_paraphrase
[7] https://huggingface.co/docs/transformers

the contributions of the different data generation methods.

5.1 Custom test set

The full results of our experiments on our custom test set can be found in Appendix B. All data generation methods improve performance over the originally provided training set, while there are some notable differences between the methods. For instance, when looking at the individual methods, we observe that adding the hyponyms has a rather small effect, especially considering that the size of the dataset is almost doubled. The size of the dataset also does not seem be a direct indicator of increased performance. Inverting applicable templates, for example, increases the training set by about 120 sentences, but increases the F1 score from 53.1 to 61.7.

Another surprising effect can be observed in the lemmatized and normal versions of the same datasets. With the individual methods we can see a clear increase in performance, but this effect is not visible with the fully combined methods. The same applies to the inverting method, which resulted in worse performance in some cases in the fully combined methods, which was not the case when it was used on its own.

5.2 Official test set

The official evaluation for the first subtask was twofold:

1. Ranking per language.
2. Global ranking - the average score across all three languages.

While the systems were evaluated using the metrics of precision, recall, micro F1 and macro F1 scores, the official rankings were based only on macro F1 scores.

With our submission, we achieve an average macro F1 score of 79.6, which ranks our system 14th out of 21 participants. We achieve macro F1 scores of 80.3, 78.6 and 79.7 for English, Italian and French respectively. Our system improves over the baseline system, which obtains a macro F1 score of 67.4.

5.3 Error analysis

Once the official test set with labels was available, we conducted ablation experiments to see what effects the different data generation methods had on our submission. Of all methods, the sentences generated with the Pegasus model seem to contribute the most to our final model. The full results of these experiments can be seen in Table 2. To our surprise, the split of our best dataset *without* the new words scores better on the official test set. An explanation could be that using the extensive word lists, which contain rare words, can lead to the generation of vague or uncommon sentences. However, this effect was not apparent in our custom test set, both as an individual method as well as combined with others. Apart from this, the scores are all quite close and again show that the increase in dataset size does not directly lead to better performance.

	Sentences	Acc	Pre	Rec	F1
Templates, new words, hyponyms, pegasus (used for final submission)	211,354	80.7	86.0	70.4	77.4
- pegasus	33,571	77.2	80.0	68.9	74.0
- new words	108,819	81.9	84.1	75.9	79.8
- hyponyms	116,234	79.0	79.9	74.1	76.9

Table 2: Ablation test with final expanded training dataset on official test set.

For each ablation test, we analyze incorrectly predicted examples from a particular model, which were predicted correctly by the others. We look at both the templates and words of the official test set. Additionally, the official set provides information about the structure that was used by the task organizers to generate a particular sentence, which we also include in the analysis.

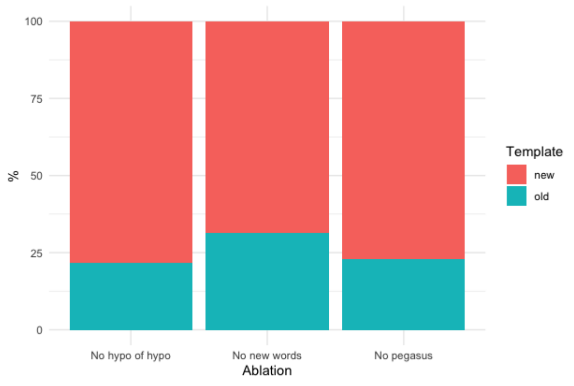

Figure 2: The ratio of incorrectly predicted instances with old and new templates per ablation test.

In Figure 2 we can see the effects of the ablation methods on the templates in the test set. Not adding new words results in a lower error rate for new templates. This is unexpected, as generating sentences with new words was also done using new manual templates, however the test set still contains completely unseen templates. Another surprise is that not including paraphrasing did not result in relatively more incorrect predictions on new templates, since paraphrasing does introduce some variation in templates to an extent.

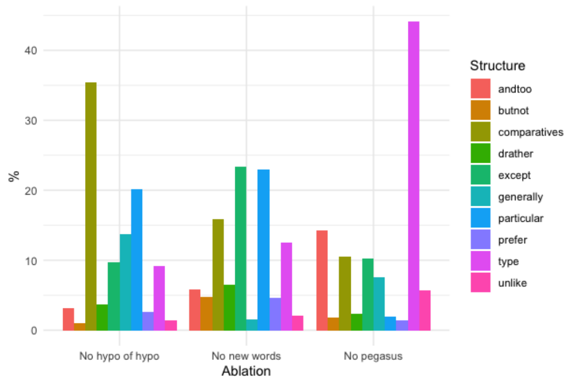

Figure 3: The ratio of structure types in the incorrectly predicted instances per ablation test.

Figure 3 displays the effect of the ablation tests on the different structures. Without the hyponyms of hyponyms method, the error rate of the *comparatives* is high. Excluding the paraphrases results in a higher error rate for the *type*-structure and a lower error rate for the *particular*-structure. This could be because the *type*-sentences are mostly paraphrased correctly which is not the case for *particular*-sentences.

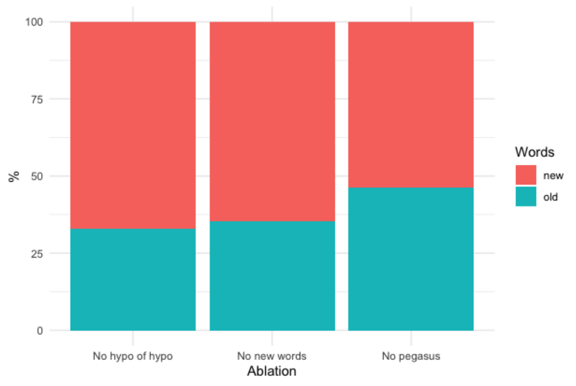

Figure 4: The ratio of incorrectly predicted instances with old and new words per ablation test.

Figure 4 shows the effect of the ablation tests on old and new words. We expected the error rate for ablating new words to be higher. However, new words in the test set were mostly from completely new categories, as opposed to more words from the same categories, which our approach was based on.

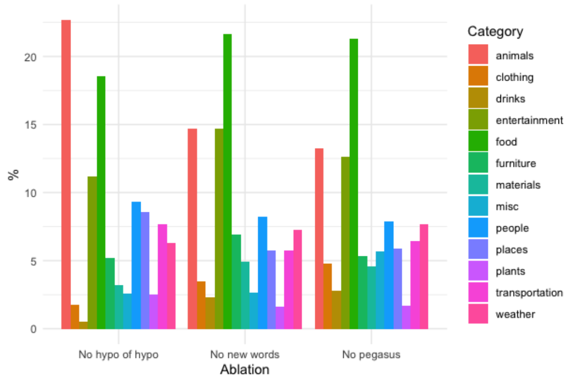

Figure 5: The ratio of word categories in the incorrectly predicted instances per ablation test.

Figure 5 shows the effect on the different categories of words for the ablation tests. These are categorized in the same manner as described in the 'new words' section. There are two new categories in the official test set: *places* and *weather*. Both did not see an increase in error rate by ablating any method. The error rate of *animals* increased by ablating hyponyms of hyponyms. The extensive manner in which the taxonomy of animals is represented in WordNet might be the reason behind this.

6 Conclusion

We have outlined several data generation methods and show that all methods improve the performance of a model trained on the expanded datasets compared to the original training data. Especially new words, new templates and paraphrasing are effective, even by themselves. Surprisingly, adding hyponyms is not that effective by itself, but combined with the previously mentioned methods it scores quite well. The final system we used to participate in the task was trained on a dataset created from those four methods. With this system, we improve the baseline set by the task organizers, placing us 14th out of 21 participants.

As we have shown, some unexpected effects occur when looking at how different data generation techniques perform when combined. In future research, it might be interesting to explore this in a broader context: what can cause such differences? Furthermore, since the provided dataset consisted of short and specific template-based sentences, it could be interesting to experiment with longer sentences that contain more complex constructions.

7 Acknowledgments

We are grateful to Tommaso Caselli and Lukas Edman for their supervision and helpful comments. We also want to thank the Center for Information Technology of the University of Groningen for providing access to the Peregrine high performance computing cluster.

Abstract

Recognizing lexical relationships between words is one of the formidable tasks in computational linguistics. It plays a vital role in the improvement of various NLP tasks. However, the diversity of word semantics, sentence structure as well as word order information make it challenging to distill the relationship effectively. To address these challenges, SemEval-2022 Task 3 introduced a shared task PreTENS focusing on semantic competence to determine the taxonomic relations between two nominal arguments. This paper presents our participation in this task where we proposed an approach through exploiting an ensemble of multilingual transformer models. We employed two fine-tuned multilingual transformer models including XLM-RoBERTa and mBERT to train our model. To enhance the performance of individual models, we fuse the predicted probability score of these two models using weighted arithmetic mean to generate a unified probability score. The experimental results showed that our proposed method achieved competitive performance among the participants' methods.

1 Introduction

Lexical relations are regarded as the most important semantic relations to infer the meanings of words effectively (Khoo and Na, 2006). Therefore, identifying such relations is beneficial to understand the semantic competence and distill the underlying context of the textual expression. If we consider the NLP applications, it has a significant impact on several tasks including semantic search, automatic question/answering, story generation, relation extraction, and machine translation (Barkan et al., 2020). However, most of the prior works focused mainly on syntactic (Luu et al., 2014) and contextual relation (Maksimov et al., 2018) to infer the lexical relation in between words.

Sentence	Language	Label / Score
Sub-task 1		
Apprezzo il vino , ma non il Chianti.	It	1
J' aime les chats, sauf les beagles.	Fr	0
I like movies, but not comedies.	En	1
I like earrings, except socks.	En	0
Sub-task 2		
Amo i merli piÃ¹ degli uccelli.	It	1.9
J'aime les chats, et aussi les canards.	Fr	6.17
I like cats, but not sparrows.	En	4.77

Table 1: Examples of sub-task 1 and sub-task 2.

Considering this PreTENS shared task at SemEval 2022 (Zamparelli et al., 2022) introduce a new task that focuses mainly on semantic competence with specific attention on the estimating taxonomic relations between two nominal arguments. The taxonomic relation here means one argument is a supercategory of the other, or in extensional terms, one argument is a superset of the other. The task is divided into two subtasks. The first one is a binary classification subtask, where a system needs to predict the acceptability label for given text considering the taxonomic relation. The second one is a regression subtask, where a system needs to predict the percentage of acceptability label on a seven-point Likert-scale for a given text considering the same scenario. Besides, the task addresses the challenges of multilingual expression and comprises a dataset of three different languages including Italian (It), French (Fr), and English (En). To illustrate a clear view of the task definition and research goal, we articulate a few examples from different languages and corresponding labels for each subtask in Table 1.

We articulate the rest of the contents as follows: Section 2 describes our proposed approach

**The first two authors have equal contributions.

whereas, in Section 3, we present our experimental setup and conduct performance analysis against the various settings and participants' methods. Finally, we conclude our work with some future directions in Section 4.

2 Proposed Framework

In this section, we describe our proposed approach for the PreTENS shared task. Our goal is to determine the semantic competence between two arguments focusing on the taxonomic relations. The task is articulated into both the binary classification subtask and the regression subtask. We depict the overview of our proposed framework in Figure 1.

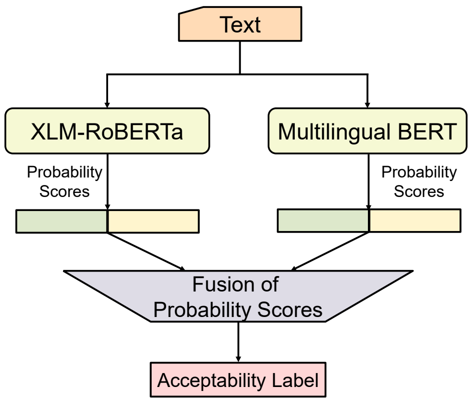

Figure 1: Overview of our proposed framework.

Given an input sentence containing two nominal arguments, we employ two transformer models including XLM-RoBERTa and multilingual BERT (mBERT) to extract the diverse contextual features. Later, a feed-forward linear layer is employed in each model to estimate the probability score of each class. In Figure 2, we illustrate an overview of the setup of mBERT transformer model. Finally, we fuse these models' predictions by taking the weighted arithmetic mean of these scores to determine the final label.

2.1 XLM-RoBERTa

The Facebook AI launched the XLM-RoBERTa as an upgrade to their initial XLM-100 model (Conneau et al., 2020). It is a scaled cross-lingual sentence encoder. Using self-supervised training approaches, it offers state-of-the-art performances in cross-lingual understanding where a model is taught in one language and then applied to multiple languages with no additional training data. This model showed increased performance on numerous NLP applications. XLM-RoBERTa creates the

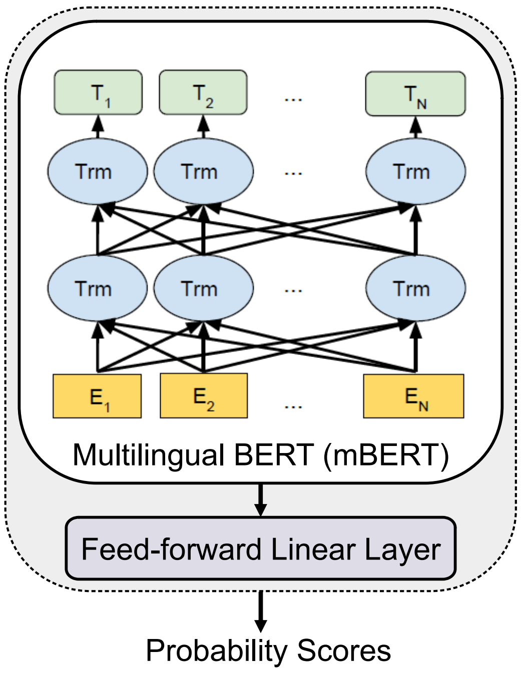

Figure 2: Multilingual BERT (mBERT) model.

possibility for a one-model-for-many-languages approach rather than a single model per language.

However, XLM-R maps the same sentence in different languages to similar representations which is crucial for this PreTENS task to learn semantic competence in cross-lingual form. Here, we use the HuggingFace's implementation of the XLM-RoBERTa-base model (Conneau et al., 2020). It is composed of 12-layers (i.e. transformer block), the dimension of hidden size is 768, the number of the self-attention head is 12, the size of vocabulary is 250K, and containing 270M parameters.

2.2 Multilingual BERT

Multilingual-BERT (mBERT) (Devlin et al., 2019) is a version of BERT that is gaining popularity for effective contextual representation of textual contents in various multilingual tasks including natural language inference in cross-lingual characteristics, named entity recognition in multilingual corpora, and dependency parsing (Chi et al., 2020). It is pretrained on 104 different languages in Wikipedia. It provides an effective path to zero-shot cross-lingual model transfer.

Multilingual-BERT representations are influenced by high-level grammatical features that are not manifested in any one input sentence which is critical to learn taxonomic relations in PreTENS task. In our approach, we employ the huggingface

https://huggingface.co/xlm-roberta-base

implementation of the bert-base-multilingual-cased model and perform finetuning the model with the task-specific data.

2.3 Fusion of Transformer Models

To enhance the performance of individual models, we fuse the predicted probability score of two models to generate a unified probability score for each class. We use the weighted arithmetic mean to average both model's probability scores to determine the each class confidence of the fused model. After calculate the both class probability score of fused model, our system predict the best confidence class, which is our final label. The estimation is computed as follows:

$$f(x_i, y_i) = \begin{cases} 0, & \text{if } W_0 > W_1 \\ 1, & \text{otherwise} \end{cases}$$

$$W_i = \frac{x_i * M + y_i * R}{M + R}$$

x_i and y_i correspond to the mBERT and XLM-RoBERTa probability score, where M and R represents their weight respectively. W_i (i.e. i = {0, 1}) is the unified probability score for each class.

3 Experiment and Evaluation

3.1 Dataset Description

The organizers of the SemEval-2022 PreTENS shared task 3 (Zamparelli et al., 2022) provided a benchmark dataset to evaluate the performance of the participants' systems. The dataset comprises in 3 languages including English, Italian, and French. The French and Italian are slightly adapted translations of the English dataset. The dataset statistics is summarized in Table 2.

Language	Sub-task 1		Sub-task 2	
	Train	Test	Train	Test
It	5837	14560	524	1009
Fr	5837	14560	524	1009
En	5837	14560	524	1009
Total	17511	43680	1572	3027

Table 2: The statistics of the datasets used in PreTens shared task.

Dataset of each languages contained about 20K artificially generated text samples that enforces presuppositions on the taxonomic status of their arguments A and B, e.g. comparatives (I like A more than B), exemplifications (I like A, and in particular B), generalizations (I like A, and B in general), and others. In Subtask 1, all samples are provided with an acceptability label either 1 or 0 where 1 stands for acceptable (i.e. the taxonomical relations is compatible with the construction at issue) and 0 stands for not acceptable (not compatible). Besides, a subset of 1533 samples of the whole dataset i.e. 5% of the total and representative of the patterns considered, was used for the subtask 2. It was annotated via a crowdsourcing campaign on a seven point Likert-scale, ranging from 1 (not at all acceptable) to 7 (completely acceptable). The average judgment is considered as the final label for each sample.

https://huggingface.co/bert-base-multilingual-cased

3.2 Experimental Settings

We now describe the details of our experiments and set of parameters that we have used to design our proposed CSECU-DSG system for each subtask.

Parameter	Optimal Value
Subtask 1: Parameters used in both models	
Learning rate	3e-5
Max-len	100
Epoch	3
Batch size	16
Manual seed	4
Subtask 2: Parameters of XLM-RoBERTa	
Learning rate	3e-5
Max-len	100
Epoch	5
Batch size	8
Manual seed	4

Table 3: Model settings for each subtask.

In Subtask 1, we utilize the Huggingface (Wolf et al., 2019) implementation of the two state-of-the-art multilingual transformer models with finetuning, including XLM-RoBERTa and mBERT. We finetune these models with the provided training data. To generate the unified prediction, we fuse the probability score of each model as described in Section 2.3. Since XLM-R typically perform better than the mBERT, so we don't count both model confidence weight as equal. However, from some sets of experimental result we choose the weight R = 0.6 for XLM-RoBERTa and M = 0.4 for mBERT in equation 2.3. However, in Subtask 2, we only employed the XLM-RoBERTa model with finetuning strategy. The optimal parameter settings used in both subtasks are articulated in Table 3 and we used the default settings for the other parameters.

3.3 Evaluation Measures

To assess the performance of the participants' systems, PreTENS task organizers (Zamparelli et al., 2022) used different strategies and metrics for subtask 1 and subtask 2. Since the evaluation file contains instances from all three languages, the average of the F1-macro score from all the three languages is used as the global ranking score (GRS) to rank the participants' systems. We can write this as follows:

$$\text{Global Rank Score, } GRS = \frac{AS}{3}$$

where AS=(F1-macro (English) + F1-macro (French) + F1-macro (Italian)).

In subtask 2, the average of the Spearman correlation (Rho) scores from all the three languages is used as the global ranking score (GRS) to rank the participants' systems. We can write this as follows:

$$\text{Global Rank Score, } GRS = \frac{AS}{3}$$

where AS=(Rho (English) + Rho (French) + Rho (Italian)).

3.4 Results and Analysis

In this section, we analyze the performance of our proposed approaches in the PreTENS shared subtasks. The dataset comprises of 3 different languages including English, Italian, and French and the overall performance of the system is estimated considering the average score obtains in each languages dataset. Considering this, we analyze the performance of our CSECU-DSG system, based on each language. The corresponding results for subtask 1 and subtask 2 are reported in Table 4 and Table 5, respectively.

Results showed that in Subtask 1 our CSECU-DSG system achieved a pretty good score in all sets of datasets considering three languages. It demonstrates the generalizability of our approach in diverse types of languages. However, our method limited to obtain a good score in Subtask 2 for all the datasets. One plausible reason behind this is to use only single transformer models instead of the fusion approach and failed to address and analyze the challenges of subtask 2 properly.

Language	F1-macro	F1
It	91.113	90.620
Fr	90.732	90.334
En	91.506	91.189
All (CSECU-DSG)	91.117	-

Table 4: Results of our proposed CSECU-DSG system on individual monolingual tracks (subtask 1).

Language	Spearman Cor. (Rho)
It	0.207
Fr	0.081
En	0.191
All (CSECU-DSG)	0.160

Table 5: Results of our proposed CSECU-DSG system on individual monolingual tracks (subtask 2).

Next, the obtained results of our proposed CSECU-DSG system in the PreTENS shared task along with other top performing and competitive participants systems in subtask 1 and subtask 2 are articulated in Table 6 and Table 7, respectively. Following the benchmark of the PreTENS shared task, participants' systems are ranked based on the primary evaluation measures of each subtask.

Team (Rank)	F1-macro			
	Global	It	Fr	En
CSECU-DSG (4th)	91.117	91.113	90.732	91.506
Performance of team based on F1-macro score				
LingJing (1st)	94.485	93.047	93.236	97.172

holdon (6th)	89.579	86.903	87.281	94.551
cnxupupup (10th)	86.676	86.755	86.390	86.883
breaklikeafish (15th)	77.985	74.398	82.345	77.213
Baseline (18th)	67.394	59.588	72.126	70.468

Table 6: Comparative results with other selected participants (Sub-task 1).

Results showed that our system ranked 4th among the participants' systems in subtask 1. This deduces the efficacy of our approach in addressing

Team (Rank)	Spearman Correlation (Rho)			
	Global	It	Fr	En
CSECU-DSG (8th)	0.160	0.207	0.081	0.191
Comparative performance of team based on Rho score				
LingJing (1st)	0.802	0.807	0.841	0.758
huawei_zhangmin (3rd)	0.669	0.631	0.740	0.636
daydayemo (6th)	0.206	0.121	0.284	0.212
breaklikeafish (11th)	0.078	0.186	-0.010	0.059
thanet.markchom (13th)	0.056	0.089	-0.043	0.122
Baseline (4th)	0.309	0.344	0.317	0.265

Table 7: Comparative results with other selected participants (Sub-task 2).

the challenges of the PreTENS shared task. However, in subtask 2, our system obtained a poor score though we ranked 8th in this task.

To further analyze the effectiveness of the components used in our approach, we estimate the performance of each model used in the fusion approach in subtask 1. The results are reported in Table 8. It shows that our fusion strategy improves the overall performance of the model compared to the performance of the mBERT and XLM-RoBERTa. However, considering the individual model's performances XLM-RoBERTa performed better compared to the mBERT.

Method	F1-macro			
	Global	It	Fr	En
CSECU-DSG	**91.117**	**91.113**	**90.732**	**91.506**
Performance of individual model				
XLM-RoBERTa	90.217	90.322	89.853	90.475
mBERT	88.076	86.477	88.288	89.463

Table 8: Performance analysis of individual model using subtask 1 test dataset.

4 Conclusion and Future Directions

In this paper, we presented our proposed system to address the challenges of the PreTENS shared task. We employed the weighted fusion of two state-of-the-art multilingual transformer models predictions. Experimental results demonstrate the competency of our approach in Subtask 1.

In the future, we have a plan to incorporate the task specific features and technologies to address the challenges properly. We also have a plan to explore the causal inference techniques to distill the taxonomic relation.

Abstract

In human languages, there are many presuppositional constructions that impose a constrain on the taxonomic relations between two nouns depending on their order. These constructions create a challenge in validating taxonomic relations in real-world contexts. In SemEval2022-Task3 Presupposed Taxonomies: Evaluating Neural Network Semantics (PreTENS), the organizers introduced a task regarding validating the taxonomic relations within a variety of presuppositional constructions. This task is divided into two subtasks: classification and regression. Each subtask contains three datasets in multiple languages, i.e., English, Italian and French. To tackle this task, this work proposes to fine-tune different BERT-based models pre-trained on different languages. According to the experimental results, the fine-tuned BERT-based models are effective compared to the baselines for classification. For regression, the fine-tuned models show promising performances with the possibility of improvement.

1 Introduction

Taxonomic relations are one of the significant lexical relationships that have been used in many applications such as question answering (Yih et al., 2013), sentiment analysis (Araque et al., 2019) and biomedical ontologies (Bodenreider, 2004). In natural languages, there are many constructions that constrain the taxonomic relation between two nouns based on the order of these two nouns. For instance, given a sentence "I have a dog, not a pet". The construction "I have a ..., not a ..." implies that the taxonomic relation does not hold between "dog" and "pet". This can be seen as a presupposition imposed by the construction. However, this is not true since dogs are pets. Thus, with various presuppositional constructions, validating taxonomic relations becomes more complicated in the real world.

To address this issue, SemEval2022-Task3 Presupposed Taxonomies: Evaluating Neural Network Semantics (PreTENS) (Zamparelli et al., 2022) introduces the task where taxonomic relations have to be validated in different presuppositional constructions. This task proposes novel datasets in multiple languages (i.e., English, Italian and French) containing sentences with different two-noun constructions. Each sentence is labeled by an acceptability label for classification and an acceptability score for regression. Two challenges have been raised in this task: (1) a taxonomic relation between two nouns in the sentence must be detected, and (2) the construction which embeds the two nouns must also be validated.

To effectively validate taxonomic relations in such constructions, understanding the contexts or semantic meanings of these constructions are the key. Many previous studies have shown that pre-trained models comprise the prior knowledge of context comprehension (Yang et al., 2019). Recently, the language mode called BERT has been widely used in several tasks. The BERT model can be pre-trained with the self-supervised method to generate word/token or sentence representations enriched with prior knowledge. Then, they can be fine-tuned specifically for many downstream tasks including validating taxonomic relations. Therefore, in this work, we adopt the pre-trained BERT-based models in different languages to utilize the prior knowledge from the resources that they were pre-trained with. Then, elaborating on the pre-training, we fine-tune these pre-trained models to predict the acceptability of each sentence.

2 Related Work

Pre-trained language models such as GloVe (Pennington et al., 2014) and ELMo (Peters et al., 2018) have been widely used to generate word/sentence representations for many NLP applications. These representations have been proven to be effective since they are enriched with knowledge from the pre-training resources. Recently, the transformer architecture (Vaswani et al., 2017), a multi-layer multi-head self-attention, has made the major success in NLP. With this architecture as a fundamental, a language model called BERT (Devlin et al., 2019) was proposed. Such model can be first pre-trained with two self-supervising tasks, masked LM and next sentence prediction. After that, they can be fine-tuned with additional output layers to create new models for various downstream tasks. Due to the huge success of the BERT model, many language models stemming from it have been proposed. These include RoBERTa (Liu et al., 2019), the more robust BERT model, and DistilBERT (Sanh et al., 2020), the modified BERT model using knowledge distillation methods.

All of these BERT-based models can be pre-trained on different corpora/resources depending on various purposes. Previously, there are variations of the BERT-based models pre-trained in different languages. MDZ Digital Library team at the Bavarian State Library introduced the variations of the BERT-based models pre-trained on Italian and German corpora[1]. Le et al. proposed FlauBERT, pre-trained on a large French corpus consists of texts in diverse topics and writing styles. Although they have been used to solve several tasks in many languages, how to use these models in validating taxonomic relations in real-world contexts still remains an open issue.

3 System Overview

This task consists of two sub-tasks (1) a binary classification sub-task and (2) a regression sub-task. For sub-task 1, each sentence in the datasets is labeled with 1 if it is acceptable and 0 otherwise. For sub-task 2, each sentence is labeled with the average score assigned by human annotators. The score is on a seven point Likert-scale ranging from 1 that means “not at all acceptable” to 7 that means “completely acceptable”.

This paper proposes two similar approaches of fine-tuning the BERT-based models for taxonomic relation classification and regression. For both sub-tasks, we select three pre-trained BERT-based models that were pre-trained on three corpora with different languages. For English, we choose *DistilBERT-Base-Uncased* [2], pre-trained on Toronto Book Corpus and full English Wikipedia. The model has 6 layers, 12 heads, and 768 embedding dimension and has 66M parameters in total. For Italian, we select *BERT-Base-Italian-XXL-Uncased* [3], the Italian BERT model pre-trained on texts from a recent Wikipedia dump and the OPUS corpora collection. This model consists of 12 layers, 12 attention heads and 768 embedding dimension. The total number of parameters is 110M parameters. Lastly, for French, we select *FlauBERT-Base-Uncased* [4], pre-trained on text corpus consists of 24 sub-corpora gathered from different sources such as Project Gutenberg [5] and Common Crawl [6]. This model has 12 layers, 12 attention heads and 768 embedding dimension. The total number of parameters is 137M parameters. Based on these pre-trained models, an additional layer is added in each model to fine-tune these models. Each sub-task has different settings for fine-tuning.

Sub-task 1: Binary Classification To fine-tune the models for sub-task 1, a fully-connected layer is added on top of the pooled output (the sequence embedding, i.e., the “[CLS]” token embedding from the pre-trained model). This layer has an output size 2 and the softmax activation function. It outputs the probability of each class (1 and 0). The loss function for fine-tuning is the binary cross-entropy loss. The final prediction of each sentence is made by selecting the class with the maximum probability.

Sub-task 2: Regression Similarly to sub-task 1, we add a fully-connected layer on top of the pooled output for model fine-tuning. This layer has an output size 1. This output is the predicted score for a regression task. The mean squared error loss function is used for fine-tuning this model.

4 Experiments

We conducted experiments on the training and test sets provided by the task organizers. For each sub-task, there are three training sets and three test sets for three different languages. The training set of each language has 5,837 samples while the test set has 14,560 samples. Both training and test sets consist of sentences with different presuppositional

	Fr-C	**0.763**	**0.905**	**0.828**	**0.823**	Fr-R	**3.65**	**1.91**	0.23

Table 2: Results of sub-task 1 and 2

constructions. For sub-task 1, there are 10 constructions, i.e., “andtoo”, “butnot”, “comparatives”, “drather”, “except”, “generally”, “particular”, “prefer”, “type” and “unlike”. For sub-task 2, there are 7 constructions, i.e., “andtoo”, “butnot”, “comparatives”, “ingeneral”, “particular”, “type” and “unlike”. Table 1 shows examples of sentences with different constructions. All the models were fine-tuned by using the Adam optimizer for 3 epochs with the batch size 16 and the learning rate 5e-5. For sub-task 1, the models were evaluated by Precision, Recall, F1 and F1-macro. For sub-task 2, they were evaluated by MSE, RMSE and Spearman Correlation (ρ). It is worth noting that ρ is used to measure the rank correlation between actual labels and predictions. It ranges between -1 to 1 where the higher value means the labels and predictions have a similar rank (or identical when it is 1) and the lower value means they have a dissimilar rank. (or fully opposed when it is -1) For each sub-task, a simple classification model using n-grams as features was used as a baseline.

4.1 Sub-Task 1 Results and Discussion

For this sub-task, we named the fine-tuned DistilBERT-Base-Uncased for classification as **En-C**, the fine-tuned BERT-Base-Italian-XXL-Uncased for classification as **It-C** and the fine-tuned FlauBERT-Base-Uncased for classification as **Fr-C**. Table 2 shows the results of sub-task 1. From this table, It-C and Fr-C performed better than the baseline in every evaluation metric. Meanwhile, En-C outperformed the baselines in terms of Precision, F1 and F1-macro.

We further investigated the performance of our approaches by comparing the results of En-C, It-C and Fr-C on each construction. The results are shown in Figure 1. From this figure, we can see that En-C, It-C and Fr-C performed particularly poorly on “generally” construction. To identify the mistake, we examined the confusion matrices of their performance on “generally” construction as shown in Figure 2. This figure shows that all of them failed in predicting the true positive cases of this construction. To answer why they failed to predict the true positive cases, we further examined the attention weights at the last layer of these

models using *bertviz*[7] library (Vig, 2019). Figure 3 illustrated the attention on the last layer of En-C, It-C and Fr-C given the acceptable sentence (labeled with 1) with "generally" construction as an input. In this figure, the attention is represented with lines connecting between the word being updated (on the left) and the word being attended to (on the right). The thickness of the lines indicates the weight. The thicker it is, the higher the weight will be. Since we use the embedding of "[CLS]" as the pooled output for fine-tuning, we only consider this token's attention. From Figure 3a, the attention weights of "and", "more" and "generally" tokens are relatively low compared to the other tokens. Similarly, the attention weights of "e", "più" "in" and "generale" in It-C and the attention weights of "et", "plus" and "généralement" in Fr-C are also low as shown in Figure 3b and 3c respectively. This suggests that these models ignored these tokens when they were fine-tuned. However, these tokens are important, since they act like keywords indicating the presuppositional "generally". Therefore, ignoring them may result in mistakenly predicting the acceptability labels of this construction.

4.2 Sub-Task 2 Results and Discussion

For sub-task 2, we named the fine-tuned DistilBERT-Base-Uncased for regression as **En-R**, the fine-tuned BERT-Base-Italian-XXL-Uncased for regression as **It-R** and the fine-tuned FlauBERT-Base-Uncased for regression as **Fr-R**. The overall results are shown in Table 2. From this table, our approaches outperformed the baselines in terms

(a) English (b) Italian (c) French

Figure 5: Distributions of the actual acceptability scores and the predicted acceptability scores of our approaches En-R, It-R and Fr-R on each test set (a) English, (b) Italian and (c) French respectively

of MSE and RMSE. Nonetheless, only En-R produced the results with the higher ρ than the baseline while the others failed to compete with their baselines. This suggests that the proposed approaches predicted the acceptability scores close to their actual scores but their ranks are dissimilar. Figure 5 shows the distributions of the actual acceptability scores and the predicted acceptability scores of our approaches, En-R, It-R and Fr-R on each test set, English, Italian and French. From this figure, we can see that all En-R, It-R and Fr-R tended to predict scores with low variances. This is possibly caused by using the mean squared error loss for fine-tuning these models.

As in sub-task 1, we also compared the results of them on each construction as shown in Figure 4. From Figure 4a and 4b, in terms of MSE and RMSE, En-R and It-R performed well on most constructions except "ingerneral" and "particular". Fr-R performed also well on almost every construction except "particular" and "unlike". On the other hand, in terms of ρ, the proposed models failed on most of the constructions as shown in 4c. En-R produced positive ρ on only "comparative" and "unlike". It-R only produced positive ρ on "type" and "unlike". Fr-R produced positive ρ on "butnot", "ingeneral", "particular" and "unlike". Overall, our models produced negative ρ in most of the constructions. This indicates that they failed to predict the acceptability scores with the same tendency as the actual scores. One possible reason is that the added regression layers are not suitable for fine-tuning these models.

5 Conclusion

This work proposes to fine-tune the pre-trained BERT-based models to validate taxonomic relations in different presuppositional constructions. Three different pre-trained BERT-based models are selected and fine-tuned to perform classification and regression on three different languages, English, Italian and French. According to the results, the fine-tuned models using the binary cross-entropy loss for classification are effective compared to the baseline. As for the regression subtask, the fine-tuned models using the mean squared error loss for regression performed less effectively than the baseline when evaluated with Spearman Correlation. This might be the result of using the mean squared error loss for fine-tuning. This leaves room for improvement in fine-tuning the BERT-based models for taxonomic relation regression.

Abstract

Synonyms and antonym practices are the most common practices in our early childhood. It correlated our known words to a better place deep in our intuition. At the beginning of life for a machine, we would like to treat the machine as a baby and build a similar training for it as well to present a qualified performance. In this paper, we present an ensemble model for sentence logistics classification, which outperforms the state-of-art methods. Our approach essentially builds on two models including ERNIE-M and DeBERTaV3. With cross-validation and random seed tuning, we select the top performance models for the last soft ensemble and make them vote for the final answer, achieving the top 6 performance.

1 Introduction

Synonym, antonym and their relations from unstructured text are fundamental problems in information classification field. These problems can be decomposed into three subtasks: word extraction using regrex, relation extraction (Zelenko et al., 2003), (Bunescu and Mooney, 2005), and classifying the logistics between them. However, an end-to-end model, i.e. ERNIE-M model (Ouyang et al., 2020), is proposed to solve the three tasks.

Presupposed Taxonomies - Evaluating Neural-network Semantics (PreTENS) (Zamparelli et al., 2022) is a task to predict the acceptability of simple sentences containing constructions whose two arguments are presupposed to be or not to be in an ordered taxonomic relation. In this paper, we first present a simple approach with the ERNIE-M model to solve the task. Although the ERNIE-M model performs unexpectedly impressive, the model has poor robustness. Hence, the additional pre-trained model is introduced to solve the robustness problem. The latest model DeBERTaV3 (He et al., 2021) has outstanding performance on cross-linguistic tasks, which outperforms BERT and DeBERTa on many tasks. The proposed model consists of two parts: the basic ERNIE-M model and the pre-trained model DeBERTaV3. The DeBERTaV3 model shares the same pre-trained data with ERNIE-M called XNLI (Conneau et al., 2018), which can improve the performance and robustness as well. The DeBERTaV3 model is trained independently, which has significant improvement for English but somehow brought no improvement for other languages. Based on the above conclusion, we employ the DeBERTaV3 model for English-task only.

To better understand the effectiveness of the proposed model, we started a bunch of analyses. The first problem is the data-set limitation. Two additional datasets were imported, i.e., the translated dataset from Google translation which is translated from three languages, and the XNLI dataset. However, larger datasets don't lead to better performance. We compared the performance of the ERNIE-M model on four sets of data: the given data, the given data with translated data, the given data with XNLI augmentation, and the given data with both the translated data and XNLI data. We do the same experiments with the DeBERTaV3 model as well. The results show that the combination of ERNIE-M with all the three datasets and DeBERTaV3 with the given English data perform the best.

2 Related Work

Multilingual model ERNIE-M proposes a new training method that encourages the model to align the representation of multiple languages with monolingual corpora, to overcome the constraint that the parallel corpus size places on the model performance. There are two models in ERNIE-M which are Cross-Attention masked language modeling (CAMLM) and Back-Translation masked language modeling (BTMLM).

Cross-Attention masked language modeling (CAMLM) is to align cross-language semantic representations on parallel corpora. Then, the multilingual representation is enhanced with transferability learned from parallel corpora.

Back-Translation masked language modeling (BTMLM) is trained to generate pseudo-parallel sentences from monolingual sentences. The generated pairs are then used as the input of the model to further align the cross-lingual semantics, thus enhancing the multilingual representation.

DeBERTaV3 presents a new pre-trained language model, which improves the original DeBERTa model by replacing mask language modeling (MLM) with replaced token detection (RTD), a more sample-efficient pre-training task. They all come from an important field, multilingual models.

Since the related paper was published at the end of 2021, there are no similar tasks have been done and published.

3 Our Approach

In this section, we first introduce the methods to solving the multi-language problem and then present our work about improving the performance on uni-language. To extenuate over-fitting for a specific language, our team uses a multi-language ensemble learning strategy that includes a pre-trained language model and a multilingual language model. Based on the approach above, it makes the learned representation generalizable across languages and improves the performance in finding the suitable taxonomic relations in two nominal arguments.

3.1 Multilingual Language Model Training

Our key idea of solving multilingual language tasks is to learn the language invariant feature space shared among multiple languages. We tried multilingual masked language modeling (MMLM), translation language modeling (TLM), and cross-attention masked language modeling (CAMLM) have been tried. However, the scale of the parallel corpus is quite limited, which limits the performance of the model.

However, we found that using the transferability learned from parallel corpora to enhance the model's learning of large-scale monolingual corpora to enhance multilingual semantic representation can achieve a good effect. ERNIE-M does this by making the predictions of tokens depending on tokens in another language, but not on other tokens in this language. Therefore, we choose ERNIE-M as the baseline model for this task and explore on this basis to improve the prediction effect.

In the process of using multilingual language models, we mainly adopt random search to fine-tune the ERNIE-M model and data augmentation methods are used for model training. Cross-lingual natural language inference (XNLI) dataset is used and the English training set is translated to Italian (E2I set). Firstly, the English training set is combined with the French and E2I set. Then, the model is fine-tuned with the combined training set. Finally, the augmented task training set in three languages is adopted for fine-tune process.

3.2 Cross-validation

To improve the robustness of our model, our team apply cross-validation for training. Firstly, by using different random seeds, we divided the training set which included all three languages ten times. Through this process, we obtained 10 folds of data, which contain 15768 training samples and 1751 validation samples in each fold. During the fine-tuning process, we used random search to optimize hyper-parameters like epochs, learning rate, and batch size. By using F1-Score as our evaluation metric, the best model at all the ten-fold of training is saved. Finally, by making predictions on the test set, we save the mean of the probability of all ten best-saved models. This result is our final output of ERNIE-M. Cross-validation process is shown in Figure 1.

3.3 Pre-trained Language Model

To enhance the effect in a single language subtask, we consider using an enhanced mask decoder and a disentangled attention mechanism to improve the effect. DeBERTaV3 meets our needs by using Electra-style pre-training and gradient unwrapping embedding sharing. We have tried to use DeBERTaV3 for training in each single language subtask respectively.

3.4 Ensemble

By using the multilingual language model and pre-trained language model respectively, we have two groups of validation set results for each language. We adopt the mean of the best-saved models from ERNIE-M and DeBERTaV3 after making predictions on the validation set. After comparing the

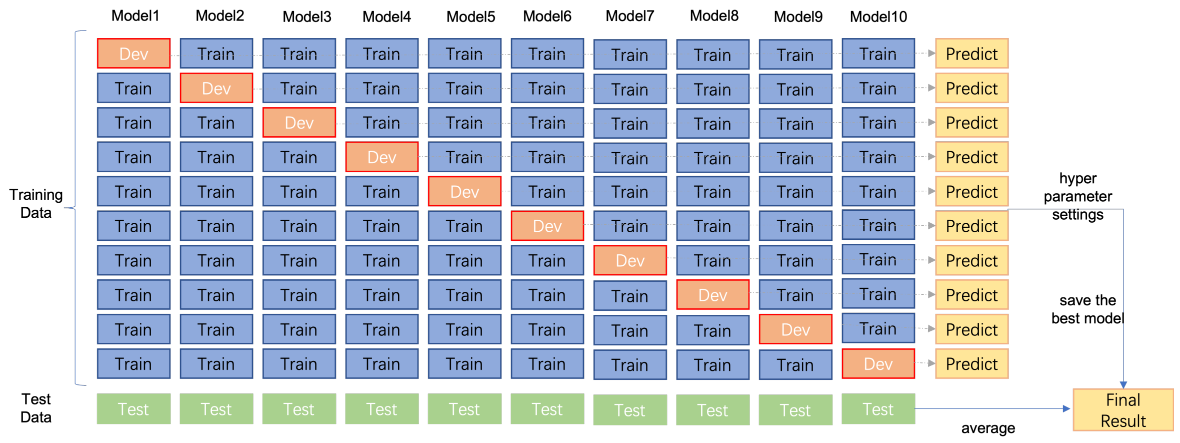

Figure 1: The process of 10-fold cross-validation and ensemble. The training set which includes all three languages is divided randomly 10 times by setting different random seeds. In each division, the training set is divided into 10 parts, of which 9 parts are respectively used as the training set and the remaining 1 part is used as the validation set. And finally, the average of all saved best models predicted on the test set is the final results.

combination result, we finally used different strategies in different languages. For the English subtask, we retain the strategy of merging the two types of models. For French and Italian subtasks, the result from cross-validation of the multilingual language model is used directly.

3.5 Data Augmentations

As the total number of labeled data in each language is only 5840, it's liable to overfit the training data even with pre-trained models. The overfitting phenomenon may be more significant than expected because the data is generated programmatically through manually verified templates. To increase the size of training data, we use the following data augmentation methods: 1) translate English data into French and Italian by using Baidu translate 2) translate English data into French and Italian by using Google translate 3) translate French and Italian data into English by using Google translate. We find that the augmentation can help delay the overfitting occurrence slightly, especially for large models.

4 Experiments

In this section, we first describe the dataset and our data preprocessing steps, and then we present the details of the experimental setup for subtask1.

4.1 Dataset

Our dataset comes from two parts.

The first part is the trial dataset released by organizers, which is composed of English, French and Italian. Each language contains 5838 sentences. Because the trail dataset provided by organizers is only 5838 in each language, to increase the amount of data and make the model better, we use Google translator and Baidu translator to translate the English dataset into French and Italian again. The use of two different translators also increases the diversity of data.

The other part is that we use the public dataset – XNLI. We use XNLI dataset because it is often used in similar cross-language tasks. The XNLI dataset contains a total of 15 languages, and each language contains 7500 pairs of data. We used the English and French datasets in this competition. Because the XNLI dataset itself does not contain Italian datasets, we translated the English dataset into Italian and then used the three languages in ERNIE-M model training.

4.2 Experiment Settings

In this task, we mainly use the ERNIE-M model and DeBERTaV3 model. The ERNIE-M model is composed of 24 layers, 1024 hidden, and 16 heads. In terms of parameter selection, we set a set of parameters, as Table 2 shows.

We set up 10000 times of ERNIE-M model training, in which the specific values of the above parameters are randomly selected according to the table1 at each training. And in each training process, the training method of 10 folds cross-validation is used.

The DeBERTaV3 model is composed of 12 layers and a hidden size of 768. It has only 86M

Parameter	Value1	Value2	Value3	Value4
batch size	8	16	32	
lr decay	0.8	0.85	0.9	0.95
rdrop	1.0	3.0	5.0	7.0
epoch	2	4		
learning rate	2e-5	3e-5	4e-5	5e-5
dropout	0.1	0.2		

Table 1: Parameter Setting. We set different specific values of different parameters according to some previous experience. Because the appropriate value is not fixed in different tasks, we choose to use the random combination of various values of the above parameters for model training, so as to find the most appropriate parameter value and obtain the optimal model result.

Training Methods	Language	Precesion	Recall	F1
ERNIE-M	English	0.8240	0.9547	0.8846
ERNIE-M	French	0.8185	0.9402	0.8751
ERNIE-M	Italian	0.8163	0.9307	0.8698
Ensemble Model	English	0.9266	0.9605	0.9432
Ensemble Model	French	0.8125	0.9489	0.8754
Ensemble Model	Italian	0.8081	0.9467	0.8719

Table 2: Results of different models. We select the best model from a large number of randomly generated parameter training models and compare it with the final best ensemble result. And we can see that the performance of the three languages has been improved.

backbone parameters with a vocabulary containing 128K tokens which introduces 98M parameters in the Embedding layer. And we set batch size to 8, learning rate to 2e-5, and epoch to 3.

4.3 Main Results

The best single model on the development set is the ERNIE-M LARGE. And the model that uses DeBERTaV3 doesn't perform well in French and Italian, so we just use the results on English data. The best ensemble model on the test set is trained on both the XNLI dataset and the trial dataset. The ensemble model obtained English test set F1 scores of 94.325, French test set F1 scores of 86.792, and Italian test set F1 scores of 88.807. The ensemble model achieves the F1 score of 94.325 in English data, the F1 score of 86.792 in French data, and the F1 score of 88.807 in the Italian data. The results are shown in Table 2.

For the comparative analysis of the results of using only ERNIE-M as the baseline model and the ensemble model, we can see that the improvement of the ensemble model in English is relatively obvious, but the improvement in Italian and French is very weak. We think this is due to the following reasons: Firstly, Italian is not included in the original XNLI dataset. In this task, we translate English into Italian. So to a certain extent, the understanding of English by the ERNIE-M model is increased. Secondly, because DeBERTaV3 performs well in English, we only use its results in English, So the results for Italian and French did not get a big boost. This also shows that using the ensemble model can indeed improve the prediction. In the future, we will explore ensemble models that can improve predictions in Italian and French.

5 Conclusion

To solve the problem of judging whether the meaning of a sentence is self-consistent in multilingual language tasks, that is, the problem raised in task 3, we propose an ensemble model using ERNIE-M and DeBERTaV3, and regard this problem as a binary classification problem. Furthermore, to solve the issue of the small dataset, we use various strategies, such as K-ford cross-validation, translating the dataset using different translators, and introducing an external dataset - XNLI, a dataset commonly used in multilingual problems. In future efforts, we plan to further improve our model from these aspects. The first is to enrich the data, especially Italian and French, to help the model learn better. The second is that we could train more models on standard fine-tuning, multi-step fine-tuning, multi-task learning, or adversarial training. Then try to ensemble different models to gain a better performance.

Abstract

This paper presents our strategy to address the SemEval-2022 Task 3 PreTENS: Presupposed Taxonomies Evaluating Neural Network Semantics. The goal of the task is to identify if a sentence is deemed acceptable or not, depending on the taxonomic relationship that holds between a noun pair contained in the sentence. For sub-task 1—binary classification—we propose an effective way to enhance the robustness and the generalizability of language models for better classification on this downstream task. We design a two-stage fine-tuning procedure on the ELECTRA language model using data augmentation techniques. Rigorous experiments are carried out using multi-task learning and data-enriched fine-tuning. Experimental results demonstrate that our proposed model, UU-Tax, is indeed able to generalize well for our downstream task. For sub-task 2—regression—we propose a simple classifier that trains on features obtained from Universal Sentence Encoder (USE). In addition to describing the submitted systems, we discuss other experiments that employ pre-trained language models and data augmentation techniques. For both sub-tasks, we perform error analysis to further understand the behaviour of the proposed models. We achieved a global $\text{F1}_{\text{Binary}}$ score of 91.25% in sub-task 1 and a rho score of 0.221 in sub-task 2.[1]

1 Introduction

Predicting the semantic relationship between words in a sentence is essential for Natural Language Processing (NLP) tasks. Deep neural language models accomplish outstanding results in multiple tasks involving semantics evaluation. The question posed by the shared task Presupposed Taxonomies: Evaluating Neural Network Semantics (PreTENS) is whether neural models can detect the taxonomic relationship between nouns, especially in scenarios where the pattern and/or the set of nouns in the sentence is previously unseen (Zamparelli et al., 2022). Sub-task 1 is a simpler classification task, while sub-task 2 is a more complex regression task. Both sub-tasks involve datasets in English, French and Italian. For each sub-task, teams are permitted three submissions. For each submission, the score is averaged over the three languages. The highest score from the three submissions is reported.

We propose a series of models based on pre-trained language models. We enhance the provided datasets using state-of-the-art data augmentation tools, and further increase the dataset size by employing translations. The aim of both steps is to create slightly modified versions of the sentences, such that the model can learn alternative forms of nouns and patterns.

For the classification task (sub-task 1), we obtained the 3rd place, with an $\text{F1}_{\text{Binary}}$ score of 91.25% averaged over the three languages. For the regression task (sub-task 2), we obtained the 5th place, with a Spearman's correlation coefficient ρ of 0.221 averaged over the three languages. Sub-task 2 is markedly more difficult than sub-task 1 due to sentences that can be ambiguous, such as *I like dogs, but not chihuahuas*; some humans will judge this sentence as acceptable, while some will not. We attempt to solve both tasks by employing data augmentation techniques in order to help the models understand variations in text. Our main contributions are: *(i)* we devise a special development-validation split to emulate the real situation in which the model must face new words and patterns, and *(ii)* we combine various data augmentation tools to allow the models to learn from various versions of the training dataset.

In Section 2 we present the task details and some of the related work that was done previously. In Section 3 we motivate our choice of models. The experiments we performed are in Section 4. Results and conclusions are presented in Sections 5 and 6.

[1]Our implementation of UU-Tax is publicly available at https://github.com/IS5882/UU-TAX.

2 Background

For the present task, we are provided with a list of sentences following a set of *patterns*, all of which have two slots for noun phrases. One such sentence might be: *I don't like beer, a special kind of drink*. The pattern corresponding to this sentence would be: *I don't like* [blank], *a special kind of* [blank]. Sentences are labeled according to whether the taxonomic relation between the two nouns makes sense. In sub-task 1, labels are binary; a sentence such as that shown above has a label of 1, while this sentence would have a label of 0: *I like huskies, and dogs too*. In sub-task 2, labels are continuous, ranging from 1 to 7; these scores are based on a seven-point Likert scale, judged by humans via crowdsourcing. The same dataset is presented in English, Italian and French. For sub-task 1, the training and test sets consist of 5 838 and 14 556 sentences, respectively; for sub-task 2, the training and test sets consist of 524 and 1 009 sentences, respectively.

There are two challenges to this dataset: *(i)* The test dataset is much bigger than the training dataset, and *(ii)* There are unseen patterns and noun pairs in the test set. The combination of these hampers the ability of machine learning (ML) models trained on the training set to generalize well to the test set. Indeed, that is the aim of this task: to evaluate the ability of language models to generalize to new data when it comes to inferring taxonomies.

One way to conceptualize the PreTENS task is to reformulate it as a taxonomy extraction task with pattern classification and distributed word representations. For a given sentence, extract the noun pair and the pattern from the sentence, and then determine if the taxonomic relation between the nouns matches the relations allowed by the pattern. This formulation is motivated by previous work in taxonomy construction that relied on various approaches ranging from pattern-based methods and syntactic features to word embeddings (Huang et al., 2019; Luu et al., 2016; Roller et al., 2018). As promising as this approach sounds for PreTENS, it involves manual labeling of the noun-pair taxonomic relations in the training set, as we are not allowed to use resources such as WordNet (Fellbaum, 1998) or BabelNet (Navigli and Ponzetto, 2012).

A different approach is to tackle PreTENS as a cross-over task between extraction of lexico-semantic relations and commonsense validation. There have been SemEval tasks to extract and identify taxonomic relationships between given terms (SemEval-2016 task 13) (Bordea et al., 2016), and to validate sentences for commonsense (SemEval-2020 task 4, sub-task A) (Wang et al., 2020). The aim of the common-sense validation task is to identify which of two natural language statements with similar wordings makes sense.

In the SemEval-2016 task 13, approaches related to extracting hypernym-hyponym relations to construct a taxonomy involved both pattern-based methods and distributional methods. TAXI relied on extracting Hearst-style lexico-syntactic patterns by first crawling domain-specific corpora based on the terminology of the target domain and later using substring matching to extract candidate hypernym-hyponym relations (Panchenko et al., 2016). Another team designed a semi-supervised model based on the hypothesis that hypernyms may be induced by adding a vector offset to the corresponding hyponym word embedding (Pocostales, 2016).

Participants in the SemEval 2020 commonsense validation task had an advantage over PreTENS participants: they were allowed to integrate taxonomic information from external resources such as ConceptNet (Wang et al., 2020), which eased the process of fine-tuning the language models on the down-stream task. As an example, the CN-HIT-IT.NLP team (Zhang et al., 2020) and ECNU-SenseMaker (Zhao et al., 2020) both used a variant of K-BERT (Liu et al., 2020a) with additional data; the former injects relevant triples from ConceptNet to the language model, while the later also uses ConceptNet's unstructured text to pre-train the language model. Other systems relied on ensemble models consisting of different language models such as RoBERTa and XLNet (Liu, 2020; Altiti et al., 2020).

In Section 3 we outline the architectures chosen to tackle the two sub-tasks of PreTENS. We draw on previous work, as outlined above, and provide novel combinations of datasets and algorithms to improve the performance of out-of-the box language models.

3 System Description

The systems we propose for both PreTENS sub-tasks are based on language models. In sub-task 1 we use the ELECTRA (Efficiently Learning an Encoder that Classifies Token Replacements Accurately) transformer (Clark et al., 2020), while in sub-task 2 we employ USE (Universal Sentence Encoder) (Yang et al., 2020).

3.1 Sub-task 1: Classification

In the first sub-task—binary classification—we were required to assign an acceptability label for each sentence in the three languages English, French and Italian. Of the 20 394 sentences that were provided for sub-task 1, only 5 838 sentences (28.61%) were available for training. This split causes the model to be likely to encounter unknown data formats at testing time. This is a pivotal challenge in PreTENS, as the robustness and generalization of language models is an open challenge and cannot be guaranteed (Tu et al., 2020; Ramesh Kashyap et al., 2021). In our experiments we found that every language model we used (BERT, RoBERTa, XLNet, and ELECTRA) failed to generalize well to unseen datasets, even though all of them are pre-trained on large amounts of data. To address this challenge, we built our models based on data augmentation.

While designing our model, we split the provided training data into a development set (30%) and a validation set (70%), to emulate the train-test split sizes. We deliberately leave several patterns out of the development set, including, for example: *I like* [blank], *and more specifically* [blank]. We choose these so-called *complex patterns* because, during exploratory experiments, we found that pre-trained models had trouble with them. For example, out of the 820 instances of the aforementioned pattern in the training dataset, 750 instances were misclassified by one of the early instances of our model; this includes sentences where the noun pair was included in other sentences in the training data. We thus remove complex patterns from the training data, to simulate a situation in which new unseen and difficult patterns are found in the test set.

Transformer language models like BERT (Devlin et al., 2019) are pre-trained on two tasks: Masked Language Modelling (MLM) and Next Sentence Prediction (NSP). However, in subsequent models such as RoBERTa, training on NSP was proven to be unnecessary; these models are thus pre-trained solely on MLM. ELECTRA further enhanced MLM performance while utilizing notably less computing resources for the pre-training stage. The pre-training task in ELECTRA is built on discovering replaced tokens in the input sequence; to achieve this, ELECTRA deploys two transformer models: a generator and a discriminator, where the generator is trained to substitute input tokens with credible alternatives and a discriminator to predict the presence or absence of substitution. This setting is similar to Generative Adversarial Networks (GANs) (Goodfellow et al., 2014), with a key difference that the generator does not attempt to trick the discriminator, making ELECTRA non-adversarial. In ELECTRA, the generator parameters are only adjusted during the pre-training phase. Fine tuning on downstream tasks only modifies the discriminator parameters (Clark et al., 2020).

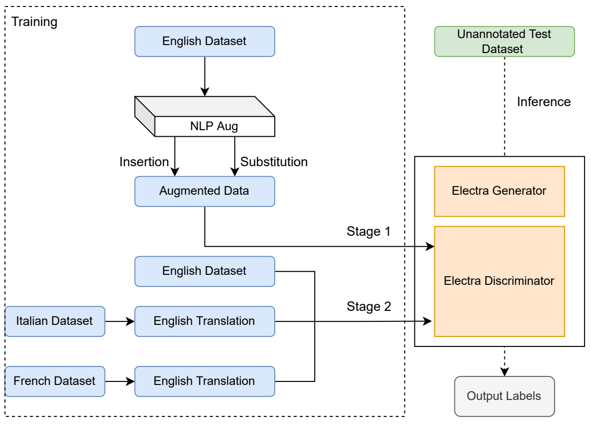

Figure 1: Sub-task 1: The English version of the proposed two-stage fine-tuning model (UU-Tax). In the French version, the Italian and English data are translated to French, and the NLPAug tool is employed on the provided French training set. Likewise in the Italian version.

Multi-stage fine-tuning has proven its effectiveness on the robustness and generalization of models (Kocijan et al., 2019; Li and Rudzicz, 2021). We perform a 2-stage fine-tuning; Figure 1 portrays our model work-flow. In the first stage, we use the NLPAug tool (Ma, 2019) to generate new sentences by making modifications to existing sentences based on contextualized word embeddings. There are several actions for the NLPAug tool; we utilize the 'Insertion' and 'Substitution' operations. The 'Insertion' operation picks a random position in the sentence, and then inserts at that position the word that best fits the local context. Meanwhile, the 'Substitution' operation replaces a word in a given sentence by the most appropriate alternative for that word. In both operations, the word choice is given by contextualized word embeddings, as will be explained in Section 4.1. To avoid drifting away from the original sentence, in both operations we limit the number of insertions and substitutions to two. Because 'Substitution' in NLPAug might turn an incorrect sentence into a correct one, we only carry out 'Substitution' on sentences labeled 1. An example of the output of the NLPAug tool is shown in Figure 4 in Appendix A.

The second stage of fine-tuning also involves data augmentation, using translation. For each language l, we translate the datasets of the other two languages into l. For example, as seen in Figure 1, when working on the English model, we translate the Italian and French datasets to English, and perform the second fine-tuning stage on the translated data along with the original data. We use the Google Translate API for all translations [2].

3.2 Sub-task 2: Regression

In sub-task 2—regression—we are required to determine the level of acceptability of sentences on a seven-point Likert scale. Our initial attempt in sub-task 2 resembles the efforts made in the first sub-task by relying on pre-trained language models. However, our first submission, which relies on fine-tuning multi-lingual BERT (Devlin et al., 2019) with translation as data augmentation, did not perform well; more elaboration on this in Section 5.2. As a result, we opt for a simpler yet more effective model using Universal Sentence Encoder (USE) (Yang et al., 2020) followed by a regressor. USE is based on two encoder models and deep averaging networks; both are equipped to generate a 512-dimension sentence embedding from a given textual input, where embeddings for words and bigrams are averaged together and then passed as input to a deep neural network that processes and outputs the sentence embeddings.

4 Experimental Set-up

4.1 Sub-task 1: Classification

We implement our submitted models using SimpleTransformers[3]. All models are trained for 4 epochs with a batch size of 8; these values were determined by validation, as we explain below. The model is optimized using AdamW (Loshchilov and Hutter, 2019) and a linear decay learning rate schedule. The learning rate is a key aspect of the performance of a trained model. A large learning rate results in quick model convergence; however, if the learning rate is too large, it will lead to drastic updates that will trigger divergent behaviour, while training a model with a too-small learning rate might lead to an under-fitted model that gets stuck in local minima (Bengio, 2012). In our two-stage model, the first stage has a lower learning rate of 3×10^{-5} as opposed to the 4×10^{-5} assigned in the second stage, which contains the PreTENS training data; this is because we want the model to learn more from the real training data than from the NLPAug-edited data. A summary of the model hyper-parameters is given in Table 1. All the hyper-parameters are tuned based on the F1 score on the validation set. The same hyper-parameters are utilized for all three languages—English, French and Italian.

For data augmentation with NLPAug, $\text{BERT}_{\text{base}}$ is employed to obtain the contextual word embeddings for both 'Insertion' and 'Substitution' operations.

Hyper-parameter	**Value**
Epochs	4
Batch Size	8
Stage 1 Learning Rate	3×10^{-5}
Stage 2 Learning Rate	4×10^{-5}
Optimizer	AdamW

Table 1: Sub-task 1: Hyper-parameters values for training the ELECTRA model. The number of epochs and the batch size were determined by validation.

4.2 Sub-task 2: Regression

For the three languages English, French and Italian we deploy multi-lingual $\text{USE}_{\text{Large}}$ as it yields better performance than mono-lingual USE for the three languages. USE is employed through its TensorFlow hub module[4]. We experiment with four different regressors: Linear Regression (LR) (Montgomery et al., 2021), K-Nearest Neighbors Regressor (KNR) (Kramer, 2013), Decision Tree (DT) (Myles et al., 2004), and Support Vector Regressor (SVR) (Awad and Khanna, 2015). We use the Scikit-Learn (Pedregosa et al., 2011) library for the implementation of the regressors. All regressors are utilized with their default parameters except for SVR epsilon ε . To define a higher margin of tolerance where no penalty is given to errors we set ε to 0.2 rather than the default value of 0.1.

[2]Only 15% of the translated sentences using Google Translate API were duplicates of the original sentence.

4.3 Evaluation measures

Sub-task 1 is evaluated using the Binary-averaged F1 score ($F1_{\text{Binary}}$) for each language, while the global rank score is calculated as the average of the $F1_{\text{Binary}}$ for all three languages. Sub-task 2 is evaluated using Spearman's rank correlation coefficient (ρ) for each language, with the global rank given by the average of the coefficients for all languages.

5 Results and Evaluation

In this section, we analyze the performance of our submitted models in both sub-tasks. We further discuss other notable experiments that were carried out.

5.1 Sub-task 1: Classification

Language	**Results**		
	Recall	**Precision**	**$F1_{\text{Binary}}$**
English	95.26 %	90.54 %	92.84 %
French	93.14 %	85.83 %	89.34 %
Italian	90.47 %	92.69 %	91.57 %
Average			91.25%

Table 2: Sub-task 1: UU-Tax submission results using a two-stage fine-tuned ELECTRA model.

Results of the submitted models for English, French, and Italian are shown in Table 2. Out of 21 teams, we were officially ranked 3rd in sub-task 1, achieving a global score of 91.25%, only 1.06, and 2.92 percentage points short of the 2nd and 1st places, respectively. In the next few sections, we explain how our experimentation led us to the model we chose: the two-stage fine-tuning using ELECTRA with data augmentation (UU-Tax).

5.1.1 Experiments

Baseline. The PreTENS organizers proposed a baseline algorithm that trains an SVM classifier with features generated by TF-IDF with n-grams ($n = 3$). Results of the baseline model are reported in Table 3.

Multi-task fine-tuning. We experimented with several models on the English dataset. We tried a multi-task approach that involves further fine-tuning on related data-rich supervised tasks. In our case, it was the 'common sense validation' task, as it is highly correlated to PreTENS as previously mentioned in Section 2. We used the dataset from SemEval-2020 Common Sense Validation sub-task A (Wang et al., 2020) and modified the sentence label to 1 if it is a valid sentence and 0 otherwise. We then fine-tuned our ELECTRA model in the first stage using this data; the second stage of fine-tuning was carried out using the augmented data from NLPAug and the provided training data. Multi-task fine-tuning has proven its effectiveness across a variety of tasks (Mahabadi et al., 2021). This model achieved an $F1_{\text{Binary}}$ of 89.09%, which demonstrates the effect of information sharing between the different tasks, particularly in cases when the downstream task is of a limited size. Nevertheless, multi-task fine-tuning suffers from several shortcomings including catastrophic forgetting, over-fitting in low-resource tasks and under-fitting in high-resource tasks (Mahabadi et al., 2021). For this reason, we did not move forward with this approach.

Data-enriched fine-tuning. As an alternative, we developed a data-enriched fine-tuning model that employed a pre-trained BERT model with an additional Bidirectional Long Short Term Memory (Bi-LSTM) layer on top. In addition to the input sentence, we concatenated the two nominal arguments to the given input. To extract the two nouns from the sentences, we leveraged the fact that nouns in this dataset tend to have very low document frequencies (DF), and classified any word with DF less than 5% as a noun. The final prompt of the input was as follows: $[\text{CLS}]Sentence[\text{SEP}]Noun\,1[\text{SEP}]Noun\,2[\text{SEP}]$ Similar to the aforementioned models, we also input to the model the augmented data generated from NLPAug. This model was implemented with PyTorch using the Hugging Face[5] Transformers library (Wolf et al., 2019). Figure 2 depicts the data-enriched fine-tuning model. The model's performance resembles that of the multi-task fine-tuning model by achieving an $F1_{\text{Binary}}$ of 89.04%.

As shown in Table 3, our submitted two-stage fine-tuning ELECTRA model (UU-Tax) achieved the highest results amongst all models, by a margin of 3.63% and 4.62% between both multi-task learning model and data-enriched fine-tuning model, respectively. We have almost 20% improvement compared to the baseline.

Model	**Results**		
	Recall	**Precision**	**F1$_{\text{Binary}}$**
Baseline (TF-IDF + SVR)	85.64 %	64.19 %	73.38 %
Multi-task fine-tuning	**95.82** %	83.45 %	89.21 %
Data-enriched fine-tuning (BERT + Bi-LSTM)	86.70 %	89.79 %	88.22 %
UU-Tax (two-stage ELECTRA)	95.26 %	**90.54 %**	**92.84 %**

Table 3: Sub-task 1: Comparison of the different experiments carried out on the English Language.

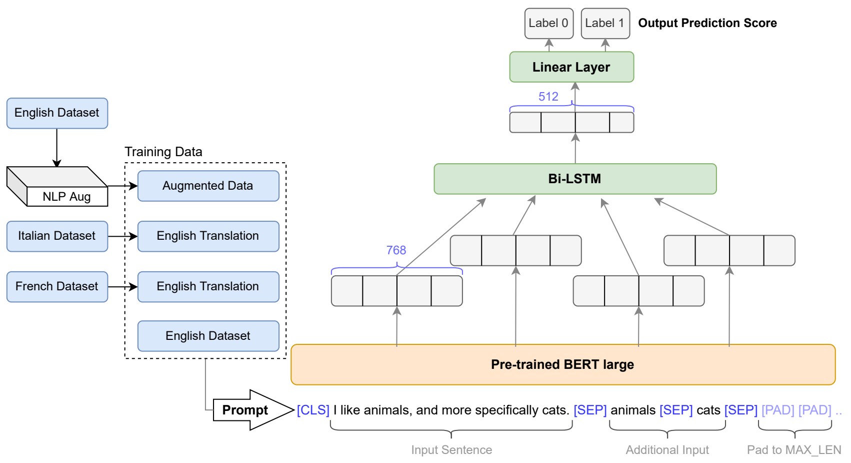

Figure 2: Sub-task 1: data-enriched fine-tuning model that employs an Bi-LSTM network on the top of pre-trained BERT. This model was used during the experimentation phase.

5.1.2 Ablation Study and Error Analysis

We conducted ablation experiments to evaluate the effect of data augmentation and our proposed two-stage fine-tuned ELECTRA model. The results of the analysis are presented in Table 4. We limit the ablation study and error analysis to the English dataset, as similar trends were observed in the French and Italian datasets [6].

Data augmentation effect. The need for data augmentation to generalize the model highly affects the performance of the pre-trained model. We perform two ablation analyses. In the first setting *(Ablation #1)*, we removed the translated dataset from the second stage, and our model was fine-tuned on data obtained from the NLPAug tool in the first stage and on the original training dataset in the second stage. The precision massively dropped by 11.42%. Similar behavior is observed in the second setting *(Ablation #2)*, when the NLPAug data is eliminated from our two-stage training, and the first stage is trained on the translated data instead, while in the second stage we fine-tuned using the original training data. This highlights the importance of our proposed dual augmentation using both NLPAug and translation to capture a wider range of perturbations to the original dataset.

Single-stage models' performance. To verify our two-stage fine-tuning approach, we evaluated it against a single-stage fine-tuning. This experiment was performed in two different settings; in the first *(Single-stage #1)* we trained on the originally provided data only, while in the second *(Single-stage #2)* setting we trained on the same data that was used in UU-Tax, which is obtained from NLPAug, translation, and the original training set. In both settings, we notice a drop in the F1 when comparing against UU-Tax. Nonetheless, we can observe that amongst the three experiments (UU-Tax, *Single-stage #1* and *Single-stage #2*) the highest recall of 96.26% is achieved in the (*Single stage #2*) along with the lowest precision of 71.15%. Our interpretation of this finding is that in the *(Single stage #2*) experiment, the model over-predicted positives, causing the model to achieve a high recall and a relatively low precision.

[5]https://huggingface.co/

[6]Results presented in Tables 3 and 4 may slightly vary due to fine-tuning instability of pre-trained language models (Mosbach et al., 2021).

Model Name	LM	Stage 1			Stage 2			Results		
		NLPAug	Trans	OT	NLPAug	Trans	OT	R	P	F1
Ablation #1	ELECTRA	✓					✓	95.30 %	78.73 %	86.22 %
Ablation #2	ELECTRA		✓				✓	95.59 %	95.59 %	86.58 %
Single Stage #1	ELECTRA			✓	-	-	-	90.20 %	79.41 %	84.47 %
Single Stage #2	ELECTRA	✓	✓	✓	-	-	-	**96.26 %**	71.16 %	81.83 %
Two-Stage #1	BERT	✓				✓	✓	92.36 %	68.97 %	78.97 %
Two-Stage #2	RoBERTa	✓				✓	✓	93.93 %	78.24 %	85.37 %
UU-Tax	ELECTRA	✓				✓	✓	95.26 %	**90.54 %**	**92.84 %**

Table 4: Sub-task 1: Results of various classification models trained during experimentation and ablation on the sub-task 1 dataset, using different combinations of input data obtained from NLPAug, translation (Trans) and the original training set provided (OT). Additional variations are single-stage versus two-stage models, and alternative pre-trained language models (LM). Recall (R), precision (P), and $F1_{\text{Binary}}$ (F1) are used as evaluation metrics. ✓ indicates which data is utilized in each fine-tuning stage, while - indicates that stage 2 is not applicable.

We attribute this behavior to two causes. First, the unbalanced ratio that NLPAug 'Substitution' operation caused as previously explained in Section 3.1[7]. Second, in UU-Tax a higher learning rate is deployed in the second fine-tuning stage, making the model focus more on the original dataset than on the NLPAug data.

Experimenting with different language models. Additionally, we experimented with different pre-trained language models, namely BERT *(Two-stage #1)* and RoBERTa *(Two-stage #2)*. As seen in Table 4, ELECTRA outperforms both RoBERTa and BERT by 7.47% and 13.92%, respectively, of the F1 score, which illustrates the strong generalizability of ELECTRA. Our findings agree with (Anaby-Tavor et al., 2020; Kumar et al., 2020), who demonstrate that generative models are suitable for data augmentation.

Error Analysis. By manually inspecting the wrong predictions generated by our proposed top three performing models (UU-Tax, multi-task fine-tuning, and data-enriched fine-tuning) we can observe that UU-Tax achieves the smallest percentage of incorrect predictions on both seen and unseen patterns, as observed in Figure 3. This shows that the proposed two-stage fine-tuning (UU-Tax) can learn better and generalize better than multi-task fine-tuning and data-enriched fine-tuning. In addition, we also noticed that proper names were the cause of many misclassifications. One possible mitigation to overcome this error is to create an improved model to envision proper names appearing in a sentence as hyponyms of the preceding or the subsequent noun appearing in the same sentence.

[7]The NLPAug 'Substitution' dataset is composed of 5568 instances all labeled '1', making 67.98% of the NLPAug data to have a '1' label.

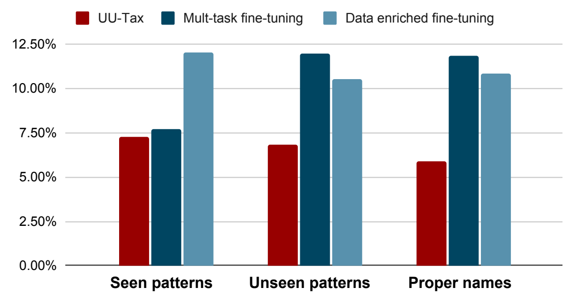

Figure 3: Sub-task 1: Percentage of incorrect predictions for all patterns in the test dataset, for the top three preforming models: UU-Tax, Multi-task fine-tuning and data-enriched fine-tuning.

5.2 Sub-task 2: Regression

Language	Model	Rho (ρ)
English	USE + SVR	0.478
French	USE + DT	-0.059
Italian	USE + LR	0.246
Average		0.221%

Table 5: Sub-task 2: UU-Tax submission results that achieved the highest score averaged over the three languages, out of the three submissions. ρ is Spearman's rank correlation coefficient.

As explained in Section 3.2, USE was employed for all three languages to obtain pre-trained word embeddings; we used SVR, DT, and LR regressors for English, French and Italian, respectively. We came in 5th in sub-task 2 out of 17 teams by achiev-

Language	Model						
	Baseline	BERT	BERT + Trans	USE + LR	USE + KNR	USE + DT	USE + SVR
English	0.247	-0.068	-0.027	-0.175	0.235	0.118	**0.478***
French	**0.230**	-0.075	-0.027	0.207	0.103	-0.059*	0.030
Italian	**0.370**	0.047	0.150	0.246*	0.081	0.171	0.137

Table 6: Sub-task 2: Rho (ρ) scores of different regression models that we experimented. Models that were part of the global score are marked with an * . Baseline is TF-IDF + SVR; BERT is multilingual.

ing a global average of 0.221. It is worth noting that we had a better performing French-language model in the first submission than in our top submission. The experiments we performed for sub-task 2 are discussed in Section 5.2.1. The ρ coefficients for the three languages in our best submission are reported in Table 5.

5.2.1 Experiments

Table 6 shows the results of our submitted models along with other experiments that we carried out using different regressors as explained in Section 4.2. In addition, we also experimented using multi-lingual BERT in two different settings; once with only fine-tuning on the provided dataset of the three languages and in the other setting, we augmented the provided training data with translation as in the translation process in sub-task 1.

In English our submitted USE + SVR model achieved the highest ρ score of 0.478 amongst all other models, surpassing the baseline by 94%. Although in the French version our final submitted model was, unfortunately, the model with the lowest score, we were able to achieve the highest score of 0.207 using LR, less than the baseline approach by $\Delta\rho = 0.023$. While in Italian, our submitted model was our highest rho score achieved of 0.246 which is $\Delta\rho = 0.123$ lower than the baseline. We infer from the fact that our model performed badly on French and Italian that USE is better optimized for English language.

5.2.2 Ablation Study and Error Analysis

Pre-trained language models did not perform well. We attribute this to the very limited training size of sub-task 2: only four different patterns made up the training data. The deployment of data augmentation—translation—to multi-lingual BERT was able to improve the performance on all three languages by more than 50%, which confirms our hypothesis that the limited pattern in the provided training set highly affected the performance of the pre-trained language model. This is supported by a similar trend when experimenting with different language models. Since this is a regression task, we were not able to use the NLPAug tool as the assigned score might be inaccurate after the substitution and insertion operations.

There is no consistently best performing classical ML algorithm: unlike for Italian and French, LR did not perform well on the English dataset, and SVR outperformed all other regressors on the English version. Interestingly, we see a consistent pattern across the French and Italian versions, showing that the LR regressor works best; we attribute this to the lexical and grammatical similarity between the French and Italian languages.

6 Conclusion

The limited size of the training dataset as compared to the test set made it impossible to train neural networks directly on the task. As a result, we took advantage of pre-trained language models. Nonetheless, the robustness of language models is highly affected by the size and variance of the downstream task data available for fine-tuning, which causes the language model to fail to generalize. Hereby, we relied upon data augmentation techniques using a two-stage fine-tuning process on ELECTRA. The first fine-tuning stage was carried out using an augmented version of the dataset, while in the second stage we used the translated versions of the provided PreTENS training data in addition to the original data. We ranked 3rd out of 21 teams in sub-task 1. For the second sub-task we proposed a simple model by training an SVR classifier with sentence embeddings obtained from USE; we ranked 5th out of 17 teams.

As an extension for future work, both sub-tasks could greatly benefit from adversarial training, which has proven its success across various NLP tasks in improving the model robustness and generalization (Liu et al., 2020b; Yoo and Qi, 2021).

Abstract

This paper describes our system submitted for SemEval Task 3: Presupposed Taxonomies: Evaluating Neural Network Semantics (Zamparelli et al., 2022). We participated in both the binary classification and the regression subtask. Target sentences are classified according to their taxonomical relation in subtask 1 and according to their acceptability judgment in subtask 2. Our approach in both subtasks is based on a neural network BERT model. We used separate models for the three languages covered by the task, English, French, and Italian. For the second subtask, we used median averaging to construct an ensemble model. We ranked 15th out of 21 groups for subtask 1 (F1-score: 77.38%) and 11th out of 17 groups for subtask 2 (RHO: 0.078).

1 Introduction

The recognition of lexical relationships between words and the corresponding generalization has attracted increasing attention in computational linguistics. Today, there already exist resources covering manually marked semantic relationships, e.g., taxonomic relations, such as the lexical database WordNet (Miller, 1992) or the multilingual dictionary and semantic network BabelNet (Navigli and Ponzetto, 2010).

Luu et al. (2016) define taxonomic relations between two terms as an is–a relation. In such a relation there is a hypernym, i.e., a supertype, and a hyponym, i.e., a subtype. Both the supertype and subtype are sets covering, in our task, certain semantic categories. In a relation such as *animal–dog*, the *animal* is the superordinate category and the *dog* is the subordinate term. Furthermore, those specific sets are included in a relation forming a special hierarchy (Kay, 1971). As stated by Nguyen et al. (2017), in such an is–a relation the supertype necessarily implies the subtype, but not vice versa.

SemEval 2022 Task 3 is a taxonomy detection and prediction task consisting of two subtasks: a binary classification and a regression task, both covering the languages English, French, and Italian.

We propose an approach based on the transformer-based machine learning model BERT. Since BERT is a bidirectional model producing state-of-the-art results (Devlin et al., 2019), we used this pre-trained model for our analysis. For the three different languages, the corresponding BERT models were used (Devlin et al., 2019; Polignano et al., 2019; Martin et al., 2020).[1]

2 Task Description

In the present shared task (Zamparelli et al., 2022), the taxonomic sentence structures in the given files are composed of different artificially generated constructions enforcing presuppositions.

Table 1 shows example sentences provided in the English test set. According to the task description page, the French and Italian datasets are translated versions of the English dataset that were slightly adapted.

The argument nouns in the given files come from 30 semantic categories including, among others, dogs, birds, and mammals. The given word sets already show broader and narrower categories (*mammals* vs. *dogs/birds*). Nevertheless, as shown in the examples in table 1, not all pairs of nouns reflect such a superordinate–subordinate relation (*apple* vs. *cauliflower*) as described by Nguyen et al. (2017). Therefore, the taxonomies do not only represent a direct is–a relation such that one given nominal is the subcategory and the other one is the supercategory. Thus, it has to be considered that human language consists of many argument and sentence structures that restrict such relations. That means the sentence structures also cover comparisons where both nouns come from

[1]The source code of our model is available at `https://github.com/cicl-iscl/SemEval3`.

Construction	Example
`andtoo`	I like teaspoons, and mugs too.
`butnot`	I like cats, but not frogs
`comparatives`	I like apples as much as cauliflower.
`drather`	I would rather have veal than salmon.
`except`	I like seafood, with the only exception of salmon.
`generally`	I like peaches, and more generally fruits.
`particular`	I like jewelry, and in particular necklaces.
`prefer`	I do not like tiramisu, I prefer broccoli.
`type`	I like parrots, not other types of birds.
`unlike`	Unlike glass, PVC is often mentioned in this text.

Table 1: Example sentences from subtask 1 with a binary label 1 (i.e., acceptable).

the same broader category. This has also been covered in the work by Clarke (2012), who refers to taxonomies as a framework represented in a hierarchy where lexical counterparts or synonyms are considered. Therefore, the given shared task comes with a challenge different from only recognizing the taxonomic relation—furthermore, the embedding construction allowing or disallowing the given relation had to be checked.

The participants were provided with two datasets to work with the individual subtasks. The training set for subtask 1 was composed of 5,837 sentences for each language with binary labels representing 1 as an acceptable sentence and 0 as an unacceptable sentence. This subtask covers the binary prediciton of acceptability labels of each sentence given in the test set with 14,560 samples. Subtask 2 consists of the prediction of an average score on a seven-point Likert scale for 1,009 sentences in the test set. The original scores in the training set were annotated by humans.

Figure 1 shows the scores assigned to the sentences presented in the training set in subtask 2. This figure only shows the scores averaged over all annotators since per-annotator information is not available.

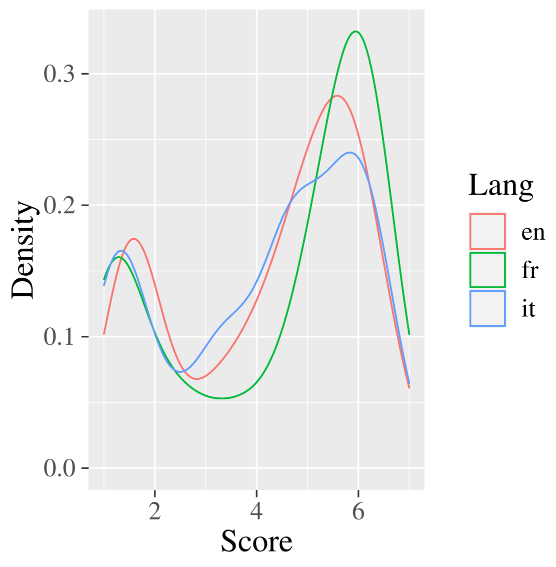

Figure 1: Distribution of the scores given to the sentences from the training set of subtask 2 by annotators.

3 System Overview

We used pre-trained BERT (Devlin et al., 2019) networks for subtasks 1 and 2. Separate models were used for each of the languages, specifically, the AlBERTo model (Polignano et al., 2019) was used for Italian, BERT base uncased was used for English, and the monolingual CamemBERT (Martin et al., 2020) model was used for French. The BERT models are powerful and highly versatile language models that possess the benefit of having learned good representations of the language they were trained on. This gives them a decisive edge over using models that are trained exclusively with the data provided for training as these pre-trained models will, for example, have encountered and learned representations for words that are not in the training set but are in the test set, whereas a model trained only on the training set will have trouble dealing with these unfamiliar words. As such they offer the opportunity for better generalization.

The bigger challenge of these tasks was not to produce models that perform well on the limited training data but to produce models that generalize well and do not merely overfit on the provided data. To this end, standard deep learning regularization techniques such as weight decay, dropout, and model averaging were used; nonetheless, the models performed much worse on the test data than on the validation data. Actually producing models that perform better at generalizing would likely have required data augmentation and/or alternative training routines.

The models were not shared between subtasks 1 and 2, meaning that while the same pre-trained models were used for subtasks 1 and 2, the model used for subtask 2 was not fine-tuned for subtask 1 and vice versa.

3.1 Subtask 1

For subtask 1, the sentences were tokenized using the tokenizers of the pre-trained BERT models. The BERT model was extended with one fully connected hidden layer and an output layer. The model was trained to perform the classification task using cross-entropy loss, backpropagated using the Adamw optimizer (Loshchilov and Hutter, 2017), which combines the Adam optimizer (Kingma and Ba, 2017) with weight decay regularization. Dropout was used for further regularization. Gradient clipping by-norm was applied to solve the exploding gradient problem. Thirty percent of the data was used as a validation set, learning was terminated through early stopping with the loss function as the stopping criterion.

3.2 Subtask 2

The model for subtask 2 is similar to the model for task 1, again extending the BERT models with a hidden layer and one output layer producing a single number for the regression task. The output and targets were normalized to be between zero and one. The inverse transformation was then applied to the model output to get the final output on the original scale. The model was trained on seventy percent of the training data using mean squared error as the loss function. Dropout was used and weight decay was applied through the AdamW optimizer. The training was terminated using early stopping with the remaining thirty percent of the training data used for validation. For this task, we trained ten models per language, each with its own training split of the data. The final prediction for the test set was the median prediction of these models. We chose to use the median and not the mean as it is less affected by outlier predictions.

3.3 Hyperparameters

Hyperparameters were determined using grid search over a limited selection of plausible candidate values, including learning rate (1×10^{-5} for all models), the number of fully connected layers, neurons per layer, and in the case of subtask 2 a multiclass approach was also tested. For subtask 1 choosing bigger models, in the end, 2 hidden layers with 512 neurons each were used, which led to improvements on the validation set but may have caused overfitting that negatively impacted performance on the test set. For subtask 2, bigger models did not perform better than small ones, and as a result, the final models contained only a single hidden layer with 16 neurons. The complete hyperparameters are listed in appendices A and C.

	total	**It**	**Fr**	**En**
Precision	0.75	0.73	0.77	0.74
Recall	0.80	0.73	0.89	0.80
F1	0.78	0.73	0.83	0.77

Table 2: Results for subtask 1. All scores are micro-averaged over different constructions. The total scores are also micro-averaged over the languages.

4 Results

Unless stated otherwise, we analyzed, evaluated, and visualized the results in R (R Core Team, 2020) with the help of the packages caret (Kuhn, 2021), dplyr (Wickham et al., 2021), ggplot2 (Wickham, 2016), plyr (Wickham, 2011), readr (Wickham and Hester, 2020), stringr (Wickham, 2019), tikzDevice (Sharpsteen and Bracken, 2020), tm (Feinerer et al., 2008), and xtable (Dahl et al., 2019).

4.1 Subtask 1

The test data contains 14,560 sentences per language. Table 2 shows the results of the evaluation for each language. Out of the 18 participating teams (and three additional teams who only submitted results for the English subset), the KaMiKla models ranked 15th in the overall competition and the Italian part and 12th and 16th in the French and English portion, respectively.

The highest overall score in the competition was 0.94, an F1 measure of 0.93 for Italian and French, and 0.97 for English. The trivial baseline that used n-grams as features reached a global score of 0.73. The F1 score for the Italian model is 0.68, 0.76 for French, and 0.73 for English.

After the evaluation phase ended, the test sets were published containing an additional label that denoted the syntactic construction used in the respective sentence. Table 1 illustrates examples of what the labels mean. Further analysis revealed that the type of construction had an enormous effect on the performance of the KaMiKla models. Figure 2 gives an overview of this. For the detailed evaluation metrics for each language by construction, see Appendix B.

The KaMiKla models performed with an F1 score in a range between 0.86 and 0.97 across all languages for `butnot`, `comparatives`, `drather`, `prefer`, and `andtoo` constructions which made up approximately 42.3% of the test dataset. These scores are about what we expected from performance on the validation set.

`except`, `particular`, and `unlike` constructions show stark differences in performance between languages. In all three cases, the French model achieves much better results than the English and Italian ones, which will be discussed in more detail later. Furthermore, the models performed poorly on `type` constructions across all languages, only overshadowed by scores close to 0 for generalizations.

4.1.1 except

Sentences containing `except` constructions made up approximately 12.9% of the test data. Especially the Italian model seemed to have trouble classifying exceptions correctly. For example, it gives the sentence *Adoro le verdure, eccetto le carote.*[2] the label "0" even though it is a semantically flawless Italian sentence. The problem seems to be the recall rather than precision. While a score of 0.82 is not much lower than the precision of the previously mentioned constructions, the recall score of 0.31 shows that the model could not accurately predict the taxonomic relations in a sentence containing an exception. This observation extends, if less prominently, to English and French.

4.1.2 particular

`particular` sentences, which make up 13% of the test data, show a striking difference in performance between languages. The precision ranges from 0.39 for the English model to 0.92 for the French model.

4.1.3 unlike

Sentences containing `unlike` constructions (9% of the test data) were still classified correctly relatively often by the French model, despite a recall score of 0.63. The Italian and English models performed much worse due to low recall. Interestingly, the English model has an almost-perfect precision of 0.99, while the Italian model only reached 0.49, which shows the difference between the models again.

[2] *I love vegetables, except for carrots.*

	total	It	Fr	En
MSE	3.72	2.88	5.29	2.97
RMSE	1.93	1.70	2.30	1.72
RHO	0.19	0.19	-0.01	0.06

Table 3: Results for subtask 2. All scores are micro-averaged over different constructions. The total scores are also micro-averaged over the languages.

4.1.4 type

About 13% of the test sentences contained `type` constructions like *I like fruits, an interesting type of lemon.* There is not much to say about them other than that the models' performance on them was terrible. F1 measures range from 0.06 to 0.11 with very low recall (0.25 to 0.47) and even worse precision (close to 0).

4.1.5 generally

Possibly the most surprising result is the utter confidence with which the models misclassified generalizations. Across languages, all evaluation metrics are below 0.05 for sentences labeled `generally`.

4.2 Subtask 2

The top-performing models reached a Spearman correlation of 0.81, 0.84, and 0.76 in Italian, French, and English, respectively, yielding an overall score of 0.80. The KaMiKla models performed much worse and ranked in 11th place with a global rank of 0.08. Table 3 shows an overview of the evaluation of the second subtask. Surprisingly, the n-gram-based regression model serving as a baseline ranked in 4th place with correlations of 0.34, 0.32, 0.27 in Italian, French, and English, respectively, outperforming many submissions, including the one present in this paper.

Similar to the first subtask, we analyzed these results grouped by the used construction. Appendix D contains the detailed analysis. The metrics considered are the mean squared error (MSE), the root mean squared error (RMSE), and Spearman correlation (RHO). The constructions of the second subtask are a subset of the ones used for the first one, with the `generally` label changed to `ingeneral`. Figure 3 visualizes the root mean squared errors of the second subtask grouped by construction.

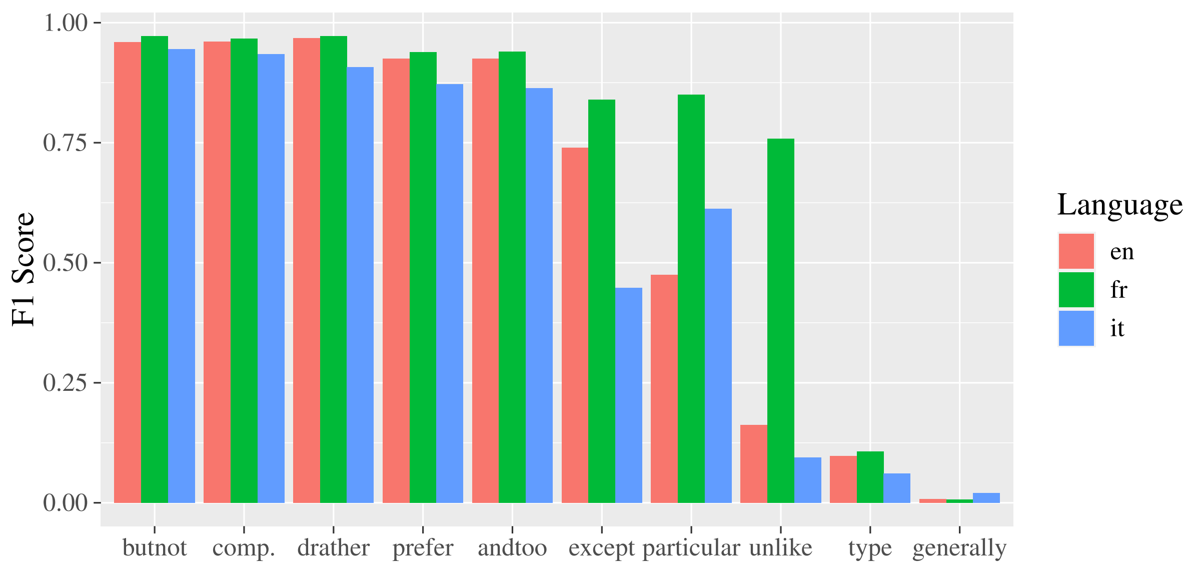

Figure 2: An overview over the F1 scores the KaMiKla models reached in subtask 1, ordered by score.

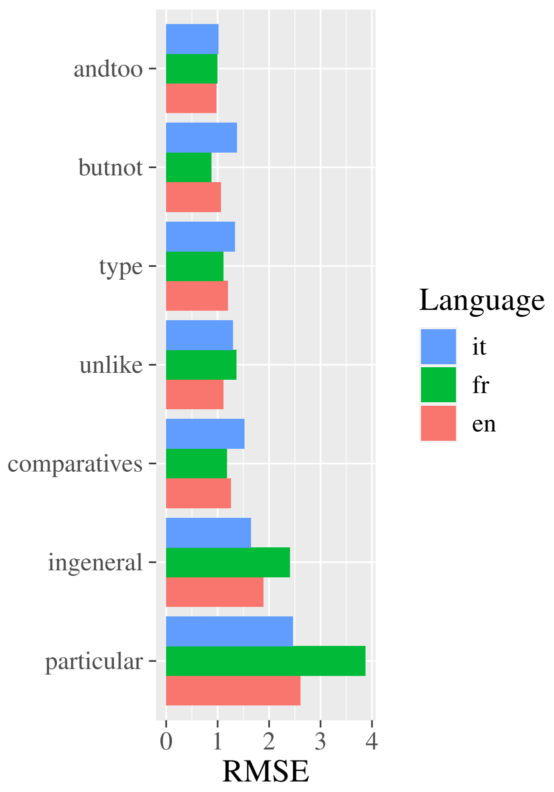

Figure 3: An overview over the root mean squared error scores the KaMiKla models reached in subtask 2, ordered by score.

The difference in performance between constructions is evident here as well. Interestingly, the French regression model seemed to have more trouble than its Italian and English counterparts, while the French classification model outperformed the other languages.

Another interesting comparison is that of the constructions. While the classification models failed on `type` sentences, those are some of the most successful sentences in subtask 2; this indicates that the bad scores on some constructions are due to fine-tuning and not some inherent difficulty the BERT models have with understanding them. On the other hand, this might be a side effect of the models not performing very well in general.

5 Discussion

Our models performed considerably worse on the test dataset than on the validation set, and these differences vary across languages and constructions. While we can't determine for sure where this significant drop in performance comes from, there are some theories worth investigating.

Of course, one challenge (especially of the second part) of the task is the scarcity of data. Subtask 1 contains 5,837 sentences in the training data per language; and 14,560 sentences in the test set. For subtask 2, there are 524 training sentences and 1,009 test instances in each language. Possibly, the regression models performed unsatisfyingly simply because there wasn't enough training data available.

We also wanted to investigate the inherent differences between train and test data. Figure 4 compares the sentence lengths of the train and test set, grouped by language. There are huge differences between the languages and, perhaps more importantly, between the train and test sets of the three languages. The French training data contained sentences of similar length to those in the test data (mean of 8.94 for the test and 9.28 for the training set), and those sentences were generally longer than those of the other two languages. The data from the Italian test set seems to contain sentences of more varied lengths than the training set.

The data of the second subtask show a similar discrepancy between training and test sentences. The sentences from the test data are longer on average than those from the training data in all languages. The lengths also seem to be more variable in the test set, possibly due to the higher number of sentences. The gap between the input sentences could have led to finetuning not remarkably improving the performance of the models.

We furthermore looked at the distribution of different types of constructions in more detail. There were no construction labels for the training data, so we trained a simple Naive Bayes classifier on the tf-idf-transformed test sentences in Python using pandas (pandas development team, 2022) and scikit-learn (Pedregosa et al., 2011). Because of the simple structure of the input sentences and a cross-validation score of 100%, we will assume the construction labels to be accurate in further discussion.

Figures 5 and 6 compare the distributions of the construction labels in train and test sets of subtask 1 and 2, respectively. There are once again huge differences between training and test set. Notably, the training data does not contain a single `unlike` sentence. Despite that, the models did not necessarily perform worse on this type of construction. In total, it does not seem like the distribution of construction types in the training data influenced model performance much at all. There are instances of models performing inadequately on frequent constructions in the training data, like `type` constructions in the first subtask. However, `drather` constructions were often classified correctly despite the scarcity of training sentences.

6 Conclusion

In this work, we discussed an approach to modeling taxonomic relationships using pre-trained language models, namely AlBERTo (Polignano et al., 2019), BERT (Devlin et al., 2019), and CamemBERT (Martin et al., 2020) in the context of the SemEval Task 3 of the year 2022. The KaMiKla group participated in both the classification and the regression subtask. While the performance of the models was overall unsatisfying, further analysis revealed that the type of taxonomic relation that the words in a given sentence severely affected how well the models did. While the reason for this remains unclear, it might be interesting to tailor the finetuning of the BERT-based model to specific constructions or combine it with a classifier that classified the input sentences according to the type of taxonomic relation.

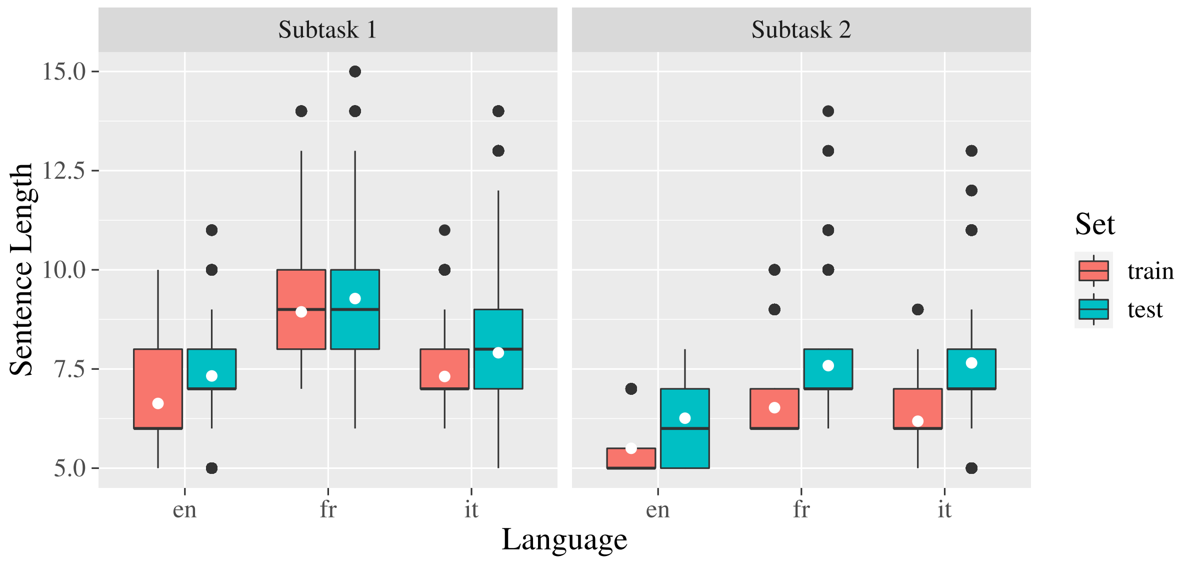

Figure 4: A comparison of the sentence lengths of train and tests sets in the different languages for both subtasks. The mean is visible in white. The difference seems to be less pronounced in the French data of subtask 1, which might have contributed to the better scores. In subtask 2, the sentences seem to be generally longer in the test data than the training data in all languages.

Abstract

In the paper, we describe a unified system for task 3 of SemEval-2022. The task aims to recognize the semantic structures of sentences by providing two nominal arguments and to evaluate the degree of taxonomic relations. We utilise the strategy that adding language prefix tag in the training set, which is effective for the model. We split the training set to avoid the translation information to be learnt by the model. For the task, we propose a unified model fine-tuned on the multilingual pretrained model, XLM-RoBERTa. The model performs well in subtask 1 (the binary classification subtask). In order to verify whether our model could also perform better in subtask 2 (the regression subtask), the ranking score is transformed into classification labels by an up-sampling strategy. With the ensemble strategy, the performance of our model can also be improved. As a result, the model obtained the second place for subtask 1 and subtask 2 in the competition evaluation.

1 Introduction

As we all know, the proposal of BERT(Devlin et al., 2018; Vaswani et al., 2017), which is based on masked language modeling, is a huge milestone in the history of natural language understanding (Peters et al., 2018; Schuster et al., 2019). Compared with various language representation models, BERT successfully pushes the GLUE score at 7.7 points absolute improvement(Devlin et al., 2018). Soon, different types of language models such as XLNet(You et al., 2019), RoBERTa(Liu et al., 2019),mBert (Devlin et al., 2018; Radford and Narasimhan, 2018) and XLM (Lample and Conneau, 2019) are also proposed. Compared with some strong monolingual models introduced above, XLM-RoBERTa is more competitive on the GLUE and XNLI benchmarks(Conneau et al., 2019). There are lots of pretrained models proposed in recent years, which are capable of learning the implicit knowledge. Some works have proved that the neural language model has learnt the implicit linguistic knowledge and this knowledge can significantly affect the predictions through fine-tuning(Miaschi et al., 2020; Puccetti et al., 2021). It has been believed that the pretrained models trained on Wikipedia and other datasets already have some implicit knowledge. Implicit knowledge could be classified into two categories: the connection between two objects, and the implicit logic and syntax behind the sentence. It means, we need to build a model which is capable of verifying the rationality and reliability of sentences, testing whether the latent knowledge can be expressed explicitly.

Presupposed taxonomy is a kind of concept in computational linguistics. Two arguments could have several different taxonomy relationships. For example, the sentence "I like piano, but not the instrument" is a classic pattern which contains two arguments. In the transition sentence, "piano" and "instrument" have a taxonomic relation, so the conclusion could be drawn that the sentence is implausible and unacceptable. Similarly, there are a set of sentences that could have such contradiction in the competition. The goal of the SemEval-2022 Task 3 (Zamparelli et al., 2022) is to recognize the presupposed taxonomy relation between two nouns, which could be a complex linguistic problem. In order to obtain the skill, the model needs to understand the implicit meaning of the sentences as well as whether the presupposed taxonomy relation exists in one pair of entities.

ID	Sentence	Labels
5155	*I like **ham**, but not **fish**.*	1
2560	*I like **restaurants**, and **clerks** too.*	1
3711	*I like **jewlry** more than **skirts**.*	1
4481	*I like **scientists** more than **geneticists**.*	0
3104	*I do not like **seafood**, I prefer **salmon**.*	0

Table 1: Dataset Samples for subtask 1

2 Task Description

Along the lines of ideas above, there are several representative pretained-models in the competition. To be specific, we tried commonly used pretrained models including Bert, Roberta-large, and multilingual language models like XLMR. At the same time, we suspect that the former model can be generalized to subtask 2. The final ranking result supports our hypothesis strongly.

Subtask 1 is a binary classification task aiming at predicting the acceptability of sentences (A(1) VS UA(0)). There are two parameters that have the presupposed taxonomy relation, followed by the label "0"(the semantic relation is not acceptable) or "1" (the semantic relation is acceptable). Note that label "0" stands for the contradictory sentences, and label "1" stands for the plausible sentence. Some samples are shown in table 1, in which most of them obey a similar pattern: "I like A, but not B" or "I do not like A, I prefer B...", etc. The bold portion shows the key entities in the sentence. It is obvious that the taxonomies relation between two entities stands for some implicit information, which should be learnt by our model.

In this multilingual task, three languages (French, Italian and English) are included. Table 1 only presents the English samples and three datasets express completely consistent arguments. The same id indicates the same meaning in a different language.

On the contrary, subtask 2 is a regression task aiming at predicting the degree of Acceptance in a seven Likert-scale. The only difference between the dataset of subtask 1 and subtask 2 is the label. In subtask 2, the label(score) is a float number between 1 and 7, which indicates the acceptable degree of the sentence. Some English data samples are shown in table 2. Note that the sentence with higher score is more reasonable than the sentence with lower one. For instance, the sentence "I like seafood, but not crabs" sounds like a correct sentence in daily life. But the sentence "I like beef, an interesting type of caviar" is a contradictory sentence without any doubt, because the beef is not a caviar.

In addition, Table 3 provides the size of the train and test set. Obviously, the size of dataset for subtask 2 is much smaller than that for subtask 1. So it becomes important to expand the size of dataset of subtask 2. There are two main subtasks in PreTENS (Presupposed Taxonomies: Evaluating Neural Network Semantics).

ID	Sentence	Scores
261	*I like **beef**, an interesting type of **caviar**.*	1.09
440	*I like **trees** more than **grass**.*	5.64
207	*I like **shrubs**, an interesting type of **fir**.*	2.67
60	*I like **trees** but not **birches**.*	1.83
436	*I like **oaks** more than **grass**.*	5.83
104	*I like **seafood**, but not **crabs**.*	6.42

Table 2: Dataset Samples for subtask 2

Task	Type	Language	Train size	Test size
Subtask 1	Classification	En	5840	14560
		Fr	5840	14560
		It	5840	14560
Subtask 2	Regression	En	526	1009
		Fr	526	1009
		It	526	1009

Table 3: Task Dataset Description

3 System

3.1 Data Process for subtask 1

Based on a suitable single model and adaptive finetuning models which have learnt enough implicit information, it becomes possible to express the explicit knowledge(taxonomies) for a model.

The baseline model provided by competition reaches accuracy at 0.8, which is an amazing result. We also find the training set is extremely unbalanced in the proportion of positive and negative samples for some patterns, as we can see in Table 9. So we tried to adjust the proportion of those unbalanced patterns. However, the accuracy decreased a lot after the adjustment. This result shows that the model is actually learning the proportion of labels in the dataset instead of the implicit information. In order to solve the problem in the competition, we need to choose some models which are capable of learning implicit knowledge.

3.1.1 Language Tags

Considering the three languages in our competition, we apply the prefix tag to indicate which language the sentence is in. The XLM-RoBERTa is a multilingual model so the input data consists of mixed sentences in three languages.

As we can see from the figure, angle brackets and language abbreviation is used as the uniform prefixes. Specifically, <fr> stands for French, <en> stands for English and <it> stands for Italian. The

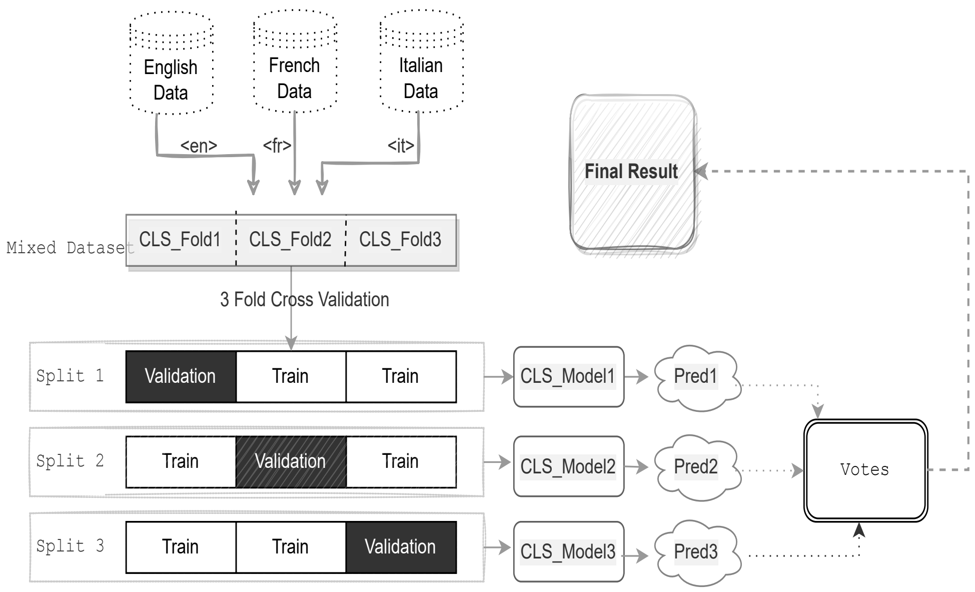

Figure 1: Ensemble classification models

Raw Sentence	**Language Tag**	**New Sentence**
I like jewelry more than skirts	en	***<en>**I like jewelry more than skirts.*
J' aime les bijoux plus que les jupes .	fr	***<fr>**J' aime les bijoux plus que les jupes .*
Amo i gioielli più delle gonne .	it	***<it>**Amo i gioielli più delle gonne .*

Table 4: Adding Language Tags for sentences with the same id

strategy helps to provide some linguistic information to the model artificially. Obviously, there are only linguistic differences between sentences with the same id, and their essential meanings are consistent. Imagining the situation without artificially added labels, there might be some difficulties in identifying sentence pairs with the same id but in different languages.

3.1.2 Dataset Split

We also apply the three-fold cross-validation in the competition. After further fine-tuning, the model has achieved good results on subtask 1. In the task description chapter, we mentioned that the same meaning is expressed in different languages in the dataset, which can be told by ids. In other words, sentences with same meanings in different languages share the common id.

We find that sentences with the same meaning might appear in the training set and the test set respectively in a multilingual language model. So, the model might learn the meaning of translation which should be avoided in our tasks. Therefore, in this section, we divide the data and put sentences with the same ID into the same set to prevent the model from learning the translation information. With such treatment, it can be ensured that the model learns implicit knowledge instead of cheating with translation.

3.2 A Unified Model for Subtask 2

The Situation becomes difficult in subtask 2. Considering the high similarity between datasets used by subtask 2 and subtask 1, and the size of the latter is much smaller than the former, it is important to use the data augmentation. In order to get good performance with the model in subtask 1, we make some efforts to transform the data provided in subtask 2 by using the method used above.

In other words, our method can be easily transferred from subtask 1 to subtask 2, which not only reduces the workload and training time but also makes the prediction more reliable because of the extension of datasets.

From table 1 to 3 which describes the sample and size of datasets, the label in subtask 2 are real values from 1 to 7. The label is a score used to assess the reasonableness of the sentence. Com-

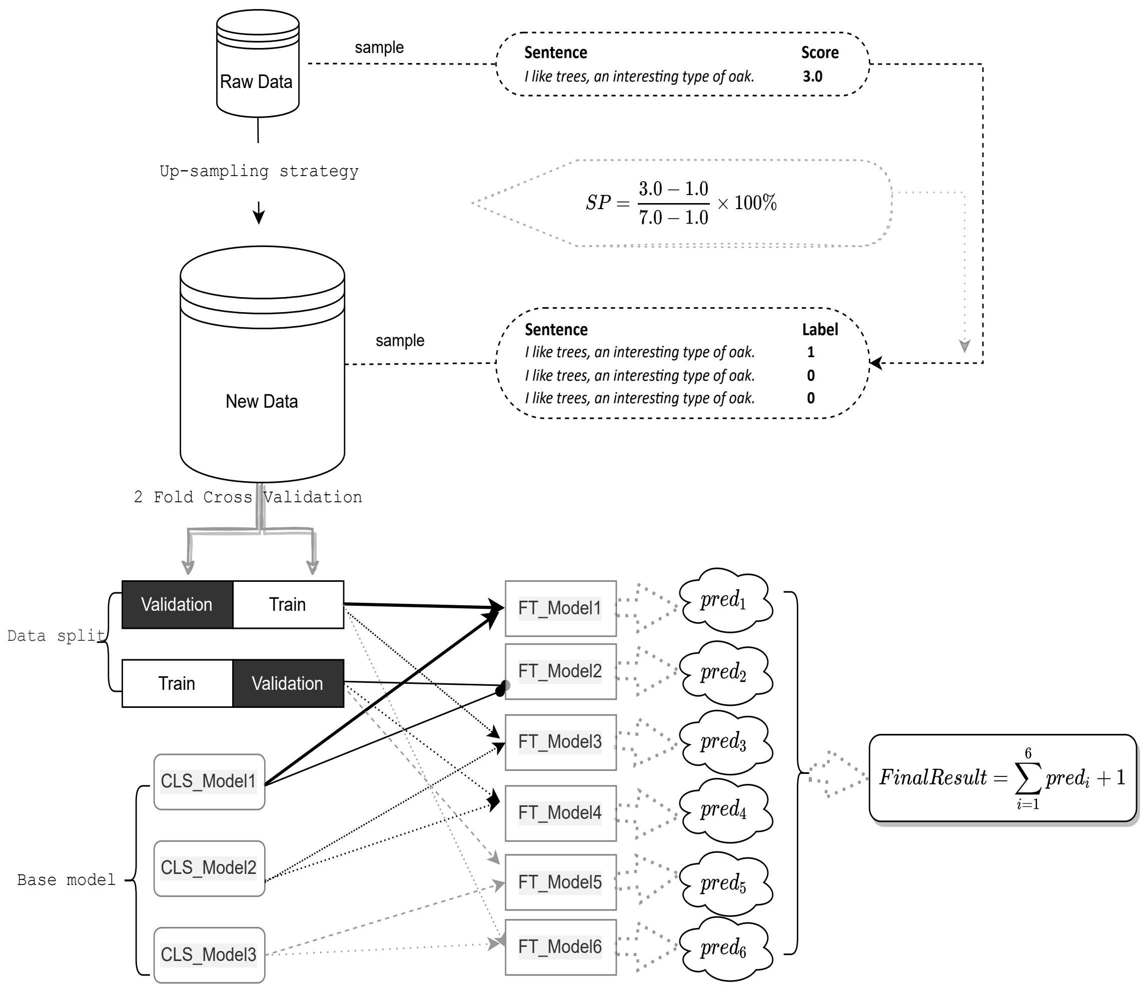

Figure 2: Ensemble regression models

paring tags in two subtasks, it is easy to imagine if sampling with the principle of score as probability, the meaning of the original score could be involved in the new label.

For each sentence from raw dataset, the score would be transformed to label according to the sampling possibility.

Sampling Probability(sp) is defined in the Eq 1, which depends on the ub(upper-bound of score) and lb(lower-bound of score).

$$sp = \frac{score - 1.0}{ub - lb} \times 100\% \qquad (1)$$

The up-sampling strategy is described in figure 2, which uses the expansion coefficient equalling 3 as an example. As for the sentence "I like trees, an interesting type of oak.", the sampling probability could be calculated according to the formula 1, which equals 1/3. Consequently, the raw sentence is duplicated to three same sentences with the label (1, 0, 0), which comes from the sampling strategy.

In data processing, we choose 10 as the expansion coefficient while converting the original score into sampling probability. 10 times the size of datasets, an expansion dataset is obtained in this way.

We use the new expansion dataset to train the model from subtask 1. At the same time, since there are three models obtained from subtask 1, and we split the new dataset into two copies, obviously $3 \times 2 = 6$ models have been used for the ensemble.

Considering the lack of regression data, we make some attempts to up-sampling the regression data. More specifically, the difference between classification data and regression data is the label. The former could be an integer while the latter could be a float between 1 and 7.

Apart from the label, the sentence have the similar pattern and entity. So it might be effective to reuse the model in subtask 1. Each original sentence is duplicated to ten same sentences with the label which might be 0 or 1 depending on the possi-

Model	**Train Set**	**Dev Set**	**Dev Acc**	**Global Rank**

Table 6: Detailed Results of ensemble models for subtask 1

bility. Obviously, the possibility and the regression score is linearly and positively correlated. After obtaining an expanded dataset which has 10 times the size of original dataset of subtask 2, our model could learn some new knowledge in training.

3.3 Ensemble

Through the step described in section 3.1.2, we obtained six models for subtask 1. According to the requirements described in the competition, subtask 2 would be evaluated by the Spearman correlation coefficient, which is a metric used to express distribution trends. In other words, when a distribution is appropriately scaled, the magnitude of the Spearman correlation coefficient would remain the same. This inspires us to directly superimpose the results of the six models for ensemble. To keep the final result size between 1 and 7, we shift the score of the result by 1.

For subtask 1, the dataset is split into three folds for cross-validation and then three models are obtained. Since the target of subtask 1 is to figure out whether the sentence is plausible or not, we use the voting strategy for ensemble. Specifically, three models could have three decisions about the label of one sentence. Naturally, the voting ensemble strategy could be applied in the stage. The final result would be the majority decision.

For subtask 2, the situation is different. It has been cleared that there are three models in the classification task. Based on each model, we use the strategy of up-sampling to expand our dataset and transform it into the classification one.

4 Results and Analysis

Table 5 and Table 6 illustrate the ensemble strategy and ensemble results for subtask 1. The accuracy is the metric to evaluate the result in subtask 1. The results of subtask 2 are illustrated in table 7 and table 8, and the metric is Spearman. Because of the relative measurement of the metric, there are some small shifts in our predictions actually bring no influence to the value of Spearman. Those results indicate that our model has an outstanding improvement compared to baselines.

Except for the experiments introduced above, there were still a lot of directions we tested, but not all of them were useful.

1) From the perspective of the pattern, we found the positive and negative patterns are unbalanced in the dataset. From the Table 9, there are some examples that appear in the dataset. The number of positive samples and negative samples is very unbalanced. So, we balanced the dataset and trained the model. However, this strategy was useless for our model, and it even decreased the accuracy of the model. We suspect that the test set is also an unbalanced dataset.

2) We tried to extract the entities of each sample, and concatenated the embeddings of entities and embeddings of "<CLS>". Eq 2 shows the change between origin embedding and the new embedding.

$$[EA, EB] -> [CLS, EA, EB] \qquad (2)$$

Then, we classified it with a binary classifier (Softmax). But there were no improvements in the performance.

Model	Base Model	Train Set	Dev Set	Dev Spearman
FT_Model1	CLS_Model1	Reg_fold1	Reg_fold2	0.6871
FT_Model2	CLS_Model1	Reg_fold2	Reg_fold1	0.7429

Ensemble	0.7572	0.7591	0.8050	0.7060

Table 8: Detailed Results of Ensemble Fine-tuned Model for subtask 2

3) We tried to extract all entities and capture all the related contents on Wikipedia and trained our language model based on the dataset. But it only brought limited improvements. Because Wikipedia is a very common dataset, the language model might be trained on the dataset before.

Pattern	Label 0/1
He trusts a , except his b.	0 / 12
He does not trust a , he prefers his b.	12 / 0
He likes a , an interesting type of b .	0 / 9

Table 9: Some patterns with unbalanced ratio of positive samples with negative samples.

5 Conclusion

In the experiment, we propose a solution for two subtasks of SemEval2022 Task 3. We illustrate the importance of data preprocessing. The data split and the use of the language tags both have a positive influence on the model performance. Considering the similarity of the dataset and the good performance of the model in subtask 1, we also explore the feasibility of a unified model. The unified model has great performance on both subtask 1 and subtask 2. In the future, there are some other directions that could be tried in the following explorations. We find that the model trained on a large dataset performs well, so, exploring large models might be an interesting direction.

Abstract

This paper presents an overview of Task 4 at SemEval-2022, which was focused on detecting Patronizing and Condescending Language (PCL) towards vulnerable communities. Two sub-tasks were considered: a binary classification task, where participants needed to classify a given paragraph as containing PCL or not, and a multi-label classification task, where participants needed to identify which types of PCL are present (if any). The task attracted 77 teams. We provide an overview of how the task was organized, discuss the techniques that were employed by the different participants, and summarize the main resulting insights about PCL detection and categorization.

1 Introduction

The study of unfair, misleading or offensive language has attracted the interest of many scholars from the NLP research community. Most relevant tasks in this context focus on explicit, aggressive and flagrant phenomena, such as fake news detection or fact-checking (Conroy et al., 2015; Nakov et al., 2018; Atanasova et al., 2019; Barrón-Cedeno et al., 2020); detecting propaganda techniques (Da San Martino et al., 2020); modeling offensive language (Zampieri et al., 2019, 2020) identifying hate speech (Basile et al., 2019); and rumour propagation (Derczynski et al., 2017). However, there also exist subtler but equally harmful types of language, which have received less attention by the NLP community, and which, due to their subtle nature, we can expect to be more difficult to detect. This is the case, among others, for Patronizing and Condescending Language (PCL), which was the focus of Task 4 at SemEval-2022.

An entity engages in patronizing or condescending communication when its use of language reveals a superior attitude towards others. These attitudes, when normalized, routinize discrimination and make it less visible (Ng, 2007). Furthermore, the use of PCL is often unconscious and well-intended, especially when referring to vulnerable communities (Wilson and Gutierrez, 1985; Merskin, 2011). This good will can make PCL especially harmful, as the audience receives this discriminatory language with low defense and is often unaware of its effects.

Research in sociolinguistics presents PCL as a subtle, often unconscious but harmful and discriminative kind of language (Mendelsohn et al., 2020). It creates and feeds stereotypes (Fiske, 1993), which result in greater exclusion, rumour spreading and misinformation (Nolan and Mikami, 2013). PCL also tends to strengthen power-knowledge relationships (Foucault, 1980), calling for charitable action instead of cooperation and presenting those who can help as *saviours* of those in a less privileged position (Bell, 2013; Straubhaar, 2015). Furthermore, PCL tends to conceal who is responsible for very deep-rooted societal problems, sometimes by implicitly or explicitly blaming the underprivileged communities or individuals for their situation, and often involves ephemeral and simple solutions. (Chouliaraki, 2010). The use of PCL by privileged communities has also been related to the so-called pornography of poverty (Nathanson, 2013), a communication style that depicts vulnerable situations with a pity discourse to move a target audience to charitable action and/or compassionate attitudes.

While the negative impact of PCL, both in social interactions and in corporate and political discourse, has been extensively studied in the social sciences, it still remains an under-explored phenomenon in NLP. Nonetheless, we believe that PCL detection offers a number of important challenges for NLP research, which warrant more work in this area, especially given the societal benefits that would result. For instance, given its subtle and subjective nature, we can expect PCL detection to be harder than tasks that are focused on more flagrant phenomena. Moreover, PCL detection often involves the need for an implied *understanding* of human values and ethics, which requires a form of commonsense reasoning that NLP models are likely to struggle with. In this context, we have organized SemEval 2022 Task 4: Patronizing and Condescending Language (PCL) Detection. This task has attracted more than 300 participants, organized in 77 teams, during the official competition. The competition remains open on CodaLab to encourage further research on this topic[1].

2 Related Work

As already mentioned in the introduction, PCL has been extensively studied within the context of sociolinguistics (Margić, 2017; Giles et al., 1993; Huckin, 2002; Chouliaraki, 2006). Within NLP, however, modelling of patronizing discourse has only received limited attention. As a notable exception, Wang and Potts (2019) compiled a corpus of Reddit comments, which were annotated as using a condescending tone or not. Note that in contrast to our SemEval task, their work did not specifically focus on vulnerable communities. In our previous work (Perez-Almendros et al., 2020), we introduced *Don't Patronize Me!*, which is, to the best of our knowledge, the first annotated corpus of PCL towards vulnerable communities. This corpus was used as the training data for the SemEval task. Some other works have studied types of discourse that are highly related to condescension, including Sap et al. (2020), who studied how certain uses of language indicate power relations, Mendelsohn et al. (2020), who discussed the dehumanization of minorities through language and Zhou and Jurgens (2020), who investigated how some expressions of condolences and empathy interplay with authoritative voices in online communities.

3 Dataset

The seed material for this task is *Don't Patronize Me!* (DPM), an annotated dataset with Patronizing and Condescending Language towards vulnerable communities, which was introduced in our previous work (Perez-Almendros et al., 2020). This dataset contains 10,469 paragraphs, which were used as the training set for the SemEval task. To create the test set for this task, we annotated 3,898 additional paragraphs, following the same process. All paragraphs were extracted from news stories from media in 20 English speaking countries, originally provided by the News on Web (NoW) corpus[2] (Davies, 2013).

We used a keyword-based strategy to collect paragraphs, focusing on texts in which vulnerable communities are mentioned (e.g., refugees or homeless). The data was annotated by three annotators, with backgrounds in communication, media and data science. For the main dataset, two annotators annotated the instances with the following labels: 0 (not PCL), 1 (borderline), and 2 (PCL), achieving an inter-annotator agreement (IAA) of 41% for the raw annotations and 61% when removing borderline cases. For all the total disagreements (paragraphs labeled 0 by one annotator and 2 by the other), the third annotator acted as a referee, providing a final label. The final dataset uses a scale from 0 to 4, indicating the level of agreement between the annotators. Labels 0 and 4 correspond to clearly not condescending and clearly condescending (i.e. both annotators assigned 0 or both assigned 2), label 2 means that both annotators marked that paragraph as a borderline case (1-1), and labels 1 and 3 correspond to cases where either one of the annotators assigned the borderline label (0-1 or 1-2), or there was a disagreement that was resolved by the third annotator. Each positive example from the dataset is furthermore labelled with one or more PCL categories. We briefly recall the meaning of these categories.

Unbalanced power relations (UNB): the author entitles themselves as being in a privileged situation, considering themselves as *saviours* of those in need (Bell, 2013; Straubhaar, 2015).

Shallow solution (SHAL): a charitable, superficial and short-term action is presented as life changing.

Presupposition (PRES): stereotypes and *clichés* are used to describe a community, relying on assumptions without having all the information.

Authority voice (AUTH): the author stands as spokesperson and defendant of the community or individual and/or allows themselves to give expert advice about how to overcome underprivileged situations.

Metaphor (MET): the author describes a difficult situation in a more poetic way through

[1]https://competitions.codalab.org/competitions/34344

[2]Used with permission from the author.

Cat.	Examples
UNB	*They deserve another opportunity* or *You can make a difference in their lives.*
SHAL	*Raise money to combat homelessness by curling up in sleeping bags for one night.*
PRES	*Elderly or disabled people who are simply unable to evacuate due to physical limitations.*
AUTH	*Accepting their situation is the first step to having a normal life.*
MET	*Poor children might find more obstacles in their race to a worthy future.*
COMP	*[...] discarded in the streets of Europe [...]*
MERR	*Her mom is disabled and living with her gives her strength to face everyday's life* or *Refugees are wonderful people.*

Table 1: Examples of the different PCL categories.

figures-of-speech such as metaphors and euphemisms.

Compassion (COMP): the message uses flowery wording to reflect on the vulnerability or toughness of the situation, raising a feeling of pity among the audience.

The poorer, the merrier (MERR): the author praises the vulnerability, granting positive values to all members of a vulnerable community and showing their admiration.

Table 1 contains examples for each of these categories. The average of the IAA among categories is 57.43%[3]. It is worth mentioning that the distribution of labels is highly unbalanced in our dataset, with only around 9.5% of the inputs being labeled as containing PCL (positive cases). For the categories, the distribution is as follows: 73% UNB, 19% SHALL, 23.1% PRES, 23.6% AUTH, 48.7% COMP, 20.1% MET and 4.1% MERR.

4 Task Description

The aim of the proposed task is to identify the presence of PCL (Subtask 1), and to identify the categories of PCL that are present in a given paragraph (Subtask 2).

Training data The 10,469 annotated paragraphs from the DPM corpus were provided as training data. To frame Subtask 1 as a binary classification problem, paragraphs with labels 0 and 1 were considered as negative examples, while paragraphs with labels 3 and 4 were considered as positive examples of PCL. The original labels on the scale from 0 to 4 were also made available. The 993 positive examples in the training data are labelled with the corresponding PCL categories. Span annotations for these categories were also provided.

Test data A total of 3,898 paragraphs were released as test set, with the same format and meta-information as the training set, but without labels and span annotations. Paragraphs initially labelled as 2 were excluded from the test data, as these correspond to borderline cases.

External resources We welcomed the use of external resources in this task. Participants were encouraged to explore transfer learning or data augmentation techniques with a variety of source corpora and language resources.

Evaluation System submissions were ranked in the two subtasks as follows: **Subtask 1**: F1 score for the positive class. **Subtask 2**: Macro-averaged F1 over all categories.

4.1 Participation Framework

The task was hosted on CodaLab[4], with participants needing to register and submit their results through the platform. The competition involved the following three phases:

- **Practice phase:** The 10,469 paragraphs from the training data were split into 8,376 training paragraphs and 2,095 validation paragraphs. This was done to allow participants to compare their systems on a public leader board. The training-validation split respected the natural distribution of labels in the data.

- **Evaluation phase:** This was the official evaluation phase for the SemEval competition. The test data was released and the leader board for this phase remained hidden to prevent participants from fine-tuning their systems on the test data. Each participant was allowed two different submissions for each subtask.

- **Post-evaluation phase:** The learderboard for the evaluation phase and the official ranking for each subtask were published, as the SemEval competition ended. Participation in the SemEval task is no longer possible, but the

[3]See Perez-Almendros et al. (2020) for further details.

[4]https://competitions.codalab.org/competitions/34344

competition remains open on CodaLab to allow participants to re-test and further improve their systems.

5 Results and Discussion

A total of 77 different teams participated in the evaluation phase of our task, with 145 valid submissions for Task 1 and 84 for Task 2. For the competition, we allowed a maximum of 2 submissions per team. A total of 42 out of 77 teams outperformed the baseline for Subtask 1, while 37 out of 48 outperformed the baseline for Subtask 2. Tables 2 and 3 present the rankings for Subtask 1 and 2, respectively, where we have only listed the best performing system for each team. For Subtask 1, the best-performing systems used the following strategies:

Team PALI-NLP used an ensemble of pre-trained RoBERTa models (Liu et al., 2019). While training, they applied grouped Layer-Wise Learning Rate Decay, a variant of LLRD (Howard and Ruder, 2018), based on the idea that different layers capture different types of information (Yosinski et al., 2014). By optimizing the learning rate in different layers, the model captures more diverse and fine-grained linguistic features of PCL. To tackle the class imbalance in the dataset, they use weighted random samples (Hashemi and Karimi, 2018) to emphasize the positive instances.

Team STCE created adversarial examples to train an ensemble model of RoBERTa and DeBERTa (He et al., 2020). They also used weighted samples to address the class imbalance and explored different loss functions, establishing Cross Entropy and the contrastive loss algorithm NT-Xent introduced by Chen et al. (2020) as first and second loss function, respectively.

For Subtask 2, the best-performing systems used the following strategies:

Team BEIKE NLP participated with a system based on prompt learning (Petroni et al., 2019; Brown et al., 2020). They first reformulate PCL detection as a cloze prompt task and then fine-tune a pre-trained DeBERTa model.

Team PINGAN Omini-Sinitic proposed an ensemble model which used prompt training and a label attention mechanism, by adding a new label-wise attention layer ((Dong et al., 2021; Vu et al., 2021). Their system over-samples the positive examples. They also use a form of transfer learning from Subtask 1 to Subtask 2, by pre-training on Subtask 1 and using the resulting model as the starting point for training a model for Subtask 2.

For both sub-tasks, unsurprisingly, most systems rely on pre-trained language models, although a few teams have used CNN, LSTM, SVM or Logistic Regression based systems (XU, PC1, I2C, Ryan Wang, McRock, Amrita_CEN, SATLab and Team Lego, among others), or an ensemble of some of the above together with language models (UTSA_NLP, Taygete). Although the use of language models usually outperformed other systems in this task, some LSTM models, such as the one submitted by team Xu, achieved competitive results.

The ensembling of different models has also been a popular technique. Other strategies that proved successful include adversarial training, data augmentation and multitask learning. In the following, we summarize how these techniques have been used by the different systems.

Ensemble learning Ensembling different models has previously been found useful for text classification (Nozza et al., 2016; Kanakaraj and Guddeti, 2015; Fattahi and Mejri, 2021). Accordingly, ensembling was one of the most common strategies for improving on baseline PCL detection methods. Most of the teams combined different language models (e.g. PALI-NLP, STCE, PINGAN Omini-Sinitic,PAI_Team, LRL_NC, SSN_NLP_MLRG, ASRtrans, amsqr, UMass PCL). Considering the choice of language models, the most successful systems either used RoBERTa, DeBERTa or an ensemble which included the former ones and other models. For instance, these models were used by the best performing teams for both subtasks, i.e. PALI-NLP and STCE for Subtask 1 and BEIKE NLP and PINGAN Omini-Sintic for Subtask 2. To fine-tune the language models effectively, incorporating a contrastive loss function, in addition to the standard cross-entropy loss, has also proved useful. Finally, it should be noted that the combination of language models with different types of neural networks (Taygete, UTSA_NLP) has also proven useful.

Table 3: SemEval Task 4: Ranking by teams for Subtask 2: Categories Classification. The table reports F1-Score (%) for each one of the categories and the macro-averaged F1-score (%) for all categories. The categories stand for: Unbalanced Power Relations (UNB), Shallow Solution (SHAL), Presupposition (PRES), Authority Voice (AUTH), Metaphors (MET), Compassion (COMP) and The poorer, the merrier (MERR).

Balancing class distribution The class imbalance in the dataset has been addressed by participating teams in different ways. Some teams opted for downsampling the number of negative examples (Ryan Wang, LastResort, MS@IW), while others tried a cost-sensitive learning approach to address this issue (Amrita_CEN). However, the most popular approach to balance the class distribution has been through data augmentation (amsqr, Xu, Utrech Uni, UMass PCL, among others). To create new positive examples, participants have used strategies such as the use of large generative models like GPT3 (Brown et al., 2020) or T5 (Raffel et al., 2020) (MS@IW, PINGAN Omini-Sinitic and Tesla); back-translation (Taygete); the addition of synonymous sentences to the original data (I2C), or the application of the so-called Easy Data Augmentation methods, a set of simple but effective techniques such as synonym replacement, random insertion, random swap, and random deletion (AliEdalat) (Wei and Zou, 2019; Rastogi et al., 2020).

External resources Various types of external resources have been used. For example, lexical databases such as WordNet (Miller, 1995) have been used to augment, enrich and improve the training data (Ali Edalat). Datasets from related tasks, including TalkDown (Wang and Potts, 2019), and two metaphor detection datasets, namely MOH (Mohammad et al., 2016) and VUA (Steen et al., 2010), have been used both for pre-training and / or for data augmentation by different teams. PAWS, a dataset with Paraphrase Adversaries from Word Scambling, (Zhang et al., 2019) and xTREME, a bechmark for Cross-Lingual Transfer Evaluation of Multilingual Encoders (Hu et al., 2020), have also been used to improve several systems (Ali Edalat, ASRtrans, Tesla, MaChAmp). Other related NLP challenges have served as auxiliary tasks for pre-training PCL models (AliEdalat, UMass PCL), although such strategies have not always been successful (ULFRI). The MaChAmp team used 7 SemEval-2022 tasks, including ours, for training a model based on multi-task learning. The DH-FBK team also opted for multi-task learning, but they only used the data from the Don't Patronize Me dataset itself to create auxiliary tasks. For instance, they trained their model to predict the uncertainty of a label in Subtask 1, using the fine-grained set of labels (0-4); the agreement of the annotators in Subtask 2; the spans where the categories were present; or the country of origin of the news outlets. AliEdalat similarly used the meta-information from the Don't Patronize Me dataset as additional features for training their model.

Prompt learning Using prompts has also proven useful for PCL detection (BEIKE NLP, PINGAN Omini-Sintic, Ablimet). Specifically, the teams used prompts such as "*[paragraph]* is *[label]*", or "is *[paragraph] [label]*?" where *[paragraph]* is the original input. For Subtask 1, *[label]* is a natural language description of the binary class label (e.g. *"is (not) condescending or patronizing"*). For Subtask 2, *[label]* is the label of a given PCL category.

6 Conclusions

Patronizing and Condescending Language detection is a relatively new challenge for the NLP community. However, the high level of participation in this task has provided the community with valuable new insights about how to tackle this problem. A total of 42 out of 77 teams in Subtask 1 and 37 out of 48 for Subtask 2 outperformed the RoBERTa baseline. The performance of the best-performing systems shows that a judicious usage of state-of-the-art text classification techniques can bring significant benefits to PCL detection, especially when it comes to addressing the relative scarcity of the available training data and closely related external resources. However, there still remains considerable scope for further improvements. It is our expectation that further improvements may need to rely on techniques that are specifically targeted at PCL, e.g. by exploiting insights from linguistics about the linguistic features of PCL, or by building explicit models of stereotypes of vulnerable communities.

JUST-DEEP at SemEval-2022 Task 4: Using Deep Learning Techniques to Reveal Patronizing and Condescending Language

Mohammad Makahleh and **Naba Bani Yaseen** and **Malak Abdullah**
Jordan University of Science and Technology
Irbid Jordan
maalmakahleh20, nmbaniyaseen21 @cit.just.edu.jo, mabdullah@just.edu.jo

Abstract

Classification of language that favors or condones vulnerable communities (e.g., refugees, homeless, widows) has been considered a challenging task and a critical step in NLP applications. Moreover, the spread of this language among people and on social media harms society and harms the people concerned. Therefore, the classification of this language is considered a significant challenge for researchers in the world. In this paper, we propose JUST-DEEP architecture to classify a text and determine if it contains any form of patronizing and condescending language (Task 4- Subtask 1). The architecture uses state-of-art pre-trained models and empowers ensembling techniques that outperform the baseline (RoBERTa) in the SemEval-2022 task4 with a 0.502 F1 score.

1 Introduction

The language used when talking about other people significantly impacts society and individuals. Talking about others and using caring and sympathetic language to express them causes them to be concerned, regardless of the author's intention, which is often to help others by raising awareness of their cause. Unfair treatment of vulnerable groups on social media increases exclusion and inequality(Kučak et al., 2018).

Several researchers study modeling language that intentionally undermines others, such as offensive language or hate speech (Zampieri et al., 2019; Faraj and Abdullah, 2021). PCL modeling is still a relatively new topic of research in NLP. For illustration, the use of PCL in the media is frequently unconscious, subtler, and more subjective than the sorts of discourse that are typically addressed in NLP. To the best of our knowledge, a particular focus on PCL for vulnerable communities has not yet been considered. Through a broader context, some work on PCL had been studied on communication between two people, such as in social media interactions, where others patronize an individual. For example, the authors in (Inui et al., 2019) published the talk down corpus for detecting condescension in Reddit comment-reply pairs. Finding or creating a high-quality dataset that covers all or most cases of PCL is very difficult and requires significant effort from specialized researchers. As researchers in NLP, we use it to investigate PCL in vulnerable communities(Perez-Almendros et al., 2020).

In this paper, we describe our model on task 4 of Semeval 2022 sub task1 (P'erez-Almendros et al., 2022) to identify PCL and categorize the linguistic techniques used to express it. Specifically when referring to communities identified as being vulnerable to unfair treatment in the media. We compare the outcomes of multiple pre-trained models (BERT, RoBERTa, and ensemble on them). We furthermore show the effect of tuning their hyperparameters values (batch-size and epoch) on model prediction. Also, we illustrate our proposed architecture where we feed the data to an ensemble model with the stacking of 2 BERT models and -in parallel- to another ensemble model with the stacking of 2 RoBERTa models. Finally, the results of the two ensembling models are fed to a max voting ensemble, which predicts the outcome with achieving the best F1 score at 0.502.

The rest of the paper is organized as follows; section 2 presents a Related Work, and section 3 offers Methodology. Results are discussed in section 4. Finally, section 5 presents conclusion.

2 Related Work

Many researchers applied machine learning models to classify text (Abdullah and Shaikh, 2018; Qawasmeh et al., 2019). Lai et al.(Lai et al., 2015) classified text using a recurrent convolutional neural network. They captured the key components in texts using the max-pooling layer from word representations. Then they grabbed contextual information from it. To check the efficacy of the proposed method, they conducted several experiments on four commonly used data sets. As a result, they found that their suggested method outperforms the latest methods in many data sets.

Gunal et al.(Kowsari et al., 2019) studied text classification algorithms on several sides. Like limitations of each technique and its application in real-world situations are discussed. They found some steps useful in decreasing the time complexness and memory complexity of existing text classification algorithms like central component analysis and incidental projection, etc.

Using deep neural networks with LSTM modules, Semberecki et al.(Semberecki and Maciejewski, 2017) classified text documents. They tried to construct feature vectors, which represent the documents to be categorized: each feature vector represents the sequence of words that are included in the documents. First, they convert the terms into vector representations and then use the sequences of these vector representations as features of the documents. They evaluated the feasibility of this approach to text categorization utilizing a set of Wikipedia articles. They show that the LSTM network-based approach with documents represented as vectors achieves an accuracy of 86%.

3 Methodology

Our approach methodology can be summarized as follows: We begin by describing the dataset for this task. Then, the preprocessing step is described. Our final section describes how JUST-DEEP can identify the patronizing language in the text.

3.1 Data Set:

The SemEval-task 1 competition provided three files (rial, train, and test dataset(Perez-Almendros et al., 2020)) The files contain several columns as follows:

- par_id: the identification number for each paragraph.
- art_id: the identification number for each article.
- keyword: word related to patronizing. .
- country_code: the code for each country.
- text: the text that we want to classify.
- label: denotes if the text contains patronizing or not (4 levels 0,1,2,3 where 0 and 1 means no PCL, as well as 2 and 3, means high PCL).

3.2 Data pre-processing:

In this section we describe the basic data preprocessing steps we applied for all of our experiments:

1. In the beginning, we transform the Label column into a binary format. If the value is zero or one, we convert it to zero. And if it is two or three, we convert it to One. So with this transformation, the Label is a Binary column with two values: the Zero means that there are no PCL in the text, and the value One implies that there is PCL.We converted the column to binary because we are working on sub-task one, so we want to determine if it contains PCL or not; we don't care about the degree of PCL.

2. Pre-trained models don't work with raw text, so we converted the text into numbers and added unique tokens to separate sentences at the beginning and end of each sentence. Then we pass the resulting sequence to the models to perform the classification process.

3. Pre-trained models work with fixed-length sequences. So we used a simple strategy to choose the appropriate maximum length for all sequences. First, we found that most series have a size of 160, so we set the size of all series to 160.

3.3 JUST-DEEP Architecture:

Our task aims to detect whether a text contains PCL language or not. As shown in Figure 1, JUST-DEEP architecture uses multiple pre-trained language models (BERT and RoBERTa) from the transformers library.

The first step is data pre-processing. The training dataset is fed to the augmentation processor, responsible for adding more data to the training dataset since it is originally imbalanced data where the number of Zero class instances is ten times the One class instances. The augmentation processor input is all One instances text. The processor augments the text of the input instances by adding the same instance to the primary dataset multiple times with slightly different text but with the same meaning. Next, the textual data is processed into their corresponding embeddings(tokens) to feed them to the classifiers.

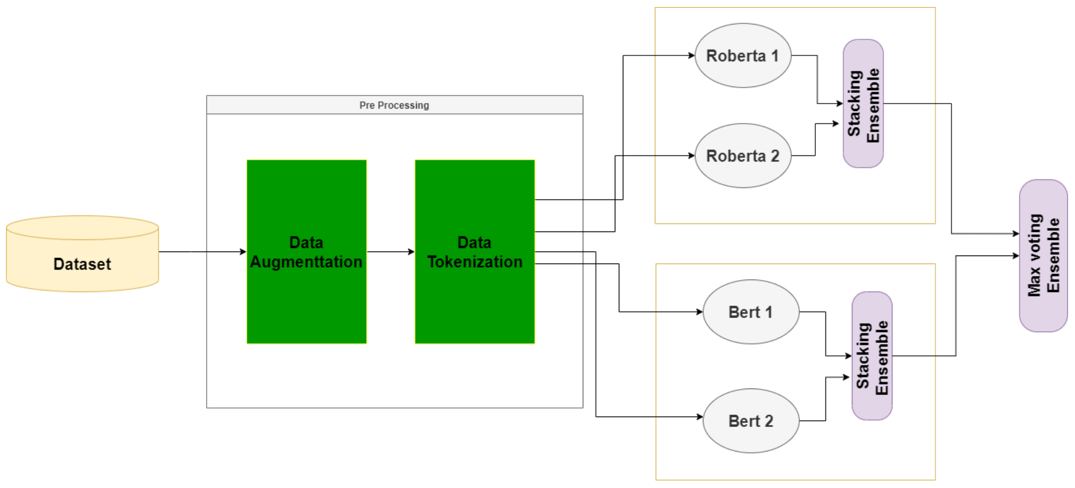

Figure 1: Model Architecture

The second step is the classification step. Finally, the input tokens are fed in parallel to two ensembling models; the first is composed of stacking of 2 BERT models, and the second contains stacking of 2 RoBERTa models.

Finally, the predictions of the two ensembling models are joined by a max voting classifier to produce the final prediction output. We conducted several experiments with different models and hyperparameters, but the JUST-DEEP architecture achieved the best results.

Figure 2 show an example use case for architecture. If we fed the sentence *'Fast food employee who fed disabled man becomes internet sensation'* which is an example from the train data labeled as 1 (contains PCL). In augmentation step we generate more instances with same meaning of this row by the augmentation processor which might add data like *'Fast food worker who fed weakened guy becomes internet rumor'*. Next, the sentence is converted into numeric token and passed to both ensemble models.
For instance, the first ensemble model which contains stacking of 2 RoBERTa models produce the prediction of 1 for this row. The other ensemble model with stacking of 2 Bert classifiers predicts Zero as a class label. Finally, the last step which implement a max voting will generate One as the final output label for the instance.

4 Result

We performed several experiments to determine which is the best suitable model for this task and which model produces the highest value of F1 score. First, we experimented with BERT and RoBERTa pre-trained models and tuned their hyperparameters (batch_size and epoch) to achieve the maximum possible F1 score. Table 1 shows the experiments we did, the models, their parameters, and the value of the f1 score we got in each experiment in the test dataset.

As a first step, we explored BERT and RoBERTa's best hyperparameters, such as batch_size, epochs, and max sequence length. Table 2 describes these hyperparameters.

We use five different models: BERT model, RoBERTa model, stacking of 2 BERT, stacking of 2 RoBERTa, and JUST-DEEP model as described in the architecture section. As shown in the table1 model, JUST-DEEP achieves the best results compared to the rest of the models we tested, as it reached an F1 score value equal to 0.502.

As we explained earlier, in the JUST-DEEP model, we trained the dataset with augmentation. Then we applied the Stacking Ensemble Technique separately on 2 BERT Models and 2 RoBERTa Models. Then, we took the Max voting between the two models as a result; therefore, this model produces the best results because it combines the two models that we used, BERT and RoBERTa.

The other models show less favorable results; the application of the stacking ensemble technique to the 2 BERT models gives the highest results after the JUST-DEEP, where the F1 result is close to 46%, followed by the model resulting from the application of the stacking ensemble technique to the 2 RoBERTa, where it achieved results close to 0.44. Then, RoBERTa's model achieved the F1 with a score of 0.43. The worst model was Bert achieved 0.42.

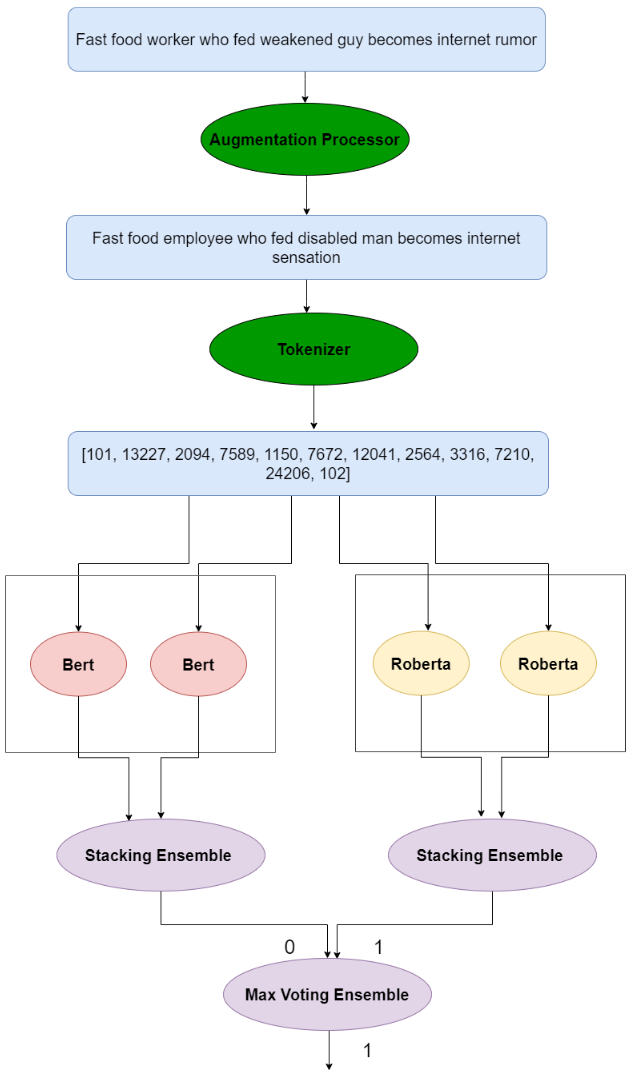

Figure 2: Example Description

5 Conclusion

Deep learning helped in the development of many aspects these days, and with in-text classification, we become to have the ability to make a lot of applications related to it and so on. In this paper, we describe our JUST-DEEP model solving the SemEval-2022 Task 4 Subtask 1 to check if the text contains any form of PCL. The JUST-DEEP model obtained an F1 score of 0.5 using ensembling of pre-trained language models BERT and RoBERTa. Our strategy depends on training data set with augmentation then applying stacking ensemble technique to 2 BERT and 2 RoBERTa and take max voting between the models to achieve F1 score higher than the other experiments we conduct where we use plain BERT and RoBERTa models with different hyperparameters.

Abstract

This paper describes the second-placed system for subtask 2 and the ninth-placed system for subtask 1 in SemEval 2022 Task 4: Patronizing and Condescending Language Detection. We propose an ensemble of prompt training and label attention mechanism for multi-label classification tasks. Transfer learning is introduced to transfer the knowledge from binary classification to multi-label classification. The experimental results proved the effectiveness of our proposed method. The ablation study is also conducted to show the validity of each technique.

1 Introduction

Patronizing and Condescending Language (PCL) is proposed by Pérez-Almendros et al. (2020), which builds a dataset for PCL detection. The Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022) contains two text classification tasks. Subtask 1 is a binary classification task, which requires a system to predict whether the paragraph contains any form of PCL. Subtask 2 is a multi-label classification task, which must identify which PCL categories express the condescension.

PCL Detection is a sentiment analysis task and we treated subtask 2 as an Aspect-Based Sentiment Analysis (ABSA) (Jo and Oh, 2011) task, which is also a multi-label classification to classify the sentence sentiment on different aspects.

Early works on ABSA focus on feature engineering (Wagner et al., 2014) and subsequent neural network-based methods (Wang et al., 2017). Recently, Pre-trained Language Models (LMs) such as BERT (Devlin et al., 2019), ROBERTA (Liu et al., 2019), ALBERT (Lan et al., 2020) have been proposed and brought significant improvement in various NLP applications. As there is not much improvement in ABSA task through direct implementation of those pre-trained LMs, Bert-pair (Sun et al., 2019) has been proposed to help them adapt to ABSA effectively. Furthermore, Bu et al. (2021) proposed an attention between sentence embeddings and label embeddings to focus on the crucial tokens which are related to the label. Recently, CapsNet-Bert (Jiang et al., 2019) used the attention between the label and the input with capsule network to improve the performance.

Nowadays, the Pattern-Exploiting Training (PET) (Schick and Schütze, 2021) and P-tuning (Liu et al., 2021) has been proposed to utilize the pre-trained LMs more effectively, which trains finetune model by the pre-training tasks such as Mask Language Modeling (MLM) by adding a prompt sequence to the input.

Considering the similarity between PCL and ABSA, we applied PET and Bert-pair in PCL Detection through the following steps: Firstly, we treat the subtask 1 as a prompt training task (as described in PET) by using a PCL description as the prompt. Secondly, we transform the subtask 2 from a multi-label classification task to multiple binary classification tasks by using the label names as the prompts. Thirdly, we conduct transfer learning from subtask 1 to subtask 2 to further improve the performance. Last but not least, we also proposed a label attention mechanism based on the multi-prompt training for multi-label classification.

Our contribution can be summarized as follows: we apply prompt training on PCL detection subtask 1 and 2, and prove its effectiveness on both tasks; in subtask 2, we propose a label attention mechanism with multi-prompt training; we apply transfer learning from subtask 1 to subtask 2, where the transfer learning is proved to be effective in ABSA.

2 Background

2.1 Task Description

The tasks intend to detect whether the input paragraphs have any forms of PCL, and which PCL categories are contained. The PCL categories defined

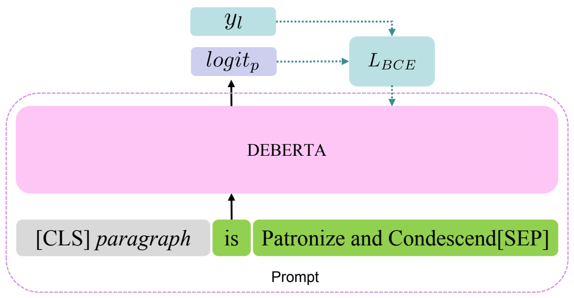

Figure 1: Subtask 1 overview, $logit_p$ is the corresponding logits of the word "is" in prompt.

in the task paper Pérez-Almendros et al. (2022) are 'Unbalanced power relations', 'Shallow solution', 'Presupposition', 'Authority voice', 'Metaphors', 'Compassion','The poorer, the merrier'. The tasks can be formalized as follows:

The training data of subtask 1 consists of tuples (q, l_{binary}), where q is a paragraph extracted from articles, and l_{binary} is the binary classification label with values 0, 1. The training data of subtask 2 consists of tuples (q, $l_{category}$), where q is a paragraph extracted from articles and $l_{category}$ is the label for multi-label multi-classification task. $l_{category}$ is a 7-digit binary vector. Each digit represents whether the paragraph contains the corresponding PCL category and it is possible for one paragraph to contain multiple PCL categories. We also defined a set A, which contains the names of categories. $a \in A$ represents a category name from all PCL categories.

2.2 DEBERTA

Our comparison of present large pre-trained Language Models(LM) showed that DEBERTA (He et al., 2021b) seems to be the most effective model. Different from other works, DEBERTA implemented a disentangled attention mechanism which utilizes the input contents and relative positions. We conduct most experiments based on DEBERTA-v3 (He et al., 2021a), which trained the DEBERTA model with replaced token detection (RTD) pre-training task, proposed by ELECTRA (Clark et al., 2020). RTD is a more sample-efficient pre-training task than replacing Mask Language Modeling (MLM). The experiments in He et al. (2021a) shows that DeBerta-v3-large model achieves better performance on GLUE benchmark even compared with larger pre-trained LMs.

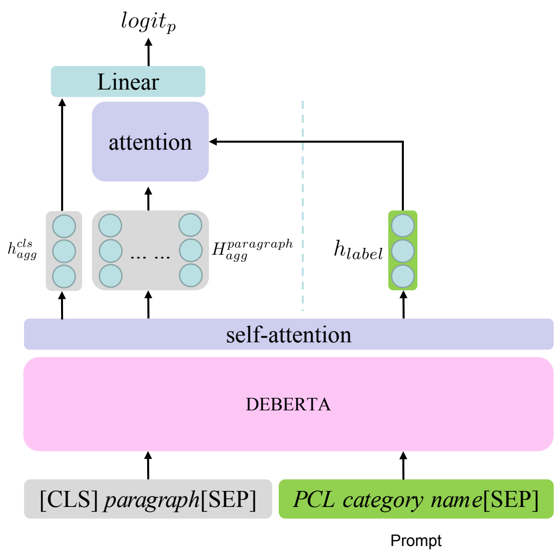

Figure 2: Subtask 2 overview, we conduct a attention mechanism between the logits of paragraph and the logits of label name.

3 System overview

3.1 Prompt Classification

Inspired by PET, we adopt a prompt design on traditional classification tasks based on pre-trained LMs. As shown in Figure 1, we adopt DEBERTA-v3 as the pre-trained LM. The input sequence consists of the original paragraph q and the prompt sequence, which is "is patronize and condescend" in subtask 1, denoted as r. The total input sequence can be described as "$[CLS]\, q\, r\, [SEP]$" for subtask1. Since the DEBERTA-v3 trained by RTD as same as ELECTRA, we don't use the hidden states of [CLS] for classification. Instead we use the hidden state of word "is" (as described in Figure 1) for a binary classification, and the label is 1 when the paragraph contains PCL, 0 when the paragraph has no PCL. The input sequence is forward to DEBERTA and the hidden states are calculated by Equation 1

$$H_q = F([q; r]) \tag{1}$$

$$logit_p = D(H^p_q) \tag{2}$$

where F is the pre-trained 24-layer transformers and D is a linear layer which classify the hidden states of prompt word from DEBERTA. Then we use the hidden states $H^p_q \in \mathbb{R}^d$ selected from H_q as the input to D, which denotes the hidden states of the prompt word "is", the d is the hidden size of DEBERTA. BCE (Binary Cross Entropy) loss, which measures the Binary Cross Entropy between the golden label and the output, is used for binary classification as Equation 3.

$$L_{BCE} = BCE(Sigmoid(logit_p), l_{binary}) \quad (3)$$

where l_{binary} is the binary label of subtask 1.

In this way, the semantics of prompt can be jointly learned with the input paragraph. By using the same training method with pre-trained LM, the representations stored in the pre-trained LM has been maximum reserved.

3.2 Multi-label Prompt Classification

For subtask 2, we transform the multi-label classification task to multi binary classification tasks by concatenating the paragraph with each PCL category label names. As shown in Figure 2, the input paragraph q is concatenated with one PCL category name a, which can be denoted as "[CLS]q[SEP]a[SEP]". We use an self-attention layer as an aggregator to aggregate the sequence embeddings, which is more effective then using the [CLS] embedding. It can be formulated as:

$$H_q = F([q; a]) \quad (4)$$

$$H_{agg} = S(H_q) \quad (5)$$

where S is the self-attention layer proposed by BERT (Devlin et al., 2019), and H_{agg} represents the aggregated hidden states of input sequence. Then we use the [CLS] aggregated hidden states H^{cls}_{agg} to classify whether the paragraph has the corresponding PCL category, which can be formulated as:

$$logit_{cls} = D(H^{cls}_{agg}) \quad (6)$$

$$L_{BCE} = BCE(Sigmoid(logit_{cls}), l_c) \quad (7)$$

where l_c is the binary label of PCL category detection, selected from the category label $l_{category}$. The real output for subtask 2 is the combination of all PCL category detection results.

From previous works, this approach have been proved effectively for improving the multi-label classification tasks. We named this approach MPrompt in this paper.

3.3 Label Attention

As shown in Figure 2, we also propose a label attention above the MPrompt approach. Although the transformers model has self-attention between every tokens, an external attention between paragraph and label prompt is still helpful for the model to focus on more important words in the paragraph. First, We split the output hidden states H_{agg} into $H^{paragraph}_{agg}$ and H^{label}_{agg}, where $H^{paragraph}_{agg}$ is the hidden states corresponding to the sequence "[CLS]q[SEP]", and H^{label}_{agg} is the hidden states corresponding to the sequence "a[SEP]". Then, the label embedding h_{label} is computed as average pooling over H^{label}_{agg}, where $h_{label} \in \mathbb{R}^d$.

As shown in equation 8, we use an attention layer to combine the h_{label} and $H^{paragraph}_{agg}$, where h_{label} is used as query (Q), and $H^{paragraph}_{agg}$ is used as key (K) and value (V) followed the definition of Scaled Dot-Product Attention in Vaswani et al. (2017).

$$h_{LA} = softmax(\frac{QK}{\sqrt{d}})V \quad (8)$$

where h_{LA} denotes the output of attention layer. Then we concatenate h_{LA} with the aggregated hidden states of [CLS] as follows:

$$logit_p = D([H^{cls}_{agg} : h_{LA}]) \quad (9)$$

where D is the Linear layer for binary classification.

3.4 Transfer Learning

We also implemented multi-task learning, joint learning and transfer learning between subtask 1 and 2. Only the transfer learning has improved the performance of subtask 2. First we trained a subtask 1 model with prompt training, then we use the subtask 1 model as the initial checkpoint, trained a subtask 2 model with MPrompt. Experiments in section 5.1 proved the effectiveness of this approach. Unfortunately, transfer learning from subtask 2 to subtask 1 or other approach has no improvement.

3.5 Other Tricks

The DEBERTA which has large amount of parameters tends to over-fit on small training dataset. We utilize RecAdam (Chen et al., 2020) to fine-tune the pre-trained model to address the over-fitting problem. RecAdam optimizer is proposed to address the catastrophic forgetting problem of sequential transfer learning paradigm by introducing a recall and learning mechanism into Adam optimizer, which maintain the learned knowledge in pre-trained model while learning a new task.

The numbers of each category is very unbalanced in train dataset, we over-sample the positive samples to alleviate this problem. On subtask 2, we keep the proportion of each positive category unchanged during oversampling.

Data augmentation is not applied in our approach because we haven't find other proper datasets.

4 Experimental setup

4.1 Data

We use the official released dataset of SemEval2022 Task4 for experiments. The dataset contains 8375/2094/3832 samples for train, dev and test data. The subtask 1 and subtask 2 share the same input paragraphs, and has different labels respectively. The maximum, mean length of training data is 1005 and 55.28 in words perspective, and 90% of training data are shorter than 95 words. The ratio of positive samples is only 9.48% in subtask 1, even much smaller in subtask 2, since some of PCL category such as "The poorer, the merrier" is quiet few. The shortage of positive samples makes the model more difficult to distinct the PCL descriptions from negative samples, and is hard to train a model with good generalization.

4.2 Parameter settings

Our implementation is based on the Pytorch framework for transformer-based models Wolf et al. (2020). We trained our model based on the pre-trained DEBERTA-v3-large model. We use Adam/RecAdam optimizer with a learning rate of 3e-5, batch-size of 32 to train our models. The max sequence length is 256 and the epoch of training is set to 10 in subtask 1, 3 in subtask 2. To address the over-fitting problem, we apply RecAdam with sigmoid annealing function, where the annealing rate is 0.01 and the annealing time-step is 500. Specially, in subtask 2, we apply one self-attention layer as the aggregator and one attention layer to calculate the label attention. We pick the best checkpoint based on the performance on the dev set. Besides using DEBERTA, we also trained models based on ROBERTA, which is competitive with DEBERTA on subtask 2.

Since only 2 submissions are permitted in submitting phase, we trained multiple models under different settings for model ensemble. We also adopt 7-fold cross-validation training to improve the system generalization.

4.3 Ensemble

Two strategies are used for our final submissions on test data: 1) we ensemble all 7 models from 7-fold cross-validation training by averaging their outputs, which is trained on the train data of each subtask; 2) we trained multiple models on the train data with different model structures. Eight top different models are selected based on the dev accuracy for models ensemble, then average their outputs as the final output.

5 Results and Analysis

5.1 Single Model Performance

In subtask 1, the F1-score of PCL is used as the official metric and the results of dev set is shown in Table 2. We implement a baseline model for comparison, which is the traditional classification model with pre-trained LMs by using the [CLS] embedding. We trained two traditional classification models which are based on ROBERTA and DEBERTA. The results shown that DEBERTA is better than ROBERTA for subtask 1. The prompt classification improved the F1-scores by 2.80% on the same pre-trained LM, which proved that prompt classification is more suitable with the pre-trained LMs.

In subtask 2, the official metric is the average score of F1-scores of all PCL categories. As shown in Table 1, our method achieves significant improvement compared with baselines. The ROBERTA and DEBERTA denote the baseline models which uses a multi binary classification head upon pre-train LMs. The MPrompt both improved the performance on ROBERTA and DEBERTA by 8.28%, 20.29%, respectively. The information of label names is utilized by MPrompt method effectively.

For Transfer Learning(TL), as shown in Table 1, the scores is improved by 3.62% based on DEBERTA, while is dropped by 3.17% based on ROBERTA. We assume that is because the structure of ROBERTA in subtask 1 is not suitable for MPrompt in subtask 2.

Label Attention(LA) is also proved to be an effective approach both on ROBERTA and DEBERTA. Since the transfer learning is not useful in ROBERTA, we further experiment the ROBERTA MPrompt with LA and the DEBERTA MPrompt

Method	Unb	Sha	Pre	Aut	Met	Com	Poo	avg-F1
ROBERTA	59.28	47.05	25.00	30.76	42.85	49.73	42.85	42.50
ROBERTA MPrompt	58.95	38.09	46.15	35.00	48.71	55.23	39.99	46.02
+TL	61.53	36.36	40.00	34.61	45.83	51.74	42.10	44.56
+LA	61.42	47.05	45.87	37.38	43.03	54.63	39.99	47.05
DEBERTA	55.24	29.16	34.28	25.28	45.45	49.26	19.99	36.95
DEBERTA MPrompt	57.14	40.54	32.81	30.76	44.44	52.77	52.63	44.45
+TL	57.65	29.63	43.10	39.34	60.67	47.61	44.44	46.06
+TL+LA	60.25	30.55	43.69	45.97	53.48	49.49	47.61	**47.29**

Table 1: Single model performance of subtask 2 on dev dataset, Unb...Poo denotes the F1-scores of each categories, avg-F1 is the average F1-score. TL denotes the Transfer Learning, and LA denotes the Label Attention.

Method	Acc	Recall	F1
ROBERTA	60.56	64.82	62.62
DEBERTA	66.67	61.31	63.87
DEBERTA Prompt	65.50	65.82	**65.66**

Table 2: Single model performance of subtask 1 on dev dataset.

	Method	Subtask1	Subtask2
Dev set	7-fold ensemble	-	-
	top ensemble	72.16	52.99
Test set	7-fold ensemble	**62.73**	**43.87**
	top ensemble	58.93	43.20

Table 3: Ensemble performance on dev and test dataset, where 7-fold is the models from 7-fold cross-validation training, top ensemble means that ensembles the models with top dev accuracy.

with TL and LA. The results shown that LA can improve the performance by 2.23% on ROBERTA, and 2.67% on DEBERTA, which proved that an external attention between tokens and label names is benefit for picking more important tokens related to the label category.

5.2 Ensemble Performance

The performances of ensemble models are shown on Table 3, which is obtained from the competition leader-board. Our system got the second place in subtask 2 and the ninth place in subtask 1. Ensemble results on dev dataset are exhibited for comparison. Since the 7-fold training has trained the dev set, we don't exhibit the dev ensemble results of 7-fold training. It is obvious that the top ensemble method is much over-fit on dev set, for the scores of test set dropped much on top ensemble method. 7-fold ensemble method is an effective way to avoid over-fitting and got the best test scores of our system.

In top ensemble, we also found that integrating different pre-trained models improves the results significantly. The top ensemble method will be more useful if the distribution of dev set and test set are similar.

6 Conclusion

In this paper, we propose a multi-prompt training with label attention mechanism to improve the performance of multi-label classification task. Pre-trained models have made great performance gain compared to traditional neural network models in many natural language tasks. The above experimental results may suggest that the current pre-trained model mechanism still has room for improvement in ABSA tasks.

Abstract

PCL detection task is aimed at identifying and categorizing language that is patronizing or condescending towards vulnerable communities in the general media. Compared to other NLP tasks of paragraph classification, the negative language presented in the PCL detection task is usually more implicit and subtle to be recognized, making the performance of common text-classification approaches disappointed. Targeting the PCL detection problem in SemEval-2022 Task 4, in this paper, we give an introduction to our team's solution, which exploits the power of prompt-based learning on paragraph classification. We reformulate the task as an appropriate cloze prompt and use pre-trained Masked Language Models to fill the cloze slot. For the two subtasks, binary classification and multi-label classification, DeBERTa model is adopted and fine-tuned to predict masked label words of task-specific prompts. On the evaluation dataset, for binary classification, our approach achieves an F1-score of 0.6406; for multi-label classification, our approach achieves an macro-F1-score of 0.4689 and ranks first in the leaderboard.

1 Introduction

Patronizing and Condescending Language (PCL) towards vulnerable communities in the media has become a hot issue, which is heatedly discussed in society at present. The language often refers to the discourse which is published with a mixture of pity and superiority towards unprivileged groups. Such attitude is always adopted unconsciously or even out of kindness, however, its negative effect indeed exacerbates social prejudice and routinizes discrimination towards disadvantaged people (Ng, 2007). Despite the PCL emerging in numerous media, its style can not be precisely captured by far, since the usage of PCL is commonly unintended, unaffected, and subjective. This poses many challenges to the detection of PCL, which attracts great attention from the NLP community. Even though there exist substantial NLP studies on paragraph identification in various fields, research specifically for PCL identification has not been yet seriously introduced (Pérez-Almendros et al., 2020). Nowadays with social discrimination continuously rising, an effective approach, which can automatically identify PCL towards vulnerable communities, becomes more and more necessary and important to our society.

To encourage more research on the PCL problem, SemEval-2022 Task 4 (Pérez-Almendros et al., 2022) provides an English PCL dataset for language-modeling study and evaluation. The main task contains two PCL-classification subtasks, one for binary classification (SubTask 1) and the other for multi-label classification (SubTask 2). Given a paragraph, SubTask 1 is aimed to identify whether or not it is written with PCL style. F1 over the positive class is taken as the evaluation metric of this task. For the same paragraph, the goal of SubTask 2 is to classify which specific PCL categories it belongs to. In detail, there are 7 different PCL types needed to be recognized, and one paragraph can have up to 7 PCL labels at the same time. For evaluation, SubTask 2 introduces macro F1 over the 7 classes as the metric.

In this paper, we propose our approach targeting PCL detection, which is submitted to SemEval-2022 Task 4. To tackle the sparsity and implicity issues of PCL language, we first reformulate the task as a specific form of cloze prompt, and then apply prompt-based learning on it to predict the appropriate label words and corresponding task labels. To take advantage of the pre-trained Language Model (LM), DeBERTa (He et al., 2020) is adopted as our based model, which improves BERT (Devlin et al., 2018) by introducing two novel techniques: disentangled attention and decoding enhanced masking.

[*] Corresponding Author

The same classification method and model architecture are used for both subtasks to train and predict. Experiments are conducted to show the effectiveness of our approach. At last, during the evaluation phase, our approach achieves an F1 score of 0.6406 on SubTask 1 (rank 4th on the leaderboard), and a macro-F1 score of 0.4689 on SubTask 2 (rank 1st on the leaderboard).

2 Related Work

Condescending and patronizing treatment is a controversial social problem, which attracts attention from researchers of various fields (Margić, 2017; Huckin, 2002). To the NLP community, although extensive work on detecting different kinds of harmful language is presented, the targeted language styles are often explicit, aggressive, and flagrant, which can be perceived obviously. Unlike the previously studied language, the style of PCL language can not be easily sensed, since the usage of PCL is commonly unintended, unaffected, and subjective, which makes it a challenging identification problem. In recent years, more and more researchers (Mendelsohn et al., 2020; Sap et al., 2019) start researching this emergent NLP topic, but the room for progress is still large.

Paragraph classification is a basic and important NLP task, which has been continuously studied by industry and academia. Applications based on paragraph classification are increasingly permeating our lives, such as spam filtering (Kumar, 2020) and text sentiment analysis (Gao et al., 2019). Traditional classification models, such as SVM (Joachims, 1998) and XGBoost (Chen and Guestrin, 2016), predict the category of paragraph mainly based on the statistical features extracted from raw text data. With the appearance of BERT (Devlin et al., 2018), many researchers (Croce et al., 2020; Jin et al., 2020) achieve success on paragraph classification, by utilizing the contextualized word vectors of pre-trained language models.

In recent years, with the development of prompt-based learning (Schick and Schütze, 2020b,a; Brown et al., 2020), researchers start reformulating the paragraph classification problem as a masked language modeling problem. Unlike the traditional models, prompt-based models first predict the label word of mask in a prompt and then map the label word to the label of category by a verbalizer. Thanks to the power of pre-trained language models, prompt-based models (Hu et al., 2021; Gu et al., 2021) demonstrate their strength in performing few-shot or even zero-shot learning on the scenarios of paragraph classification with few or no labeled data. The above studies have shown that prompt-based learning is highly effective to solve the problem of paragraph classification. To study the effect of prompt-based learning on identifying paragraphs of PCL, in the rest of this paper, our modeling method and experimental analysis are introduced.

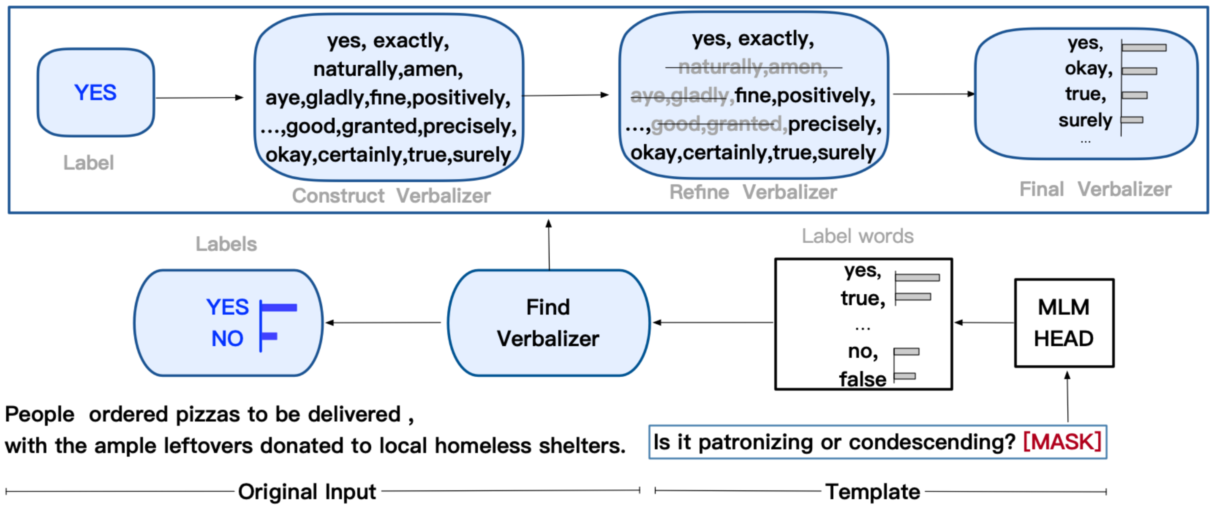
3 Our Approach

In this section, we present our approach to utilize prompt-based learning for PCL detection. We first give the overall paradigm of our model and then introduce the ensemble strategy used in this task.

3.1 Prompt-Based Model

Unlike other traditional classification methods which take original text as input, the prompt-based classification method first wraps the original text with some specific-designed template and then feeds the synthesized text into a language model for classification. In this way, the paragraph classification problem is reformulated into a masked language modeling problem. Formally, let $x = (x_0, x_1, ..., x_n)$ be a raw paragraph with a length of n from the PCL dataset, T be a prompt template and x^T be the reformulated paragraph of x using T. For an example of SubTask 1 shown in Fig 1, with x = *"People ordered pizzas to be delivered , with the ample leftovers donated to local homeless shelters."* and T = *"Is it patronizing or condescending? [MASK]"*, we wrap them into x^T as *"People ordered pizzas to be delivered , with the ample leftovers donated to local homeless shelters. Is it patronizing or condescending? [MASK]"*.

After the PCL problem is reformulated, an LM model M can be used to compute the probability of each word v in a vocabulary list to appear in the position of [MASK], denoted as $P([\text{MASK}] = v|x^T)$. To answer the cloze question *"Is it patronizing or condescending? [MASK]"*, if M has a large probability to fill [MASK] with some words of the meaning related to *"YES"*, then x is predicted as PCL class; if words having similar semantics to *"NO"* are more likely to be filled, then x is deemed as non-PCL class. In order to map the probabilities of predicted words to the probabilities of the labels *"YES"* and *"NO"*, we define a verbalizer to map a word v, from the label word set V_y, to a label y, form the label set Y. To construct the verbalizer,



YES
Label
yes, exactly, naturally,amen, aye,gladly,fine,positively, ...,good,granted,precisely, okay,certainly,true,surely
Construct Verbalizer
yes, exactly, ~~naturally,amen,~~ ~~aye,gladly,~~fine,positively, ...,~~good,granted,~~precisely, okay,certainly,true,surely
Refine Verbalizer
yes, okay, true, surely ...
Final Verbalizer
Labels
YES
NO
Find Verbalizer
Label words
yes, true, ... no, false
MLM HEAD
People ordered pizzas to be delivered , with the ample leftovers donated to local homeless shelters.
Is it patronizing or condescending? [MASK]
Original Input
Template

Figure 1: An example to illustrate our approach.

we first use synonym dictionaries to find the synonyms of labels as the candidate label words, and then we select the top-k candidate words, according to their usage frequency in public corpora, as the final label words. Assuming that all label words of the same label contribute equally to label prediction and the prior distribution of them is uniform, we use the mean of their predicted probabilities as the output probability of their corresponding label. Then, given a reformulated paragraph x^T, its predicted label $\hat{y}$ can be obtained by

$$\hat{y} = \arg\max_{y \in Y}\left(\frac{1}{|V_y|}\sum_{v \in V_y} P([\text{MASK}] = v|x^T)\right)$$

With the above definitions, in the training process, a cross-entropy loss is applied to fine-tune the model M as our output model.

In SemEval-2022 Task 4, for the two subtasks, we use the same method to model and solve them. The only difference is the template used for each subtask. For the binary-classification subtask, only one template is provided to identify whether or not a paragraph is PCL class. For the multi-label-classification subtask, as there exist 7 PCL categories, each of them is given with a unique template for type detection.

3.2 Ensemble Strategy

To improve the robustness of the proposed approach, we take advantage of the cross-validation to make our model more stable and reliable. We randomly split the original PCL dataset into 10 parts, each of which has 1/10 samples of the dataset. According to the hold-one-out strategy, 10 folds of the data can be acquired, and each fold has 9/10 samples for training and 1/10 samples for validation. During the training process, the best-trained model for each fold is saved, and the average output probability of all models is taken as the final prediction score. According to the score, each instance is assigned with a predicted label, and then the predicted labels are compared with the golden labels to compute the F1 score for validation. The best models acquired in the validation process are kept for the final online evaluation.

4 Experiment

4.1 Settings

The PCL dataset (Pérez-Almendros et al., 2020) containing 10,469 paragraphs is shared by both SubTask 1 and SubTask 2. The goal of SubTask 1 is to detect 993 PCL samples from the whole dataset, and the goal of SubTask 2 is to classify the 993 PCL samples into 7 specific PCL types. In our experiments, all trials are performed with Nvidia Tesla A100 and large-DeBERTa is used as the based pre-trained language model. Considering the small size of the task data, we take AdamW as the optimizer in the experiments with a learning rate of 1e-5 and a maximum epoch number of 10. Early-Stop strategy is also used in our training process. For other parameters, we set the batch size as 16 and the maximum sequence length as 256.

4.2 Used Strategies

For the sake of result analysis, we list all strategies used in our approach towards SemEval-2022 Task

Strategy	SubTask 1			SubTask 2		
	R	P	F1	macro-R	macro-P	macro-F1
CLS	61.7%	61.0%	61.4%	41.7%	41.1%	41.3%
Prompt	62.2%	61.8%	61.9%	44.3%	44.7%	44.4%
Prompt + Ensemble	63.0%	61.6%	62.3%	46.6%	46.3%	46.4%
Prompt + Ensemble + R-Drop	63.1%	62.0%	62.5%	46.7%	46.4%	46.5%
Prompt + Ensemble + R-Drop + EDA	63.3%	63.0%	63.1%	46.6%	48.2%	47.5%

Table 1: Experimental Results on SubTask 1 and SubTask 2

4 as the following.

- **Prompt:** Prompt strategy is the method described in Section 3.1.
- **Ensemble:** Ensemble strategy is the method described in Section 3.2.
- **CLS:** We directly feed the original text into DeBERTa model and apply a softmax layer on the CLS token for classification. This method is used as a comparison strategy, which does not reformulate the classification problem.
- **EDA:** (Wei and Zou, 2019) is a method of data augmentation, which introduces 4 operations, synonym replacement, random insertion, random swap, and random deletion, to boost performance on paragraph classification.
- **R-Drop:** (Wu et al., 2021) is a method to regularize dropout, which minimizes the bidirectional KL-divergence between the distributions of two sub-models sampled by dropout, to reduce model randomness.

4.3 Results and Analysis

Table 1 shows all strategy results with Precision, Recall, and F1. From the results, the effect of each strategy we used can be clearly observed. The last method including all Prompt, Ensemble, EDA and R-Drop performs best compared to other settings.

To show the superiority of the Prompt paradigm, we first compare it with CLS, which uses the traditional paradigm of classification. From the table, it can be seen that Prompt leads CLS by about 0.5% F1 score in SubTask 1 and 3.1% macro-F1 score in SubTask 2. As Prompt has natural advantages on few-shot learning and the size of the PCL dataset is small, such result is not out of expectation. With the limited training data, to avoid the occurrence of overfitting and improve the robustness of our model, we then apply Ensemble strategy to the learning process. As shown in the table, with the robustness improved, a 0.4% increase of F1 score is achieved in SubTask 1. And for SubTask 2, the improvement is larger with a 2% increase of macro-F1 score, since the data size of each category in SubTask 2 is far less than 1/10 of that in SubTask 1. To further enhance model robustness, R-Drop is also adopted in our approach, which aims to reduce the randomness generated by the dropout module of network. Though the performance improvement of R-Drop is not big, the stability and convergence of our approach increases, making the results of repeated trials more similar.

Besides the techniques of modeling, we also try to improve the learning by increasing the quantity of the training data. As described in the previous sections, the size of the training data is small and PCL language is often written in an implicit style. Therefore, EDA strategy is performed to augment the PCL data, which replaces implicit words with their synonyms, and transforms the structure of paragraphs variously, to produce more data for training. With the augmented data, our approach achieves a 0.6% lift of F1 score on SubTask 1 and a 1% lift of macro-F1 score on SubTask 2.

5 Conclusion

In this paper, we propose a prompt-based learning approach for PCL detection, based on pre-trained language models. To reformulate the PCL detection problem into a masked language modeling problem, how our prompt template is designed have been fully discussed. We also introduce several other techniques, which have a positive impact on prompt-based learning. Through experimental comparison, our approach is proven as an effective solution to detect PCL language. As a result, in SemEval-2022 Task 4, our approach ranks 4th on the leaderboard of SubTask 1, and ranks 1st on the leaderboard of SubTask 2.

DH-FBK at SemEval-2022 Task 4: Leveraging Annotators' Disagreement and Multiple Data Views for Patronizing Language Detection

Abstract

The subtle and typically unconscious use of patronizing and condescending language (PCL) in large-audience media outlets undesirably feeds stereotypes and strengthens power-knowledge relationships, perpetuating discrimination towards vulnerable communities. Due to its subjective and subtle nature, PCL detection is an open and challenging problem, both for computational methods and human annotators. In this paper we describe the systems submitted by the DH-FBK team to SemEval-2022 Task 4, aiming at detecting PCL towards vulnerable communities in English media texts. Motivated by the subjectivity of human interpretation, we propose to leverage annotators' uncertainty and disagreement to better capture the shades of PCL in a multi-task, multi-view learning framework. Our approach achieves competitive results, largely outperforming baselines and ranking on the top-left side of the leaderboard on both PCL identification and classification. Noticeably, our approach does not rely on any external data or model ensemble, making it a viable and attractive solution for real-world use.

1 Introduction

Detecting patronizing and condescending language (PCL) is an open, challenging, and underexplored research area in natural language processing (Pérez-Almendros et al., 2020; Wang and Potts, 2019). A patronizing and condescending attitude is expressed as a good-natured and beneficial attitude from a person of authority towards others, who are typically depicted in a subtly compassionate way (Pérez-Almendros et al., 2020).

PCL is a mildly perceived phenomenon. It is often unconscious, driven by good intentions, and expressed through *flowery wordings* (Wong et al., 2014; Huckin, 2002). This makes PCL identification and classification difficult both for NLP systems and human annotators (cf. Figure 1), as it cannot be linked to specific words. Nonetheless,

Figure 1: Example showing that patronizing and condescending language is a subtle linguistic phenomenon that human annotators (a_1, a_2) often perceive differently, and thus annotate in different ways.

it undesirably conveys harmful messages in many ways, as it promotes stereotypes, and a superiority and discriminatory mindset (Fiske, 1993). This is particularly damaging when used by large-audience media outlets, since it drives greater exclusion of already vulnerable communities (Pérez-Almendros et al., 2020). Automatically detecting PCL has the potential to enable a range of applications and research directions, such as suggestion tools for news editors to mitigate condescension in writing before publication, and studies on the interplay between condescension and sociodemographic factors.

To encourage research on patronizing and condescending language detection, the SemEval-2022 Task 4 (Pérez-Almendros et al., 2022) has recently been proposed. The shared task aims at investigating methods for the identification of PCL (subtask 1; Figure 1, top) and the categorization of the linguistic techniques which are used to express it (subtask 2; Figure 1, bottom) on English news stories mentioning vulnerable communities (Section 2).

In this paper, we present the **DH-FBK** entry for the SemEval-2022 Task 4 (Pérez-Almendros et al., 2022). Motivated by the subtle nature of

Example	Category
“We can be extremely proud of the current women winemakers”	Unbalanced power relations
“The inclusion of a refugee team”	Shallow solution
“An immigrant to a developed country lives in two worlds”	Presupposition
“women must wake up”	Authority voice
“trapped in the prison of poverty”	Metaphor
“more than 400 suspected asylum seekers are awaiting their fate”	Compassion
“how talented disabled people can be”	The poorer, the merrier

Table 1: Examples of text excerpts expressing patronizing and condescending language, along with their category.

patronizing language and the subjectivity of human interpretation, we propose a multi-task, multi-view learning approach which leverages annotators' uncertainty and disagreement as auxiliary tasks (Section 3) in judging for PCL presence (subtask 1) or category (subtask 2). Further, we investigate the effectiveness of sequentially fine-tuning on subtasks of increasing complexity (subtask 1 $\mapsto$ subtask 2), as well as the use of additional information such as the geographical provenance of news outlets.

Our systems achieve competitive results on the SemEval-2022 Task 4, outperforming the organizers' RoBERTa (Liu et al., 2019) baseline by a large margin (subtask 1: $+8.8$ F_1; subtask 2: $+26.9$ F_1) and consistently ranking on the top-left side of the leaderboard (subtask 1: 18th out of 78 teams; subtask 2: 13th out of 49 teams) without using any external data or ensemble strategy, making it a viable solution for real-world use. We make our code publicly available to the research community to encourage future work on this direction.[1]

2 Data and task description

In this section, we present relevant details on data and the associated shared task. We firstly summarize the dataset (Section 2.1) and describe the task setup (Section 2.2). Next, we focus on the data annotation process as it is central for understanding our methods (Section 2.3).

2.1 “Don't Patronize Me!” data

The organizers of SemEval-2022 Task 4 provide participant teams with the “Don't Patronize Me!” annotated dataset, originally introduced in Pérez-Almendros et al. (2020) and further updated for the purpose of the shared task (v1.4). The dataset comprises a selection of 10,469 paragraphs published in the news of 20 English-speaking countries[2] from all over the world between 2010 and 2018, and sampled from the “News on Web” corpus (NoW; Davies, 2013). Each paragraph mentions one of ten selected vulnerable communities (i.e., *disabled*, *homeless*, *hopeless*, *immigrant*, *in need*, *migrant*, *poor families*, *refugee*, *vulnerable*, and *women*). These communities have been chosen because they are often target of PCL. Notably, attention has been paid to balance paragraphs across communities and news outlets' countries. For further details, we refer to Pérez-Almendros et al. (2022, 2020).

2.2 Task setup

The SemEval-2022 Task 4 challenge is divided into the following two subtasks:

1. **PCL identification**: given an input paragraph, identify whether it entails any form of PCL. Formally, this is a binary classification task;

2. **PCL classification**: given an input paragraph, decide what linguistic techniques are used to express the condescension (if any). This is a multi-label classification task, with 7 possible labels – i.e., *unbalanced power relations* (UNB), *shallow solution* (SHA), *presupposition* (PRE), *authority voice* (AUT), *metaphor* (MET), *compassion* (COM), and *the poorer, the merrier* (THE). These categories follow a validated PCL taxonomy (Pérez-Almendros et al., 2020) that we summarize in Appendix A. Examples for each category are in Table 1.

As PCL is a subtle and mild phenomenon, the annotation process was not straightforward (Pérez-Almendros et al., 2020). In the following section, the annotation scheme followed by dataset creators

[1]The source code is available at `https://github.com/dhfbk/pcl-detection-disagreement`.

[2]Covered English-speaking country codes: au, bd, ca, gb, gh, hk, ie, in, jm, ke, lk, my, ng, nz, ph, pk, sg, tz, us, and za.

Annotation task	Individual decisions (a_1,a_2)	Score	Instances	Gold label
Subtask 1: *"Does the paragraph contain any form of PCL?"* Values: $0, 1, 2$	(0,0)	0	8,529	NO
	(0,1), (1,0), *	1	947	
	(1,1), *	2	144	YES
	(2,1), (1,2), *	3	458	
	(2,2)	4	391	
Subtask 2: *"Which PCL category does the span express (if any)?"* Values: $c_i, c_j \in C$, NONE	(c_i, NONE), (NONE, c_i)	1	1,359	c_i
	$(c_i, c_j)_{c_i \neq c_j}$, $(c_j, c_i)_{c_j \neq c_i}$			c_i, c_j
	(c_i, c_i)	2	1,401	c_i

Table 2: The annotation process from individual annotators' decisions to gold labels for both subtasks. For subtask 1, two annotators (a_1, a_2) assigned value 0 (no PCL), 1 (mild PCL) or 2 (high PCL) to each instance of the dataset. The "Score" column indicates the sum of their decisions. In subtask 2, the annotators further characterized the PCL instances of subtask 1, by identifying exact text spans and determining categories of the PCL (if any). We generalize with $c_i, c_j \in C$ two of the $|C| = 7$ possible PCL categories which annotators could have chosen, to show the process in case of disagreement. The "Score" column indicates the number of annotators which agreed on the category. *Includes cases of total disagreement – i.e., (0,2) and (2,0) – resolved by a third annotator a_3.

is presented, as it is especially relevant for understanding the data itself and our methods.

2.3 Annotation process

The dataset has been manually labeled by expert annotators[3] following a two-step process as described below. The resulting annotations are the gold-standard reference for the subtasks (Section 2.2).

Subtask 1 The annotation was performed by three annotators. Two annotators labeled the whole dataset (a_1 and a_2), while a third one (a_3) intervened in case of clear disagreement between a_1 and a_2. Authors reported that "*this annotation step proved more difficult than expected, stemming from the often subtle and subjective nature of PCL*" (Pérez-Almendros et al., 2020). Because of this difficulty, annotators were given the possibility to assign each paragraph a value 0 (no PCL), 1 (borderline), or 2 (highly PCL). Information about the annotation is available as a 5-point scale, which reflects a joint notion of uncertainty and agreement between annotators. For subtask 1, organizers map values into a binary form (i.e., $\{0, 1\} \mapsto$ NO-PCL, $\{2, 3, 4\} \mapsto$ PCL), evaluating systems accordingly. As anticipated, cases of total disagreement (i.e., a_1: 0 and a_2: 2, and viceversa) received a third independent annotation by a_3.[4] If a_3 considered the paragraph not to contain PCL, a borderline case, or an otherwise clear PCL case, the paragraph was assigned a value of 1, 2 or 3, respectively. This has the effect to leave extreme values (0 and 4) reserved for clear-cut cases. The number of PCL-expressing paragraphs is 993 (9.5%). A summary of the annotation process for subtask 1 is in Table 2, top.

Subtask 2 In the second round of annotation, paragraphs previously labeled as containing PCL were further characterized by a_1 and a_2. The aim is two-fold: (i) identify the paragraph segments (or spans) that express PCL, and (ii) categorize each of them into one or more PCL categories (cf. Section 2.2). As a consequence, each identified span exhibits one or multiple labels, depending on whether one or both annotators identified it, and on their agreement on the type(s) of condescension expressed by the text segment. This results in a per-span per-type agreement information on a 2-point scale (1 or 2). Organizers frame subtask 2 as a paragraph-level classification problem, and thus each paragraph can express zero or more condescension types based on the resulting 2,760 span annotations (2.8 annotations per paragraph, on average). An overview of the annotation process for subtask 2 is presented in Table 2, bottom.

3 Methods

Models proposed for PCL identification and classification are all based on multi-task learning (Caruana, 1997) and use multiple views of input data, inspired by Clark et al. (2018). In this section, we firstly introduce the general framework on which all our models are based on (Section 3.1).

[3] Dataset authors reported the annotators' background is on the fields of communication, media, and data science.

[4] According to the first dataset release, these account for 5.5% of the annotations (Pérez-Almendros et al., 2020).

Then, we provide details on data- and task-specific components that we use in our systems, namely dataset views (Section 3.2) and auxiliary tasks (Section 3.3). Lastly, we present the composition of our final models (Section 3.4).

3.1 General framework

Our approach is based on multi-task learning, a learning paradigm that aims to leverage training signals of related tasks at the same time by exploiting a shared representation in the model (Caruana, 1997). In all our models, we employ a *main* task, namely PCL identification or classification, which is a task of direct interest. Additionally, we employ *auxiliary* tasks (see Section 3.3), namely tasks which can provide useful signals to potentially improve the performance on the main task.

All our models use RoBERTa-base (Liu et al., 2019) as shared encoder, and a separate decoder for each task. This way, all tasks benefit from mutual signals encoded by a shared contextualized representation that is jointly fine-tuned during training.

The input is a text instance that is encoded using byte-pair encoding (BPE; Sennrich et al., 2016), whereas the output label is given by task-specific decoders which consist of a linear classification layer and operate on the contextual embedding of the special `[CLS]` classification token.

In our models, each auxiliary task makes use of a specific form (or view) of the original dataset, which we introduce in the following (Section 3.2). When training with multiple views of data, each input batch to the model consists of examples from a single data view, and the loss function is only activated for tasks associated to that data view. For further details on multi-view (or multi-dataset) training, refer to van der Goot et al. (2021). An overview of the framework is presented in Figure 2.

3.2 Data views

Our models employ different forms (or views) of the original "Don't Patronize Me!" dataset provided by organizers. Specifically, we use (i) paragraph and (ii) span views as detailed as follows.

Paragraph data view (D_P) This corresponds to the dataset in its standard form – i.e., whole paragraphs – as provided by organizers (Section 2.1).

Span data view (D_S) A dataset consisting of all text excerpts – i.e., paragraph substrings – that have been marked as expressing patronizing and condescending language. As a result, this dataset represents a different view of D_P data, where only snippets of PCL are included. Examples of text instances in D_S are reported in Table 1.

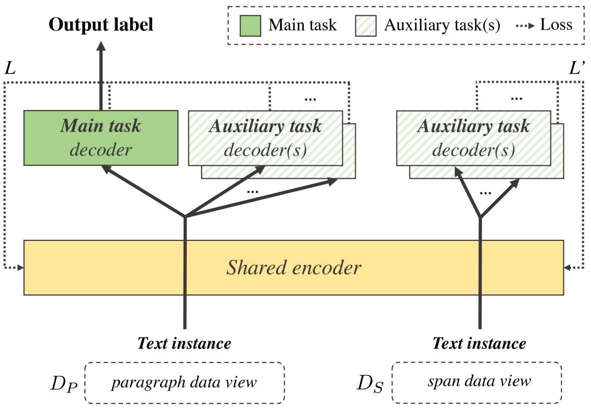

Figure 2: A high-level overview of our multi-task, multi-view learning framework.

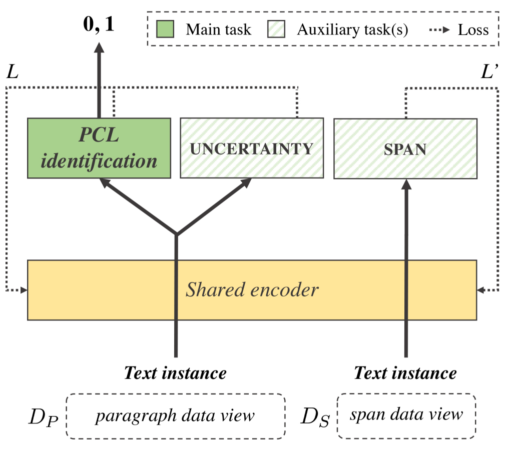
These different data views are used by specialized task decoders, as presented in Section 3.3.

3.3 Auxiliary tasks

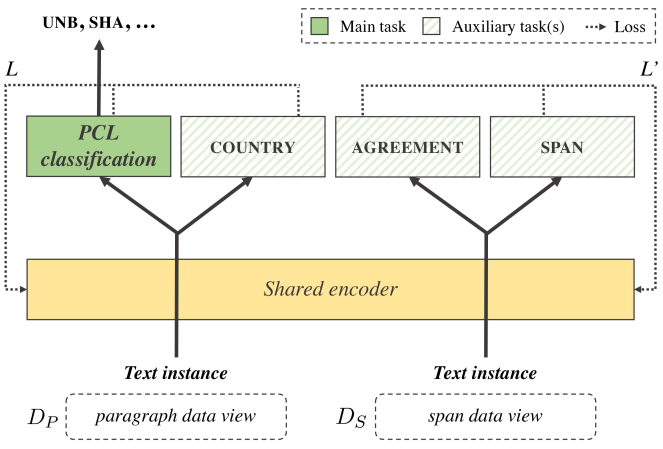
In this section, we describe the auxiliary tasks we used in one or more of our final models (Section 3.4), along with the data view each task uses. For details on the interplay between main and auxiliary tasks, we refer the reader to Section 4.1.

Paragraph uncertainty level (UNCERTAINTY) This task is used for subtask 1 to consider different annotators' point of view in identifying PCL. We use the aggregated 5-point scale score (cf. Section 2.3, subtask 1) assigned to each paragraph as auxiliary task. Although disaggregated annotators' decisions have not been made available for the shared task, we argue that the combined annotation provided by organizers can be viewed as a joint notion of uncertainty and agreement between annotators in identifying PCL, and is thus valuable information that can inform PCL identification. Since this is a paragraph-level information, this auxiliary task uses the D_P data view. For each paragraph, a label $l \in \{0, 1, 2, 3, 4\}$ must be predicted.

Span agreement level (AGREEMENT) This task is used for subtask 2 as it potentially drives useful signals for PCL classification. We hypothesize that the number of annotators which agree on a particular PCL category for a span (cf. Section 2.3, subtask 2) is a crucial information as it can provide the main task with different shades of PCL based on annotators' interpretation and sensibility. The



(a) MTMW(UNC+SPAN) model for subtask 1.



(b) MTMW(AGR+COU+SPAN) model for subtask 2.

Figure 3: Our selected models for PCL identification (subtask 1) and classification (subtask 2).

agreement level is a span-level information, and thus we use the D_S view for the associated task. For each span, a label $l \in \{1, 2\}$ must be predicted.

Span categorization (SPAN) This auxiliary task is used for both subtask 1 and 2, as we argue that making use of small and focused units of information such as condescending text excerpts would be useful to inject knowledge in the encoder about which paragraph segments are important for recognizing PCL. The task uses the D_S data view, and for each span a label $l \in \{$UNB, SHA, PRE, AUT, MET, COM, THE$\}$ has to be predicted (i.e., one among the condescending types in Section 2.2).

News outlet country (COUNTRY) We employ this auxiliary task for our subtask 2 model.[5] We hypothesize that the diverse background culture of countries results in variation in language use, and thus could have an impact on the expression of patronizing and condescending language. The news outlet provenance is provided by organizers along with the original dataset. The auxiliary task uses the D_P view, and the label to be predicted is a country code, i.e., $l \in \{$au, bd, ca, gb, gh, hk, ie, in, jm, ke, lk, my, ng, nz, ph, pk, sg, tz, us, za$\}$.

3.4 Models

Our approaches to PCL identification and classification are all centered on the hypothesis that leveraging annotators' uncertainty and disagreement during training is beneficial for capturing the subtle language which characterizes PCL. This is in line with recent work emphasizing the importance of modeling annotators' disagreement in subjective tasks (Davani et al., 2022; Leonardelli et al., 2021; Uma et al., 2021) and initiatives supporting the release of disaggregated annotations in NLP (Abercrombie et al., 2022).

We participated in the SemEval-2022 Task 4 challenge with two submissions for both subtasks. To this end, we built three models. Two models are our best systems – as evaluated on the development set (cf. Section 4.3) – on subtask 1 (Section 3.4.1) and subtask 2 (Section 3.4.2). We submit them for the corresponding subtasks. The third model was instead built aiming at a generic and unified solution, and represents our second submission for both subtasks (Section 3.4.3).

3.4.1 MTMW(UNC+SPAN) model for PCL identification (subtask 1)

In this multi-task, multi-view model (MTMW), we consider PCL identification as the main (binary classification) task, and employ UNCERTAINTY and SPAN as auxiliary tasks, as described in Section 3.3. We refer to this model to as MTMW(UNC+SPAN). An overview of the resulting approach for PCL identification is presented in Figure 3a.

3.4.2 MTMW(AGR+COU+SPAN) model for PCL classification (subtask 2)

In this multi-task, multi-view model (MTMW), the main task is PCL classification, whereas AGREEMENT, COUNTRY and SPAN are auxiliary tasks. For PCL classification, each label is modeled through a dedicated binary classification decoder. We use MTMW(AGR+COU+SPAN) to refer to this approach in the remainder of this paper. We graphically

[5]We have experimented with this auxiliary task on subtask 1 too; however, we noticed a substantial performance degradation compared to using uncertainty only (cf. Section 4.3).

present the model in Figure 3b, and refer the reader to Section 3.3 for details on auxiliary components.

3.4.3 Sequential PCL identification and classification (subtasks 1 & 2)

Given that PCL classification is a fine-grained version of the PCL identification task, we argue that sequentially fine-tuning encoder weights on tasks of increased complexity should be beneficial to improve the performance on both subtasks. This approach borrows the idea from modern data-centric adaptation methods in NLP (Ramponi and Plank, 2020) such as continued pretraining of language models (Gururangan et al., 2020), however employing it at the fine-tuning stage, similarly to intermediate-task transfer (Phang et al., 2018).

We firstly run the PCL identification model described in Section 3.4.1. Then, we use the resulting fine-tuned encoder weights as initialization for the encoder of the PCL classification model (Section 3.4.2) with SPAN auxiliary only.[6] Finally, we fine-tune it on subtask 2. This results in a single model that has incrementally learnt the complexity of PCL detection as a whole. Prediction of labels for subtask 1 were done simply considering a paragraph as containing PCL if it exhibits at least a PCL category label in subtask 2. We refer to this approach to as SEQ. FINE-TUNING model.

4 Experiments

In this section, we first outline the experimental setup (Section 4.1). Then, we present the results of our models (Section 4.2), as well as additional analyses and discussion (Section 4.3).

4.1 Experimental Setup

We implemented our models using the MaChAmp v0.2 toolkit (van der Goot et al., 2021) and employ RoBERTa-base (Liu et al., 2019) as shared encoder since it has been shown to outperform other commonly used pretrained language models on PCL detection tasks (Pérez-Almendros et al., 2020).

For training, we use default hyperparameters (Appendix B) and fine-tune each model – roughly 110M trainable parameters – for 10 epochs on a single GPU.[7] We use a cross-entropy loss with balanced class weights to give equal importance to all classes during fine-tuning, and thus emphasizing underrepresented classes in training data. The multi-task learning loss is computed as $L = \sum_t \lambda_t L_t$, where L_t is the loss for task t, and λ_t the corresponding weighting parameter. In our experiments, we empirically set $\lambda_t = 1$ for the main task, and $\lambda_t = 0.25$ for auxiliary tasks.[8]

We solely rely on data provided by organizers, and use the provided 80% train and 20% development split as one fold, additionally creating the remaining 80%/20% splits in a stratified fashion. To avoid confounding our results, we ensure training splits for the span data view do not contain any text excerpt appearing in development data of the paragraph data view. This results in 5 folds that we use for selecting models for our submissions. For official test set evaluation, we then submit the selected models trained on the provided data split.

For the purpose of the shared task, models for PCL identification (subtask 1) are evaluated using F_1 score over the positive class, whereas models for PCL classification (subtask 2) are evaluated based on macro-average F_1 score. We employ the same metrics at the model selection stage.

	P	R	F_1
Organizers' baseline	39.35	65.30	49.11
MTMW(UNC+SPAN)	64.23	52.68	**57.89**
SEQ. FINE-TUNING	53.99	55.52	54.74

Table 3: Official test set results of our models compared to the organizers' RoBERTa baseline on PCL identification (subtask 1). P: Precision; R: Recall; F_1: F_1 score over the positive class. Best results are in bold.

4.2 Results

We present the official results for our proposed models for subtask 1 and 2 in Table 3 and Table 4, respectively. We also include scores of the organizers' RoBERTa baseline for informed comparison based on the shared task metrics.

Subtask 1 As shown in Table 3, our submitted MTMW(UNC+SPAN) model outperforms the RoBERTa baseline by a large margin, with most of the benefit coming from the precision metric. This indicates that the uncertainty and agreement

[6]This choice is motivated by the need for a simpler and unified solution for both subtasks. We decided to leave country and agreement auxiliaries out for this submission due to negligible differences in performance on subtask 2 (Section 4.3).

[7]NVIDIA Tesla V100-SXM2.

[8]Except for AGREEMENT, for which we empirically set $\lambda_t = 0.125$ since it is actually *auxiliary of an auxiliary task*. A thorough investigation on the impact of the weighting parameter on individual auxiliary tasks is left for future work.

	UNB	SHA	PRE	AUT	MET	COM	THE	F_1
Organizers' baseline	35.35	0.00	16.67	0.00	0.00	20.87	0.00	10.41
MTMW(AGR+COU+SPAN)	52.46	36.22	26.95	**37.71**	**31.86**	**45.95**	**30.30**	**37.35**
SEQ. FINE-TUNING	**54.00**	**46.73**	**28.07**	22.22	29.73	44.28	20.69	35.10

Table 4: Official test set results of our models compared to the organizers' RoBERTa baseline on PCL classification (subtask 2). UNB: Unbalanced power relations; SHA: Shallow solution; PRE: Presupposition; AUT: Authority voice; MET: Metaphor; COM: Compassion; THE: The poorer, the merrier; F_1: macro-average F_1. Best results are in bold.

level as well as the use of focused text excerpts do play a positive role in PCL identification. On the other hand, while also the SEQ. FINE-TUNING approach provides better results compared to the baseline, it scores lower than MTMW(UNC+SPAN). A reason for this behavior can be attributed to the way we infer labels for this subtask (i.e., based on predictions for subtask 2, as anticipated in Section 3.4.3), or due to *catastrophic forgetting* (McCloskey and Cohen, 1989), a phenomenon in which prior knowledge is largely forgotten when learning a new task. On the shared task leaderboard, MTMW(UNC+SPAN) ranked 18th out of 78 teams.

Subtask 2 Similarly to results for subtask 1, both our submitted systems largely outperform the RoBERTa baseline, as shown in Table 4. We notice that the SEQ. FINE-TUNING approach still scores lower than a tailored approach for subtask 2, i.e., MTMW(AGR+COU+SPAN). Specifically, MTMW(AGR+COU+SPAN) shows an absolute improvement of +26.9 points in macro-average F_1 score over the RoBERTa baseline, with a clear advantage over the SEQ. FINE-TUNING model on underrepresented classes (i.e., AUT, MET and THE). Our MTMW(AGR+COU+SPAN) model ranked 13th out of 49 participating teams on the official leaderboard. Overall, our models do not require any external data or model ensemble, and we think this makes them viable approaches for real-world use.

4.3 Analysis and discussion

In order to provide insights for future work on PCL detection, we conduct analyses on the contribution of auxiliary tasks to performance of our models (Section 4.3.1), and an in-depth study on the role of uncertainty and disagreement (Section 4.3.2).

4.3.1 Contribution of auxiliary tasks

Our submitted models for PCL identification and classification leverage training signals coming from selected auxiliary tasks (cf. Section 3.4). These

	Model	F_1 score
subtask 1	Our single task baseline	$56.73_{\pm 3.2}$
	Multi-task setup	
	+ COUNTRY	$55.99_{\pm 2.7}$
	+ UNCERTAINTY	$56.92_{\pm 3.2}$
	+ COUNTRY, UNCERTAINTY	$57.74_{\pm 3.5}$
	Multi-task, multi-view setup	$55.69_{\pm 2.0}$
	+ COUNTRY	$57.35_{\pm 1.9}$
	+ UNCERTAINTY	$\mathbf{58.38}_{\pm 3.7}$
	+ COUNTRY, UNCERTAINTY	$57.53_{\pm 4.6}$
subtask 2	Our single task baseline	$37.02_{\pm 2.8}$
	Multi-task setup	
	+ COUNTRY	$36.26_{\pm 2.3}$
	Multi-task, multi-view setup	$38.25_{\pm 3.6}$
	+ COUNTRY	$37.16_{\pm 2.3}$
	+ AGREEMENT	$37.53_{\pm 0.8}$
	+ COUNTRY, AGREEMENT	$\mathbf{38.81}_{\pm 2.9}$

Table 5: Contribution of auxiliary tasks to performance of models for subtask 1 (top) and subtask 2 (bottom). We report mean and standard deviation of F_1 scores on development splits. The multi-task, multi-view setups use SPAN by default. Results for AGREEMENT and its combinations in the multi-task setup of subtask 2 are omitted, since they would require the D_S view, and thus only refer to the multi-task, multi-view configuration.

model variants have been chosen after a thorough performance evaluation on the development splits. In Table 5 we report the mean and standard deviation of F_1 scores for each model with different auxiliary task configurations. We denote with "Our single task baseline" our baseline RoBERTa model with no multi-task nor multi-view learning. Note that this is different from organizers' RoBERTa baseline, since we employ a different hyperparameter setup with the addition of class weights (Section 4.1). We do not include the organizers' baseline here due to incomparability –

we only have access to results on a single development split. For reference, organizers reported 48.29 F_1 on subtask 1, and 13.40 F_1 on subtask 2 for their baseline. Multi-task setups refer to configurations where D_P-based auxiliaries are used, whereas multi-task, multi-view setups also exploit the D_S view, thus using SPAN as default auxiliary task on all experiments.

Subtask 1 Table 5 (top) shows the results of models with different auxiliary task combinations on subtask 1 development data. All multi-task, and multi-task multi-view setups outperform the baseline, with the only exception of the multi-task configuration solely using COUNTRY as auxiliary task. Overall, the use of UNCERTAINTY as auxiliary task consistently improves the performance over the baseline, even when coupled with other auxiliaries. The best results are obtained when employing a multi-task, multi-view setup with UNCERTAINTY only (58.38 F_1), suggesting that information coming from the COUNTRY auxiliary is not as useful as in the multi-task scenario. We hypothesize this behaviour could be attributed to the use of SPAN in the multi-task, multi-view setup, which indirectly provides a more useful inductive bias for PCL identification. In future work we aim to further dig into this aspect, exploring various loss weight configurations to assess the strength of this finding.

Subtask 2 We present in Table 5 (bottom) the contribution of auxiliary tasks on subtask 2 development data. Similarly to subtask 1, COUNTRY in the multi-task setup is the only auxiliary task that does not improve the performance over our single task RoBERTa baseline. However, when coupled with AGREEMENT in the multi-task, multi-view configuration, it provides the best overall performance over all model variants (38.81 F_1). This suggests that the AGREEMENT auxiliary provides signals orthogonal to COUNTRY, as shown by the multi-task, multi-view alternatives employing these auxiliaries in isolation. By a closer look, the performance of the multi-task, multi-view setup alone (i.e., SPAN only) are highly competitive, confirming our hypothesis that using PCL-expressing text excerpts is beneficial for PCL detection as a whole.

4.3.2 Role of uncertainty and disagreement

To delve into the role of agreement and uncertainty, we further study performance of our best systems on subtask 1 and 2 as a function of the agreement/uncertainty level. To the goal, we use the predictions of our models on development splits.

level	0	1	2	3	4
F_1	49.27	44.67	27.32	33.39	41.95

Table 6: Performance of our model for subtask 1 as a function of different levels of uncertainty/disagreement. F_1 scores are averages over the five development splits.

Subtask 1 To investigate the impact of uncertainty/agreement on the performance of our model for subtask 1, we first divided each development split by uncertainty/agreement level (cf. "Score", Table 2, top). Then, we calculated the per-level F_1 score on each split. Finally, we averaged the per-level performance on all folds. We report the experimental results in Table 6. It is interesting to observe how in this task the uncertainty/agreement levels 0, 2 and 4 reflect agreement between annotators (0+0, 1+1, or 2+2), but performance for score 2 – where both annotators agree in being uncertain – is much worse. This suggests a prominent role of uncertainty in worsening classifier's performance, rather than disagreement. On the other hand, uncertainty and disagreement represent two sides of the same coin, as the less certain and clear a decision is, the greater probability is to have disagreement between annotators.

Subtask 2 We perform a similar analysis for subtask 2. The agreement level (cf. "Score", Table 2, bottom) has a clear effect on model's performance: out of the 2,760 PCL-expressing spans, only 44% of 1,359 spans with an agreement level of 1 are correctly labeled, compared to 56% of 1,401 spans for which both annotators signaled a form of PCL. Considering paragraphs with a single PCL-expressing span only, this results to 35% of 801 examples for agreement level 1, and 52% of 798 examples for agreement 2, further confirming that instances exhibiting disagreement are more difficult to classify.

5 Conclusion

In this paper, we presented our submitted systems to SemEval-2022 Task 4. We showed that leveraging annotators' uncertainty and disagreement during training in a multi-task, multi-view framework is beneficial for the identification and classification of patronizing and condescending language, and achieves competitive results on the official leaderboard without relying on any external data or model ensemble. We also showed that sequential fine-tuning is a viable alternative to tackle PCL identification and classification jointly, with the goal of reducing the use of computational resources during inference, although it obtains lower performance compared to our tailored solutions. A thorough analysis on the impact of diverse auxiliary tasks on the performance of our models for PCL detection, and an investigation on the role of uncertainty and disagreement further confirmed the importance of considering annotators' point of view in PCL detection. As future work, we aim to test the presence and assess the impact of spurious lexical biases in the dataset (Ramponi and Tonelli, 2022) and extend our models to other genres, such as social media (Wang and Potts, 2019). We hope this work will encourage future efforts towards annotators-centric NLP, on PCL detection and other subjective tasks more broadly.

Appendix

A PCL categories

In the following, we provide the precise definitions of the PCL categories according to Pérez-Almendros et al. (2020).

Unbalanced power relations "*By means of the language, the author distances themselves from the community or the situation they are talking about, and expresses the will, capacity or responsibility to help them. It is also present when the author entitles themselves to give something positive to others in a more vulnerable situation, especially when what the author concedes is a right which they do not have any authority to decide to give.*"

Shallow solution "*A simple and superficial charitable action by the privileged community is presented either as life-saving/life-changing for the unprivileged one, or as a solution for a deep-rooted problem.*"

Presupposition "*When the author assumes a situation as certain without having all the information, or generalises their or somebody else's experience as a categorical truth without presenting a valid, trustworthy source for it (e.g. a research work or survey). The use of stereotypes or cliches are also considered to be examples of presupposition.*"

Authority voice "*When the author stands themselves as a spokesperson of the group, or explains or advises the members of a community about the community itself or a specific situation they are living.*"

Metaphor "*[Metaphors] can conceal PCL, as they cast an idea in another light, making a comparison between unrelated concepts, often with the objective of depicting a certain situation in a softer way. [...] Euphemisms are considered as an example of metaphors.*"

Compassion "*The author presents the vulnerable individual or community as needy, raising a feeling of pity and compassion from the audience towards them. It is commonly characterized by the use of flowery wording that does not provide information, but the author enjoys the detailed and poetic description of the vulnerability.*"

The poorer, the merrier "*The text is focused on the community, especially on how the vulnerability makes them better (e.g. stronger, happier or more resilient) or how they share a positive attribute just for being part of a vulnerable community. People living vulnerable situations have values to admire and learn from. The message expresses the idea of vulnerability as something beautiful or poetic. We can think of the typical example of 'poor people are happier because they don't have material goods'.*"

Abstract

Patronizing and condescending language (PCL) has a large harmful impact and is difficult to detect, both for human judges and existing NLP systems. At SemEval-2022 Task 4, we propose a novel Transformer-based model and its ensembles to accurately understand such language context for PCL detection. To facilitate comprehension of the subtle and subjective nature of PCL, two fine-tuning strategies are applied to capture discriminative features from diverse linguistic behaviour and categorical distribution. The system achieves remarkable results on the official ranking, including 1st in Subtask 1 and 5th in Subtask 2. Extensive experiments on the task demonstrate the effectiveness of our system and its strategies.

1 Introduction

"*Don't worry, I know this is a mistake you usually make, we all make it sometimes, but I am bringing you a solution.*", which is a typical example of Patronizing and Condescending Language (PCL) (Giles et al., 1993; Huckin, 2002), shows a superior attitude and apparent kindness towards others, while is generally expressed unconsciously. The impact of PCL can potentially be very harmful, as it feeds inequalities and routinizes discrimination (Ng, 2007), especially if it is geared towards vulnerable communities in the media. If we are able to detect and identify when we are condescending or patronizing towards others, a corrective action (e.g., a more inclusive message) could be taken for a more responsible communication.

Recently, some works (Wang and Potts, 2019; Sap et al., 2020) on PCL are gradually emerging in NLP community. Remarkably, Pérez-Almendros et al. (2020) have shown that general pre-trained language models (Devlin et al., 2019; Liu et al., 2019) can achieve nontrivial performance. However, the behaviour of PCL is usually more unconscious, subtler, and subjective than other harmful types of discourse that are widely studied, i.e., hate speech (Basile et al., 2019), offensive language (Zampieri et al., 2019), intended sarcasm (Du et al., 2022), fake news (Zhang et al., 2021b) and rumor (Wei et al., 2021). These characteristics make PCL detection a difficult challenge, both for human judges and existing NLP systems.

To address this, we propose a novel Transformer-based model BERT-PCL (and its ensembles) with two **discriminative fine-tuning** strategies, to accurately understand such language context for PCL detection. The two strategies are grouped layer-wise learning rate decay (Grouped LLRD) and weighted random sampler (WRS), and both are beneficial for task-adaptive fine-tuning based on language models.

A brief description of these two strategies is as follows: **1)** As different layers capture different types of information (Yosinski et al., 2014), Grouped LLRD, a variant of LLRD (Howard and Ruder, 2018; Zhang et al., 2021a), is applied to group hidden layers of the pre-trained Transformer (Vaswani et al., 2017) into different sets and apply different learning rates to each in a certain extent. And then, we can make full use of different layers to capture more diverse and fine-grained linguistic features, which can boost understanding of the subtle and subjective nature of PCL. **2)** There is a quite common phenomenon that positive samples (patronizing or condescending) have a smaller number than the negative, which reflects usage rates of PCL in public forums (Wang and Potts, 2019; Pérez-Almendros et al., 2020). But the positive samples are more important when detecting PCL, due to the harmful impacts. To deal with imbalanced classes scenarios, we introduce WRS to place more emphasis on the minority classes. Under this strategy, our classifier can capture discriminative features from the categorical distribution and detect whether it contains PCL in an unbiased manner.

At SemEval-2022 Task 4 (Pérez-Almendros

et al., 2022), our proposed system achieves **1st in Subtask 1** and **5th in Subtask 2** on the evaluation leaderboard[1]. Meanwhile, in the post-evaluation phase, we further verified the results of the system on the test set of both subtasks. For Subtask 1, the single model BERT-PCL and its ensembles obtained **63.69%** and **65.41%** performance in terms of F1 of positive class, respectively. For Subtask 2, the single model BERT-PCL and its ensembles obtained **43.28%** and **45.66%** performance in terms of macro-average F1, respectively. Moreover, a series of experiments are conducted on the two subtasks of PCL detection. Results consistently demonstrate that our model and its ensembles significantly outperform comparison methods and the effectiveness of two strategies used in our system.

2 Background

2.1 Task and Data Description

The aim of SemEval-2022 Task 4 (Pérez-Almendros et al., 2022) is to identify PCL, and to categorize the linguistic techniques (categories) used to express it, specifically when referring to vulnerable communities in the media.

This challenge is divided into two subtasks, each corresponding to a subset of the *Don't Patronize Me!* (DPM) dataset (Pérez-Almendros et al., 2020). The 10,469 annotated paragraphs (i.e., sentences in context) from the DPM corpus are used as training data, where each paragraph mentions one or several predefined vulnerable communities. These paragraphs are collected using a keyword-based strategy and cover English language news sources from 20 different countries. A short description of the two subtasks and training data is as follows:

- **Subtask 1: Binary classification**. Given a paragraph, a system must predict whether or not it contains any form of PCL. The training set consists of 10,469 paragraphs annotated with a label ranging from 0 to 4. Label 2, 3, and 4 means positive examples (condescending or patronizing) of PCL and the remaining labels means negatives.

- **Subtask 2: Multi-label classification**. Given a paragraph, a system must identify the categories of PCL that are present. The 993 unique paragraphs (positive examples) in the training set, totaling 2,760 instances of PCL, are labeled with one or more PCL categories: *Unbalanced power relations*, *Shallow solution*, *Presupposition*, *Authority voice*, *Metaphor*, *Compassion*, *The poorer, the merrier*.

In addition, the test set for the evaluation phase contains around 4,000 manually annotated paragraphs with the PCL annotation scheme. More details about the task can be found on the competition page[2].

2.2 Related Work

Harmful language detection/recognition has been widely studied in various forms of discourse, such as hate speech (Basile et al., 2019), offensive language (Zampieri et al., 2019), intended sarcasm (Du et al., 2022), fake news (Zhang et al., 2021b) and rumors (Wei et al., 2021; Hu et al., 2021). Unlike these works generally focused on explicit, aggressive and flagrant phenomena, the study of patronizing and condescending Language (PCL) (Giles et al., 1993; Huckin, 2002; Chouliaraki, 2006; Margić, 2017) has been almost ignored in NLP community until recently.

To encourage more research on PCL language, Wang and Potts (2019) present a condescension detection task and provides a *TALKDOWN* dataset in comment-reply pairs from Reddit. Besides, Pérez-Almendros et al. (2020) introduce a *Don't Patronize Me!* dataset and the challenge of PCL detection towards vulnerable communities (e.g. refugees, homeless people, poor families). These works establish several advanced baselines using pre-trained language models (Devlin et al., 2019; Liu et al., 2019), and suggest that detecting such language is a challenging task both for humans and NLP systems due to its subtle and subjective nature.

3 System Overview

In this section, we review our system adopted in SemEval-2022 Task 4, where we design a novel Transformer-based model BERT-PCL (and its ensembles) with two discriminative fine-tuning strategies for both subtasks of PCL detection.

3.1 Model Architecture

BERT (Devlin et al., 2019) uses masked language models to enable pretrained deep bidirectional representations, and can be fine-tuned to create task-

[1] https://sites.google.com/view/pcl-detection-semeval2022/ranking

[2] https://competitions.codalab.org/competitions/34344

specific models with powerful performance (Wei et al., 2020; Hu and Wei, 2020). Inspired by this, our system utilizes Transformers (Vaswani et al., 2017) to learn contextual representations of the input sentence under the BERT-like architecture.

Formally, given an input token sequence $x_{i1}, ..., x_{iN}$ where x_{ij} refers to j-th token in the i-th input sample, and N is the maximum sequence length, the model learns to generate the context representation of the input token sequences:

$$\mathbf{h}_i = \text{BERT}([\text{CLS}], x_{i1}, ..., x_{iN}, [\text{SEP}]), \tag{1}$$

where [CLS] and [SEP] are special tokens, usually at the beginning and end of each sequence, respectively. $\mathbf{h}_i$ indicates the hidden representation of the i-th input sample, computed by the representation of [CLS] token in the last layer of the encoder.

3.2 PCL Detection

3.2.1 Subtask 1: Binary Classification

Subtask 1, a binary classification task, aims to predict whether or not a paragraph contains any form of PCL. After encoding, we apply a fully connected layer with the Softmax function to predict whether or not the input contains any form of PCL:

$$\hat{\mathbf{y}}_i = Softmax(\mathbf{W}\mathbf{h}_i + \mathbf{b}), \tag{2}$$

where $\mathbf{W}$ and $\mathbf{b}$ are trainable parameters. We leverage Cross-entropy loss to optimize the system. The objective function of Subtask 1 is defined as:

$$L = -\frac{1}{N}\sum_i (\mathbf{y}_i \log(\hat{\mathbf{y}}_i) + (1 - \mathbf{y}_i)\log(1 - \hat{\mathbf{y}}_i)) \tag{3}$$

where $\mathbf{y}_i$ is the ground-truth label of PCL.

3.2.2 Subtask 2: Multi-Label Classification

Subtask 2 is a multi-label classification task. Its goal is to determine which PCL categories a paragraph expresses. After encoding, we also apply a fully connected layer with the sigmoid function to predict the probability of each PCL class:

$$\hat{\mathbf{y}}_i^c = \sigma(\mathbf{W}^c\mathbf{h}_i + \mathbf{b}^c), \tag{4}$$

where σ is the sigmoid function. $\mathbf{W}^c$ and $\mathbf{b}^c$ are trainable parameters. We use Binary Cross Entropy (BCE) loss (Bengio et al., 2013) for the multi-label classification task, denoted as:

$$L = -\frac{1}{N}\sum_i \sum_{c=1}^{M} [\mathbf{y}_i^c \log(\hat{\mathbf{y}}_i^c) + (1 - \mathbf{y}_i^c)\log(1 - \hat{\mathbf{y}}_i^c)], \tag{5}$$

where M is the number of classes, $\hat{\mathbf{y}}_i^c$ indicates the predicted probability that the i-th sample belongs to the c-th class.

3.3 Fine-tuning Strategies

For discriminative fine-tuning of the model, we introduce two strategies to boost the accurate understanding of PCL context, namely grouped layer-wise learning rate decay (Grouped LLRD) and weighted random sampler (WRS).

3.3.1 Grouped LLRD

As different layers capture different types of information (Yosinski et al., 2014), they should be fine-tuned to different extents. Therefore, instead of using the same learning rate for all hidden layers of the Transformer, we tune each layer with different learning rates. Layer-wise learning rate decay (LLRD) (Howard and Ruder, 2018; Zhang et al., 2021a) is a popular fine-tuning strategy that applies higher learning rates for top layers and lower learning rates for bottom layers. Inspired by this, we group layers into different sets and apply different learning rates to each, denoted as Grouped LLRD.

Formally, we split all hidden layers of the Transformer into G sets with embeddings attached to the first set. The parameters of layers are denoted as $\{\theta^1, ..., \theta^G\}$, where θ^g refers to the g-th group. The corresponding learning rate values are denoted as $\{\eta^1, ..., \eta^G\}$, where η^g indicates the learning rate of the g-th group. To capture discriminative features, a multiplicative decay rate λ is used to change relative value of initial learning rates from adjacent groups in a controlled fashion. At time step t, the update of parameters θ is computed by:

$$\theta_t^g = \theta_{t-1}^g - \eta^g \cdot \nabla_{\theta^g} J(\theta), \tag{6}$$

where $\nabla_{\theta^g} J(\theta)$ is the gradient with regard to the model's objective function. The learning rate of the lower layer is applied as $\eta^{g-1} = \eta^g/\lambda$ during fine-tuning to decrease the learning rate group-by-group. In addition, same as LLRD, we use a learning rate that is slightly higher than the top hidden layer for the pooler head and classifier.

Under the above setting, we can capture more diverse and fine-grained linguistic features by flexibly optimizing different hidden layers of the Transformer. It can boost understanding of PCL's subtle and subjective nature.

3.3.2 Weighted Random Sampler

The PCL dataset is highly imbalanced, which causes problems for training the above models. To alleviate this imbalanced classes problem, we use a Weighted Random Sampler (WRS) to place more emphasis on the minority classes. The samples are weighted and the probability of each sample being selected is determined by its relative weight.

For both subtasks, the sampling weight of the i-th sample is computed by:

$$s_i = \begin{cases} 1/\sqrt{\kappa_p}, & \text{if it contains PCL,} \\ 1/\sqrt{\kappa_n}, & \text{otherwise,} \end{cases} \tag{7}$$

where κ_p and κ_n refer to the ratio of positive and negative examples of PCL in training data, respectively. Then, the elements are sampled based on the passed weights. It is worth noting that the number of samples is equal to the length of the training set. During training, the sampler tends to select samples from positive examples with small data volume. In this way, we can have positive and negative classes with equal probability. And the classifier can capture discriminative features from categorical distribution in an unbiased manner.

3.4 Ensemble

For the final submissions, we apply a voter-based fusion technique (Morvant et al., 2014) to ensemble several BERT-PCL models. Concretely, we train the proposed BERT-PCL with five different random seeds. Then, we select Top-3 models according to average result of k-fold cross-validation on the training data. Finally, results of the test set predicted by the three optimal models are voted to get the final submission.

4 Experimental Setup

4.1 Comparison Methods

We compare BERT-PCL and its ensembles with the following several methods:

- **Random** is based on random guessing, choosing each class/label with an equal probability.

- **BERT** (Devlin et al., 2019) is a language model pre-trained in a self-supervised fashion based on deep bidirectional transformers. We use *bert-base-uncased*[3] to initialize BERT.

- **ALBERT** (Lan et al., 2020) presents two parameter-reduction techniques to lower memory consumption and increase the training speed of BERT. We use *albert-large-v2*[3] to initialize ALBERT.

- **ERNIE 2.0** (Sun et al., 2020) is a continual pre-training framework, which builds and learns incrementally pre-training tasks through constant multi-task learning. We use *nghuyong/ernie-2.0-large-en*[3] to initialize ERNIE 2.0.

- **RoBERTa** (Liu et al., 2019) optimizes the training procedure of BERT and removes the next sentence predict objective when pre-training. We use *roberta-large*[3] to initialize RoBERTa.

4.2 Implementation Details

For both subtasks, stratified k-fold cross validation (Kohavi, 1995; Sechidis et al., 2011) is performed to split limited training data into 5 folds. We choose the optimal hyperparameter values based on the the average result of validation sets for all folds, and evaluate the performance of systems on the test data. BERT-PCL is initialized with the *roberta-large*[3] parameters, due to the nontrivial and consistent performance in both subtasks. Following Pérez-Almendros et al. (2020, 2022), the evaluation metrics are F1 over the positive class for Subtask 1 and macro-average F1 for Subtask 2.

We group layers into 3 groups, i.e., $G = 3$. The learning rate for layers in the lower, median, and higher groups as η/λ, η, and $\eta * \lambda$, respectively, where η is set to 1e-5. λ is a hyperparameter searched from $\{0.6, 1.6, 2.6, 3.6, 4.6, 5.6, 6.6\}$. For the training of BERT-PCL, the optimal value of $lambda$ is 1.6 for Subtask 1 and 3.6 for Subtask 2. The experiments are conducted with batch size of 4, maximum length of 250, and dropout rate of 0.4. The number of epochs is set to 10 and the maximum patience number of early stopping is set to 50 batches. AdamW optimizer (Kingma and Ba, 2015) is used with a weight decay of 0.01. A cosine annealing schedule (Loshchilov and Hutter, 2017) is applied to decay the learning rate, with a linear warmup for the first 10% steps.

To effectively utilize the country term and search keyword term corresponding to each paragraph in the corpus, we concatenate these terms with the original paragraph as the input sequence. In the

implementation, two special token pairs (i.e., <e> and </e>) are introduced as the term boundary.

5 Result and Discussion

5.1 Overall Result

The overall results in both subtasks are summarized in Table 1 and 2. Unsurprisingly, all pre-trained models clearly outperform the random baseline. The proposed BERT-PCL and its ensembles (i.e., Ensemble 1.0 and Ensemble 2.0) consistently obtain the best performance than the comparison methods on both subtasks. Specifically, BERT-PCL gains 1.09% and 5.39% absolute improvements for Subtask 1 and 2, respectively. These results show the superiority of our models.

In Table 1, both Ensemble 1.0 and Ensemble 2.0 are fused by three optimal full BERT-PCL models with different seeds and obtain a better performance than BERT-PCL in Subtask 1. In Table 2, Ensemble 1.0 is fused by the three optimal BERT-PCL that removes WRS, since we found that it is worse when performing WRS according to weights of category label in Subtask 2. Different from it, in the post-evaluation phase, we perform WRS according to weights of positive samples (patronizing or condescending) and fuse three optimal full BERT-PCL as Ensemble 2.0. As shown in Table 2, Ensemble 2.0 obtains a better performance than BERT-PCL and Ensemble 1.0 in Subtask 2.

Then, we qualitatively analyze the performance of BERT-PCL and typical baselines on the validation set for both subtasks. The results are illustrated in Figure 1. From the figure, BERT-PCL consistently obtains the best performance on the validation set for both subtasks, which confirms again the superiority of the proposed method.

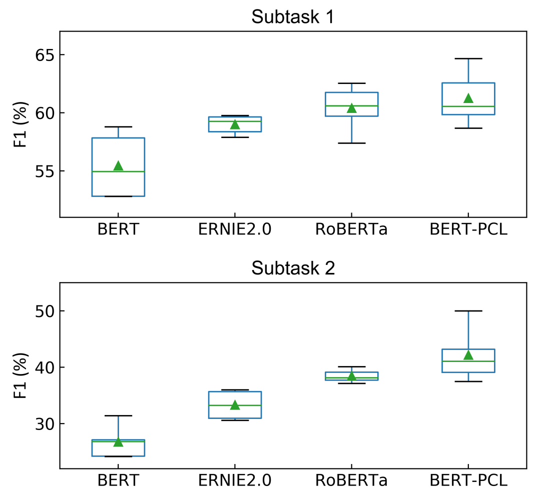

Figure 1: Results on the validation set for both subtasks. The box displays the distribution of results where the green triangle indicates the mean of results, the green line and two blue lines represent the 25%, 50%, and 75% quartiles, respectively, and black lines are the maximum and minimum values. For Subtask 1, we report F1 score of the positive class; and for Subtask 2, we list macro-average F1 score.

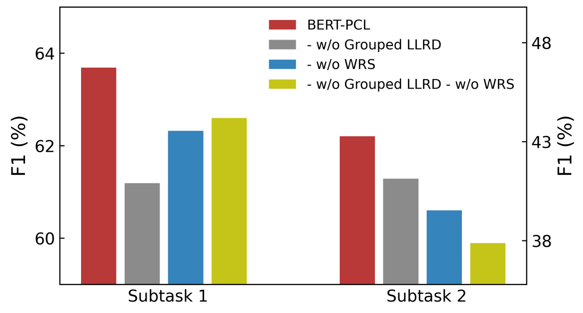

Figure 2: Results of ablation study for PCL detection. For Subtask 1, we report F1 score of the positive class; and for Subtask 2, we list macro-average F1 score.

5.2 Ablation Study

We conduct ablation studies by removing key components of BERT-PCL: 1) **- w/o Grouped LLRD** refers to removing the Grouped LLRD. 2) **- w/o WRS** refers to removing the WRS. 3) **- w/o Grouped LLRD - w/o WRS** refers to removing both Grouped LLRD and WRS, degenerated to RoBERTa.

Figure 2 shows results of ablation studies on two subtasks of PCL detection. The full model yields the best performance on both subtasks. When removing either Grouped LLRD or WRS, the results

Table 2: Results for the problem of categorizing PCL, viewed as a paragraph-level multi-label classification problem (Subtask 2). We report the per-class F1 and macro-average F1. All compared pre-trained model are fine-tuned on the task dataset. [†] indicates the results on the official ranking. The considered seven categories are *Unbalanced power relations* (unb.), *Shallow solution* (shal.), *Presupposition* (pres.), *Authority voice* (auth.), *Metaphor* (met.), *Compassion* (comp.) and *The poorer, the merrier* (merr.).

of variants decline significantly on both subtasks. Specifically, when only removing Grouped LLRD, the model achieves 2.50% and 2.14% degradation of performance in Subtask 1 and 2, respectively. When only removing WRS, the results decline by 1.37% and 3.74% in terms of F1 scores in Subtask 1 and 2, respectively. The above results consistently indicate the effectiveness of the two components.

When removing both components, the performance also decreases on both subtasks. Note that **- w/o Grouped LLRD - w/o WRS** achieves a better F1 score of the positive class than **- w/o WRS** or **- w/o Grouped LLRD** in Subtask 1. This can be explained that ignoring Grouped LLRD limits to explore diverse features of positive samples, and further removing WRS may magnify this limitation due to the imbalanced class problem. Therefore, the model with two modules removed yields slightly better results than ablation models with only one module removed. Different from Subtask 1, Subtask 2 is a multi-label classification problem and we report the macro-average F1 score. Using Grouped LLRD can capture diverse features of each category label in positive samples, and WRS according to weights of positive and negative samples further promotes the model's attention to positive samples. Hence, removing both modules obtains the worst performance in Subtask 2.

5.3 Parameter Analysis

In this part, we explore the performance of BERT-PCL against different λ in Grouped LLRD. Bottom groups often encode more general and broad-based information, while top groups closer to the output encode information more localized and specific to the task on hand. In our model, a suitable value λ can control and balance these different layers of the

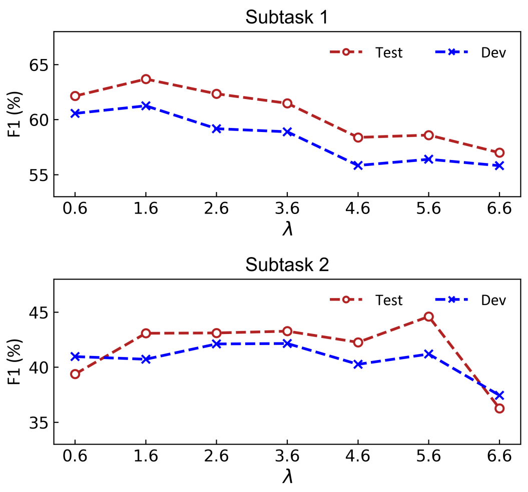

Figure 3: Results against different values of hyperparameter λ in Grouped LLRD on both test and validation sets. We report F1 score of the positive class for Subtask 1, and list macro-average F1 score for Subtask 2.

Transformer to capture different kinds of features from diverse linguistic behaviour.

The results are illustrated in Figure 3. Based on k-fold cross validation on training data, we find the local optimum of λ, 1.6 for Subtask 1 and 3.6 for Subtask 2, and the resulting model consistently performed excellently on the test set. Under the optimal setting, different layers in the model can capture more diverse and fine-grained linguistic features, enhancing the understanding of the subtle and subjective nature of PCL. However, larger λ would make the model overfit to small datasets and suffer catastrophic forgetting during fine-tuning. Hence, the performance degrades as λ increases.

It is worth noting that in when λ is up to 5.6 for Subtask 2, the model achieves suboptimal results on the validation set but performs exceptionally well on the test set. This may be because the model

5.4 Case Study

Table 3 and Table 4 show several typical examples in the training set from Subtask 1 and 2, respectively. Their gold labels and predictions by BERT-PCL, RoBERTa and ERNIE 2.0 are presented in the corresponding columns.

In Table 3, the first case is correctly classified by BERT-PCL, while is misclassified by other methods. We can easily observe that this example has the characteristics of *Unbalanced power relations* and *Authority voice*, and the language expression of the latter is more subtle. Unlike other methods, BERT-PCL can capture the linguistic phenomena of PCL through a discriminative fine-tuning process, and thus detect them correctly. For the second, BERT-PCL and RoBERTa can accurately identify the positive paragraphs, using the sentence representation ability learned by the pre-trained model. The latter two examples are consistently predicted as false negatives and false positives by all methods, respectively. We notice that both paragraphs have been annotated by two human annotators as borderline PCL. Unsurprisingly, these methods also struggle to detect such cases.

As seen in Table 4, only BERT-PCL can correctly determine fine-grained PCL categories of the first two cases, which again illustrates the superiority of our method. It can be noticed that the third example has three PCL sub-categories (i.e., unb., pres., met.) with a certain internal correlation, and the gold label (i.e., merr.) of the fourth example appears too little in the training set. These phenomena increase the difficulty of identifying the two examples, which leads to wrong predicted labels. We believe that identifying multiple related sub-categories simultaneously and controlling the imbalance of positive PCL labels are urgent challenges for Subtask 2.

6 Conclusion

In this paper, we propose an advanced BERT-like model and its ensembles to accurately understand and detect patronizing and condescending language. Based on the pre-trained Transformer, we apply two fine-tuning strategies to capture discriminative features from diverse linguistic behaviour and categorical distribution. At SemEval-2022 Task 4, our system achieves 1st in Subtask 1 and 5th in Subtask 2 on the official ranking. Extensive experiments demonstrate the effectiveness and superiority of the proposed system and its strategies.

ASRtrans at SemEval-2022 Task 4: Ensemble of Tuned Transformer-based Models for PCL Detection

Ailneni Rakshitha Rao
Indian Institute of Technology, Gandhinagar
rao_ailneni@alumni.iitgn.ac.in

Abstract

Patronizing behavior is a subtle form of bullying and when directed towards vulnerable communities, it can arise inequalities. This paper describes our system for Task 4 of SemEval-2022: Patronizing and Condescending Language Detection (PCL). We participated in both the sub-tasks and conducted extensive experiments to analyze the effects of data augmentation and loss functions used, to tackle the problem of class imbalance. We explore whether large transformer-based models can capture the intricacies associated with PCL detection. Our solution consists of an ensemble of the RoBERTa model which is further trained on external data and other language models such as XLNeT, Ernie-2.0, and BERT. We also present the results of several problem transformation techniques such as Classifier Chains, Label Powerset, and Binary relevance for multi-label classification.

1 Introduction

In this paper, we discuss various linguistic techniques used for detecting Patronizing and condescending language (PCL). This task particularly poses a new challenge in the field of NLP because of its subjectivity, subtle usage, and requirement of world knowledge. A person is said to be condescending or patronizing when he/she uses a superior tone to talk down to people or tries to raise pity by describing their situation. Even though people often use PCL with good intentions, it encourages stereotyping, discrimination and leads to greater exclusion. Therefore, it is important to devise methods that facilitate the automatic detection of PCL. SemEval 2022 Task 4 (Pérez-Almendros et al., 2022) is the first attempt to detect the usage of PCL towards vulnerable communities. It has two subtasks: In sub-task A, we need to detect if the given paragraph contains PCL or not. Sub-task B aims to classify PCL text further among potential intersecting categories.

The two main challenges faced in this task are extreme class imbalance in the dataset and the subtle nature of PCL present in the text which makes it hard, even for humans to classify it correctly. Also, the model needs to differentiate between actual news of extremely vulnerable situations from text containing PCL.

Pre-trained language models such as BERT, XLNeT, etc., have emerged as the state-of-the-art models for many NLP tasks such as text classification, machine translation, sequence tagging, etc. However, they are trained on typical day-to-day texts. PCL text is not trivial and classifying certain classes requires some level of world knowledge and commonsense reasoning. In this paper we conduct detailed experiments using the following models: RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2020), Ernie-2.0 (Sun et al., 2019), BERT-large (Devlin et al., 2019), label specific attention network (LSAN) (Xiao et al., 2019) and their ensembles for PCL detection. Additionally, we test the Classifier Chain approach for multi-label classification.

We achieved significant improvement over the baseline RoBERTa model in both the sub-tasks. We were ranked 52^{nd} with an F1 score of 0.4421 in sub-task A and 33^{rd} with an F1 score of 0.1889 in sub-task B among 81 teams. We release the code for models and experiments via GitHub [1]

The rest of the paper is organized as follows: Section 2 describes the challenge, followed by a brief literature survey. Section 3 explains the proposed approach in detail, while section 4 presents the experimental details required to reproduce the results. Results and analysis are shown in section 5. Finally, conclusions are drawn in section 7.

2 Background

2.1 Problem Description

SemEval 2022 Task 4: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022) is a paragraph-level text classification problem that consists of two sub-tasks. **Task A** is a binary classification task designed to predict if the text consists of any form of PCL. In **task B**, we need to further classify PCL text among potential categories namely *unbalanced power relations*, *shallow solution*, *presupposition*, *authority voice*, *metaphor*, *compassion*, and *the poorer the merrier*.

2.2 Related Work

Hate language detection Though the detection of patronizing and condescending language has not been studied in depth in the field of NLP, extensive work has been done in several forms of harmful language detection such as Automated hate speech detection (Davidson et al., 2017), rumor propagation (Gorrell et al., 2019), fake news detection (Conroy et al., 2015), and trust-worthiness prediction (Barrón-Cedeño et al., 2018). However, recently (Wang and Potts, 2019) introduced a labeled dataset named *TalkDown* derived from Reddit communication threads for modeling condescension. (Sap et al., 2020) introduced *Social Bias Inference* corpus to study the unbalanced power relations present in the condescending language.

Multi-label text classification There are mainly three different techniques to solve a multi-label text classification problem: Binary Relevance, Classifier Chains (Dembczyński et al., 2010) and Label Powerset method (Boutell et al., 2004). Binary Relevance treats each class independently and ignores label dependence. The Label Powerset method considers each combination of labels as a distinct class, thereby transforming a multi-label classification problem into a single-label problem. (Chen et al., 2007) propose document transformation by assigning label weights based on label entropy. (Alvares-Cherman et al., 2012) tries to incorporate label dependency into the Binary Relevance method. ReliefF and Information Gain are combined with Binary Relevance and Label Powerset approaches in (Spolaôr et al., 2013) to evaluate the importance of each label. (Wang et al., 2017) show that regularising the model during the training phase and using support inference during prediction along with F-optimizer improves the F1 score of the multi-label problem.

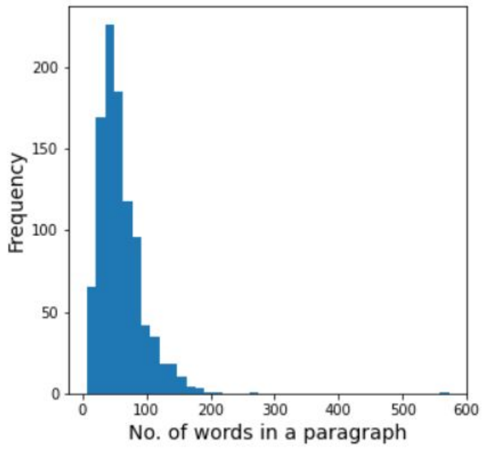

Figure 1: Frequency distribution of the text length.

Label	No. of samples
Unbalanced power relations	230
Shallow solution	716
Presupposition	196
Authority voice	224
Metaphor	469
Compassion	197
The poorer, the merrier	40

Table 1: Distribution of training data for Task B.

Transfer Learning Pre-trained transformer-based language models such as BERT, RoBERTa, etc., often outperform many traditional models trained from scratch. This success can be attributed to their rich contextual embeddings. Therefore, these models are used for many downstream tasks. (Li and Xiao, 2020) use SpanBERT for the detection of propaganda techniques in news articles. (Ranasinghe and Hettiarachchi, 2020) use BERT-based multilingual models for offensive language identification in social media.

3 System Overview

3.1 Data

The *Don't Patronize Me!* dataset (Pérez-Almendros et al., 2020) provided as training data for both the sub-tasks consists of paragraphs extracted from the News on Web (NoW) corpus. The distribution of different labels in the dataset is shown in table 1. Each training example in sub-task A consists of a *doc-id*, *keyword*, *country-code*, *paragraph*, and *label*. The text was retrieved from the news of 20 English-speaking countries based on 10 keywords belonging to vulnerable communities like disabled, homeless, etc. The frequency distribution of text

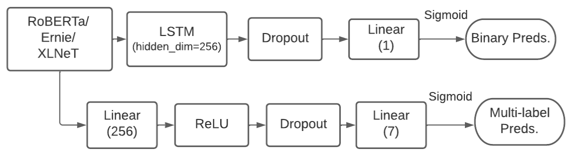

Figure 2: Flow chart for multi-task learning.

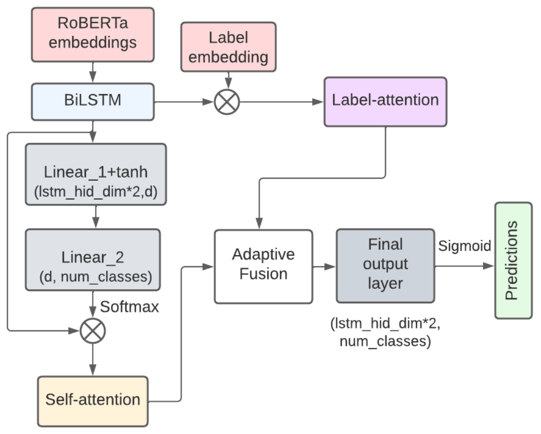

Figure 3: Architecture of LSAN.

length is shown in figure 1. The dataset for task B contains span-level annotation of PCL among seven categories mentioned earlier.

3.2 Transformer-based models

Our approach is to train several pre-trained language models including RoBERTa, Ernie-2.0, XLNet, and BERT-large individually and in an ensemble with different problem transformation approaches for both the sub-tasks. We conduct experiments with two different settings: Multi-task and single-task learning. The model used for multi-task learning is described in figure 2.

3.2.1 Using External data

A RoBERTa model is further trained using the HuggingFace library with metaphor and condescension datasets since the language and content present are similar to our training dataset. This improves the accuracy of the contextual embeddings. We extracted around 7000 text instances for training RoBERTa from the talk-down corpus (Wang and Potts, 2019), MOH corpus (Mohammad et al., 2016), VUA dataset (Steen et al., 2010) and Trofi dataset (Birke and Sarkar, 2006). We call this trained model as tuned RoBERTa (tRoBERTa) for the entirety of this paper.

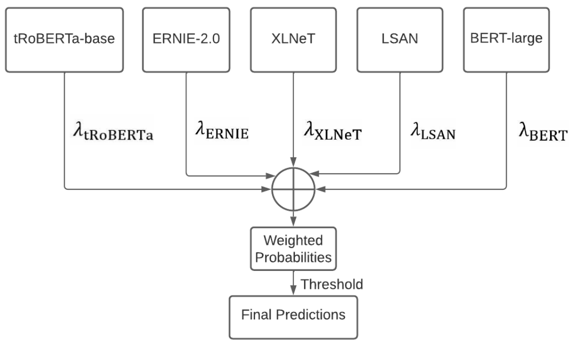

Figure 4: **Weighted-Average Ensemble**. $\lambda_{RoBERTa}$, λ_{ERNIE}, λ_{XLNeT}, λ_{LSAN}, and λ_{BERT} represent the weights of the respective models.

3.3 Label-Specific Attention Network

For sub-task B, in conjunction with transformer-based models, we used LSAN (Label-Specific Attention Network) (Xiao et al., 2019) for multi-label classification. LSAN tries to determine the label-related text from the given paragraph. It has two parts: self-attention and label-attention as shown in the figure 3. Self-attention aims to calculate the contribution of each word to a particular label. While it takes into account the context of the given text, the semantic meaning of labels themselves is captured by label-attention. The importance of these two mechanisms is determined by two trainable fully connected layers. Finally, an MLP layer with Sigmoid activation is used to get the final output.

3.4 Ensembles

Large Language models differ in the training procedures and the datasets on which they are trained. Hence, they may focus on different aspects of the input text even though they give comparable results. Therefore, it is a good practice to combine the results of these language models to get accurate word / sentence embeddings. There are several ways to combine them: we can concatenate embeddings of different models and project them to a low dimensional space for prediction, but this will require high computational power. Instead, we can tune different language models (tRoBERTa, ERNIE, XLNeT, LSAN and BERT) independently on the entire dataset and later combine their predictions as shown in the figure 4. Final results are obtained by taking a weighted average of the predictions. In this case, the weights are obtained by

Model	**Task B**							
	UPR	**SS**	**PS**	**AV**	**M**	**C**	**PM**	**Avg. F1**
Baseline	0.3535	0	0.1667	0	0	0.2087	0	0.1041
Ours	0.186	0.0875	0.0826	0.198	0.1324	0.2784	0.3571	0.1889
Ours*	0.1413	0.1706	0.0594	0.2086	0.2297	0.2874	0.238	0.1904

Table 2: Comparison of test results our models with baseline RoBERTa model for sub-task B. UPR: Unbalanced power relations, SS: Shallow solution, PS: Presupposition, AV: Authority voice, M: Metaphor, C: Compassion, PM: The poorer the merrier.

Model	**Task A**		
	Precision	**Recall**	**F1 score**
Baseline	0.3935	0.653	0.4911
Ours	0.3558	0.5836	0.4421
Ours*	0.5389	0.5678	0.5530

[*] Modified System after submission and not submitted in the task.

grid search on the validation dataset. Another way to combine the predictions is the Voting Ensemble method, where the class predicted by the majority of the models is considered as the final output. We tested both approaches and found that the weighted average method yields better results than the voting ensemble method.

3.5 Classifier Chains

The classifier Chains approach connects binary classifiers in a chain such that the output of one classifier is treated as the input feature for the subsequent classifier. One of the factors that influence the performance of classifier chains is the sequence of labels used for training. The sequence of labels can be decided based on various approaches such as easiest-to-predict labels, most frequent labels first, etc. We tested the path 1–> 2 –> 6–> 7–> 4–> 5–> 3 based on the first approach. In the end we used an ensemble of the paths, 1–> 2–> 3–> 4–> 5–> 6–> 7 (P1) and 1–> 2–> 6–> 7–> 4–> 5–> 3 (P2).

4 Experimental setup

We used Pytorch (Paszke et al., 2019) and HuggingFace library (Wolf et al., 2019) for training and inference. All the models are trained on Google Colab. AdamW (Loshchilov and Hutter, 2019) optimizer with a learning rate of 2e-5 is used for training all transformer-based models and Adam is used for training all the other models. The maximum length of the text is limited to 200. We chose a batch size of 32 for training all the models.

4.1 Text preprocessing

We cleaned the text by removing punctuation, special characters, URLs, etc. We removed the contractions by mapping them to regular text and annotated the sentences with a [CLS] token before passing them into transformer-based models. We did not remove the stopwords as it deteriorated performance. We augmented the data based on contextual augmentation proposed in (Kobayashi, 2018) and back-translation technique.

4.2 Loss functions

We trained our model for sub-task A with binary cross-entropy loss, whereas for sub-task B we used focal loss. Focal loss (Lin et al., 2020) is a form of cross-entropy loss, but it is dynamically scaled. It is computed as:

$$FL(p_t) = (1 - p_t)^{\gamma} \log(p_t)$$

By setting $\gamma > 0$, we are reducing the relative loss for easy, well-classified examples ($p_t > 0.5$). For prediction, we used a threshold of 0.35.

4.3 Training details

We split the original training data into train and development sets with 80% and 20% of the data respectively. For Sub-task A, we used *Stratified-ShuffleSplit* option from *sklearn* library to split the dataset whereas for Sub-task B we used *iterative stratification* of order 1 from *skmultilearn* library. In the case of multi-task models, we used early stopping criteria on dev set independently for each task.

5 Results and Analysis

Our model for sub-task A consists of an ensemble of tuned RoBERTa (tRoBERTa), XLNet, and Ernie-2.0 models trained with binary cross-entropy

Model	Task A	Task B
Ernie-2.0 (ST)	0.535	0.498
tRoBERTa (ST)	0.537	0.503
XLNeT (ST)	0.539	0.500
LSAN	-	0.493
BERT-large	-	0.497
Avg. Ensemble (ST)	0.538	0.502
tRoBERTa (MT)	0.541	0.505
ULMFiT (ST)	0.510	0.487
tRoBERTa (CC with P1)	-	0.548
tRoBERTa (CC with P2)	-	0.550

Table 4: F1 score (Dev) of the other major models for both the sub-tasks. ST stands for single-task models, MT stands for multi-task models, CC stands for Classifier Chains with paths P1, P2 and Avg. Ensemble is the weighted average ensemble method.

Model	Task A	Task B
HAHNN (CNN)	0.530	0.493
C-BiLSTM	0.500	0.485
USE + BiLSTM	0.520	0.485
SVM (word n-grams)	0.486	0.469
SVM (ELMO)	0.492	0.475
SVM (char n-grams)	0.485	0.462
SVM (composite)	0.489	0.471
LR (ELMO)	0.485	0.465
RF (ELMO)	0.484	0.470

Table 5: Results of RNN-based and ML models.

loss. Model for sub-task B consists of a weighted average ensemble of tRoBERTa, XLNet, Ernie-2.0, BERT-large, and LSAN trained with focal binary cross-entropy explained in section 4.2. We also tested the Classifier Chain approach with tuned RoBERTa in post-evaluation phase. For this approach, we tested two sequences of labels P1, P2 (described in 3.5) and their ensemble. The official results of the models for sub-task A and sub-task B along with the baseline results on the test dataset are summarized in table 3 and 2 respectively. Apart from these models, the results of other major transformer-based models are shown in table 4.

Besides transformer-based models, we also tested Hierarchical Attentional Hybrid Neural Networks for Document Classification described in (Abreu et al., 2019), C-BiLSTM model, and a BiLSTM-attention model with USE (Cer et al., 2018) sentence embeddings. In the C-BiLSTM model, we apply convolutional and max-over-time pooling layers on the word embeddings and pass them through a bi-LSTM layer with an attention mechanism. This approach is the combination of work used in (Wang et al., 2016) and (Yang et al., 2016). We implemented traditional machine learning models like Support Vector Machine (SVM), Logistic Regression (LR), and Random Forests (RF). We used TF-IDF on words (both unigrams and bigrams), TF-IDF on character n-grams (1-5 characters), ELMO embeddings (Peters et al., 2018) and the composite features utilized in (Anzovino et al., 2018) as features for the ML models. The composite features are a combination of features based on the adjective count, length of the text, n-grams, POS tags, and doc2vec (Le and Mikolov, 2014). The results of the above RNN-based and ML models are summarized in table 5.

The comparison among three different problem transformation approaches to Multi-label classification is shown in table 6. The Label Powerset (LP) method gives the lowest F1 score as it doesn't perform well with unseen label combinations not covered in the training dataset. Classifier Chain performed better than Binary relevance as it takes label correlations into account. Incremental analysis of our system is shown in table 7. This analysis shows the importance of further training RoBERTa and focal loss.

Data augmentation is widely used to generate slightly variant larger datasets from the existing smaller ones. Since one recurring issue among all the models we trained is overfitting, three types of data augmentation techniques are tested to address this issue. We applied contextual augmentation for labeled sentences as proposed in (Kobayashi, 2018). In this method, we replace the words in a sentence with words predicted by a bi-directional language model. We also tested the back-translation approach proposed in (Sennrich et al., 2016) and easy data augmentation (EDA) techniques described in (Wei and Zou, 2019). We observed that while back-translation and contextual augmentation slightly improved the performance of the model, the use of EDA degraded it. We conclude this is because of a contextual mismatch in the text generated with EDA. Since random deletion is one of the techniques used in EDA, it may have led to the deletion of the keywords like *'them'*, *'us'*, *'poor'* etc., resulting in bad performance.

As the training dataset provided for this task is small and extremely imbalanced, we focused on analyzing the effects of data augmentation and choice

Approach	F1 Macro
Label Powerset	0.479
Classifier Chain	0.506
Binary Relevance	0.492

Table 6: Results of various problem transformation approaches on Dev set.

System	Precision	Recall	F1
RoBERTa	0.529	0.515	0.521
+ Tuned RoBERTa	0.539	0.521	0.530
+ Focal loss	0.550	0.525	0.537
+ Ensemble	0.557	0.530	0.543

Table 7: Sub-task A (Dev): Incremental analysis of our system.

of the loss function in this paper. F1 score for the *the poorer the merrier* class has greatly improved even though it is the least represented class in the entire dataset. Also, the F1 score of the *metaphor* class has improved. This improvement is the result of tuned RoBERTa which is trained on metaphor datasets. *Shallow solution* and *presupposition* are the classes with the lowest F1 score. This is because they require some form of world knowledge. Surprisingly, even though *unbalanced power relations* is the easiest class to predict, our model seemed to struggle with it.

6 Conclusion and Future Work

We have presented the results of various experiments using pre-trained language models such as RoBERTa, XLNeT, Ernie-2.0, BERT-large, and their ensembles for the detection of patronizing and condescending language. For the sake of comparison, we also presented experimental results of several RNN-based and traditional machine learning models with different features such as character n-grams, ELMO embeddings, etc. We also conducted experiments with different problem transformation approaches like Classifier Chains for multi-label classification. Since the dataset for this task is imbalanced, we also tested the effect of several data augmentation techniques and loss functions. We have achieved sizeable improvements over the baseline model by task-specific training and using techniques to mitigate class imbalance. In future work, we plan to explore other forms of Classifier Chains to more effectively model label dependence and hierarchy.

radhika.mamidi@iiit.ac.in

Abstract

This paper presents our solutions for Task4 at SemEval2022: Patronizing and Condescending Language Detection. This shared task contains two sub-tasks. The first sub-task is a binary classification task whose goal is to predict whether a given paragraph contains any form of patronising or condescending language(PCL). For the second sub-task, given a paragraph, we have to find which PCL categories express the condescension. Here we have a total of 7 overlapping sub-categories for PCL. Our proposed solution uses BERT based ensembled models with hard voting and techniques applied to take care of class imbalances. Our paper describes the system architecture of the submitted solution and other experiments that we conducted. Our best performing models achieve an F1 score of 59.4 and 15.7 on sub-tasks 1 and 2 respectively.

1 Introduction

Patronizing and condescending attitude in language generally denotes the writer's sense of superiority over others. If someone is patronizing or condescending, it means what they write/say is accompanied by a sense of pity or compassion. Often, usage of PCL is relatively unconscious, and the intent of the writer is not to hurt a particular group or person they are referring to. So while being harmless in its intention. Usage of PCL still poses a risk of harming vulnerable people or groups by stereotyping them or normalizing specific behaviour towards them.

Task4 at SemEval-2022 (Pérez-Almendros et al. (2022)), Patronizing and Condescending Language Detection provides two sub-tasks. The goal of subtask1 is to identify if the given paragraph contains PCL. The goal of sub-task2 is to determine which subcategory of PCL expresses the condescension. The seven subcategories are Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion and The poorer, the merrier. A given paragraph can show instances of multiple subcategories.

We experimented with multiple transformer-based models. We used focal loss and Weighted Random Sampling to address the class imbalance; we also tried out ensembling models with hard voting, which improved the accuracy over the baseline models for both the sub-tasks.

The paper is structured as follows: Section 2: describes the dataset and related work. Section 3: describes our system and model architecture. Section 4 has information regarding the dataset size and splits with libraries used. Section 5 discusses the findings from our experiments, and section 6 concludes our paper.

2 Background

There has been work done to detect potentially harmful forms of language. Liu et al. (2019a) used BERT and LSTM based models to detect offensive language in the dataset, Offensive Language Identification Dataset (OLID) provided by Zampieri et al. (2019) at SemEval 2019. Indurthi et al. (2019) used InferSent (Conneau et al. (2018)) semantic sentence representations to detect Hate Speech against Immigrants and Women in the dataset provided by Basile et al. (2019) at SemEval 2019.

PCL's subtle and often unrealised nature makes its detection an arduous task for humans and Artificial Intelligence systems alike. There has been some recent work done when it comes to addressing PCL. Wang and Potts (2019) presents a dataset of social media messages annotated for condescending acts in context.

2.1 Dataset and Task Description

SemEval2022 Task 4 provides the Don't Patronize Me! dataset (Pérez-Almendros et al. (2020)). The dataset contains 10469 paragraphs. We divide the data into training and validation datasets. The paragraphs in the dataset are annotated for PCL.

Paragraph	Label
Call to restore hope for homeless through inquiry	1
farooqui said women 's groups were demanding fast-track courts to deal with rape and other crimes against women .	0

Table 1: Example for Sub-Task1

Paragraph	Label
the word of god is truth that 's living and able to penetrate human souls (heb. 4:12) . consider how powerful scripture is : it can change hearts , save lives from eternal condemnation , and give hope to the hopeless	Unbalanced power relations , Compassion
these poor ladies are definitely going through some traumatic issues right now , and i am asking that they come forward so that i help them ? together with women parliamentarians - to be able to heal.	Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Compassion

Table 2: Example Of Sub-Categories of PCL for Sub-Task2

The paragraphs marked positively for PCL are then annotated for seven different categories of PCL. The dataset has paragraphs in the English language and was collected by the News on Web (NoW) corpus. They queried the corpus for paragraphs using ten keywords related to vulnerable communities widely covered by the media and from the 20 English speaking countries in the corpus. Detailed information of the dataset can be found in the task description paper (Pérez-Almendros et al., 2019).

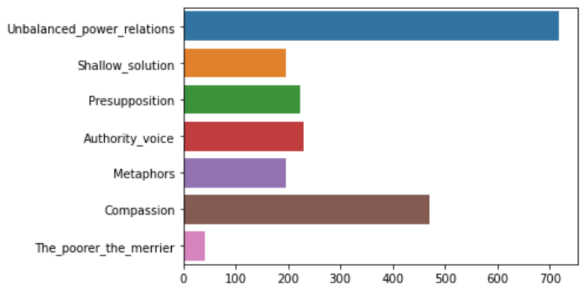

Figure 1: Frequencies of PCL subcategories

2.1.1 Sub-task1

The first sub-task is a binary classification task where given a paragraph, we have to classify whether it contains PCL. The annotation in the original paper has labels from 0 to 4. The paragraphs marked 0 and 1 are marked negative for PCL, while those marked 2 and above are marked positively. Table 1 shows positive and negative PCL examples from the dataset for sub-task 1.

2.1.2 Sub-task2

The second sub-task is a multi-label classification problem where given a paragraph, we have to classify whether it belongs to one or many of the seven subcategories of PCL. The subcategories are Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier. Table 2 shows examples for paragraphs marked for different categories of PCL.

3 System-Overview

For our solution, we have relied on using pre-trained transformer-based models like RoBERTa (Liu et al. (2019b)) which robustly optimizes the original Bidirectional Encoder Representations from Transformers(BERT) Devlin et al. (2019). It is pre-trained on much larger datasets, bigger batches and employs dynamic masking wherein a masking pattern is generated every time a sequence is fed to the model.

We also experimented with the newer Decoding-Enhanced BERT with Disentangled AttentionV3 (He et al. (2021a)), which is an improved version of the original DeBERTa (He et al. (2021b)). It leverages ELECTRA style (Clark et al. (2020)) pre-training by replacing DeBERTa's original mask language modelling (MLM) with a more sample-efficient pre-training task, replaced token detection (RTD), where the model is trained as a discriminator to predict whether a token in the corrupted input is either original or has been replaced by a generator.

As the dataset is highly imbalanced, we use two different ways to deal with the imbalance, focal loss and Weighted Random Sampling.

Model	UNB_POW	SHAL	PRES	AUTH	MET	COMP	POOR_MERR	AVG
RoBERTa $_{\text{sep}}$	19.4	15.9	9.3	5.3	13.9	11.3	9.1	12.0
RoBERTa $_{\text{ens}}{}^{*}$	15.8	24.8	10.0	**9.3**	16	11.2	14.8	14.6
DeBERTa $_{\text{ens}}$	15.7	24.8	10.0	9.2	16	11.3	14.9	14.6
RoBERTa $_{\text{WRS\_sep}}{}^{*}$	23.2	16.3	9.7	8.0	14.7	10.1	9.5	13
DeBERTa $_{\text{WRS\_sep}}$	16.3	24.9	10.3	9.1	10.0	11.6	13.8	13.7
RoBERTa $_{\text{focal\_sep}}$	10.9	**25.0**	8.1	8.8	**22.9**	**16.2**	**17.7**	**15.7**
DeBERTa $_{\text{focal\_sep}}$	15.7	24.8	10.0	9.2	16	11.2	14.8	14.5
RoBERTa $_{\text{baseline}}$	**35.35**	0.0	**16.7**	0.0	0.0	20.8	0.0	10.4

Table 3: F1 scores: Sub-Task2

3.0.1 Focal Loss

Focal loss (Lin et al. (2018)) is an improved version of Cross-Entropy Loss that tries to handle the class imbalance problem by assigning more weights to hard or easily mis-classified examples and down-weight easy examples. It results in the reduction of the contribution of easy examples. It also makes so that there is more emphasis on correcting misclassified examples.

$$L = \begin{cases} \alpha(1-p)^{\gamma}\log(p) & \text{if y} = 1 \\ (1-\alpha)p^{\gamma}\log(1-p) & \text{otherwise} \end{cases} \tag{1}$$

where p is model prediction and y is the ground truth label; α and γ are hyper-parameters, α is used to control the loss weight of positive and negative samples, and γ is used to scale the loss of difficult and easy samples. The values we take for α is 0.25 and γ is 2.0 which is the default values used in the original paper.

3.0.2 Weighted Random Sampling

Data sampling provides a way to transform a training dataset to better balance the class distribution. Data sampling techniques are helpful in cases of data imbalance as the class distribution is skewed, resulting in the models predicting the dominant class more while learning to ignore the classes with very few samples.

We use Weighted Random Sampling (WRS), which samples items from our set such that the probability of sampling item i is proportional to a given weight w_i which is equal to the class weight for the label of the i'th item.

$$w_i = 1/n_i \tag{2}$$

Here n_i is the number of items in the dataset with label i.

3.1 Sub-task1

The first sub-task is a binary classification task. We use our pre-trained BERT based transformers for this task. We experiment with either using Focal Loss or Weighted Random Sampling to deal with imbalanced data. We pass the output of the transformer model through a fully connected layer; we add a Tanh activation function with a dropout layer before passing it through our final fully connected layer, which gives us the output. We also train an ensemble of models using 5-fold cross-validation and use hard voting method to decide the final labels and combine it with Weighted Random Sampling for dealing with class imbalance

3.2 Sub-task2

For the second sub-task, we have a multi-label classification problem. We experiment with treating it as multiple binary classification tasks where for each label to be predicted, we train a separate classifier(sep). Even here, we experiment with focal loss and Weighted Random Sampling to deal with imbalanced classes.

We also train an ensemble of multi-label classifiers using 5-fold cross-validation and hard voting to decide on the final labels. As not all labels are imbalanced, we decided to use binary cross-entropy as our loss function for ensemble models for this task. We add weights to the positive samples in the loss function as done by researchers at (Gupta et al., 2021) to address the classes which do have imbalances. The formula is given below:

$$\begin{aligned} \ell(\mathbf{x},\mathbf{y}) &= -\frac{1}{Nd}\sum_{n=1}^{N}\sum_{k=1}^{d}\left[p^k y_n^k \log x_n^k + (1-y_n^k)\log(1-x_n^k)\right] \\ p^k &= \frac{1}{f^k}(|K| - f^k) \end{aligned} \tag{3}$$

Where N is the batch size, n index denotes n^{th} batch element, d is the number of classes, f stands for a vector of class absolute frequencies calculated on the train set, $\mathbf{x}$ is the output vector from the last Sigmoid layer, $\mathbf{y}$ is a vector of multi-hot encoded ground truth labels and $|K|$ is the size of the train set.

Model	Precision	Recall	F1
RoBERTa $_{\text{focal}}$	64.6	45.4	53.3
DeBERTa $_{\text{focal}}$	**68.3**	34.7	46.0
RoBERTa $_{\text{WRS}}$*	51.5	59.9	55.4
DeBERTa $_{\text{WRS}}$	50.1	65.6	56.8
RoBERTa $_{\text{ens\_WRS}}$	53.2	**67.1**	**59.4**
DeBERTa $_{\text{ens\_WRS}}$	56.2	59.6	57.9
RoBERTa $_{\text{baseline}}$	39.35	65.3	49.1

Table 4: Results: Sub-Task1

4 Experimental setup

Parameter	sub-task1	sub-task2
Dropout	0.3	0.3
BatchSize	8	8
Epochs	5	8
Learning Rate	1e-05	1e-05
Optimizer	Adam	Adam

Table 5: Hyperparameters

The dataset contains 10469 paragraphs about potentially vulnerable social groups. 9476 examples were marked negatively for PCL, while 993 were marked positively for PCL. For the second sub-task, only the 993 examples were used for training as they were marked positively for PCL.

80% of the dataset was used for training while the rest was used for validation. We only use the organisers' test set for testing out our final models. Hyper Parameters used are mentioned in table 5. Not much time was spent on hyperparameter tuning as using other previously mentioned techniques and different models gave better and more varied results.

The primary evaluation metrics used is the F1 scores. For sub-task1, precision and recall scores are also given. For sub-task2, we have individual F1 scores for each PCL subcategory along with the average F1-score. We use huggingface [1] library for our transformer models implemented in PyTorch [2].

[1]Transformers,v4.16.2,`https://huggingface.co/docs/transformers/index`

[2]PyTorch, v1.10.2, `https://pytorch.org/`

The models were trained on 4 GeForce RTX 2080 Ti GPUs.

5 Results And Discussion

The results from all our experiments conducted for sub-task1 and sub-task2 can be seen in Tables 4 and 3, respectively. The models submitted in the evaluation phase are marked * in the tables, but we have shown results from all our experiments. We experimented with several models and techniques during the development and evaluation phases. We use the F1 score to judge our models, which is also the official metric. We ranked 23rd on the first task and 36th on the second task on our submitted models. We achieved better results on other models for both tasks, and the results are shown in their tables, respectively.

We see that all methods, namely focal loss, Weighted Random Sampling(WRS) and ensembling performed better than the baseline model. The 5-fold cross-validation, hard voting ensemble model with WRS achieves the best F1-score and Recall score for sub-task1, more than the models where only WRS is applied.

For the second task, we see the best average score from RoBERTa model trained separately (sep) for each label with focal loss to achieve the best average F1 score. Focal loss performs poorly on Unbalanced power relations, which has the highest number of positive samples (716 out of 993) and performs better on imbalanced labels having a lower number of positive samples like Metaphors and Poorer The Merrier having 197 and 40 positive samples out of 993 respectively.

6 Conclusion

This paper presents and describes our solution system for the SemEval2022 Task4: Towards Patronizing and Condescending Language Detection. We have applied BERT based pre-trained language models RoBERTa and DeBERTa with hard voting ensembling techniques along with techniques to deal with imbalanced datasets like focal loss and Weighted Random Sampling. Our submitted solutions scored F1 scores of 0.5539 and 0.1456 for the two sub-tasks, respectively.

Abstract

This paper describes the authors' submission to the SemEval-2022 task 4: Patronizing and Condescending Language (PCL) Detection. The aim of the task is the detection and classification of PCL in an annotated dataset. The authors of this paper worked on two different models with finetuned hyperparameters focusing on number of epochs, training batch size, evaluation batch size, gradient accumulation steps and learning rate. The authors submitted one RoBERTa model and one DistilBERT model. Both systems performed better than the random and RoBERTA baseline given by the task organizers. The RoBERTA model finetuned by the authors performed better in both subtasks than the DistilBERT model.

1 Introduction

With the rise of social media, online hate speech has skyrocketed and has posed a problem for social media platforms: How can the giant number of messages on social platforms be surveilled, so that hateful comments can be reported and deleted? The answer to this is hate speech detection, a discipline within Natural Language Processing that has become increasingly popular and successful in recent years.

However, apart from hate speech, there is also other harmful language that should be studied. This is what the research by Perez-Almendros, Espinosa-Anke and Schokaert dives into. They collected an annotated dataset that focuses on a type of harmful language that is not so easily detected: patronizing and condescending language (PCL). The researchers describe PCL as follows: "An entity engages in PCL when its language use shows a superior attitude towards others or depicts them in a compassionate way." (Perez-Almendros et. al., 2020)

One of the difficulties in detecting PCL as opposed to openly hateful speech, is that persons who use PCL often do not intend to do harm, but instead want to support the groups that they name. PCL is usually aimed at vulnerable communities which makes the detection of PCL even more important.

The SemEval 2022 task 4 competition is based on this research by Perez-Almendros et. al: the detection of PCL. In two subtasks, one a binary classification and one a multi-label classification, the participants of the SemEval competition were tasked to submit up to two models.

The authors of this paper participated in both subtasks and propose a finetuning based approach on a pre-trained RoBERTa language model. Two models were submitted to the task organisers, one RoBERTa model and one DistilBERT model. The RoBERTa model performed better in both subtasks.[1]

In this paper, the authors will first describe the task set out by the SemEval 2022 competition in sections 2. In section 3, the authors explain the relevance of related work to this topic. Section 4 gives an overview over the BERT model. In the subsequent section, the two pre-trained models are presented. In the section experimental setup, the two different finetuned models are described in detail. Section 7 presents the results of the competition and section 8 the conclusion.

[1] The code can be found here: https://github.com/julia-ecrevisse/SemEval2022

2 Task description

This research paper contributes to task 4 of the SemEval 2022 competition[2]: PCL detection. The starting point of the research task is the paper "Don't Patronize Me! An annotated Dataset with Patronizing and Condescending Language Towards Vulnerable Communities" (Perez-Almendros et al., 2020). The researchers provide an annotated dataset with paragraphs taken out of news articles from English speaking countries[3] where vulnerable communities are mentioned. The following communities are included: disabled, homeless, hopeless, immigrant, in need, migrant, poor families, refugee, vulnerable and women. The dataset includes a total of 10,637 paragraphs extracted from the News on Web corpus. 3,554 of the paragraphs had been labeled as PCL by the annotators.

The aim of the SemEval task is 1) to identify which paragraphs include PCL and 2) if the paragraph includes PCL which category or categories it belongs to. The two subtasks are described as follows:

Subtask 1: Binary classification. Given a paragraph, a system must predict whether or not it contains any form of PCL.

Subtask 2: Multi-label classification. Given a paragraph, a system must identify which PCL categories express the condescension. There are seven different categories: Unbalanced power relations, shallow solution, presupposition, authority voice, metaphor, compassion and the poorer, the merrier.

3 Related Work

While other areas related to hate speech and hateful language have been a focus of NLP research in recent years, the research into PCL is still limited. However, there are a few researchers that have delved into this discipline from different angles.

Wang and Potts (2019) discuss condescending language and its detection in their research and also point out that high quality data for this kind of language detection is still limited. They introduce the dataset "Talkdown" which is a data set from the social media platform Reddit. Their approach concentrated on BERT baseline models and the researchers concluded that condescending language is highly connected to context (Wang and Potts, 2019).

Taking a different angle, Sap et al. (2020) write about the social and power implications of language. They claim that by using language with, e.g. social bias, stereotypes and prejudices are reinforced. Their collected data stems from different social media sites. They state in their results that previously successful models can categorize social bias relatively well, but they have difficulties classifying the social bias frames which were developed by the authors (Sap et al., 2020).

BERT

The state of the art in natural language processing is significantly characterized by architecture-based transformer-encoder models called BERT (Bidirectional Encoder Representation from Transformers) (Peters et al., 2018).

BERT's architecture relies on a two-part training process, a pretraining using unlabeled text corpora and a subsequent test run using labeled data (Develin et al, 2019). Here, BERT models do not use any decoder layers (Rothman, 2021) and fully rely on the encoder structures developed by Devlin et al. (2018). Here, these models are divided into base and large.

In order not to have to perform the training process, which is time-consuming, for each new task, especially pre-trained models are made available on platforms such as Huggingface. These can be adapted to the respective requirements by means of fine-tuning.

This previous research into hate speech and hateful language as well as the research into BERT model provides the basis of this paper. The challenge of condescending or patronizing language as opposed to hate speech is that condescending or patronizing language is often more difficult to detect as it is often not on purpose or not as obvious. Still, the steps taken by previous authors show a way on how to tackle these challenges.

4 System overview of pretrained models

In the paper "Don't Patronize me!" which is the starting point of the SemEval Task, the researchers

[2] https://sites.google.com/view/pcl-detection-semeval2022/home?authuser=0

[3] News on Web Corpus: https://www.english-corpora.org/now/

point out that an NLP model with BERT achieves the best results. More specifically RoBERTa performs slightly better than DistilBERT and BERT-base (Perez-Almendros et. al., 2020).

4.1 RoBERTa model

The RoBERTa model stands for Robustly Optimized BERT Pretraining Approach and is based on the basic architecture of BERT, which, however, has been insufficiently trained for the subtasks to be handled. RoBERTa increases performance by improving the pretraining processes. To generate this progress, the number of pretraining transformers is increased. An example of this is the omission of WordPiece tokenization (Song et al., 2021) and the associated structuring at the byte-level byte pair encoding level (Rothman 2021).

For both subtasks, the RoBERTa base model was used, which consists of 12 encoders. In contrast, the RoBERTa large consists of 24 (Nester, 2022). The decisive factor for the choice of the model was the improved modification of the hyperparameters in the fine-tuning, which were our primary focus. In addition, the large amount of data used to pre-train RoBERTa was a reason for the choice. From this, we aimed to improve the generalization of the responding capability compared to the conventional BERT model (Delobelle et al., 2020).

Apart from the RoBERTa baseline, another RoBERTa model from the transformers library was tried (Devlin et al, 2019): *xlm-roberta-base* (Huggingface), with the following results: Subtask 1 F1 score: 0.466, Subtask 2 average F1 score: 2: 0.110. As this baseline performed worse than the original baseline, the authors decided to continue with the original RoBERTa baseline.

4.2 DistilBERT model

DistilBERT is often called the "faster and cheaper" version of BERT. Using up massive amounts of data is expensive and also wasteful. In their research Sanh, Debut, Chaumond and Wolf describe that they were able to "reduce the size of a BERT model by 40%, while retaining 97% of its language understanding capabilities and being 60% faster" (Sanh et. al., 2020). That is why it makes sense to see if there are promising results with a DistilBERT model also for this SemEval task.

Two different DistilBERT models from transformers were tried for the two subtasks: *distilbert-base-uncased* and *distilbert-base-uncased-finetuned-sst-2-english*. Both were first tried as a baseline. Comparing both models, the *distilbert-base-uncased* showed better results for the baseline, especially for subtask 2 (see table 1),

Baseline	***distilbert-base-uncased***	***distilbert-base-uncased-finetuned-sst-2-english***
Subtask 1 F1 score	0.488	0.433
Subtask 2 average F1 score	0.121	0.060

Table 1: DistilBERT baselines F1 scores

that is why it was decided to continue with this model in the following fintetuning stage. For the multilabel classification of subtask 2 the most promising predictions of the *distilbert-base-uncased* baseline were in the categories unbalanced power relations, presupposition, and compassion.

The *distilbert-base-uncased-finetuned-sst-2-english* model only showed a good F1 score for the category unbalanced power relations, whereas all other categories had a F1 score of 0.0.

5 Experimental setup

Fine-tuning was performed on Google Colab. The authors used the train and test set as it was provided by the task organizers.

5.1 RoBERTA model

Subtask 1

The experimental setup used was the RoBERTa baseline, which was provided by the Semeval 2022 team for the task. For fine-tuning, 9 different hyperparameters were run in different combinations with the model. For this, the F1 score was set as a benchmark and depending on the development, the hyperparameter was pushed to its limit. Using the example of the epochs, a steady improvement of the F1 score could be observed up to level 5, before it deteriorated again. If such a limit of a parameter was reached, it could be set as default and the tuning could be supplemented by another one. This resulted in a combination of 5 epochs, a learning rate of 3e-5, an evaluation batch size of 32, a training batch size of 16 and gradient accumulation steps of 2.

In addition, the weight_decay, adam_epsilon, max_grad_norm and the warmup_steps were implemented at different levels. However, these led to a deterioration of the precision and the F1 score in all variants. However, it is worth mentioning that there was a significant improvement of the recall by using warmup_steps= 3500. Without further illuminating this direction, a recall of 0.804 was achieved, which cannot yet be called a maximum.

Subtask 2

The findings from Subtask 1 were to be applied to multi-labeling. For this purpose, both the RoBERTa-baseline model and the same hyperparameters were adopted. Again, the different hyperparameters were pushed to maximum improvement with the goal of obtaining the highest possible mean value of the individual F1 scores of the labels. Epochs could be increased to 20 until the peak was reached. All other efforts to obtain an optimized result away from the epochs or in combination with them were unsuccessful. The mean value reached its possible optimum after 20 epochs with a result of 0.258.

5.2 DistilBERT model

For the DistilBERT model, three hyperparameters were tried by the authors: number of trained epochs, the evaluation batch size and the training batch size. The number of trained epochs has been adapted from 1 to 20 epochs, while for the evaluation and training batch size 16, 32 and 64 was used respectively.

	Subtask 1	Subtask 2
Number of trained epochs	5	20
Evaluation batch size	32	64
Training batch size	32	16

Table 2: Hyperparameters used for DistilBERT model

The best results were achieved with the hyperparameters described in Table 2.

6 Results

An overview of the results can be found in table 3 and 4.

	RoBERTa model	DistilBERT model	Baseline RoBERTa
Precision	0.401	0.357	0.394
Recall	0.773	0.640	0.653
F1	0.528	0.459	0.491

Table 3: Results subtask 1

F1 scores	RoBERTa model	DistilBERT model	RoBERTa baseline
unbalanced power relations	0.366	0.352	0.354
shallow solution	0.351	0.345	0
presupposition	0.176	0.2	0.167
authority voice	0.221	0.163	0
metaphor	0.211	0.095	0
compassion	0.285	0.271	0.209
the poorer, the merrier	0.167	0.0	0
average	0.254	0.204	0.104

Table 4: Results for subtask 2

6.1 RoBERTa model

In Subtask 1 as well as in Subtask 2 significant improvements could be achieved compared to the baselines. This is reflected in the results of the test data set as well as the final data set. The finetuning improved the initial value (F1: 0.483) of the RoBERTa baseline in Subtask 1 by about 0.05 to 0.547. A significant increase of about 0,10 (0.441 to 0.350) was observed in the Precision section. In the Competition a similar value was achieved with, so that the robustness of the system and its configuration is given. An overfitting could not be determined. The results were ranked 31st with a Precision of 0.401, a Recall of 0.773 and the F1 0.528.

In Subtask 2, RoBERTa nearly doubled the mean F1 score from baseline 0.134 to 0.258. On the official leaderboard, an almost identical value of 0.2536 was achieved, so that here, as in Subtask 1, no overfitting prevailed and the robustness of the system was confirmed. The RoBERTA model performed best in the categories “unbalanced power relations” and “shallow solution” (see table 4). The worst results were reached for the categories “presupposition” and “the poorer the merrier”.

6.2 DistilBERT model

A comparable scenario occurred when running the DistilBERT model with the test data. Compared to the Random as well as the RoBERTa Baseline, the results significantly improved in both subtasks. In the comparison, however, the Random Baseline is used first. An increase from 0.174 (Random) to 0.512 could be achieved by applying the above mentioned hyperparameters. The RoBERTA baseline was thus also exceeded by approximately 0,30. However, in the official results, the score was not repeated and was 0.459 (see table 3).

In Subtask 2, the Random Baseline result with the test data of 0.055 for the mean of the F1 scores was almost tripled to 0.146. However, compared to the RoBERTa baseline of 0.134, only a small improvement was observed.

Surprisingly, the model performed much better with the official data and thus achieved its maximum value of 0.203. Also, for the DistilBERT model, the categories with the best results were “unbalanced power relations” and “shallow solutions” (see table 4). The DistilBERT model performed worse than the RoBERTA model in most categories, except “presupposition”. The system performed worst for the category “the poorer, the merrier” compared with the other categories.

7 Conclusion

The purpose of this work was to identify PCL in texts using NLE. For this purpose, existing text classification models were used and adapted to the task by fine tuning. The goal was to achieve the highest possible F1 scores by the model, which is equivalent to the percentage detection of condescending terms. A complete detection of all these terms was not achieved, but in the binary classification with RoBERTa a score above 0.52 could be obtained. The multi classification was the bigger challenge and could only finish with a score around 0.250.

Despite these results, a basis, if not an improvement, has been created for future work. The hyperparameters which were used can already be set to default in the next works at the beginning and thus increase the speed of the development process for researches in PCL detection by BERT models. More research could also be done into the different categories of PCL. There were categories that consistently performed better than others (unbalanced power relations and shallow solution), while the systems had more difficulties with other categories (especially the poorer, the merrier).

There are still a lot of directions that the research into PCL detection can continue. As stated above, PCL detection in NLE is an emerging field that would benefit from further research. The task is more difficult than traditional hate speech detection as PCL is often more subtle. However, PCL can contribute to repeating and furthering stereotypes and discrimination, especially among vulnerable communities and therefore the research into PCL detection systems is a vital endeavor.

Acknowledgments

We would like to thank our professor Dr. Udo Kruschwitz at the University of Regensburg for encouraging us to take part in the SemEval 2022 evaluation and supporting us during the process. We would also like to thank our study colleagues Aenne and Amela with whom we exchanged ideas and approaches throughout the timeframe of the SemEval 2022 competition.

Abstract

In this description paper we outline the system architecture submitted to Task 4, Subtask 1 at SemEval-2022. We leverage the generative power of state-of-the-art generative pretrained transformer models to increase training set size and remedy class imbalance issues. Our best submitted system is trained on a synthetically enhanced dataset with 10.3 times as many positive samples as the original dataset and reaches an F1 score of 50.62%, which is 10 percentage points higher than our initial system trained on an undersampled version of the original dataset. We explore possible reasons for the comparably low score in the overall task ranking and report on experiments conducted during the post-evaluation phase.

1 Introduction

Task 4 of SemEval-2022 focuses on the detection of patronising and condescending language (PCL) in news (Pérez-Almendros et al., 2022). PCL in popular media and news sources is detrimental to an emancipated and equal society, as it is usually targeted towards minorities and socially disadvantaged communities, often in an unsuccessful attempt to show solidarity (Perez Almendros et al., 2020). PCL has the potential to strengthen existing stereotypes by representing minorities either as passive entities to be pitied and supported, thus taking away their agency and focusing on their vulnerabilities or praising members of vulnerable groups for everyday achievements simply because of their background (Nolan and Mikami, 2013). In contrast to hate speech, PCL is usually subtle, well intentioned, and free of discriminatory phrases or racial slurs, which makes it an interesting Natural Language Processing (NLP) problem.

In other domains with more discriminatory classes such as hate speech detection, generative models have recently become increasingly popular and successful as a tool to increase classification performance (Wullach et al., 2021; Anaby-Tavor et al., 2020). In our contribution to the shared task, we explored to what extent this approach is feasible for the presented use case, where classification of a text sample is less distinct and often relies on world knowledge (Perez Almendros et al., 2020). The dataset provided for the task was fairly small, with less than 10% of the data belonging to the positive class. We thus enhanced the original dataset in two ways for our system runs:

- balancing the dataset by generating only PCL samples
- increasing overall dataset size, by generating an equal amount of PCL and non-patronizing (nPCL) samples

We generally followed the approach used by Wullach et al. (2021) and initially fine-tuned a BERT classifier on the original dataset. We then fine-tuned GPT-3 (Brown et al., 2020) and generated samples of PCL and nPCL which were classified using our fine-tuned system. Samples for which the BERT classification did not correspond to the intended output were discarded. We then fine-tuned a new BERT instance with the modified dataset PCL*enhanced* including the synthetic data. Although our system only ranked middle field in the competition, both classifiers trained on the modified datasets improve our initial classifier trained on the original dataset by multiple percentage points. We conclude that this approach does add value to classification, even in cases where the distinction between the positive and the negative class relies on subtleties. The code described in the following as well as the synthetic data used for the modification of the original dataset is available on Github[1].

Text	Class
Meanwhile "throughout this island, the high level of suicide is terrible and terrifying. "As Christians" we can give hope, where a person feels only darkness and hopelessnes," he said	PCL
As the house prices go up, so do rents , and the pohara poor families ca n't afford to live. Those who own houses, and are only just making it through, will be rated out of their homes	nPCL

Table 1: Examples of PCL and nPCL in the DPM.

2 Background

We participated in Subtask 1 of the competition, which entailed the binary classification of news paragraphs as either patronizing or not patronizing. Basis for the task was the *Don't Patronize Me! dataset* (DPM) (Perez Almendros et al., 2020), which contains 10,469 paragraphs of annotated data from 20 English news sources. While all paragraphs include references to potentially vulnerable groups, only 993 are examples of patronising speech. The dataset included meta-information about the country each paragraph was published in, an article id, a keyword indicating which vulnerable group is addressed, and a label ranging from 1 to 4, where 0 and 1 are treated as non-patronizing and 2 to 4 as patronizing. The task organizers define PCL as often unconscious, subtle and subjective ways in which the speaker conveys a superiority "concealed behind a friendly or compassionate approach towards the situation of vulnerable communities" (Perez Almendros et al., 2020). They explicitly exclude hate speech and discriminatory speech from PCL, making it harder to be identified not only by NLP-systems, but also by humans. We include examples of both classes in Table 1.

Transformer-based generative models such as GPT (Radford et al., 2018) and its successors have become prevalent in various NLP tasks. For instance, Liu et al. (2021a) explored the idea of synthetically constructing benchmark datasets to concur with existing benchmarks such as SQuAD, while Zhang et al. (2018) showed that a fine-tuned GPT model can accurately mimic the personal conversation style of an individual, leading to improvements in the Persona-Chat dataset.

Another increasingly popular use case is the generation of data on tasks with small labeled corpora to synthetically increase dataset size in order to train better performing classifiers. Dekker and van der Goot (2020) used synthetic data for lexical normalisation, while other researchers employed such data to train question answering models (Puri et al., 2020). Even in maths, researchers have proposed ways of creating synthetic theorems (Firoiu et al., 2021). Wullach et al. (2021) used GPT-2 (Radford et al., 2019) for their approach to hate speech detection. Their datasets were small to medium sized (6-53k labelled examples) and highly unbalanced, with as little as 1-6k hate speech samples per dataset. They created three mixed datasets containing 10k, 80k and 240k synthetic samples respectively, as well as 80% of the original datasets. The classification models trained on the largest created dataset outperformed those trained on the smaller datasets in most cases. Anaby-Tavor et al. (2020) generated data using GPT and improved sentence-level topic classification on three datasets, ranging from 4.2k to 17k entries. Wullach et al. (2021) and Anaby-Tavor et al. (2020) fine-tuned the respective GPT models on relatively small datasets, and find statistically significant improvements on classifier performance through incorporating synthetic data in the datasets used for fine-tuning classifiers.

While GPT and GPT-2 were trained on 117M and 1.5B parameters respectively, GPT-3 models were trained on up to 175B parameters (Radford et al., 2018, 2019; Brown et al., 2020). As it has been shown that an increase in model size systematically leads to improvements in text synthesis as well as common downstream tasks (Brown et al., 2020), GPT-3 is likely to produce higher quality and more natural sounding data than its predecessors. We thus expect GPT-3 generated data to have an even greater impact on performance in intricate language classification tasks such as PCL detection. We know of only few other research teams which used GPT-3 in their experiments, for instance to search for more suitable prompts for Natural Language Understanding (NLU) tasks (Liu et al., 2021b) or using prompts for few-shot generation (Yoo et al., 2021). Both achieved strong results on classification benchmarks.

While using foundation models for data generation has the potential to increase the power of language models and mitigate the data scarcity prob-

Dataset	PCL	nPCL	% PCL	$F1_{pos}$	Pre_{pos}	Rec_{pos}

Table 2: Overview of the datasets used for fine-tuning as compared to the original dataset and test classification metrics.

lem prevalent in many NLP fields (Budzianowski and Vulić, 2019), this also bears potential risks not yet fully explored. For instance, past research showed that GPT-3 is biased in some cases, and that its defects are inherited by downstream models (Bommasani et al., 2021). Similarly, Bender et al. (2021) note, that the widespread application of foundation models carries a cost - both monetary and ethically. Thus, this approach's ethical implications should be investigated more thoroughly in future work.

3 System Overview

To generate the synthetic data, we used GPT-3's Curie model. Curie has about 13B unique parameters, while Davinci has about 175B. Although Davinci performs significantly better on a number of NLP tasks than Curie, we chose Curie, as it is more financially viable than the larger model, while retaining a comparatively strong performance (Brown et al., 2020).

For fine-tuning, we split the dataset into PCL and nPCL data and modified it to meet the API's requirements. As the API requires a prompt-completion pairing, the prompt was set to be empty (") and the completion contained the data sample. Afterwards, two GPT-3 Curie instances were fine-tuned on the PCL and nPCL data, respectively. We thus created two models, one to generate PCL and one for nPCL phrases. Following Wullach et al. (2021), we called the models with an empty (") prompt in the pipeline for synthetic data generation and the default parameters. We set *max_tokens* to the rounded mean length of the samples in the original dataset (60 for PCL and 54 for nPCL). With each iteration, we generated the maximum number samples (128), resulting in a total of 24.321 synthetic phrases by the nPCL model and 24.197 by the PCL model.

Like (Wullach et al., 2021), we classified all synthetic samples after generating the data. We used an initial baseline classifier and discarded all samples where the intended and predicted class did not match. Due to the high class imbalance of the original dataset, we randomly undersampled the negative class to the size of positive samples for training of the baseline classifier. We fine-tuned $BERT_{base}$-cased (Devlin et al., 2018) across three epochs using a learning rate of 1e-5 on the undersampled dataset. Since the synthetically generated data consisted solely of text for each label, we did not use any of the meta-information or context provided in the dataset and fine-tuned solely on text and labels. In the future, it might be useful to take meta-information into account for text generation.

39% of the generated PCL samples were classified as such by the baseline classifier, whereas 85,5% of generated nPCL samples were classified as nPCL. We explain this with the much larger sample size of nPCL in the DPM allowing the GPT-3 pipeline to generate better suited data. Based on the predictions, we created two enhanced datasets: For $DPM_{enhanced}$, we added a similar amount of synthetic PCL (9448) and nPCL (9357) samples to the DPM. For $DPM_{enhancedPos}$, we added 7086 PCL samples to balance the original dataset. For a comparison of sample sizes and share of PCL in the DPM and the different datasets used for fine-tuning see Table 2. On each of the enhanced datasets, we trained a $BERT_{base}$-cased instance the same way as our initial classifier. We submitted the classifier trained on $DPM_{enhancedPos}$ for our first and the classifier trained on $DPM_{enhanced}$ for the second run.

4 Results and Discussion

The evaluation metric used for ranking in the task was F1 over the positive class. Our baseline classifier reached an F1-score of 40.74% on the test set provided by the task organisers after the end of the competition's evaluation phase. Although it had a high recall of over 80%, precision was very low, leading to a suboptimal F1-score. The classifier trained on $\text{DPM}_{\text{enhanced}}$ scored almost 10% higher than the initial classifier, but had neither the highest recall, nor the highest precision of the three classifiers trained before the post-evaluation phase. This was suprising, as we initially expected the classifier trained on $\text{DPM}_{\text{enhancedPos}}$, which was the larger balanced dataset out of the three, to perform best. This leads to the assumption that with synthetic data, sheer amount might be more important than balancing out the dataset.

Although in the official task scoring, our system trained on $\text{DPM}_{\text{enhanced}}$ ranked in place 41 of 78 and surpassed the official baseline (fine-tuned RoBERTa) by only about 1%, we note that using both synthetically enhanced datasets led to a boost in performance compared to our initial classifier. This might seem surprising, especially considering the low performance of the initial classifier used to filter the GPT-generated data. In the post-evaluation phase, we repeated the experiments from our two system runs without previous filtering of the GPT-output, to explore the role of the initial classifier in our system's performance. Neither $\text{DPM}_{\text{enhancedUnfiltered}}$ nor $\text{DPM}_{\text{enhancedPosUnfiltered}}$ led to better performance than $\text{DPM}_{\text{enhanced}}$. Thus, using a baseline classifier for filtering seems to be the most sensible option when working with synthetic data, regardless of its performance strength. We report on detailed classification results in Table 2. Since our baseline system did not perform very well in terms of classification, future work should first and foremost focus on improving it. The baseline system forms the basis of our approach and classification errors at this stage are likely to significantly lower the usefulness of the synthetic data.

We also looked at some of the synthetic data generated by GPT-3. Both for PCL and for nPCL, the generated samples were not always coherent on a semantic level and the occurrence of incoherent text appeared to be more common in the nPCL condition. However, it seems like coherence did not impact classification, as in both cases incoherent synthetic samples could be found in the final dataset (see Table 3).

We also found a lot of text in languages other than English, possibly because of the small size of the dataset in comparison to the vast amount of training data used to create GPT-3. We expect that filtering out such samples would increase performance further. In addition, basic data-cleaning of the synthetic data before classification might be in order. Both of this could potentially be achieved by only using data samples for which a confidence score above a certain percentage (i.e. 70%) is returned in classification. Another approach might be using an unrelated dataset to filter out all synthetic data unrelated to the task at hand. In the context of PCL detection, this could help discard generated data that is not related to vulnerable groups.

The approach of using an empty prompt (") while fine-tuning the models is debatable, because the prompt is such a powerful tool (Yoo et al., 2021; Liu et al., 2021b) and should probably be utilized. A possible approach would be to train a single model on both PCL and nPCL data, and put PCL/nPCL information in each samples' prompt. The currently unused meta-information of the dataset could also be incorporated, possibly causing additional improvements in the quality of the generated data.

5 Conclusion

We described our system submitted to Task 4, Subtask 1 of SemEval-2022. Although the system's performance did not score highly on the overall leaderboard, ranking 41st place, incorporating synthetic data in the original training set still boosted performance by up to 10% compared to our initial baseline system, which leads to the assumption that pairing this approach with more sophisticated classification systems has some potential to increase classification performance significantly. We derive some lessons learned from the presented experiments as follows:

- Using a baseline classifier to filter the synthetic data after generation seems to be essential.
- The size of the additional data seems to be more important to increase performance than balancing the data.
- Further data cleaning and filtering might be necessary to improve classification performance.
- Synthetic data leads to better performance, even if it includes a lot of incoherent samples and the baseline classifier has low performance.

In the future, we plan to improve the baseline classifier and explore different data cleaning and filtering techniques, such as using confidence scores returned by the classifier for our data selection, using unrelated datasets to filter whether a data sample fits in the task-specific domain or making use of prompts during GPT-3 fine-tuning and data generation. Exploring other augmentation strategies such as back-translation or synonym replacement of either the original data or the generated samples might further increase classification performance.

Team LEGO at SemEval-2022 Task 4: Machine Learning Methods for PCL Detection

Abhishek Kumar Singh
GLA University, India
sabhishek.kumar166@gmail.com

Abstract

In this paper, we present our submission to the SemEval 2022 - Task 4 on Patronizing and Condescending Language (PCL) detection. We approach this problem as a traditional text classification problem with machine learning (ML) methods. We experiment and investigate the use of various ML algorithms for detecting PCL in news articles. Our best methodology achieves an F1- Score of 0.39 for subtask1 with a rank of 63 out of 80, and F1-score of 0.082 for subtask2 with a rank of 41 out of 48 on the blind dataset provided in the shared task.

1 Introduction

The explosion of social media in recent years also enables increasing the number of patronizing and condescending language (PCL). Patronizing and condescending language depicts apparently kind or helpful behavior but betraying a feeling of superiority on others. Previously, harmful behavior in language for example, hate speech (Fortuna and Nunes, 2018), offensive language (Razavi et al., 2010), fake news (Oshikawa et al., 2018), rumor propagation or misinformation (Zhou and Zafarani, 2020), and many others has been widely studied in NLP, PCL has been a neglected area of study until very recently.

Identifying PCL is hard even for humans because it is subjective and subtle. For instance, one might find condescending something which another person might consider an objective portrayal of a situation or some people might not see the harm in describing how those in a privileged position donate their remainings to those who need them. Also, we would expect a member of a so-called vulnerable community to feel more patronised than one person who does not belong to such group while reading how others refer to them.

The goal of SemEval 2022-Task 4 is to design a system to detect whether or not the text contains any form of PCL and furthermore, identify which PCL category expresses the condescension. The organizers provided two datasets, one annotated based on the intensity of PCL and other with the PCL categories. We approach this problem using various machine learning approaches using the linguistics features.

Class	Nb of Samples
PCL	9476
Non-PCL	993

Table 1: Dataset Statistics Task 1

The structure for the rest of the paper is as follows. Section 2 describes a background about the dataset. Section 3 describes the experimental setup of our experiments. It involves pre-processing, feature engineering, implementation details for all the respective ML models. Section 4 describes the results and discussion for both the subtask. And lastly, in Section 5, we concluded the paper and suggest ideas for future research.

2 Dataset

The dataset (Perez-Almendros et al., 2020) provided for this challenge was collected from the News on Web (NoW) corpus (Davies, 2013). For task1, we are provided with 10469 text paragraphs. Each paragraph instance in the dataset is provided with paragraph-level label, vulnerable community-info which includes (disabled, homeless, hopeless, immigrant, in-need, migrant, poor families, refugee, vulnerable and women), and along country of origin. There are 5 classes (0-4) based on the intensity of PCL. For task2, we are provided with 993 paragraphs. Each paragraph instance in the dataset is provided with keyword, country of origin, span-text, category label, and number of agreeing annotators. The labels comprise of 7 classes: *Unbalanced Power relations*(unb) , *Shallow solution*(shall), *Presupposition*(Pres), *Authority Voice*(Auth), *Metaphor*(Meta), *Compas-*

Class	Nb of Samples
Unbalanced power (unb)	716
Shallow solutions (shall)	196
Presupposition (Pres)	224
Authority Voice (Auth)	230
Metaphor (Meta)	197
Compassion (Comp)	469
The poorer,the merrier (Poorer)	40

sion(Comp), *The poorer,the merrier*(poorer). For our experiments, we perform 80-20 data split with random state 0 for both the tasks to train the models for all experimental setup.

3 Experiment Setup

3.1 Pre-processing

Task1 is a binary text classification. The dataset is annotated from 0 to 4 on the basis of PCL intensity in the text. We further re-label the dataset instances using the intensity score where 0,1 referred to Non-PCL text and (2-4) referred to PCL text. (Ref . Table 1)

Task2 is multi-label classification. Each dataset instance is annotated with different PCL category labels and the text span reflecting the PCL label is provided respectively. Many paragraph instances were annotated for more than one category of PCL over a different span of text. (Ref . Table 2)

For our experiments, we remove stopwords by using NLTK(Natural Language Toolkit) library and other non-ascii symbols from the text before performing feature engineering.

3.2 Feature Engineering

Count Vectorizer Feature extraction (Vectorization) on text, encodes the text as integers or floating point values for using as input in machine Learning algorithms. Scikit-learn's CountVectorizer is used to convert a collection of text documents to a vector of term/token counts.

Term Frequency- Inverse Document Frequency (TF-IDF) We use Sklearn TF-IDF, which is an approach to quantify words in a set of documents by computing a score for each word to signify its importance in the document or corpus.

TF-IDF = Term Frequency (TF) * Inverse Document Frequency (IDF)

TF is the ratio the frequency of a word in a document and the frequency with the total number of words in the document whereas, document frequency (DF) is the normalized count of documents in which the term is present. Inverse Document Frequency is the inverse of the document frequency which measures the informativeness of a term in the document. We used the features generated on the entire corpus and the feature length was 20244.

3.3 Models

Support Vector Machine (Burges, 1998) is an effective technique for classifying high dimensional data. It learns the optimal hyperplane that separates training examples from different classes by maximizing the classification margin. Each row vector of the word-document matrix represents the vectorization of text that are mapped to a latent semantic space in this module by LSA vector space model, to generate representation vectors and further classify them. We perform Principal Component Analysis (PCA) (`number of components`=500) to perform dimension reduction over text features before inputting to this model.

Logistic Regression (Cramer, 2002) is a classification algorithm used to solve binary and multi-label classification. The logistic regression classifier uses the weighted combination of the input features and passes them through a sigmoid function.

Stochastic Gradient Descent (Ruder, 2016) is an iterative algorithm that starts from a random point on a function and travels down its slope in steps until it reaches the lowest point of that function. We perform feature scaling before inputting the features to the model.

AdaBoost (Freund and Schapire, 1997) Adaptive Boosting is very popular boosting technique that combines multiple local weak classifiers into

Model	Unb	shall	Pres	Auth	Meta	Comp	poorer	Average F1

Roberta-baseline	0.3535	0	0.1667	0	0	0.2087	0	**0.104**

Table 5: F1-Score for ML Models for task2 on test set

a single strong classifier. It can be used to significantly reduce the error of any learning algorithm that consistently generates classifiers whose performance is a little better than random guessing. We initiate the model with `number of estimators` = 400, `learning rate` = 1, and `base classifier` = DecisionTreeClassifier with `criterion` ='entropy'.

Multilayer Perceptron (MLP) (Rosenblatt, 1961) is a classical type of neural network. They are composed of one or more layers of neurons. Data is fed to the input layer, there may be one or more hidden layers providing levels of abstraction, and predictions are made on the output layer, also called the visible layer. MLPs are suitable for classification prediction problems because they are known to be capable of modelling complex functions. We used number of `hidden layers`= 30(for task1),and 1000 (for task2), and `maximum iteration` = 2000 to initiate the MLP model. Activation functioned used for the hidden layer is by default i.e ReLU (Nair and Hinton, 2010).

3.4 Ensemble

For our submitted system, after predictions were extracted from different models, we calculate the ensemble (Kuncheva and Whitaker, 2003) using the mode to find the most frequently occurring label. In the presence of a tie-breaker scenario, we select the label predicted by the best performing model.

3.5 Implementation

For all the models, we used Scikit learn library for our (Pedregosa et al., 2011) implementation. For task1, our validation set has 2094 examples and for task2, we have 199 examples from the training data according to the initial data split. All the models were initiated with `class_weight` ='balanced' setting , `maximum iteration`=1000. For the rest of the hyper-parameters we use the default setting otherwise specified in their sections. The github repository containing all the details of our experiments is made publicly available[1].

4 Results & Discussion

We evaluate and report the performance of different models on our validation set and the blind-test set (Table 3, 4, 5). We can see that logistic regression model performs the best among all the models with TF-IDF features as the input for task1 and SVM works better than of LR classfier for task2.

We see a steep drop in the performance of model on the test-set. This can be attributed to the difference distribution in the training and testing data which reduces the effectiveness of the TF-IDF features. The imbalance in the dataset also can be a reason for the model to perform badly on the 'Non-PCL' class in task1 (1) and 'poorer' class in task2 (1) . The machine learning models are not effective compared to the roberta-baseline as we see that

Table 7: Examples of incorrect predictions made by Logistic Regression Classifier in Task 2.

static text features are less helpful in the detection of PCL.

The table 6, 7 contains examples from the task1 and task2 validation set respectively, where the model failed to label the paragraph instances correctly. We can see that, the presence of vulnerable community keywords (Highlighted Table 6,7) often confuses the model leading it to mislabel the instances. We observe that TF-IDF features are not able to capture contextual information as they rely only on the presence of the word indicators . We believe that this is the reason behind the inefficiency of the ML models.

5 Conclusion

This paper presents our study of machine learning models for the binary and multi-label text classification on the PCL detection shared task. We find that tf-idf features can be effective in cases where train and testing data are from the same distribution but it may fail otherwise. For future work, we plan to experiment with contextual embeddings from BERT, and other transformer-based models. We also would like to look into bootstrapping and data augmentation techniques to solve the class imbalance problem more effectively.

Abstract

An understanding of patronizing and condescending language detection is an important part of identifying and addressing discrimination and prejudice in various forms of communication. In this paper, we investigate several methods for detecting patronizing and condescending language in short statements as part of SemEval-2022 Task 4. For Task 1a, we investigate applying both lightweight (tree-based and linear) machine learning classification models and fine-tuned pre-trained large language models. Our final system achieves an F1-score of 0.4321, recall-score of 0.5016, and a precision-score of 0.3795 (ranked 53 / 78) on Task 1a.

1 Introduction

Patronizing and Condescending Language (PCL) is characterized by expressions that reveal a sense of compassion or superiority toward others. Research suggests that PCL can perpetuate–and even veil–discrimination toward vulnerable groups (Ng, 2007). To make matters worse, its presence is often more subtle than other offensive language (Mendelsohn et al., 2020).

Detecting PCL is a challenging task for humans annotators–and the task becomes even trickier for artificial systems. Given the varied nature of condescension, current NLP models struggle to accurately detect PCL. Part of the issue is defining what patronizing and condescending language is, exactly–what one reader considers condescending might be deemed perfectly respectful by another.

SemEval-2022 Task 4 attempts to address some of these issues (Pérez-Almendros et al., 2022). Pérez et al. classify PCL into seven distinct categories: *unbalanced power relations*, *shallow solutions*, *presupposition*, *authority voice*, *metaphor*, *compassion*, and *the poorer, the merrier*.

Task 1a seeks to determine whether the sequence of text contains any form of patronizing or condescending language. Task 1b seeks to identify the PCL category that corresponds to the sequence of patronizing or condescending text. Overall, developing systems that perform well on these tasks—-that are capable of flagging condescending language–is a critical step toward reducing discrimination toward minority groups in media. We investigate various lightweight models to determine whether such models trainable on an extremely small compute budget could effectively identify PCL, as well as larger pre-trained transformer models to identify whether performance improves as models increase in size and complexity.

2 Dataset

For Task 1a, we train and validate our models on the SemEval-2022 Task 4 training set (Pérez-Almendros et al., 2020). Each paragraph has been annotated by two annotators on a Likert-type scale from 0 to 2 as shown in Table 1. The scores from each annotator are summed together: an overall score of 0 signifies that both annotators gave scores of 0, 1 that just one annotator gave a score of 1, and 2-4 that any higher score given by both annotators was summed together. A summary of the PCL status based on the two annotators' scores is shown in Table 2.

We did not investigate Task 1b.

Rating	Description
0	no presence of PCL
1	borderline PCL
2	contains PCL

Table 1: Likert scale for annotators to describe PCL status.

2.1 Train-test split

The dataset has a total of 14366 examples, split 10469–3897 between training and testing sets. The testing set was not provided until the last phase of the competition, so we created our own validation

Sum	Description
0-1	Not a PCL paragraph
2-4	A PCL paragraph

Table 2: Summary of PCL status based on two annotators' scores.

set using a 75/25 train/validation split. For this reason, our train set has 7851 examples, and our validation set has 2618 examples. In our paper, all "validation-set" performance is reported on this internal held-out set.

3 Methods

3.1 Systems Overview for Task 1a

The aim of this task is to classify a given sequence of text as patronizing and condescending or not. We implement the following lightweight machine learning classifiers in **Scikit-learn** (Pedregosa et al., 2011):

- **Logistic Regression** is a supervised classification algorithm that employs a logistic function to categorize data into discrete classes. (LaValley, 2008)
- **Support Vector Machine** is a supervised classification algorithm that maps data points in a hyperplane to maximize the width of the gaps between two or more categories. (Gold and Sollich, 2003)
- **Random Forest** is an supervised learning technique that utilizes random bagging of different bootstrap samples of data to create a prediction from uncorrelated trees that is more accurate than any one tree. (Liaw et al., 2002)
- **Multi-layer Perceptron** is a feed-forward neural network with an input layer, an output layer, and any number of hidden layers. (Gardner and Dorling, 1998)
- **Gradient Boosting** is a greedy additive algorithm that sequentially ensembles an number of weak learners (typically decision trees) (Natekin and Knoll, 2013).
- **AdaBoost (Adaptive Boosting)** is a form of gradient boosting that adds weights to each subsequent weak learner (also typically decision trees) with incorrectly classified samples until either all data points have correctly classified or the maximum iteration has been reached. (Hatwell et al., 2020)

Ensemble We also experiment with a Voting-Classifier ensemble which incorporates one Logistic Regression, one Random Forest, and one Gaussian-hybrid models. Our models were averaged with equal weights.

We also experiment with the following pre-trained language models to try and effectively classify the presence of PCL in sentences:

- **BERT** is a pre-trained masked language model. We use BERT-cased, BERT-Large-cased, BERT-uncased, and BERT-Large-uncased in our experiments. (Devlin et al., 2018)
- **RoBERTa** is an optimized BERT model that utilizes the same architecture but various changes such as larger mini-batches and learning rates. We use RoBERTa and RoBERTa-Large. (Liu et al., 2019)

3.2 Experimental Setup

Normalization We investigate standardizing the dataset (implemented with the **Scikit-learn** *StandardScaler* preprocessing function) for the lightweight models.

Pre-Trained Models Regarding the large pre-trained models, we trained with binary cross-entropy loss for 5 epochs, using a learning rate of 1×10^{-5} and batch sizes of 8 (BERT and RoBERTA-base) and 3 (BERT and RoBERTa-Large).

4 Results

The official evaluation set performances for our classifiers are listed in Table 3, while the unofficial validation set performances for our Scikit-learn and Transformer-based models are listed in Table 4.

For Task 1a (patronizing and condescending language binary classification), we submitted our two highest-performing lightweight models (Support Vector Machine and Random Forest models). Due to error, we did not submit our BERT model. Overall, we ranked 53rd out of 78 on this task, achieving a positive-class F1 score of 0.4321.

Model	positive-class F1 (1a)	recall-score (1a)	precision-score (1a)
Support Vector Machine	**0.4321**	**0.5016**	**0.3795**
Random Forest	0.3310	0.3691	0.3000

Table 3: Official validation set performance of our lightweight models on Task 1a (binary classification).

Model	Features	positive-class F1 (1a)	Accuracy (1a)	Normalize
Logistic Regression	GloVe	0.37	0.76	False
Logistic Regression	GloVe	0.37	0.76	True
Support Vector Machine	GloVe	0.37	0.73	False
Support Vector Machine	**GloVe**	**0.48**	**0.89**	**True**
Random Forest	GloVe	0.38	0.87	False
Random Forest	GloVe	0.39	0.86	True
Multi-layer Perceptron	GloVe	0.40	0.90	False
Multi-layer Perceptron	GloVe	0.34	0.88	True
AdaBoost	GloVe	0.31	0.90	False
AdaBoost	GloVe	0.31	0.90	True
VotingClassifier Ensemble	GloVe	0.42	0.87	False
VotingClassifier Ensemble	GloVe	0.42	0.87	True
RoBERTa-base	—	0.54	0.92	False
RoBERTa-large	—	**0.55**	**0.92**	**False**
BERT-cased	—	0.55	0.91	False
BERT-uncased	—	0.51	0.91	False
BERT-large-cased	—	0.56	0.93	False
BERT-large-uncased	—	0.53	0.92	False

Table 4: Unofficial validation set performances of candidate models on Task 1a (binary classification). For this task, the highest-performing lighweight models are the Support Vector Machine model and the Random Forest model, and the highest-preforming pre-trained models are BERT-cased and RoBERTa-large.

5 Conclusion

We have proposed lightweight and pre-trained systems that are able to detect PCL in text.

We find that reasonably lightweight models such as Support Vector Machine and Random Forest are effective at predicting the level of patronizing and condescending language. However, we note that ensembling these models together does not improve performance.

Additionally, normalizing the dataset had little effect for most models—-and in the case of the Multi-layer Perceptron model actually returned a lower positive-class F1 score. However, it substantially increased the F1 score with the Support Vector Machine model from 0.37 to 0.48.

Finally, we find that fine-tuning large pre-trained models like BERT and RoBERTa achieves results at least as accurate as lightweight models–if not better.

An area of interest for future work may be further experimentation with ensembles of lightweight models, as well as inquiries into adversarial and contrastive learning to improve overall accuracy.

Overall, our results show that both lightweight and fine-tuned models can achieve reasonable results at detecting patronizing and condescending language in human channels of communication.

Abstract

The act of appearing kind or helpful via the use of but having a feeling of superiority condescending and patronizing language can have have serious mental health implications to those that experience it. Thus, detecting this condescending and patronizing language online can be useful for online moderation systems. Thus, in this manuscript, we describe the system developed by Team UTSA SemEval-2022 Task 4, Detecting Patronizing and Condescending Language. Our approach explores the use of several deep learning architectures including RoBERTa, convolutions neural networks, and Bidirectional Long Short-Term Memory Networks. Furthermore, we explore simple and effective methods to create ensembles of neural network models. Overall, we experimented with several ensemble models and found that the a simple combination of five RoBERTa models achieved an F-score of .6441 on the development dataset and .5745 on the final test dataset. Finally, we also performed a comprehensive error analysis to better understand the limitations of the model and provide ideas for further research.

1 Introduction

Patronizing and condescending language (PCL) generally appears as an act to hold a superior attitude, resulting in language that "talks down" to others. For instance, PCL may describe someone in a power position as the potential "savior" of a vulnerable community (e.g., "*A donation of one dollar can save a life*"), masquerading a sense of superiority as compassion. There has been recent research suggesting that PCL can have adverse effects on the mental health of individuals (Giles et al., 1993; Shaw and Gordon, 2021), particularly in the context of ageism. While there has been substantial research on PCL in various contexts (Huckin, 2002; Komrad, 1983; Giles et al., 1993; Shaw and Gordon, 2021), unfortunately, there have been few efforts to develop PCL detectors in the field of Natural Language Processing (NLP). Hence, this paper describes our team's (UTSA NLP) contributions on the SemEval-2022 Task 4 (Pérez-Almendros et al., 2022) that introduced a new dataset for detecting PCL language.

NLP has investigated a broad spectrum of problematic language usages, such as hate speech (Vidgen et al., 2021), sarcasm language (Bamman and Smith, 2015), fake news (Hu et al., 2021), and the spread of rumors and disinformation. However, PCL has only recently been explored in the NLP community (**?**). To alleviate this issue, SemEval-2022 Task 4 expanded on the work by **?**, releasing a large PCL dataset for two PCL subtasks. Subtask 1 focuses on detecting the presence of PCL in news stories. PCL detection consists of a variety of sub-problems, for instance, identifying the exact PCL type expressed post (if any). There are multiple technical challenges for identifying PCL. For instance, accurate models must handle imbalanced data (most news stories do not contain PCL) and complex semantic understanding to relate shallow solutions for helping vulnerable populations. For instance, **?** describe "Shallow Solutions" as a type of PCL, e.g., "*Raise money to combat homelessness by curling up in sleeping bags for one night*". Nevertheless, for a model to understand this is an example of PCL, it would need to understand that "curling up in sleeping bags for one night" is unlikely to help the general problem of homelessness. Hence, we hypothesize that different models will learn to detect different types of PCL with varying accuracy; thus, combining multiple methods can result in better performance than a single method.

Overall, this paper describes our system for Task 1. Specifically, we evaluate multiple combined methods to handle PCL's complex nature better than a single method. Hence, for our methodology, we trained a RoBERTa model and two traditional deep learning models (a Convolutional

Neural Network and a Long Short-Term Memory Network) for comparison. In addition, we experimented with different model hyperparameters, random seeds, thresholds, and pre-trained word embeddings using the performance on the validation set to assess model variants. Finally, we evaluate multiple simple, yet effective, methods of combining the neural network models in an ensemble.

2 Background

Based on the work of **?**, the SemEval Task 4 dataset contains 10,637 news stories about vulnerable people published in 20 English-speaking countries, with a novel PCL taxonomy consisting of three top-level categories (The savior, The expert, and The poet) and seven low-level PCL categories describing the different types of condescension (Perez Almendros et al., 2020). Thet task contains two subtasks: binary classification (subtask 1) and multi-label classification (subtask 2). The binary classification for subtask 1 annotated the data with one of two categories: PCL and Not PCL. Subtask 2, the multi-label classification task, categorizes the news stories into a subset of of seven different PCL categories: unbalanced power relations, authoritative voice, shallow solution, presumption, compassion, metaphor, and the pooer, the merrier. A complete description of each category can be found in **?**.

PCL has been studied in a wide array of contexts, from sociolinguistics to healthcare (Huckin, 2002; Komrad, 1983; Giles et al., 1993; Shaw and Gordon, 2021). However, much of the prior work has focused on interviews and general qualitative methods. Thus, automated PCL detection models can provide social scientists with tools to understand the impact of PCL at scale. For instance, PCL models would allow linguistics to understand the implicit language actions related to condescension and aid social scientists in researching the link between condescension and other characteristics like gender or socioeconomic status because these superior attitudes and discourse of pity can routinize discrimination and make it less visible(Ng, 2007). However, much of the research on harmful language in NLP has concentrated on the explicit, offensive, and apparent phenomena like false news identification, trustworthiness prediction and fact-checking, modeling offensive language, both generic and community-specific (Vidgen et al., 2021; Zampieri et al., 2019; Schmidt and Wiegand, 2019); or how rumors spread (Ma et al., 2017). Recently, some work on condescending language has begun to surface. For example, based on the challenge that condescension is often undetectable from isolated discourse because it depends on discourse and social context, Wang and Potts (2019) introduces the task of modeling the phenomenon of condescension in direct communication from an NLP perspective and developing a dataset with annotated social media messages. Likewise, **?** also trained various baseline models to examine how existing NLP approaches perform in this task. Although they observe that recognizing PCL is achievable, it is still difficult. Hence, the work by **?** formed the basis of SemEval Task 4.

3 System Description

Overall, we developed an ensemble model strategy for the PCL challenge. Specifically, we evaluated three individual methods: RoBERTa, Convolutional Neural Networks, and Long Short-Term Memory Networks. Furthermore, we experimented with various ensemble combinations. Approaching the task we conduct multiple experiments with a variety neural network architectures using Convolutional Neural Networks (CNN) (Kim, 2014), Bi-directional long short term memory (BiLSTM) (Huang et al., 2015), and the pre-trained transformer-based model, RoBERTa (Liu et al., 2020). Each model and ensemble method is described in the section below.

CNN. We use the CNN model introduced by Kim (2014). Intuitively, the CNN model learns to extract predictive n-grams from the text. For the CNN architecture, we used filter sizes that span two, three, and four words. For the activation functions, we used ReLU (Glorot et al., 2011). Furthermore, we only needed two filters for each filter size [1]. Between the max-pooled outputs from the convolutional layer and the the full-connected output layer, we use dropout with the probability set to 0.5 during training. The final fully-connected output layer uses a Softmax activation and outputs class probabilities for PCL or Not PCL. The model was trained with the Adam optimizer (Kingma and Ba, 2015). Furthermore, we trained the CNN models with various learning rates randomly selected from 1e-4 to 1e-3 for a maximum of 35 epochs.

[1]We experimented with filter normal filter sizes from 100 to 300, but two seemed to perform just as well. We hypothesize this is because of the small number of PCL examples in the dataset.

BiLSTM. While CNNs only extract informative n-grams from text, recurrent neural networks (RNNs) are able to capture long term dependencies between words. For our RNN method, we use a Bidirectional Long Short-Term Memory Network (LSTM) (Hochreiter and Schmidhuber, 1997), specifically we use a variant introduced by Graves (2012). For the hyper-parameters, we did not use dropout, trained for a maximum of 35 epochs, and used variety hidden layer sizes (128, 256, and 512). The models were trained with the Adam optimizer (Kingma and Ba, 2015). Furthermore, we trained the BiLSTM models with various learning rates randomly selected from 1e-4 to 1e-3.

RoBERTa. In our study we used a variant of BERT (Kenton and Toutanova, 2019), namely RoBERTa (Liu et al., 2020) model, which is lighter and faster. Specifically, we use the roberta-base variant in the HuggingFace package (Wolf et al., 2019). We trained the RoBERTa model for 20 epochs with a mini-batch size set to 8 with the Adam optimizer. The learning rate was initially set to 2e-5 (other hyper-parameters same as (Liu et al., 2020)) and the adjusted stepwise linear decay was used to modify the learning rate through training, with step sizes of two and three used. Moreover, we used the last layer's CLS token which is passed to a final softmax layer. The model was check-pointed after each epoch, and the best version was chosen using the validation data.

Pre-trained Word Embeddings. For the CNN and BiLSTM models, we compare the following pre-trained word embeddings: Word2Vec vectors trained on Google News corpus (Mikolov et al., 2013), GloVe vectors trained on Wikipedia2014 and Gigaword5 corpus (GLoVe-Word) and Twitter (GLoVe-Twitter) corpora (Pennington et al., 2014), and FastText vectors trained on CommonCrawl corpora (Bojanowski et al., 2017).

Ensemble Model. There has been a wide array of research showing that ensembles of deep learning models have are useful for boosting model performance (Allen-Zhu and Li, 2020; Peng et al., 2018). We built different ensemble models by taking an unweighted average of the probability outputs of each of the independently trained models. This includes models trained with different hyperparameters, e.g., hidden state size for the BiLSTM models, different learning rates, and different random seeds. For the CNN and BiLSTM, each model was trained on four different pre-trained word vectors described above. The CNN and LSTM models were also trained on four different random seeds, for each combination of word embedding and learning rate. The RoBERTa model was trained with eleven random seeds and a number of two different step-wise learning rate schedulers using step sizes of two and three. Overall, we trained a total of 46 different models for the PCL task. Next, we experimented with two methods of model averaging (i.e., an ensemble): Ensemble 1 and Ensemble 2.

Model	Embedding	Seed	LR	HL
CNN	FastText	99	0.002	NA
LSTM	Glove_Twitter	99	0.002	128

Table 1: The hyperparameters for the best CNN and LSTM models found using random search. We report random seed (Seed), learning rate (LR), and pretrained embeddings (Embedding), and hidden layer size (HL) in this table.

First, for **Ensemble 1**, we simply average the top five model instances—which resulted in different RoBERTa models trained with different random seeds and learning step settings, i.e. step sizes of two with random seed of three; step size of three with random seed of zero, two, four, or seven. Second, for **Ensemble 2**, we experimented with taking the top five models combined with the top two CNN and BiLSTM models, and the hyperparameters (e.g., learning rate and embedding size) of the best performing models are shown in Table 1.

4 Dataset, Experimental Setup, and Training Details

For subtask 1, we use the train dataset provided by the PCL organizers. We choose the best epoch and the best hyperparameters using performance assessed in terms of F1-score on this development set based on the random search (Bergstra and Bengio, 2012). We saved the best epoch and best hyperparameters for each model variant. For evaluation, we use the provided test and validation datasets released by the organizers. We implemented our models on four GPUs using PyTorch (Paszke et al., 2019) to train binary classifiers for PCL. We use Cross-Entropy Loss in all our experiments as the loss function. We ran the experiments on a server using a GPU CUDA Version: 11.4. We selected the epoch based on the F1 score on the development set to save the best version of each model.

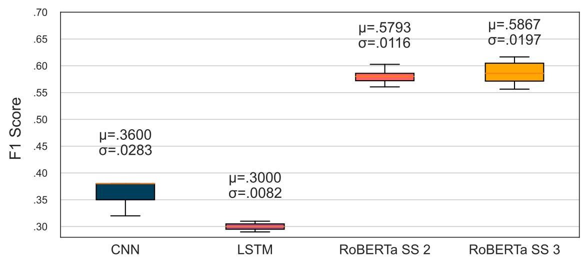

Figure 1: F1 score distributions for the best CNN, LSTM and RoBERTa models with the same hyperparameters, but different random seed values on the development dataset. SS stands for the learning rate step size.

To build a basis for comparison, all models were trained using the training data provided by the task organizers and evaluated against the provided validation dataset. The best-performing models were then submitted for evaluation against the test dataset during the task evaluation period. The training method was repeated three times for CNN and LSTM and eleven times for Roberta, each with a new random seed. This is because changing the random seed used in fine-tuning RoBERTa models can provide significantly different outcomes, even if the models are similar in terms of hyper-parameters (Dodge et al., 2020). The best-performing hyperparameters in each model were saved for the remainder of the ensemble study. We examined three random seeds (17, 42, and 99) for the best CNN and LSTM models, with standard deviations .0283 and .0082, respectively. We also evaluated ten random seeds for the RoBERTa model with step sizes of 2 and 3, yielding standard deviations for variance of .0116 and .0197, respectively. The distribution of each model's performance for different random seeds is shown in Figure 1.

We attempted to build a robust ensemble classifier with softmax output aggregation. For the ensemble model, the default threshold for interpreting probabilities as class labels is 0.5, but due to the imbalanced classification problem, we adjust the optimal threshold range from 0.1 to 0.9 when converting probabilities to class labels. We found the optimal probability threshold of CNN, LSTM, and RoBERTa that resulted in the best F1 score on the validation dataset were .1, .35, and .35, respectively.An optimal threshold was also chosen for the ensemble model, which was found to be .35.

		AVG P.	AVG R.	AVG F1

5 Results

Table 2 shows the average recall, precision, and F1 score. The scores are averaged across the different random seeds and hyperparameters used to train the models. Overall, we notice that the RoBERTa model outperforms both the CNN and BiLSTM models by more than 20%. For the CNN model, we find that the GoogleNews word embeddings perform best. However, for the BiLSTM model, we find that the model performs similarly across all pretrained embeddings, with the Glove Word embeddings slightly outperforming others.

In Table 3 we report the results of the two ensemble models: Ensemble 1 (only RoBERTa Models) and Ensemble 2 (Combining RoBERTa with the CNN and RNN models). On the development set, we find that that a single RoBERTa model achieves an F1 of .6311, with the next best four models achieving an F1 of around .61. The F1 of Ensemble 1 improves on the best RoBERTa models result

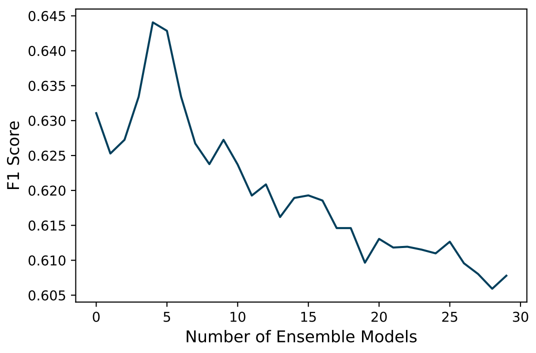

Figure 2: F1 score for different sized ensembles on the development dataset.

	FPs	FNs	Total PCL	Total
homeless	15	9	29	212
poor-families	13	17	38	190
women	3	8	14	233
in-need	15	2	33	226
immigrant	0	4	7	218
hopeless	15	9	26	217
vulnerable	6	4	20	209
migrant	2	3	5	207
disabled	4	7	14	194
refugee	8	3	13	188

Table 4: Summary of the false positives and false negatives found in each of the then PCL types.

by more than 1%. Ensemble 2 only improves on the Best F1 by .1%. However on the final test set, we find that the differences is not meaningful, with Ensemble 2 slightly outperforming Ensemble 1 (.56 vs. .57).

Next, in Figure 2 we report the results of averaging different number of models in our ensemble. More specifically, we evaluate averaging the best two models, best three models, and best N models, for N up to an ensemble of 30 different models. The model is chosen based on the top N performing models across all model types and random seeds. Overall, we see that initially the result of an ensemble of size 1 (i.e., only using the best RoBERTa model) has an F1 of around .63. However, that slowly increases beyond .64 at around the top five models. After that, the results slow decrease. Overall, we find that while a few models with varying performance improves the results. The more inaccurate models slowly outweigh the best performing model, thus decreasing the overall results. However, we find that the results stabilize around 0.61. Finally, in Table 4 we measure the number of False Positives and False Negatives for each of the main keywords identified in the PCL dataset (e.g., they keywords are provided by the organizers indicating a vulnerable group). The model produced 66 false negative predictions and 81 false positives predictions in total, but most of false positive errors are come from homeless,in-need, poor families, and hopeless. And the false negative error occur more frequently among the homeless, woman, immigrant, migrant and disabled topic.

5.1 False Positives and False Negatives

In addition to an exploration of the observation results, we perform an error analysis by manually comparing the true labels and predictions of Ensemble 1. First, for False Positives, we analyze an example related to "hopelessness/homelessness":

FP Example:"The City Without Drugs organisation is still active , as is their YouTube channel . It features hundreds of videos of drug addicts being dragged half-conscious through the street , their faces not blurred , or confessing their alleged worthlessness , their hopelessness , their shame."

This paragraphs is predicted as PCL, but the ground-truth is Not PCL. This example indicates that the Ensemble incorrectly identifies sentences as PCL when they contain many PCL-related words that may be related to PCL-like text (e.g., related to hopelessness), even when the text is not directly indicating a feeling of superiority. Another false positive example is from the "homeless" topics:

FP Example:"Viral photo helping fund homeless kid , his dog."

We can see that the entity of this sentence is a single individual. This paragraph is recognized as PCL by the system, maybe because the PCL system believes it contains the shallow solution (i.e., viral photo). However, it neglected the fact that financing a specific homeless child may be realistic, i.e. it may not be a shallow solution for a single person. Perez Almendros et al. (2020) also mention that shallow solutions are also often overlooked by RoBERTa, where recognizing shallow solutions in the text requires external knowledge of the situation and the needs of those affected. Thus, a large number of false positive results are generated by misidentifying the entities and the relationship between patronizing and condescending language. Next, we look at a False Negative:

FN Example: "Charity plans to forgo parking so homeless can have gym and medical centre."

Here we find another issue with shallow solutions. Specifically, the model is not able to associate the proposed procedure as not being a method of really addressing homelessness. Specifically, the PCL system unaware that "forgoing parking" is not a complete solution to help homeless people, which is a simple and superficial philanthropic effort that is unlikely to make a significant difference on vulnerable communities. The second example of a false negative concerns presuppositions. People need to decide whether the assumption made is reasonable or not for this type of PCL. We found for the political topic, like immigrant and migrant topics, there are many preconceived assumptions in this kind of news. For example, in the following situation, the author assumes Filipino families are poor and need assistance based on stereotypes.

FN Example:"But if the Supreme Court gives a favorable decision for the president , his immigration program would immediately take effect , changing the lives of eligible Filipino families and other immigrants."

This error suggests that the model is incapable of understanding complex relationships between vulnerable communities and ideas. A future interesting research avenue would explore methods for incorporating relevant knowledge bases, similar to recent work on common sense generation (Xing et al., 2021), into transformer models to address these errors.

6 Conclusion

In this paper, we have presented our submission for the PCL detection system submitted to the SemEval-2022 Task 4. Our team are focus on the subtask1 to identify whether the paragraphs contain the PCL or not. We proposed several ensemble models that leverages pre-trained word vectors and three different deep learning architectures. In future efforts, we plan to further improve our model by incorporating structured knowledge bases.

Abstract

This paper presents the AliEdalat team's methodology and results in SemEval-2022 Task 4: Patronizing and Condescending Language (PCL) Detection. This task aims to detect the presence of PCL and PCL categories in text in order to prevent further discrimination against vulnerable communities. We use an ensemble of three basic models to detect the presence of PCL: fine-tuned bigbird, fine-tuned mpnet, and BERT+BiGRU. The ensemble model performs worse than the baseline due to overfitting and achieves an F1-score of 0.3031. We offer another solution to resolve the submitted model's problem. We consider the different categories of PCL separately. To detect each category of PCL, we act like a PCL detector. Instead of BERT+BiGRU, we use fine-tuned roberta in the models. In PCL category detection, our model outperforms the baseline model and achieves an F1-score of 0.2531. We also present new models for detecting two categories of PCL that outperform the submitted models.

1 Introduction

Increasing internet access rates and the development of a diverse range of online forums have allowed people around the world to engage in a tremendous range of topics. This has been accompanied by an increase in unhealthy online texts whose negative effects on people have been significant. One type of such unhealthy texts is a text with patronizing and condescending language (PCL). When a person's language expresses a superior attitude towards others or describes their situation in a benevolent way that creates a sense of pity, the person has used this type of language. In the media, vulnerable communities seem to be a good target for this type of language. However, this type of language can normalize discrimination. We believe that unfair treatment of vulnerable groups leads to greater deprivation and inequality for these groups. Therefore, recognizing the existence of this type of language and its variations is important and can prevent these problems.

So far, significant work has been done on modeling the language that deliberately and openly undermines others, such as offensive language or hate speech, but little has been done on the language of humiliation and pity. This language of humiliation and pity is used in the media subtly and indirectly and different from other types of unhealthy languages. The special focus on the language of humiliation and compassion for vulnerable communities has been noted only in the work of Pérez-Almendros et al., (2020). In this work, a dataset to identify this type of language is presented, but no significant work has been done in designing a model to classify this type of text.

Unhealthy text papers usually focus on obvious and aggressive phenomena such as detecting fake news, fact-checking, modeling offensive language, and spreading rumors. There has been a few work on PCL recently. Wang and Potts (2019) introduced compassion modeling in direct communication from the perspective of natural language analysis. They created and tagged a dataset with social media messages. Sap et al. (2019) Discussed the specific uses of language and power, especially the unbalanced power relations often present in degrading treatment, and the social consequences of these applications. Unfair treatment of disadvantaged groups was also examined as an example of these cases. Price et al. (2020) Provided datasets for classifying unhealthy speech on social media. They provided fine-grained classifications for all kinds of unhealthy writings, one of which was PCL.

Of course, the use of this type of writing is not limited to weak groups in society. There is still a need to design a model to detect such language towards vulnerable communities. PCL is a toxic language that implicitly has a negative impact on public opinion. There are tasks that generally identify toxic language that can be used to provide an answer to this problem. For example Lees et al. (2021) proposed the use of a fine-tuned BERT model to detect veiled toxicity.

To design a model to detect this language in vulnerable communities, we participated in SemEval 2022 task 4 competition (Pérez-Almendros et al., 2022). This paper describes the models we provide for detecting PCL. The contest data is taken from the work of Pérez-Almendros et al., (2020).

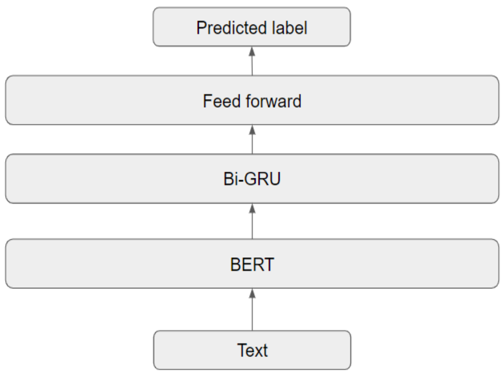

Figure 1 The general structure of BERT+BiGRU model

To detect the presence of PCL, we present an ensemble model. This model consists of three basic models: fine-tuned bigbird, fine-tuned mpnet and BERT + BiGRU. The models are combined with the weighted average. This model cannot perform better than the baseline because our model is overfitted. In this paper, we present a solution to this model's problem and create a new model that can achieve an F1-score of 0.5505. To identify existing PCL categories, we consider the categories separately. To detect the presence of any category, we act like detecting the presence of PCL. The basic models for making ensemble models are fine-tuned bigbird, fine-tuned mpnet and fine-tuned roberta. The model can outperform the baseline model. In addition to this model, in two categories, we improve the diagnostic model and build a new model. This model can achieve an F1-score of 0.3160. The statement of contributions is given below.

To balance the data set, we used a different method than the data set providers. Instead of using the sampling method (We sample twice the number of PCL data from non-PCL data), we used a combination of the sampling method and EDA (Wei et al., 2019). And in compassion and metaphor diagnosis, we used a set of related articles for balancing. We paid attention to the medium and high lengths of the texts and used language models with the ability to summarize long texts. We used the ensemble model for classification to help reduce the bias caused by the data set imbalance.

2 Models

In this section, we describe how to detect the presence of PCL in the text and how to detect the type of PCL in the text. We describe the models used for these diagnoses.

2.1 Subtask1: PCL detection

Recognizing the presence of PCL in the text is a two-class classification problem. To do this, we use a model that is an ensemble of three basic models. Our base models are fine-tuned bigbird, fine-tuned mpnet, and BERT+BiGRU model. We use BERT language model (Devlin et al., 2018) for this classification to prepare the BERT+BiGRU model. We also fine-tune the Big Bird language model (Zaheer et al., 2020) and the MPNet language model (Song et al., 2020) to prepare the fine-tuned bigbird and fine-tuned mpnet models.

The texts are taken from the news. For this reason, there is medium to long texts in the data, and to address this issue, we used two language models, mpnet and bigbird, to create our model. This allows the model for long texts to extract the information needed for classification. Details about the length of the texts are given in the section 4.1 .

Each of the basic models learn separately on the training data. We then combine the results of the models to predict the text class using the weighted average to generate our model prediction. To combine the models, we use the probability that the text has PCL. Each model predicts this probability for each text. First, we use the weighted average of the probabilities predicted by these two models. We use a weight of 0.4 for the mpnet model prediction and a weight of 0.6 for the bigbird model prediction. Then, we use the weighted average to combine the BERT+BiGRU model prediction and the average prediction of the previous two models. The weight of the BERT+BiGRU model in this average is equal to 0.3 and the weight of the combination of the two previous models is equal to 0.7.

2.2 BERT+BiGRU model

The model consists of three layers. The first layer of the model applies BERT. In this layer, we give the cleaned text to the language model and get the embedding of text tokens. Then we give tokens' embedding to the Bi-GRU layer. The output of the Bi-GRU layer is then given to the feed forward layer to predict the input class. The general structure of this model is shown in Figure 1. To clear the text, we remove the HTML tags, URLs, Mentions and Emojis in the text. More details of this model are given in Section 3.1 .

2.3 Fine-tuned other Language Models

To fine-tune these language models, we use a two-layer model. In the first layer, the language model takes the input text and creates a display for the entire text. The classifier token embedding is used to display the entire text. In the second layer, we predict the label using a feed forward network. In these models we do not clean the input text. Figure 2 shows the general structure of the model to fine-tune the language model.

2.4 Subtask2: PCL categories detection

The PCL categories detection problem is a multi-label classification. Given a paragraph, a system must identify which PCL categories (if any) appear in the paragraph. The problem is, a text can have multiple categories at the same time.

To solve this problem, we detect the presence of each category in the text separately from the other categories. That is, we create a separate model to identify each category. Each model solves a binary classification problem. This model determines whether the text has the desired PCL category or not.

To identify the "Unbalanced Power Relations" category in the text, we use an ensemble of two basic models. We use fine-tuned bigbird and fine-tuned mpnet as basic models. We use a weighted average to combine the two models. On this ensemble, the bigbird model weighs 0.7 and the other model weighs 0.3.

To identify the "Shallow Solution" category in the text, we also use an ensemble of two basic models. We use fine-tuned roberta and fine-tuned mpnet as basic models. We use a weighted average to combine the two models. On this ensemble, the roberta model weighs 0.7 and the other model weighs 0.3. We fine-tune the RoBERTa language model (Liu et al., 2019) for this classification to prepare the fine-tuned roberta model.

To identify the "Presupposition" category in the text, we use an ensemble of two basic models. We use fine-tuned bigbird and fine-tuned mpnet as basic models. We use a weighted average to combine the two models. On this ensemble, the bigbird model weighs 0.7 and the other model weighs 0.3 and the sum of the weights is one. In bigbird for this category, the error weight for class with "Presupposition" is 4 times that of class without "Presupposition".

To identify the "Authority Voice" and "Metaphor" categories in the text, the model structure is similar to the "Presupposition" detection model in the text. The only difference between the detection models of these categories is in the weights of the base models to create the ensemble model. In the weighted average for the "Authority Voice" category, the weights of the bigbird model and the mpnet model are 0.5 and 0.5. For the "Metaphor" category, the weight of these models are 0.6 and 0.4, respectively.

To identify the "Compassion" category in the text, we use an ensemble of three basic models. First, we combine the results of the two basic models with the weighted average. These basic models are fine-tuned bigbird and fine-tuned mpnet. We use a weight of 0.4 for the bigbird model and a weight of 0.6 for the other model. Then we combine the result of combining the previous two models with the prediction of the fine-tuned roberta model. We use a weighted average with a weight of 0.1 for the roberta model and we set the weight of the combination of the previous two models to 0.9.

We also use fine-tuned roberta to identify the "The Poorer The Merrier" category in the text.

Task 1 and Task 2 share the same input paragraphs and have different labels respectively. The reason we chose Task 1 fine-tuning models is the same as the reason for using Task 2 models. In addition to the Task 1 models, we also used the RoBERTa model for Task 2, which is the base model presented in the competition. In each category, all of these models are trained for classification, and we presented the best possible combination of these models as the final model. To determine the weights for creating the ensemble model, the performance of the constituent models has been considered. The model with better performance has more weight in the ensemble model.

3 Experimental Setup[1]

In this section, the structural details of the base models are given. All models are trained on the GPU of google colab[2] in normal account mode.

3.1 BERT+BiGRU model

In the Bi-GRU layer of this model, we use two layers. Set the dimension of the hidden layer vector to 256. The direction of one GRU (Chung et al., 2014) is the positive direction of the input sequence (from left to right), and the other is the reverse direction of the input sequence (from right to left). When feature extraction is performed on the input sequence, the GRUs in the two directions do not share the state. The state transition rules of GRU follow the transition occurrence between the same states. However, at the same moment, the output results of the GRUs in the two directions are spliced as the output of the entire Bi-GRU layer. We apply dropout to the output of this layer with a probability of 0.25.

We output the Bi-GRU layer result to the feed forward network. This feed forward network consists of a hidden layer with 256 neurons. We also set the maximum number of input tokens to 512. In the learning process of this model, we use 5 epochs. In learning phase, the error weight for PCL class is 2 times that of non-PCL class.

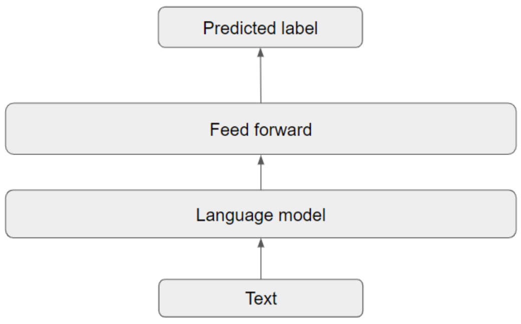

Figure 2 general structure of our model for fine-tuning the language model

3.2 Fine-tuned other Language Models

In the learning process of this model, we use 1 epoch. To fine-tune these language models, we use the ClassificationModel in the simpletransformers[3] library. The weight of the error in predicting the sample of class with label 1 can be different from the class with label 0.

4 Results and Analysis

4.1 Dataset

We use the SemEval 2022 task 4 dataset. We have three sets of training, evaluation, and testing in the competition data. The training dataset is imbalanced for both sub-tasks. Task 1 and Task 2 share the same input paragraphs and have different labels respectively. The maximum, mean, and median length of training texts are 5518, 294, and 258. Length means the number of characters. The maximum, mean, and median number of words in training texts are 911, 53, and 45.

To solve the problem of class imbalance in the learning process, we use the augmentation methods provided for toxic texts (Juuti et al., 2020). Among these methods, we use the EDA method for all binary classification problems. In some cases, we use other relevant datasets to increase minority class data.

In Task 1, we consider a constant difference of 4900 sample between the data number of the two classes. For classification, we paste the paragraph text, the keyword corresponding to the text, and the full name of the country associated with it, and consider it as the text for the classification. To reduce the data difference between the two classes, which is more than 4900, we add the texts of the Task 2 dataset that are not in the Task 1 dataset. We also add the first 100 texts of the talkdown dataset (Wang and Potts, 2019) to the collection. Wang and Potts (2019) introduced compassion modeling in direct communication from the perspective of natural language analysis. They created and tagged talkdown dataset with social media messages. Compassion is a type of PCL. For this reason, the use of compassion data helps detect the presence of PCL. All texts with a PCL type are added. We do not add the text itself, but we use the modified text

[1] Our code can be found at: https://github.com/AliEdalat/SemEval-2022-task-4-PCL-detection.git
[2] https://colab.research.google.com/

[3] https://simpletransformers.ai/docs/classification-models/

by substituting several words with the same meaning by using WordNet (Miller, 1995). We fill the rest of the difference between the two classes with two EDA methods. One way is to use modified texts that have PCL, by replacing some words with their synonyms in WordNet. Another way is to use modified texts that have PCL, by replacing some words with their nearest neighbours in Glove (Pennington et al., 2014) embedding space. Glove is a pre-trained word embedding that is trained on Twitter data.

For each category in Task 2, except for the "Metaphor" and "Compassion" categories, as in Task 1, we balance the classes. There are only two differences. We consider the difference between the two classes to be 5900 and do not use any other datasets to generate data. For the "Metaphor" category, the difference between the two categories is 5900. We get help from 1200 datapoints from vumc (Mu et al., 2019) dataset for balancing. Like the first task, we do not use this data itself and modify the text using WordNet. We fill in the rest of the gap like the other categories. For the "Compassion" category, we act like the "Metaphor" category. The only difference is the use of talkdown dataset instead of vumc.

With these methods, we prepare training data. To fine-tune non-BERT language models, we sample twice the amount of class with label 1 data from class with label 0. To predict the test data, we add the data that corresponds to the problem, with label 1 from the evaluation data to the training data.

4.2 Evaluation Metrics

We use competition metrics to evaluate system. For each binary classification, we use F1 score for label 1 as the evaluation metric. For Task 2, we use the mean F1 score for all categories as the evaluation metric.

4.3 Results

The results of the proposed model for Task 1 are given in the Table 2. In addition to the results of our model, the results of the baseline model of the competition are also included. The baseline model is fine-tuned roberta. This model uses sampling to balance the training dataset. In addition to our model, our model without using BERT+BiGRU in creating ensemble model is included ("(BigBird, MPNet)" shows this model in Table 2).

As you can see, our model did not perform well in the test and performed worse than the baseline due to overfit. But our model outperformed the baseline in evaluation. The reason for this overfit was the addition of the BERT+BiGRU model. As can be seen, if we remove BERT+BiGRU from the model, the model performs better in testing and evaluation than the baseline. BERT+BiGRU has contributed a little to the performance of the model in evaluation, but it has overfitted our model. So, the best model to solve this problem is “(BigBird, MPNet)”. Using this model, we achieved an F1-score of 0.5505.

Model	Eval F1	Test F1
(BigBird, MPNet, BERT+BiGRU) submitted system	0.5965	0.3031
(BigBird, MPNet)	0.5789	0.5505
Baseline	0.4829	0.4911

Table 2 The results of the proposed model for Task 1.

Category	Model	Eval f1	Test f1
Metaphor	**Our, submitted system (MPNet, BigBird 1:4)**	0.4557	0.1345
	PCM (MPNet, BigBird)	-	0.2947
Compassion	**Our, submitted system (BigBird, MPNet, RoBERTa)**	0.5565	0.1129
	PCM (BigBird, MPNet)	-	0.3932

Table 1 results of our models in the "Compassion" and "Metaphor" categories.

The performance of our model for Task 2 in evaluation and testing is given in the Table 3. The model presented in the Models section is called "Our Model" is listed in Table 3. The "Problem-free model in Compassion and Metaphor (PCM)" model is similar to our model, except that for the

"Compassion" category, we remove the fine-tuned roberta base model from its detection model. For the "Metaphor" category, we also set the weight of the class 1 detection error equal to the weight of the other class. As can be seen, our two models performed better than the baseline. The "PCM" model performs better than the "Our" model. Unfortunately, we did not use the "PCM" model in this competition. The reason for not using more models in two tasks was the restriction on uploading answers in the contest. Our F1-score in Task 2 of this competition was 0.2531. If we used the "PCM" model, our F1-score would be 0.3160.

The results of our two models in the "Compassion" and "Metaphor" categories are shown in the Table 1. BigBird 1:4 means that the two classes zero and one weigh one and four in the fine-tuned bigbird, respectively.

Model	Eval f1	Test f1
Our Model (submitted system)	0.3677	0.2531
Problem-free model in Compassion and Metaphor (PCM)	-	0.3160
Baseline	0.1340	0.1041

Table 3 The performance of our model for Task 2.

As can be seen, the performance of "Our Model" for the two classes in the test phase was very different from our performance in the evaluation phase. The performance of the "PCM" model in the test phase was much better than the Our Model. The difference in the performance of "Our Model" in the two stages of evaluation and testing in the "Compassion" category was due to the use of the fine-tuned model roberta as the base model. Using this model has caused overfit. The reason for the difference in performance in the "Metaphor" category was due to the different weight of the class with metaphor error compared to the class without metaphor in the bigbird model. This different weight has created a bias for our model as a whole. As can be seen, by solving these problems, the "PCM" model was able to perform better than “Our Model”

5 Conclusion

In this paper, we presented models for two tasks. For Task 1, we presented an ensemble model consisting of three basic models. We reviewed the results of this model in the competition. We examined the weaknesses of this model and presented another model with a similar structure that performed better on the test data. For Task 2, we considered identifying each category separately from the other categories. We provided a model to identify each category. We examined the result of our prediction based on these models in the competition and identified weaknesses. By solving these cases, we changed the classification model of the two categories. We were able to come up with a new prediction for test data that would have a better result than our original model. Using our second model resulted in better ranks in the testing phase. In future work for the second task, the categories can be considered related. This is because some categories have a common concept. The extracted features according to other categories, can be used to classify a category. In future work, other ways can be proposed to solve the problem of class imbalance. For example, constructor models can be used to create text for a class on a conditional basis.

Abstract

This paper describes our system for Task 4 of SemEval 2022: Patronizing and Condescending Language (PCL) Detection. For sub-task 1, where the objective is to classify a text as PCL or non-PCL, we use a T5 Model fine-tuned on the dataset. For sub-task 2, which is a multi-label classification problem, we use a RoBERTa model fine-tuned on the dataset. Given that the key challenge in this task is classification on an imbalanced dataset, our models rely on an augmented dataset that we generate using paraphrasing. We found that these two models yield the best results out of all the other approaches we tried.

1 Introduction

Detecting the presence of patronizing and condescending elements in text is an important task for NLP because of the social impact it has. PCL is characterised by a superior attitude towards others, or a manner of speech that seems to portray others in a pitying way. It is different from other problems in the field of text classification such as detection of hate speech or abusive comments because it is not necessarily done on purpose. Having an automated system that is capable of understanding and classifying language that contains PCL elements would be the first step towards making people and entities, such as media publications, aware of the kind of language they use when talking about vulnerable communities, and as a result, prevent discrimination, stereotypes and harm that could potentially arise from the use of such language.
The PCL Detection task at SemEval-2022 (Pérez-Almendros et al., 2022) aims to solve this problem by exploring different systems that are capable of detecting features that indicate and categorize PCL in the *Don't Patronize Me!* dataset (Pérez-Almendros et al., 2020). Sub-task 1 has been formulated as a binary classification problem, where the goal is to identify whether a given text falls under the category of PCL or not. Sub-task 2 is a multi-label classification problem, where a given text is either free of PCL or belongs to one or more of the seven PCL categories described in the dataset provided.
This paper describes the system developed by team Tesla for SemEval-2022 Task 4. One of the key challenges of this task is the unequal class distribution across the dataset for both sub-tasks.
In this paper, we introduce a system to detect PCL using i) a T5 (Raffel et al., 2019) model for subtask-1 and ii) a RoBERTa (Liu et al., 2019) model for sub-task 2. For our final submission, we use these two models finetuned on an augmented dataset, which we create by generating paraphrases of the sentences belonging to the minority classes in the dataset. Our system ranked 51st out of 78 teams in sub-task 1 and 27th out of 49 teams in sub-task 2, as shown in the leaderboard[1]. Our system for sub-task 2 outperforms the RoBERTa baseline, obtaining an average F1-score of 0.2445 versus 0.1041 for the baseline. All of our code is made publicly available on Github[2].

2 Task Description

The PCL detection task provides participants with the Don't Patronize Me! dataset (Pérez-Almendros et al., 2020), which consists of more than 10,000 paragraphs taken from English-language news stories across 20 different countries. Each of these paragraphs has been annotated to indicate the presence of PCL, and the dataset for sub-task 2 is further annotated with a category label from different classes proposed. These classes are focused on PCL towards vulnerable communities.
The datasets for both the sub-tasks are not balanced. The number of non-PCL examples is nearly 10

[1]https://sites.google.com/view/pcl-detection-semeval2022/ranking
[2]https://github.com/bhattsahil1/pcl_task

times more than the number of PCL instances in the dataset for sub-task 1. Similarly, the seven classes are not equally represented in the dataset for sub-task 2, and the number of examples that do not belong to any category exceeds those that belong to at least one category by a significant amount.

3 Related Work

Transformer-based approaches such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), T5 (Raffel et al., 2019), etc. have shown an impressive performance on a wide range of NLP tasks, including text classification. They have been found to yield good results on text classification that deal with problems such as detection of hate speech (Basile et al., 2019) and offensive language (Zampieri et al., 2019).
The problem of condescending language detection is explored in the TalkDown Dataset (Wang and Potts, 2019), where the authors released an annotated Reddit corpus of condescending linguistic acts in context, along with a BERT model fine-tuned on the dataset as the baseline.
Data augmentation has been widely used across various machine learning tasks, particularly in those tasks where data is scarce, such as computer vision problems in the medical domain (Sundaram and Hulkund, 2021), (Sandfort et al., 2019). These augmentation approaches allow for a larger and more diverse training dataset.
With respect to text data augmentation, (Bayer et al., 2021) discusses various approaches, both in the data space and feature space. Techniques such as synonym-replacement (Wei and Zou, 2019), embedding replacement (Wang and Yang, 2015), SMOTE (Chawla et al., 2002), generative methods (Yu et al., 2016), (Radford et al., 2018) etc. have been studied for data augmentation.
Many recent works have also used back-translation (Corbeil and Ghadivel, 2020) and paraphrasing as a way to increase training data, such as data in the areas of dialogue-generation (Gao et al., 2020).

4 System Description

4.1 Data

The dataset for sub-task 1 consists of 10469 examples, containing the paragraph ID, article ID, keyword, country, paragraph text, binary PCL label, and original annotator label (on a scale of 0-4). The labels 2,3 and 4 are considered as examples containing PCL, whereas those having labels 0 and 1 are negative (non-PCL) examples. The distribution can be seen in Table 1. The dataset in sub-task 2 follows a similar format and consists of 9368 training examples. Here the label is a one-hot encoding of the seven classes to which the text may or may not belong. These classes are: *unbalanced power relations*, *shallow solution*, *presupposition*, *authority voice*, *metaphors*, *compassion* and *the poorer the merrier*. The major challenge that both these datasets pose is the lack of positive samples. The dataset, such as the one seen in Table 1, has a positive to negative class ratio of nearly 1:10. This presents difficulties in learning features that characterize PCL since many of the existing techniques don't perform well when there is class imbalance (Madabushi et al., 2020), which is noticeable if the training and test data are dissimilar.

Class	**Instances**
PCL	993
Non-PCL	9476

Table 1: Class distribution for sub-task 1 dataset

Class	**Instances**
Unbalanced power relations (unb)	1290
Shallow solution (sha)	356
Presupposition (pre)	386
Authority voice (aut)	422
Metaphors (met)	342
Compassion (com)	832
The poorer the merrier (the)	69
(None of the seven classes)	7581

Table 2: Class distribution for sub-task 2 dataset

4.2 Data Augmentation

One of the most common problems that are faced in classification problems is the lack of data across different classes. This is an even bigger problem in the case of text classification problems, since generating new samples is not a trivial task.
Undersampling the majority class would lead to a loss of negative samples and under-utilization of the given data, hence the approach we take is on the lines of oversampling minority classes to augment data. However, instead of directly oversampling minority samples, we use a T5 model[3] finetuned for the task of paraphrase generation on the PAWS

[3]https://huggingface.co/Vamsi/T5_Paraphrase_Paws

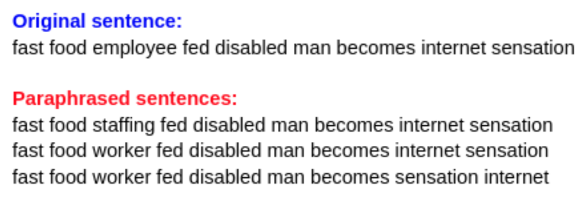
Class	Instances
PCL	8758
Non-PCL	9476

Table 3: Class distribution for sub-task 1 dataset after augmentation

Class	Instances
Unbalanced power relations (unb)	5114
Shallow solution (sha)	1413
Presupposition (pre)	1532
Authority voice (aut)	1682
Metaphors (met)	1361
Compassion (com)	3307
The poorer the merrier (the)	274
(None of the seven classes)	7581

Table 4: Class distribution for sub-task 2 dataset after augmentation

dataset (Zhang et al., 2019). The idea is to generate samples that are similar to the original text, but not the same, as we would like to avoid overfitting that could result from simple oversampling.
We use top-k sampling, in combination with top-p sampling, setting the values of k=120 and p=0.95. For sub-task 1, we generate a maximum of 8 samples for each of the paragraphs belonging to the PCL class. For sub-task 2, we generate a maximum of 3 samples for every sentence that belongs to at least one of the seven class labels. We finally get 18234 examples for sub-task 1 and 14667 examples for sub-task 2.



Original sentence:
fast food employee fed disabled man becomes internet sensation

Paraphrased sentences:
fast food staffing fed disabled man becomes internet sensation
fast food worker fed disabled man becomes internet sensation
fast food worker fed disabled man becomes sensation internet

Figure 1: An example of the paraphrases generated for one of the sentences in the dataset (after pre-processing).

4.3 Pre-processing

We remove punctuation and numbers from our text, and convert each of our sentences to lowercase before using them to generate paraphrases. We remove stop-words from the sentences after carrying out data augmentation.

5 Models

We fine-tune a range of pretrained models, described below, given their good performance on a wide range of NLP tasks. We use the transformer model implementations provided by `simpletransformers`[4] with the default hyperparameters.
BERT (Devlin et al., 2019): We try out the BERT$_{\text{BASE}}$ (uncased) model, which consists of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768.
RoBERTa (Liu et al., 2019): We try out the RoBERTa$_{\text{BASE}}$ model. Similar to BERT$_{\text{BASE}}$, RoBERTa$_{\text{BASE}}$ also consists of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768.
T5 (Raffel et al., 2019): We use the Text-to-Text Transfer Transformer (T5) released by the authors. We use the T5$_{\text{BASE}}$ model, which has about 220 million parameters, nearly twice the number of parameters in BERT$_{\text{BASE}}$.
We test all three models for sub-task 1, and for sub-task 2 we only try out BERT$_{\text{BASE}}$ and RoBERTa$_{\text{BASE}}$.

6 Experiments

6.1 Implementation details

For both the sub-tasks, we concatenate the paragraph text and the keyword associated with each sample, to explore if certain keywords have an effect on the sample being classified as PCL or not.
We train each of the models with two different conditions - using a dataset without paraphrased instances (original dataset) and a dataset with the original and the paraphrased sentences (augmented dataset). We train them for a single epoch only, to avoid overfitting since the data available is less.
We use an 80:20 train-dev split, preserving the class ratio. We use this to evaluate our model performance in sub-task 1. For sub-task 2 too, we use an 80:20 split for training and evaluating the model.
For our final submissions, we train the models for both sub-task 1 and sub-task 2 on the entire dataset.

6.2 Metrics

We report the F1-score, Precision and Recall for sub-task 1. For sub-task 2, we report the F1-score across each of the classes, along with the average score.

[4] https://simpletransformers.ai/

7 Results

Before submitting the final models, we evaluated each of the models' performances on validation sets.

Table 5 presents a comparison between all the different models tried out in sub-task 1. The $T5_{BASE}$ model yields the best F1-score among models trained on the original dataset, and the model also seems to perform decently well on the augmented dataset. The results presented in the table for models trained on the augmented dataset for both the sub-tasks are high since the validation set also contains paraphrases of sentences it might have already seen in the training set. Nevertheless, the relative scores between models trained on the augmented dataset are still a good indicator of their expected performance.

Table 6 discusses the results obtained using $BERT_{BASE}$ and $RoBERTa_{BASE}$. The average F1-score reported on the validation set does not change significantly across the four models used, however, the F1-scores for individual classes are significantly different when comparing the models trained on the original dataset versus models trained on the augmented one.

We present the results of our final submissions in Table 7 and 8.

8 Discussion and Conclusion

The $T5_{BASE}$ models that we submitted for sub-task 1 do not perform well on the test set. One reason for this could be that the $T5_{BASE}$ should have been trained for longer than one epoch. Another reason could be that BERT-based approaches (BERT, RoBERTa) might be better suited for this task. In addition to this, the results of $T5_{BASE}$ fine-tuned on the augmented dataset are not very good either, which could be due to overfitting that results from seeing many paraphrased instances of the same sentence during training. A manual inspection of the generated paraphrases also reveals that their quality needs improvement, since many of the generated paraphrases do not differ much from each other, and at times the generation gets reduced to simple oversampling.

The results of sub-task 2 are encouraging and we can see a significant improvement in F1-scores across almost all classes when we consider the $RoBERTa_{BASE}$ model trained on the augmented dataset.

This confirms that augmenting the dataset through paraphrasing does have a positive effect on model performance. Ensuring dissimilarity in the generated paraphrases, choosing an ideal number of paraphrases to generate, and using other techniques to handle imbalanced data such as cost-sensitive learning or augmentation through other methods (or a combination of them), might yield better results.

We thus, see that identifying PCL and categorizing its occurrences is feasible despite its subjective nature, and that transformer-based approaches are capable of doing this.

Acknowledgments

We thank the organisers of this task for their effort, and the anonymous reviewers for their feedback and insightful comments.

Abstract

In this paper, we describe our efforts at SemEval 2022 Shared Task 4 on Patronizing and Condescending Language (PCL) Detection. This is the first shared task to detect PCL which is to identify and categorize PCL language towards vulnerable communities. The shared task consists of two subtasks: Patronizing and Condescending language detection (Subtask A) which is the binary task classification and identifying the PCL categories that express the condescension (Subtask B) which is the multi-label text classification. For PCL language detection, We proposed the ensemble strategies of a system combination of BERT, Roberta, Distilbert, Roberta large, Albert achieved the official results for Subtask A with a macro f1 score of 0.5172 on the test set which is improved by baseline score. For PCL Category identification, We proposed a multi-label classification model to ensemble the various Bert-based models and the official results for Subtask B with a macro f1 score of 0.2117 on the test set which is improved by baseline score.

1 Introduction

Social media is a wide platform and it grows rapidly. People can communicate with each other and express their opinions easily without any hesitation on social media. Patronizing and Condescending Language (PCL) [1] is language use shows a superior attitude rise towards vulnerable communities in the social media. This effect is unconscious and the intention is trying to help communities like an individual, group of people in need by raising awareness, moving the user audience to action, and standing for the rights. However, these dominant attitudes can lead to discrimination and the user audience is unaware of this diminishing treatment due to its subtlety. Moreover, online social media publications reached more audiences in day-to-day life and we noticed that diminishing treatment of vulnerable groups leads to greater inequalities. so, PCL can potentially be very harmful, as it feeds stereotypes, routinizes discrimination, and drives to greater exclusion.

Detecting PCL language and its categorization of PCL language on social media have gained a lot of interest recently. The detection of PCL is still an emergent area of study in NLP. To the best of my knowledge, this is the first shared task [2] to detect the PCL and their categories from the vulnerable communities. The challenge is to detect that PCL is difficult both for humans and NLP systems, due to its subtle nature, and its subjectivity reasoning required to understand this kind of language. SemEval 2022 task 4 presents the problems of detecting PCL and its categorizes of PCL which express the condescending language in English tweets to the NLP community. The PCL shared task consists of two subtasks: Subtask A is to identify the content is PCL or Not PCL. Subtask B is to classify whether the content into Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier.

This paper describes the systems submitted for SemEval 2022 shared task on PCL Detection by the team SSN_NLP_MLRG. We have participated in the shared task for all the two subtasks. First, we experimented with Bert-based models and we used the ensembling strategies to enhance the performance of the model. Finally, we performed voting to decide the final output. The majority voting on 5 classification models yielded better results than individual systems. The paper is organized as follows: In section 2, we describe the Background work, in section 3, we describe our models, we present the experimental setup in section 4, and compare results in section 5, we provide the conclusion of our work.

[2] https://competitions.codalab.org/competitions/34344

2 Background

In this section, we describe the task provided to the participants and the two subtasks.

2.1 Task Description

The participants were required to produce labels indicating if a paragraph is PCL or Not PCL in the shared of subtask A, and we categorize the PCL Language in the shared task subtask B (P'erez-Almendros et al., 2022).

Subtask A is the binary classification task. Each text content took one of these labels for subtask A as follows: PCL Language: The content shows a superior attitude and language towards a vulnerable community in media. Not PCL: The content is not intended for the PCL Langauge

Subtask B is the multi-label text classification task. Each text content took into these categories of labels for subtask B as follows: Unbalanced power relations: The author keeps distance from the community or based on the situation they express the will, capacity, or responsibility to help people in need. The author also presents to give something positive to the audience in a more vulnerable situation, especially the author concedes is a right but they do not have any authority to decide to give. Shallow solution: A superficial charitable and simple action by the privileged community which is presented either as life-saving or life-changing or as a solution for a deep-rooted problem. Presupposition. The author assumes a situation as certain without having all the valid information and trustworthy source for it (e.g. a survey of research work). Examples of presupposition such as usage of stereotypes or cliches.

Authority voice: The author stands themselves as a superior power of the group, or advises the members of a community about the specific situation they are living. Metaphor. They can conceal PCL, making a comparison between unrelated concepts. An example of a metaphor is euphemisms. Compassion. The author shows the vulnerable individual or group of people about raising a feeling of pity and compassion from the audience towards them. It is commonly characterized by the use of flowery vulnerable words. The poorer, the merrier. How they spread a positive attribute towards the vulnerable community. People learn to live in vulnerable situations and to admire their values. The typical example of 'poor people is happier because they don't have material goods. Table 1 presents the sample annotated data.

2.2 Related work

The authors (P'erez-Almendros et al., 2020) described a new annotated PCL dataset which is aimed to identify and categorize language that is patronizing or condescending language towards vulnerable communities and used the Bert model to detect and classify the harmful PCL language. Recently, Several works are carried out to detection of offensive language (Kalaivani and Thenmozhi, 2020a), hate speech (Kalaivani and Thenmozhi, 2020b), fake news detection, trustworthiness (Atanasova et al., 2018) and fact-checking (Elsayed et al., 2021) prediction is driven towards a particular community. The work (Fiske, 1993) presents a theory of the power of stereotyping and controlling the power of other outcomes. The author (Giles et al., 1993) analyzed the effects of responses and attitudes based on age group towards patronizing and harmful speech. Discourse analysis promises the need to satisfy the teacher's, student's textual values that build on techniques and provide a smoother relationship (Huckin, 2002). Margić (2017) examined the communication courtesy or condescending between the native and non-native English speakers. We observed that most of the work is related to the unfair treatment of the particular underprivileged community.

3 Methodology

We used the pre-trained models BERT (Bidirectional Encoder Representations from Transformers). We fine-tune a BERT language model (Devlin et al., 2019) for PCL classification. we also fine-tuned a RoBERTa-base (A robustly optimized Bert pretraining approach) model (Liu et al., 2019) to classify PCL Language and the PCL categories which can be expressed condescension and viewed as an optimized version of BERT. We used two variants of the RoBERTa method that are RoBERTa-large-cased and RoBERTa-base-cased pre-trained models. We also fine-tune the DistilBERT (Distilled version of BERT model) model (Sanh et al., 2019) is the transformer model, which is a lighter and faster variant of BERT. We used the AlBERT (A lite BERT) model (Lan et al., 2019) to fine-tune the system to predict the PCL language. To further explore the performance, we apply the Ensemble strategies to combine the transformers models output to predict the PCL and Category of PCL

Text	Subtask A	Subtask B
1. The scheme saw an estimated 150,000 children from poor families being sent to parts of the British Empire between 1920 and 1974 , by religious orders and charities who said they would lead better lives	**1**	**[1, 0, 0, 1, 0, 0, 0]**
2. Durban 's homeless communities reconciliation lunch	**0**	**[0, 1, 0, 0, 0, 0, 0]**

Table 1: Sample annotated paragraph. For subtask A, '0' presents PCL and '1' presents Not PCL. For subtask B, Seven category of PCL are Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier

language which is based on the majority voting concept. In all cases, we trained the model for 10 epochs. Finally, we got a macro-average f1 score of 0.5172 for subtask A and f1 average score of 0.2117 for subtask B respectively.

4 Experimental setup

4.1 Data description

The dataset for SemEval 2022 Shared task 4 consists of 10,469 paragraphs are split into training, development, and testing sets for subtask A and 993 unique paragraphs, totaling 2,760 instances of PCL, for Subtask B . Don't patronize me dataset offers content from media forums. the training data size is 8,375 contents and the development data size is 2,095 contents and the size of the test data is 3,832 contents. Table 1 presents the split of experiment data. The shared task of subtask A is a binary classification task in which the aim is to build systems able to detect the given paragraph content is PCL or Not PCL. The shared task of the PCL Category classification is a Multi-label classification task in which the aim is to build systems able to classify the PCL category into Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier.

4.2 Data Preprocessing

We applied down sampling negative instances data augmentation techniques to balance the dataset because the negative instances are 7,581 contents and positive instances are only 794 contents. Preprocessing the text is an important role as the data from social media can be quite noisy and contain a lot of noisy words, excessive use of punctuation, URLs, symbols, misspelling words. We perform data preprocessing by using NLTK libraries. First, we remove the duplication because it affects the system performance. we remove the stop words. After that, we remove the punctuations, URLs, numerals, emojis and then convert all the upper case English text into lower case text.

4.3 Experimental setting

For both subtasks A and B, We implement the Ensemble model using Simple transformers. We used the colab notebook for implementation purposes with the high-end RAM, GPU for training. For the hyperparameters for the BERT-based five models, we set epochs as 10. For the multilabel classification task, we used simple transformers and a multi-label classification model to predict the PCL Language category. we analyzed the individual classification of all five BERT-based models for both the subtasks. We also examined the final output which is the combination of five models based on a majority voting system for classification.

5 Experimental analysis

This section presents the analysis of the results and submitted official results

5.1 Result Analysis

We experimented with the various transformer model are BERT, DistilBERT, AlBERT, Roberta base, Roberta large, and the ensemble of all five models. We analyzed the comparison scores of various approaches based on the evaluation metrics of precision, recall, and macro average f1 score for the shared task A. Task 1 is a binary classification task that will be evaluated using f1 over the positive class. Task 2 is framed as a multi-label classification problem. For each paragraph, your model will assign a label for each of the seven PCL categories. Then, results for this task will be evaluated using per-class f1, and the final ranking for this subtask will be based on macro-average f1. Table 2 presents the results of subtask A. Table 3 shows the results of subtask B.

Model	Precision	Recall	Macro f1
Run 1:			
BERT model	0.3832	0.6940	0.4938
Run 2:			
Ensemble model	0.4228	0.6656	0.5171

Table 2: Test Results of subtask A

Model	UNB POW	SHAL	PRES	AUTH	MET	COMP	MERR	Avg f1
Run 1:								
BERT	0.3459	0.3376	0.2068	0.1933	0.1212	0.2772	0.0	0.2117
Run 2:								
AlBERT	0.3438	0.3157	0.2056	0.1666	0.1666	0.2677	0.0	0.2094

Table 3: Test Results of subtask B. UNB POW - Unbalanced power relations, SHAL - Shallow solution, PRES - Presupposition, AUTH - Authority voice, MET - Metaphor, COMP - Compassion, MERR - Poorer and Merrier

We submitted two runs for both of the subtasks. For run 1, we submitted the prediction made by the BERT model for subtasks A and B. For run 2, we submitted the prediction made from the ensemble model for subtask A and Albert model for subtask B. We observed that the performance of the Ensemble model achieved good results compared to the BERT model for subtask A and the performance of the BERT model achieved good results compared to the Albert model. Finally, we got the macro f1 score of ensemble model is 0.5172 for the subtask A and the macro f1 average of Bert model is 0.2117 for the subtask B respectively.

6 Conclusion and Future Work

This paper presents the submitted runs for the patronizing and condensing language identification in SemEval 2022 task 4. The results show that the Not-PCL language and PCL language in the dataset receives the same macro f1 scores. We experimented with different approaches such as a BERT model, AlBERT, Roberta base, Roberta large, and Distilbert and Ensemble models. Based on the evaluation, BERT performs well for subtask B to classify the PCL content into Seven categories that express condensing language. Ensemble model performs well for subtask A to detect the content is PCL language or Not PCL language. Our team submission had a macro f1 score of 0.5172 for subtask A and a macro f1 score of 0.2117 for subtask B which are improved by the baseline f1 scores. For future work, we will handle the imbalanced dataset by using external resources and apply the data augmentation techniques to enhance the performance of our model.

Abstract

This paper introduces the related work and the results of Team Sapphire's system for SemEval-2022 Task 4: Patronizing and Condescending Language Detection. We only participated in subtask 1. The task goal is to judge whether a news text contains PCL. This task can be considered as a task of binary classification of news texts. In this binary classification task, the BERT-base model is adopted as the pre-trained model used to represent textual information in vector form and encode it. Capsule networks is adopted to extract features from the encoded vectors. The official evaluation metric for subtask 1 is the F1 score over the positive class. Finally, our system's submitted prediction results on test set achieved the score of 0.5187.

1 Introduction

Patronizing and Condescending Language (PCL) can be considered when someone's language has a superior attitude towards others, demeans others, or describes the situation of others in a compassionate way. Such expressions are often unconscious, and are used by people to try to induce action or raise awareness. Because of its subtlety and often well-meaning when used, users often overlook the demeaning elements of this expression. Such elements may contribute to the stereotyped influence of society on a group, making discrimination normalized and even leading to stronger exclusion (Pérez-Almendros et al., 2022).

Detecting PCL in media text is a challenging task. Recognizing PCL based on Natural Language Processing (NLP) can alert speakers to examine the rationality of their speeches, so that speeches can be more inclusive and constructive, which in turn leads to more responsible communication.

When processing corpus, the pre-trained model can convert text information into vector representation, making it more suitable for NLP tasks. Early pre-trained models were designed to learn representational word embeddings, such as Word2Vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014). Although such methods can capture the semantics of words through word embeddings, they cannot capture the concepts in the context. With the introduction of new technologies, there are now pre-trained models that can learn to represent contextual word embeddings, such as the ELMo (Peters et al., 2018) model based on LSTM (Shi et al., 2015) and the BERT (Devlin et al., 2018) model based on Transformer Encoder (Vaswani et al., 2017).

In recent years, using deep neural networks in NLP, such as Convolutional Neural Networks (CNNs) in text classification (Kim, 2014), has become mainstream. Capsule networks (Sabour et al., 2017), as a structure proposed on the basis of CNNs to improve spatial sensitivity in computer vision, is also used in text classification tasks (Yang et al., 2019; Ding et al., 2019). Kim et al. (2020) further suggest a simple routing method that effectively reduces the computational complexity of dynamic routing.

This task aims to predict whether each news text for each ID contains PCL. Text is represented as a vector and encoded using a pre-trained BERT model. It mainly uses the capsule networks to extract the encoded vector, and uses the output of the fully connected layer to represent the label probability. The rest of the paper is organized as follows: Section 2 introduces the system architecture. Section 3 describes the dataset, implementation details settings and experimental results. The summary and outlook for future work will be presented in Section 4.

2 System Architecture

In this section, we will introduce the system architecture we use in the task, which will consist of two parts. One is embedding and coding, and the other is feature extraction and prediction. We call the model that is ultimately used to test the class prediction results of the dataset as BERT-Caps. The architecture of BERT-Caps model is shown in Figure 1.

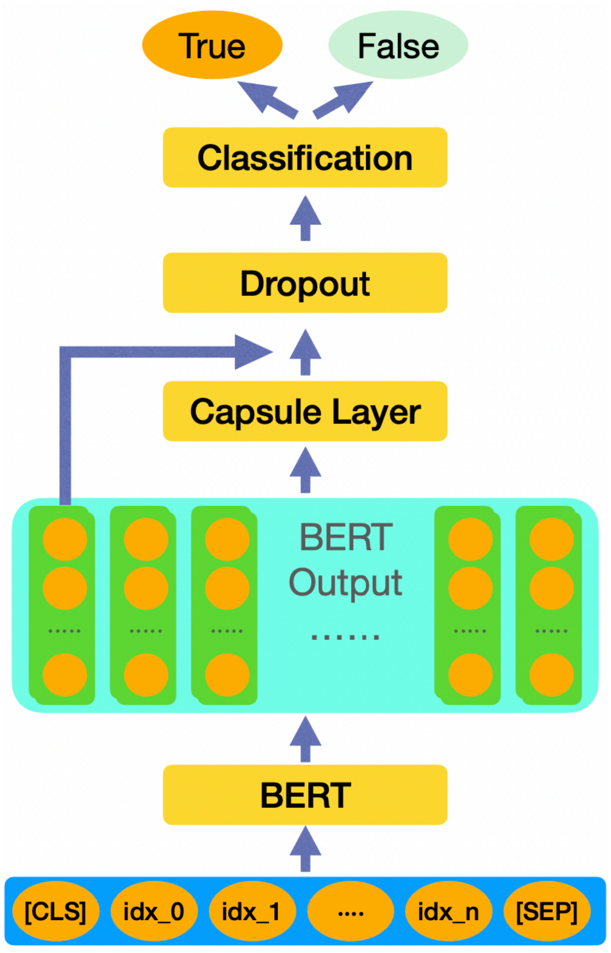

Figure 1: The architecture of the BERT-Caps model.

2.1 Embedding and Encoding

When using the early pre-trainied model for text classification, the text is usually represented as a word embedding and then the vector matrix is sent to a bidirectional recurrent network for encoding to improve the system's ability to perceive contextual information. In this paper, we mainly use the BERT-base model to represent text into vector form and encode it.

In order to fit the pre-trained model, we need to preprocess the text in the dataset accordingly. As standard news text, we do only a little text processing on the news text: unify the text to lowercase. Add markers to the beginning and end of the text. For example, when using BERT as the pre-trained model, [CLS] and [SEP] will be used to mark the beginning and end of the text, respectively. Then according to the dictionary information, the words are converted into a list of their position numbers in the dictionary. Collate to get a list that marks the beginning and the end of each sentence.

This part of the work is mainly achieved through the tokenizer attached to the module used when importing the pre-trained model. For the imported model, we set the trainable value of each layer of the model to True.

2.2 Feature Extraction and Predict

We use the capsule networks to perform feature extraction on the hidden state of the last layer of the pre-trained model. In the capsule layer, the input is firstly processed by the Conv1d function. The convolution output is treated as a set of capsules, and a new set of capsules of the specified shape is derived through the dynamic routing algorithm. The result is the output of the capsule layer.

The flattened capsule layer output and the text vector corresponding to the first bit in the pre-trained model are linked together. In order to improve the generalization ability of the model, dropout is used. During training, the concatenated outputs are first processed by dropout and then fed into the fully connected layer to predict the probability that the news text has PCL. The loss function of this model adopts categorical crossentropy.

3 Experiment and Result

3.1 Dataset and Official Evaluation Metrics

The dataset used in the experiment is provided by SemEval-2022 Task4, Patronizing and Condescending Language Detection.(Pérez-Almendros et al., 2020)

In this dataset, the degree of PCL is divided into five levels from 0 to 4. In subtask 1, the level of 0-1 is regarded as a negative example, and 2-4 is regarded as a positive example. Participants were asked to predict the presence or absence of PCL component in the text. The differentiated test set contains 9476 negative labels and 993 positive labels, almost reaching 10:1. Due to the imbalance of samples in the dataset, the F1 score over the positive class was adopted as the official evaluation metric.The formula for F1 score is as following:

$$F1 = 2 * \frac{precision * recall}{precision + recall} \tag{1}$$

Precision means the ratio of correctly predicted positive observations to the total predicted positive observations. Recall means the ratio of correctly predicted positive observations to all observations in the real class.

3.2 Implementation Details

In terms of data segmentation, we import the train_test_split function from the Scikit-learn(Pedregosa et al., 2011) module to divide the dataset into training set and validation set, set *test_size* to 0.2, *random_state* to 35.

All experiments in this paper are based on using the TensorFlow2 backend.

When using BERT-base-uncased[1] as the pre-trained model, we use the Keras-BERT (Shorten and Khoshgoftaar, 2021) module to implement the Tokenizer and import the model.

We also tried other BERT-based models, such as RoBERTa-base and DeBERTa-base. When implementing Tokenizer and importing models, we use the Transformers (Wolf et al., 2020) module.

The number of capsules, the number of hidden neurons, and the number of iterations of the dynamic routing algorithm are set to 10, 64, and 3, respectively.

The fully connected layer that outputs the final result in each model uses softmax as the activation function. The hyperparameters used are mentioned in Table1.

Parameters	**subtask 1**
Epochs	8
Batch_size	8
Max_length	128
Drop_rate	0.25
Optimizer	Adam
Initial *lr*	1e-5

Table 1: Hyperparameters

In actual training, in order to alleviate the overfitting situation, ReduceLROnPlateau is introduced. Also set ModelCheckpoint to save each model with the smallest loss on the existing basis.

3.3 Experiment and Result

The system uses the dataset provided by the task organizer for training. The BERT-Caps model that finally gets the submitted prediction results is saved at the end of the 8th epoch training.

The results are shown in Table 2. The values of RoBERTa_baseline comes from the result published on the Competition Page[2]. As can be seen from the table, as a result, our model has a greater improvement in precision than the baseline. We also tried to train some BERT-Caps models that reduced the number of capsules in the capsule layer and increased the number of hidden neurons, but there was no significant improvement in metric.

Table 2 shows that without the capsule networks, the performance of the model will be greatly reduced compared to the original model. Without dropout, the prediction performance decreases less than without the capsule networks.

We also tried to keep almost the same system architecture, only replacing the pre-trained model and tokenizer. Unexpectedly, in the experimental environment of this paper, both DeBERTa-Caps and RoBERTa-Caps are not as good as BERT-Caps.

The best test set predictions submitted by our team were produced by the BERT-Caps model. Considering with the F1 scores obtained by the top four teams in the English data are all over 0.6400, indeed, there is a gap. Team Sapphire's final ranking is 35th.

4 Conclusion

This paper describes the experiments conducted by Team Sapphire in subtask 1 of SemEval-2022 Task 4: Patronizing and Condescending Language Detection. We introduced the system architecture, experimental dataset situation and results in Section 2 and 3, respectively. From the experimental results, the BERT-Caps model can achieve better results on the test set. In future work, we will improve our method to achieve better results. For example, using other text representations, and adjusting the weight of the loss function.

Abstract

In this paper we propose four deep learning models for the task of detecting and classifying Patronizing and Condescending Language (PCL) using a corpus of over 13,000 annotated paragraphs in English. The task, hosted at SemEval-2022, consists of two different subtasks. The Subtask 1 is a binary classification problem. Namely, given a paragraph, a system must predict whether or not it contains any form of PCL. The Subtask 2 is a multi-label classification task. Given a paragraph, a system must identify which PCL categories express the condescension. A paragraph might contain one or more categories of PCL. To face with the first subtask we propose a multi-channel Convolutional Neural Network (CNN) and an Hybrid LSTM. Using the multi-channel CNN we explore the impact of parallel word emebeddings and convolutional layers involving different kernel sizes. With Hybrid LSTM we focus on extracting features in advance, thanks to a convolutional layer followed by two bidirectional LSTM layers. For the second subtask a Transformer BERT-based model (i.e. DistilBERT) and an XLNet-based model are proposed. The multi-channel CNN model is able to reach an F1 score of 0.2928, the Hybrid LSTM model is able to reach an F1 score of 0.2815, the DistilBERT-based one an average F1 of 0.2165 and the XLNet an average F1 of 0.2296. In this paper, in addition to system descriptions, we also provide further analysis of the results, highlighting strengths and limitations. We make all the code publicly available and reusable on GitHub[1].

1 Introduction

With the exponential growth of contents shared on social networks, a lot of new challenging tasks have emerged. Many are currently studied and addressed by scholars, and a pletora of novel machine learning approaches have been proposed (Arpaci et al., 2021), (Hosseinalipour and Ghanbarzadeh, 2022), (Siino et al., 2020). Some of the most common tasks, often co-located with international conferences, are those about fake news (Rangel et al., 2020), hate speech (Bosco et al., 2018), misogyny (Fersini et al., 2018) and cyberbulling (Kumar et al., 2018) detection.

For these purposes there is a constantly growing need for tools that can automatically extract and classify information from online feeds, to face with consolidated as well as with emerging social issues. Interest in Natural Language Processing (NLP) has increased in recent years with advances in machine and deep learning architectures. There have been significant efforts in developing methods to automatically detect and classify text content available online nowadays.

Together with the already mentioned tasks, an emerging one is about detecting Patronizing and Condescending Language (PCL) (Pérez-Almendros et al., 2020). The PCL Detection Task hosted at SemEval-2022 is covered in detail in (Pérez-Almendros et al., 2022) and briefly discussed here. The main task is made of two subtasks. The first one is a binary classification problem where, given a paragraph, a model has to predict wheter the paragraph contains or not PCL. The second one is a multi-label classification task where each paragraph has to be labelled with one to seven categories of PCL. Classes are not mutually exclusive and so a paragraph could express one or more categories of PCL.

To face with the first subtask we propose two deep models. The first one is a multi-channel Convolutional Neural Network (CNN). Such a network consists of parallel word embedding and convolutional layers to allow different sets of weights for trained embeddings - because of different kernel sizes employed by convolutional layers. In terms of *Precision*, *Recall* and *F1*, results of our model show certain room for improvements in future work. The

[1]https://github.com/marco-siino/McRock-SemEval-2022-Task4

second model is a hybrid bidirectional LSTM. Such a network is composed by a convolutional layer and two bidirectional LSTM layers.

For the second subtask we propose two Transormer-based models (Vaswani et al., 2017). The first one is a lighter and faster version of BERT (i.e. DistilBERT) (Sanh et al., 2019). Our model is opportunistically trained on an undersampled version of the training dataset. The model is able to outperform RoBERTa (Liu et al., 2019). The second is an XLNet-based one (Yang et al., 2019). The model is based on a generalized autoregressive pretraining method. It enables learning bidirectional contexts by maximizing the expected likelihood over all permutations of the factorization order. Under comparable experiment setting, XLNet outperforms BERT (Devlin et al., 2019) on several tasks, often by a large margin, including question answering, natural language inference, sentiment analysis, and document ranking. Our model implementation is opportunistically trained on an undersampled version of the training dataset. The model is able to outperform RoBERTa (Liu et al., 2019) in terms of average F1.

The rest of the paper is made as follows. In Section 2 we provide some background on the Task 4 hosted at SemEval-2022. In Section 3 we provide a description of the models presented. In Section 4 we provide details about the experimental setup to replicate our work. In Section 5 the results on the official task and some discussion are provided. In section 6 we present our conclusion and proposals for future works.

2 Background

In this section we provide some background about the Task 4 hosted at SemEval-2022. The aim of this task is to identify PCL, and to categorize the linguistic techniques used to express it, specifically when referring to communities identified as being vulnerable to unfair treatment by the media. Participants at the Task 4 received a dataset with sentences in context (paragraphs), extracted from news articles. Although news articles were collected from different countries, they were all provided in English. The task consists of the two subtasks listed below.

1. Subtask 1: Binary classification. Given a paragraph, a system must predict whether or not it contains any form of PCL. Two opposite labelled samples from the dataset provided are shown below.

   Non-PCL Sample Text: *"Council customers only signs would be displayed . Two of the spaces would be reserved for disabled persons and there would be five P30 spaces and eight P60 ones ."*

   Non-PCL Sample Label: [0]

   PCL Sample Text: *"It can not be right to allow homes to sit empty while many struggle to find somewhere to live, others having to sleep rough on pavements during Christmas, hoping against hope, for some charity to provide shelter. The number left homeless and destitute is alarming not necessarily at Christmas?"*

   PCL Sample Label: [1]

2. Subtask 2: Multi-label classification. Given a paragraph, a system must identify which PCL categories express the condescension. The PCL taxonomy has been defined based on previous works on PCL. The proposed categories are:

   - Unbalanced power relations
   - Shallow solution
   - Presupposition
   - Authority voice
   - Metaphor
   - Compassion
   - The poorer, the merrier

Two samples from the dataset provided are shown below. For each sample the label is an array containing seven elements. For each element, symbol *1* means that the corresponding PCL category is expressed in the paragraph.

Sample Text 1: *"Yes ... because there is NO HOPE where he lives . India is a third-world country . Do n't be fooled by call centers in big cities . Most of the country is rural and most of the population is illiterate and hopeless ."*

Sample Label 1: [1, 0, 1, 0, 0, 1, 0]

Sample Text 2: *"For refugees begging for new life , Christmas sentiment is a luxury most of them could n't afford to expect under shadow of long-running conflicts ."*

Sample Label 2: [0, 0, 1, 0, 0, 1, 0]

Task organizers released a training and a dev set before the competition officially started. For both sets the gold labels were provided. During first phase - Practice phase - participants were able to develope and test their models uploading predictions on CodaLab. After releasing the unlabelled test set the second phase - Evaluation phase - started. Results for both phases are available online [2].

3 System Overview

In this section we discuss the models presented for each subtask and the design choices made by our team motivating them. For both models the code is publicly available and reusable. Further details are provided in Section 4.

3.1 Subtask 1: Binary Classification

Given the binary nature of the task and his subject, for our first submission we developed a more versatile CNN based on the one presented in (Siino et al., 2021). Such a network is composed of parallel word embedding and convolutional layers to allow different weights for embeddings and convolutional filters. A general overview of the model architecture is shown in Figure 1. The rationale of the model presented is to have more parallel convolutional-based channel, each with different word embeddings and kernel filter weights. More properly, we set kernel size of 1, 2, 16 and 32 for each of the 32 *Conv1D* layer filters. In this way we drive our model to focus more on single token, pair of tokens, group of 16 and of 32 tokens respectively. On the basis of our experiments these are the best-performing kernel sizes for the proposed task on our preliminary 10 cross-fold validation. In addition to this behaviour we expect different coordinates for each word/token in each word embedding channel, with the aim of getting a more fine-grained positioning of words/tokens in the embedding space.

Based on our preliminary experiments, we found that on five different seeds initialization, the best word embedding size for our model is 50. This size is consistent with the common values reported in literature (Melamud et al., 2016). For each dense layer we did not use any activation function. We trained our model with a binary cross-entropy loss and using the Adam optimization algorithm (Kingma and Ba, 2014).

[2] https://sites.google.com/view/pcl-detection-semeval2022/ranking

For our second submission, we developed a light Hybrid LSTM. The model consists of a convolutional layer followed by two bidirectional LSTM layers. Such a strategy is motivated by our decision to extract relevant features from the word embedding layer before the first bidirectional one. A general overview of the model architecture is shown in Figure 2. Based on our preliminary experiments on five different seeds initialization, we found that the best word embedding size for the model was 50. For each dense layer we did not use any activation function. We trained our model with a binary cross-entropy loss and using the Adam optimization algorithm (Kingma and Ba, 2014).

3.2 Subtask 2: Multi-Label Classification

For our first submission at the Subtask 2 we choosed a transformer-based model lighter than BERT (i.e. DistilBERT). Due to the high number of experiments to perform, we needed a faster model to train. DistilBERT is a smaller general-purpose language representation model. In DistilBERT the original size of BERT model is reduced by 40%, while retaining 97% of its language understanding capabilities and being 60% faster. In terms of knowledge distillation, while BERT is the teacher, DistilBERT is the student. Student is represented by a compact model and is trained to reproduce the behaviour of the larger model (i.e. the teacher). Such a compact model is trained with a linear combination of three losses: the *distillation loss* (i.e. L_{ce}), the *masked language modeling loss* (i.e. L_{mlm}), and the *cosine embedding loss* (i.e. L_{cos}). Because of the distilled nature of the model, training and fine-tuning on a specific dataset for a specific task is of prominent importance. For a detailed discussion of DistilBERT refer to (Sanh et al., 2019). While we firstly compared the results on the dev set provided, we finally trained our model on the full training set - union of train and dev set - providing predictions on the test set. In addition we found beneficial maintaining the information about casing of characters. So we did not lowercase the text provided, implementing a cased version of DistilBERT and setting as output for each label seven digits corresponding to the seven categories of PCL. Finally we preprocessed each sample to include country and keyword of each paragraph in the input text.

For the second submission we implemented an XLNet-based model. Different unsupervised pre-

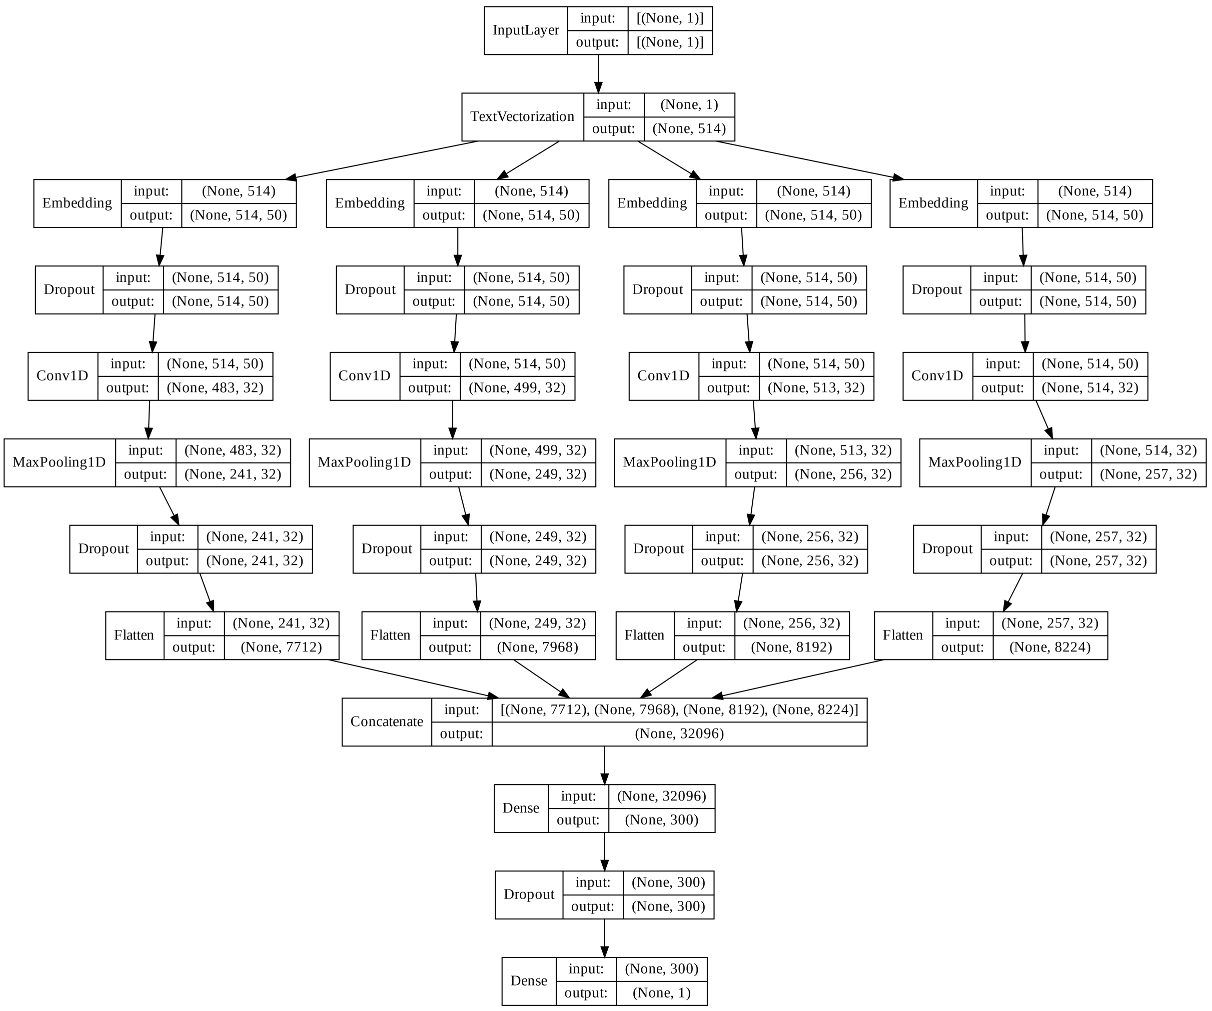

Figure 1: Overview of the multi-channel CNN presented for the first subtask at SemEval-2022. Each channel has a different kernel size at *Conv1D*, driving model attention on different sized windows of words. The kernel size of filters used at each *Conv1D* are 1, 2, 16 and 32. Each convolutional layer has 32 filters separately trained during training phase. Such a strategy allows extraction of different-sized features for a fine-grained learning.

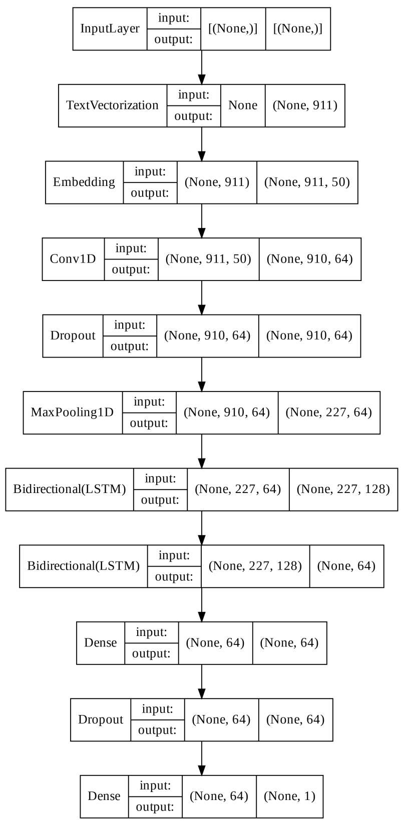

InputLayer | input: | output: | [(None,)] | [(None,)]

Figure 2: Overview of the Hybrid LSTM presented for first subtask hosted at SemEval-2022. The presence of the *Conv1D* layer is motivated by our intention to extract relevant features from the previous embedding layer. The kernel size of the 64 filters used by the convolutional layer is 2. Such a strategy should allows extraction of relevant bi-grams from the input text.

training objectives have been explored in literature. XLNet implements a generalized autoregressive pretraining method that uses a permutation language modeling objective to combine the advantages of autoregressive and autoencoding methods. The neural architecture of XLNet is developed to work seamlessly with the autoregressive objective, including the integration of Transformer-XL and the careful design of the two-stream attention mechanism. XLNet achieves substantial improvement over previous pretraining objectives on various tasks. Among them, autoregressive language modeling and autoencoding have been the two most successful pretraining objectives. Furthermore, XLNet integrates ideas from Transformer-XL (Dai et al., 2019) into pretraining. An XLNet model integrates two techniques from Transformer-XL, namely the relative positional encoding scheme and the segment recurrence mechanism. The relative positional encodings is applied based on the original sequence. Furthermore, the recurrence mechanism is included into the proposed permutation setting and enable the model to reuse hidden states from previous segments.

Training and fine-tuning of an XLNet for a specific task is of prominent importance. While we firstly compared the results on the dev set provided, we finally trained our model on the full training set - e.g., union of train and dev set - providing predictions on the test set.

4 Experimental Setup

We implemented our first two models using Keras[3] and TensorFlow[4]. The dataset provided for the binary classification task is unbalanced in terms of negative and positive PCL instances. To face with this issue we undersampled the negative instances. On the basis of our preliminary experiments, we found beneficial undersampling negative instances to be just six times more the positive ones. Furthermore we found beneficial to include in each sample (both for training and prediction) the keyword and the country field of each paragraph from the dataset. Then we used a batch size of 100. We empirically found that a good early stopping point for the training phase is obtained with 10 epochs and a learning rate of 0.001. We ran the experiments on Google Colab using the default GPU (NVIDIA Tesla K80). The training time was around 15 seconds for each

[3]https://keras.io/
[4]https://www.tensorflow.org/

of the ten epochs. The official metrics used for the task were Precision, Recall and F1 on positive instances (sample containing PCL). But during our development phase we focused on the model loss (i.e., *binary crossentropy loss*). This choose was dictated by the fact that the gold labels of the test set were not provided.

The models for Subtask 2 were implemented using Simple Transformers[5]. We used DistilBERT and XLNet as the pre-trained language models. We preprocessed the dataset to include, within the text of each sample, the country and the keyword of the paragraph. To train our final models we built a single dataset consisting of the train and the dev set. Then we undersampled negative instances (i.e. Non-PCL samples) to alleviate bias in the unbalanced dataset provided. We ran the experiments on Google Colab, using an NVIDIA Tesla K80 GPU. The official metrics used for the task were F1 for each category and average F1 among them. In this case too, during our development phase we focused only on the loss of the models to perform some fine-tuning.

5 Results

For Subtask 1 the metrics used are Precision, Recall and F1 defined as shown in 1,2,3 respectively.

$$Precision = \frac{TP}{TP + FP} \tag{1}$$

$$Recall = \frac{TP}{TP + FN} \tag{2}$$

$$F1 = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{3}$$

Each *True Positive* (TP) is computed on the positive instances (i.e. paragraphs containing PCL). So a TP is a sample containing PCL and correctly classified, a *False Positive* (FP) is a sample without PCL but wrongly classified as a PCL sample, a *False Negative* (FN) is a sample containing PCL but wrongly classified as not containing PCL. Therefore, Precision is the number of the correctly predicted PCL samples over the total number of predicted PCL samples. Recall is the number of the correctly predicted PCL samples over the total number of actual PCL samples. Finally the F1 Score is the harmonic mean of Precision and Recall.

The final ranking for the first subtask is drawn up accordingly to the F1 score on the test set provided.

[5]https://github.com/ThilinaRajapakse/simpletransformers

	F1	P	R
RoBERTa-baseline	48.29	34.99	77.89
Multi-Channel CNN	32.29	23.46	51.76
Hybrid LSTM	26.32	31.47	22.61
Random-baseline	17.35	10.40	52.26

Table 1: Performance comparison on dev set. The results of the two baseline methods provided by the organizers (i.e. RoBERTa and Random baseline) compared to our models based on a multi-channel CNN and Hybrid LSTM.

In Table 1 are shown the results on the dev set provided by the organizers. Results are ordered according to F1 score. Our model based on multi-channel CNN is able to outperform the Random-baseline provided in terms of F1 and Precision, obtaining similar results in terms of Recall. RoBERTa-baseline performs better along the three metrics provided.

It is interesting to note that RoBERTa is a model pre-trained on over 160GB of text. Compared to our proposed model it requires much more in terms of resources and time needed. Despite such efforts, RoBERTa outperforms our model by only 16% and around 11% in terms of F1 and Precision. The most significant difference is with Recall. This means that the proportion of actual positives identified correctly by our model is lower compared to RoBERTa. This could be mainly due to the inability of our model at contrasting the bias learned because of the unbalanced dataset provided, where Non-PCL paragraphs are, in fact, the vast majority. Our team did an additional submission involving two deep models based on an Hybrid LSTM (i.e. made of convolutional and bidirectional LSTM layers) and on an XLNet (Yang et al., 2019). Our proposed Hybrid LSTM is able to outperform the Random-baseline provided in terms of F1 and precision. RoBERTa-baseline performs better along the three metrics provided. Compared to the Hybrid LSTM model, the multi-channel CNN outperforms the Hybrid LSTM. However the Hybrid LSTM performs better with regard to precision. Such a result leads to the conclusion that Hybrid LSTM correctly predicts an higher number of actual PCL paragraphs with respect to the total predicted PCL paragraps. Therefore, further investigation might be conducted on combinations of main components of the two proposed models in the effort to improve the F1.

	F1	P	R
hudou (1)	65.10	64.60	65.62
RoBERTa (44)	49.11	39.35	65.30
Multi-CNN (69)	29.28	23.40	39.12
Hybrid LSTM (*NA*)	28.15	29.62	26.81
mahangchao (79)	4.48	10.59	2.84
makahleh (80)	0.0	0.0	0.0

Table 2: Performance comparison on test set. In table are shown the RoBERTa-baseline, the first classified (i.e. *hudou*), the two last classified and our models results. In parentheses are shown the positions in the final ranking according to F1 score. *NA* stands for *Not Assigned* because only the best result of the two model submitted is considered for final ranking.

In Table 2 are shown the results on the test set provided by the organizers without the gold labels. Results are ordered based on the F1 score. Compared to the winner (e.g. *hudou*), RoBERTa exhibits the most significant gap in Precision. Which means that proportion of positive instances correctly classified by the winner team is significantly more compared to RoBERTa. However, in this case too, RoBERTa outperforms our model with similar gap along the three metrics with respect to the results presented for the dev set. Our two submitted models exhibit similar performances on the test set. In this case too, the most significant gap is in Recall.

For Subtask 2 the metric used is F1 along the seven categories provided and the final ranking was drawn up considering the average F1 along the seven categories on the test set provided. For this subtask there is an important bias due to the unbalanced nature of the dataset with regard to each category. In Table 3*(a)* the results on the dev set are shown. Results are ordered based on the average F1 score. For each category our XLNet is able to outperform the Random-baseline. The average F1 is 15% more than such a baseline. It is worth noting that results with a random predictor are not uniformly distributed along each category. This distribution provides further evidences about the unbalanced nature of the dataset with regard to this multi-label classification subtask. Furthermore the random predictor outperforms F1 score of RoBERTa in four of the seven categories provided. However RoBERTa performs a lot better in detecting *Unb*, *Pre* and *Com* language (namely, *Unbalanced power relations*, *Presupposition* and *Compassion*). These performances could be motivated by the greater number of samples in the dataset expressing the first category. Compared to RoBERTa our DistilBERT-model does better for five categories out of seven. And for this single category (i.e. *Presupposition*) the gap is under 4%. Compared to our other submission, the XLNet heavily outperforms DistilBERT in terms of F1 for each category and in the final average F1. In Table 3*(b)* we report the results of the first model, our proposed models, RoBERTa and the last classified one, according to the final ranking drawn up considering the average F1. In this case too our models outperform RoBERTa, in terms of F1, for six out of seven categories. On the test set, RoBERTa performs better in detecting *Unb*. However, compared to the results on dev set, our two proposed models perform with a lower average F1 gap. And there is just a category (i.e. *Metaphor*) where DistilBERT significantly outperforms the XLNet. It is worth noting that the best performing model is able to reach an average F1 of 46.89, outperforming of over 20% and 36% our proposed models and RoBERTa respectively. This lead to a conclusion about the very large room for improvement in this multi-label task. Some of the difficulties in reaching an average F1 of at least 50% could be due to the unbalanced dataset as much as the intrinsic complexity of the task.

6 Conclusion

We propose four deep learning models to detect and classify PCL on the English dataset provided by task organizers at SemEval-2022. For the first subtask we developed a Multi-Channel CNN, training parallel word emebeddings and convolutional layers with different kernel sizes and an Hybrid LSTM. While results of these architectures exhibit a large room for improvements, the models are lighter and faster compared to the RoBERTa-baseline model proposed by the task organizers. For the second subtask we implemented a DistilBERT-based and XLNet-based models. Compared to RoBERTa, DistilBERT is smaller, faster and lighter. Instead, XLNet performs better on average F1 both on dev and test set. To face with the task proposed we opportunistically trained the models including the information about country and keyword related to each

	Unb	Sha	Pre	Aut	Met	Com	The	**AVG**

Table 3: Performance comparison on dev set *(a)* and test set *(b)* for Subtask 2. The table shows F1 calculated for each category and the average F1 in the last column. For Subtask 2 our proposed models based on DistilBERT and XLNet outperform RoBERTa on both dev and test set. In parentheses are shown positions in final ranking. NA stands for *Not Assigned* in this case too.

sample. In addition we undersampled the negative instances in the dataset to avoid the model to focus more on non-PCL samples. The trained models are able to outperform RoBERTa. However, looking at the final ranking of the task, the room for improvements is significant. In future works would be useful implementing models taking advantage of a balanced dataset. Both for the binary classification task and for the multi-label one. Another interesting aspect to further investigate would be about the behaviours of the proposed models on multilingual datasets. Although pre-trained models are actually the state of the art for many NLP tasks, the hardness of the PCL detection task - proved by the final scores obtained by the winners at SemEval-2022 - could worsen the results on each metric. Finally, it could be beneficial experimenting with hybrid and ad-hoc models combining different pre-trained and non pre-trained models to improve the results specifically on this task.

Abstract

We propose the use of a contextual embedding based-neural model on strictly textual inputs to detect the presence of patronizing or condescending language (PCL). We finetuned a pre-trained BERT model to detect whether or not a paragraph contained PCL (Subtask 1), and furthermore finetuned another pre-trained BERT model to identify the linguistic techniques used to convey the PCL (Subtask 2). Results show that this approach is viable for binary classification of PCL, but breaks when attempting to identify the PCL techniques. Our system placed 32/79 for subtask 1, and 40/49 for subtask 2.

1 Introduction

The goal of the task is to be able to identify whether or not a piece of text contains condescending or patronizing language, and if it contains patronizing language identity which linguistic techniques are used to express that sentiment (P'erez-Almendros et al., 2022). Studies have shown that PCL fuels discriminatory behavior, creates and feeds stereotypes, subtly blames needy individuals for their problems, and oversimplifies problems. In general, PCL makes it harder for needy communities to get the help they need and reach total inclusivity (P'erez-Almendros et al., 2020). This is obviously negative, and being able to combat it with AI may help automate the process and get past inherent biases that humans identifying PCL may have.

Our system's goal is to use contextualized word embeddings to feed the model, and thus have the model analyze the semantics of the text. We specifically focused on a purely textual analysis and did not provide the model with any metadata to see if the model could learn the PCL patterns just from the text, because although real world usage would likely include those features, the ability to learn from the text itself would be useful and more universally applicable.

In this task, we learnt that it is easier for a model to simply detect the presence of PCL than the techniques used in a piece of PCL. This is likely because of both unequal distributions of data and the fact that the context for the types of PCL likely look very similar, making the model default to a category of PCL with a higher frequency when not incredibly clear. We ranked 32/70 on subtask 1, which is detecting the presence of PCL, and ranked 40/49 on subtask 2, which involves identifying the PCL techniques used. In particular, the model struggled with the 'authority voice' and 'metaphor' categories.

2 Task Overview

The dataset provided was the Don't Patronize Me! Dataset (P'erez-Almendros et al., 2020), which is a collection of paragraphs mentioning vulnerable communities and published in media in 20 English speaking countries. Each paragraph has the country code where the paragraph was published and the keyword that was used to search for it. For subtask 1, the paragraphs are manually annotated with a label from 0-4 on how much PCL it contains; these are converted to binary labels on whether or not a paragraph contains PCL, where 2-4 indicate positive examples and 0-1 indicate negative examples. For subtask 2, all paragraphs in the dataset contain PCL and are annotated with spans containing categories of linguistic techniques that are used to express the condescension. These categories are:

- Unbalanced power relations
- Shallow solution
- Presupposition
- Authority voice
- Metaphor
- Compassion
- The poorer, the merrier

The training portion of the dataset for subtask 1 contained 10,636 paragraphs, and the corresponding dataset for subtask 2 had 993 paragraphs with 2,792 instances of PCL techniques.

3 System Overview

3.1 Data Representation

We felt that attempting to learn from the text itself and removing the contextual metadata could lead to more robust textual analysis. Therefore, we relied solely on the paragraph as our input feature. We tried two approaches: 1) using pre-trained GloVe embeddings with a dimension of 300, which track co-occurences of words in a global corpus (Pennington et al., 2014), and 2) tokenizing the paragraphs using a BERT tokenizer and inputting these into a pre-trained BERT model (Devlin et al., 2019). For subtask 2, where the focus was on shorter labeled spans rather than entire paragraphs, we still used the full text to provide more context for the detection of PCL.

3.2 Subtask 1

GloVe embeddings are good at capturing word analogies due to its global vectorization and its ability to capture sub-linear relationships in the vector space (Pennington et al., 2014). We felt that the analogy ability was specifically important to this task, because it could help capture tonal similarities between instances of PCL. Therefore, we began with a bag-of-words model where we summed the GloVe embeddings of each word in the text, then performed logistic regression to output a binary label indicating whether or not the text contained PCL. However, due to the high class imbalance present in the data, this model predicted no PCL for nearly all inputs.

Our final model was a fine-tuned BERT model. Initially, we re-labeled the training data with the final binary labels of PCL and not PCL, but this led to issues due to the high class imbalance. We decided to make the model a multiclass classifier which output the original 0-4 labels, and then convert these to binary labels. This allowed us to better adjust model weights to reflect the imbalances in class distributions, because the imbalances were not standard to all PCL, and varied dramatically based on the subtype.

3.3 Subtask 2

The most notable decision in this subtask was using the entire paragraph instead of focusing on the spans of PCL. We initially actually tried training on just the labeled spans, but these did not provide enough context for the BERT model to fine-tune to the data. Therefore, we used the entire text as the input to provide more context. Due to the small amount of data for the second subtask, we also chose to apply transfer learning and start our training from the fine-tuned model from the first subtask.

One major problem with the task is that the contexts between the types of PCL are all similar, as there can be many instances of categories within the same paragraph of text in smaller spans. This leads to the model defaulting to predicting the more frequent classes. We tried to address this by adding in the spans without context as training data; however this actually decreased performance.

4 Experimental Setup

We used BertTokenizerFast to tokenize the text and fine-tuned on the pre-trained BertForSequenceClassification model, both from the HuggingFace Transformers library (Wolf et al., 2020). We conducted hyperparameter optimization using the HyperOpt package (Bergstra et al., 2013), using population-based training (Jaderberg et al., 2017). It automatically generated sets of hyperparameters for us, and then based on the results of training with those hyper parameters updated the future hyperparameter sets. Our final model was trained using Adam optimization with a learning rate of 2.31468e-05 (Kingma and Ba, 2014); we trained the model for 6 epochs with a batch size of 8. We used a train/test split of 70/30 and evaluated based on accuracy and F1.

5 Results

Our model had precision 0.4017, recall 0.7666, and F1 0.5271 on the evaluation data for subtask 1, and has an average F1 of 0.0963 for subtask 2. We placed 32/79 for subtask 1, and 40/49 for subtask 2. Based on the results, the model had a hard time with the types of PCL that showed up less frequently in the data, and tended to perform best on the categories that were more frequent. In retrospect, using the same model architecture and setup on the two subtasks was not the optimal way

Metric	Score
Precision	0.4017
Recall	0.7666
F1	0.5271

Table 1: Results for Subtask 1.

PCL Category	Score
Unbalanced Power Relations	0.1596
Shallow Solutions	0.2694
Presupposition	0.0423
Authority Voice	0.0
Metaphor	0.0
Compassion	0.0864
The Poorer, The Merrier	0.1212
F1 Average	0.0963

Table 2: Results for Subtask 2.

to approach the task, despite some compelling reasons to approach it that way. We did not perform any quantitative analysis or ablations, but given the chance we would augment the less frequent PCL categories and see if that would fix the prediction issues for subtask 2, even if it wouldn't necessarily improve accuracy.

6 Conclusion

We developed a system which attempted to first classify whether or not a piece of text contained patronizing or condescending language, and then identify the technique used to convey the PCL. In particular, we focused on examining whether or not pure textual analysis using contextual word embeddings alone would be enough to perform the aforementioned tasks. Based on our results, this approach is only viable for the binary classification of whether or not a text contains PCL.

In the future, we would explore creating an ensemble of models, only one of which uses textual analysis, and the rest would focus on things like meta data and word frequencies which do not rely on context. Comparing the result of that ensemble to a traditional approach to this problem which uses many of those methods simultaneously would show whether or not there is a strong overlap between sources, locations, etc. and PCL, or whether only the text itself is the best indicator of a sign of PCL.

Abstract

Patronizing and condescending language (PCL) can find its way into many mediums of public discourse. Presence of PCL in text can produce negative effects in the society. The challenge presented by the task emerges from the subtleties of PCL and various data dependent constraints. Hence, developing techniques to detect PCL in text, before it is propagated is vital. The aim of this paper is twofold, a) to present systems that can be used to classify a text as containing PCL or not, and b) to present systems that assign the different categories of PCL present in text. The proposed systems are primarily rooted in transformer-based pretrained language models. Among the models submitted for Subtask 1, the best F1-Score of 0.5436 was achieved by a deep learning based ensemble model. This system secured the rank 29 in the official task ranking. For Subtask 2, the best macro-average F1-Score of 0.339 was achieved by an ensemble model combining transformer-based neural architecture with gradient boosting label-balanced classifiers. This system secured the rank 21 in the official task ranking. Among subsequently carried out experiments a variation in architecture of a system for Subtask 2 achieved a macro-average F1-Score of 0.3527.

1 Introduction

The aim of the current task, viz. Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022), is to identify presence of condescending and patronizing tones in text, particularly by the media when referring to vulnerable communities. Preponderance of PCL in news and different social media texts, often targeted towards marginalised and under represented communities is a major social concern these days. It can feed stereotypes, tilt the scales of superiority towards a particular community, and fuel discriminatory behaviour. Thus the task of identifying PCL particularly that directed to vulnerable communities is a crucial task.

The task is based on the English language Don't Patronize Me! dataset (Pérez-Almendros et al., 2020). It consists of two subtasks, binary classification (Subtask 1) and multi-label classification (Subtask 2). In Subtask 1, given a paragraph the aim is to predict whether the paragraph consists of any form of patronizing and condescending language (PCL). In Subtask 2, the aim is to assign each paragraph a subset of labels which express different categories of PCL. The major challenges offered in such tasks emerge from various linguistic aspects, such as use of cryptic sentences, sarcasms used, polysemous nature of the English words among others. For the present task, further challenge emerges from the imbalance of dataset as discussed in Section 2.

Experiments were conducted with various systems and the best performing ones for both the subtasks are discussed in detail. The two systems that perform best among these, for both the subtasks are ensemble techniques, which employ two or more classifier models at different stages of the system.

The paper is organized as follows. The task background is discussed in Section 2. Sections 3 and 4 discuss the details of the systems and the experimental setup, respectively. The results from the systems are given in Section 5. The paper is concluded in Section 6.

The code for the proposed systems have been made available at https://github.com/KushagriT/SemEval2022-TeamLRL_NC

2 Background

As mentioned in Section 1, this task is based on the Don't Patronize Me! dataset. The paragraphs for this dataset have been extracted form the News on Web (NoW) corpus (https://www.english-corpora.org/now/), and have been manually anno-

Label:	1	2	3	4	5	6	7
Neg/Pos	14	52	46	45	52	21	261

Table 1: Label Ratios

tated. The statistics of the subset of data used for this task are as follows. The Train subset has 8375 samples, Dev subset has 2094 samples, and the Test set has 3832 samples. The label set considered for this multi-label classification consists of seven labels, namely 'Unbalanced power relations'(1), 'Shallow solution'(2), 'Presupposition'(3), 'Authority voice'(4), 'Metaphor'(5), 'Compassion'(6), and 'The poorer, the merrier'(7). These labels are henceforth addressed by their sequence ids as mentioned above.

The number of negative examples per positive example, for the binary classification task, in the Train + Dev dataset (henceforth referred to as Training dataset), is approximately 10. For Subtask 2, the number of negative examples per positive example (approximated to nearest integer) for each label in the Training dataset is given in Table 1 (denoted as Neg/Pos). An approximation of these ratios are used as scaling factors to manage the unbalanced classes when creating gradient boosting classifiers for multi-label classification.

Work has been carried out in the field of NLP to identify different types of linguistic variations or harmful languages from text such as, sarcasm detection (Chatterjee et al., 2020), hate speech detection (Djuric et al. (2015), Gitari et al. (2015)), and fake news detection (Shu et al. (2017), Conroy et al. (2015)). Since the introduction of BERT (Devlin et al., 2019), transformer-based language models have been used for a variety of NLP tasks, such as the use of BERT for a regression task of predicting eye-tracking features for a given word of the sentence (Choudhary et al., 2021), or use of BERT for the task of document classification (**?**, Adhikari et al. (2019)).

All the methods proposed in this paper use further pre-trained transformer-based language models to extract document embeddings. The motivation comes from some recent work that has been carried out in detecting condescending language from text. Wang and Potts (2019) introduce a new labeled dataset, namely TalkDown, of condescending acts in context, and establish baselines for this dataset using BERT.

3 System Overview

Experiments were conducted with two types of models for each of the two subtasks. Each system uses transformer-based language models for generating text embeddings. These language models were further pre-trained on Masked Language Modeling (MLM) task on the given data. The paragraphs from the training dataset were prepared for MLM with the model specific tokenizer by masking tokens in the input with probability 0.15, and using truncation and padding to maximum length of 256.

The present experiments use further pre-trained RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019) language models[1]. These further pre-trained RoBERTa (roberta-base) and XLNet (xlnet-base-cased) models are henceforth denoted as MyRoberta and MyXlnet, respectively. This further pre-training is done using the given data on the existing pre-trained RoBERTa and XLNet models in order to fine-tune the models for the two specific subtasks, so they become adapted to the given corpus irrespective of the task at hand, whether it is binary classification or multi-label classification.

The systems discussed in Sections 3.1 and 3.2, use a custom attention head architecture[2]. The input to this attention head is of dimension $batch\ size \times sequence\ length \times embedding\ dimension$, and the output is of dimension $batch\ size \times embedding\ dimension$. The attention mechanism is used so that the system learns the emphasis of different tokens towards the classification. This layer is henceforth referred to as Attn_head.

Embeddings are generated using these models to extract document representations, which will be used as features in each system. For training the proposed models, discussed in sections 3.1 and 3.2, and for the training of the MyRoberta and MyXlnet models, smart batching is used, with a maximum token length limit of 256. In smart batching the dataset is sorted by length of the sequences before creating batches, and padding is done to each sequence in each batch to the length of the longest sequence in that batch. In the following subsections the model algorithms are discussed in detail. Smart batching has been used to optimize the training speed for the transformer-based models, since now most of the resulting batches will have shorter

sequence lengths which would prevent memory overload.

The following notations have been used in the further sections. The two subtasks of Binary and Multi-label classification have been referred to as, Subtask 1 and Subtask 2, respectively. The two systems in for each of these tasks have been denoted as BINARY.1, and BINARY.2 for Subtask 1, and MULTI.1 and MULTI.2 for Subtask 2. MULTI.1 and MULTI.2, each have two sub-models which are denoted as MULTI.1.A and MULTI.1.B for MULTI.1, and MULTI.2.A and MULTI.2.B for MULTI.2.

3.1 Subtask 1: Binary Classification

In this section the two proposed systems for the task of binary classification are discussed.

3.1.1 BINARY.1: MyRoberta + MyXlnet + Attn_head

The first component of BINARY.1 consists of MyRoberta and MyXlnet. Concatenation of the last hidden states from the two models is passed as an input to Attn_head. The output from this layer is sent to a fully connected layer which serves as the classifier unit. The architecture for BINARY.1 is given in Figure 1. The entire flow indicates the algorithm for BINARY.1.

This system is trained for the task of binary classification with Cross Entropy loss using AdamW optimizer which is Adam (Kingma and Ba, 2014) optimizer with weight decay (Loshchilov and Hutter, 2017). A linear learning rate scheduler with 50 warm-up steps is used. The hyperparameters for this system are given in Table 2.

Hyperparameter	Value
Train Epochs	5
Batch Size	16
Initial Learning Rate	2e-5

Table 2: Hyperparameters for BINARY.1

By using ensemble technique the quality of representation of these documents is improved, and using attention this model learns the emphasis of each token in the text sequence in contributing towards each label in the predicted label set. This can be observed from the ablation experiments discussed in Section 5.

3.1.2 BINARY.2: MyRoberta + Attn_head

The basic architecture used in BINARY.2 is similar to that of BINARY.1 described in Section 3.1.1. This system, however, trains the following model.

The first component of this system is MyRoberta. The last hidden states from this model is passed as input to Attn_head. The output from this layer is sent to a fully connected layer which serves as the classifier unit. The architecture for BINARY.2 is given in Figure 1, with its flow indicated in red. In case of BINARY.2, the input dimension for the first fully connected layer in the Attention Head unit and the classifier unit is 768 instead of 2*768, as for BINARY.1.

In this system, while training the weights in the pooler layer and the last 5 layers of MyRoberta are re-initialized. The weights for the fully connected layers in MyRoberta are re-initialized with mean 0 and standard deviation same as that of the initializer range of MyRoberta[3]. The weights and biases of the layer normalization in MyRoberta are re-initialized to constant values of 1 and 0, respectively.

This system is trained for the task of binary classification with Cross Entropy loss using AdamW optimizer. A linear learning rate scheduler with 50 warm-up steps is used. For BINARY.1 a smaller batch size is used to prevent memory overload.

Hyperparameter	Value
Train Epochs	5
Batch Size	32
Initial Learning Rate (Group 1)	1e-5
Initial Learning Rate (Group 2)	2e-5
Initial Learning Rate (Group 3)	4e-5
Initial Learning Rate (Group 4)	5e-5

Table 3: Hyperparameters for BINARY.2

The initial layers of the MyRoberta model encode the more general information that is present in the text. Additionally, since MyRoberta has already been trained on the task-specific data, the embedding layer and the first four layers of MyRoberta are given a lower initial learning rate of 1e-5. This parameter group is denoted as Group 1. As the layers move closer the output or the classifier layer, the model encodes task-specific information. Hence for the next four layers (Group 2), the learning rate is chosen as 2e-5, and for the last four layers (Group 3) the learning rate is chosen to be 4e-5. The classifier and the pooler layers are assigned a higher learning rate of 5e-5. This parameter group is denoted as Group 4. Each of these layers have weight decay of 0.01, except for bias and layer normalization weights. Table 3 shows the values of the different hyperparameters for this system.

3.2 Subtask 2: Multi-Label Classification

In this section the two proposed systems for the Subtask 2, namely MULTI.1 and MULTI.2 are discussed. MULTI.1 consists of two sub-models, MULTI.1.A and MULTI.1.B. MULTI.1.A is MyRoberta + FCL_1 where FCL_1 denotes a fully connected layer, and MULTI.1.B is a collection of label-balanced XGBoost Classifiers (XGB). MULTI.2 also consists of two sub-models. In MULTI.2.A, a similar architecture is used as in MULTI.1.A, but with different dimensions and with an additional layer named FCL_2 which a fully connected classifier unit. MULTI.2.B has two parts: i) Fuzzy C-Means clustering to extract features, ii) a multi-label classifier model based on fuzzy membership. These two parts will be denoted as FCM and Fuzzy_CLF, respectively. The flow of output between the two models are explained in Section 3.2.2.

3.2.1 MULTI.1: MyRoberta + FCL_1 + XGB

This system has two parts, namely a model to extract features from the text (MULTI.1.A), and a model to assign a set of labels to this text using a classifier (MULTI.1.B). The architecture for this model is given in Figure 2.

To extract features MyRoberta is fine-tuned for the task of multi-label text classification. The first component of MULTI.1.A is MyRoberta. The CLS embedding from MyRoberta is passed to a fully connected classifier layer with output dimension 7, corresponding to the seven labels. In this model, while training the weights in the pooler layer and the last 5 layers for the MyRoberta are re-initialized as described in Section 3.1.2.

MULTI.1.A is trained using Binary Cross Entropy loss between the true multi-labels with the output, applied with sigmoid activation. It is trained using AdamW optimizer with. A linear learning rate scheduler is used, with 100 warm-up steps and number of total steps corresponding to 25 epochs. This is done to avoid a lower learning rate at 5 epochs. The hyperparameters for this system are given in Table 4.

Hyperparameter	Value
Train Epochs	5
Batch Size	16
Weight Decay	0.01
Initial Learning Rate	5e-5

Table 4: Hyperparameters for MULTI.1.A

The output from the above model is used as input to the final multi-label classifier (MULTI.1.B). Two sets of experiments were conducted, one with the CLS embeddings from MyRoberta, and another with the output of the fully connected classifier layer from MULTI.1.A, as the desired input to MULTI.1.B. These results are given in Section 5. MULTI.1.B consists of individual binary XGBoost (Chen and Guestrin, 2016) classifiers for each of the seven labels. These classifiers account for data imbalance for each given label by

using the parameter `scale_pos_weight` to indicate the number of negative examples per positive example in the training dataset[4]. The value of `scale_pos_weight` is chosen as the approximation of this value in different partitions of the dataset (Train, Dev and Train+Dev).

3.2.2 MULTI.2: MyRoberta + FCL_1 + FCL_2 + FCM + Fuzzy_CLF

This system uses a fuzzy membership-based ensemble classifier (Tandon and Chatterjee, 2022), consisting of two sub-models, namely MULTI.2.A and MULTI.2.B. The sub-model MULTI.2.A uses fine-tuned MyRoberta for feature extraction, which is fed to the sub-model MULTI.2.B for classification. The architecture for this system is given in Figure 3.

[4]The other parameters for these XGBoost Classifiers are given in the Appendix

The first component of MULTI.2.A is MyRoberta. The CLS embedding from MyRoberta is passed to a fully connected layer with output dimension 100, followed by a fully connected classifier layer with output dimension 7. While training the weights in the pooler layer and the last five layers for the MyRoberta are re-initialized as described in Section 3.1.2. This model is trained using Binary Cross Entropy loss applied with sigmoid activation, using AdamW optimizer. A linear learning rate scheduler is used with 100 warm-up steps and number of total steps corresponding to 25 epochs. This model uses 10 train epochs. All the other hyperparameter values are same as given in Table 4.

Output from the first fully connected layer in MULTI.2.A is used as an input to MULTI.2.B. MULTI.2.B uses this input for Fuzzy C-Means (Bezdek et al., 1984) clustering algorithm, in which the clusters are considered as fuzzy sets over the set of all samples. Each cluster is represented by a fuzzy membership function. The parameters for this model are c (number of clusters) and m (the weighting exponent). This algorithm outputs Fuzzy C-partition $\mathbf{X} = [X_{i,j}]_{l\times c}$ which is used as the set of features for the main classification model. Here, l is the number of training documents. The use of this as the set of features aims at measuring the underlying uncertainty using membership-based measures.

Using these features the set of input documents $\mathcal{D}$ are clustered in k hard clusters. Each cluster thus formed is considered as a fuzzy set on the prescribed label set. In case of k clusters and p labels, the cluster is represented by a $p-$dimensional vector of fuzzy membership values which are utilized to assign the label set for an unseen example. Next, a measure of association of clusters to each of the extracted features (generated from Fuzzy C-Means clustering algorithm) is derived, which aids in retrieving a value to represent a new instance as a $k-$dimensional vector $(R_1, \cdots, R_k)$, where each R_i is the projection of the instance in the i^{th} cluster. Top s ($s \leq k$) clusters with highest R values are chosen. For a threshold value α the predicted label set for this instance is computed as the set of all labels whose membership to the union of these clusters is greater than or equal to α. The mathematical details of the algorithm are given in the Appendix.

4 Experimental Setup

The experiments were carried on Google Colaboratory in Python 3.7.12 with Nvidia Tesla P100 GPU. PyTorch (Paszke et al., 2019) and Huggingface Transformers (Wolf et al., 2020) are the key frameworks used to carry out the experiments.

The text from the training data was used to further pre-train RoBERTa and XLNet models, without any preprocessing. The text was tokenized using the fast implementations of RobertaTokenizer and XLNetTokenizer from the transformers library i.e., RobertaTokenizerFast and XLNetTokenizerFast, respectively.

The input text was tokenized using XLNetTokenizerFast for BINARY.1 and using RobertaTokenizerFast for BINARY.2.

For MULTI.1 and MULTI.2, the text in the training data was preprocessed using the following preprocessing steps.

- The punctuations `" , ; –` were removed from the text.
- Extra spaces between contractions were removed, and digits were removed from the text.
- The contractions were fixed using contractions library.[5]
- HTML symbols were removed.
- Any additional punctuations in particular, `!"#$%&()*+,-./:;<=>?@[\]^_`|~` were removed.

For MULTI.1 and MULTI.2, the preprocessed text is tokenized using RobertaTokenizerFast from the transformers library. The XGBoost classifier has been implemented using the XGBoost[6] library and the MiniBatchKmeans has been implemented using scikit-learn[7] Python library (Pedregosa et al., 2011). Fuzzy C-means is implemented using the 'fuzzy-c-means'(Dias, 2021) Python framework. For MULTI.2, the parameters are given in Table 5. These parameters are chosen by performing hyper-parameter tuning using Train and Dev partitions of the dataset.

Parameter	Value
m	1.6
c	22
k	38
α	0.55
s	4

Table 5: MULTI.2.B Parameters

5 Results

Several experiments were conducted using the systems described in Section 3 and some variations of these systems. The systems were trained on the Training dataset (Train + Dev) and the metrics obtained on Test set are discussed in this section.

5.1 Subtask 1

In BINARY.1, to understand the impact of the layers MyRoberta, MyXlnet, and Attn_head, ablation experiments were carried out. For each of these experiments, each one of these layers are systematically removed and the results are reported. Since

Table 7: Experiments: Subtask 2

BINARY.1 considers an ensemble of MyRoberta and MyXlnet, exactly one of these is eliminated in each set of experiments. Additionally, the attention mechanism on the last hidden state is substituted with using CLS embeddings (denoted CLS) from the previous layer. The results from these experiments are given in Table 6. This table also includes the result for BINARY.2 and the official roberta-baseline. Here, the proposed model in BINARY.2 is denoted by MyRoberta + Attn_head. For each of these models, the final layer is a fully connected layer which serves as a classifier unit.

The best precision is observed for the model MyXlnet + Attn_head among the BINARY.1 ablations, and for BINARY.2, overall. However proposed model i.e., MyRoberta + MyXlnet + Attn_head with the ensemble embedding layers and an attention head performs the best according to the overall F1-Score.

5.2 Subtask 2

In MULTI.1, two variations of the proposed model can be achieved, depending on the input to MULTI.1.B. The CLS embedding from MyRoberta in MULTI.1.A can be considered as an input to MULTI.1.B, or the output of the fully connected layer in MULTI.1.A can be considered as input to MULTI.1.B.

MULTI.2.A consists of three components, namely MyRoberta followed by two fully connected layers denoted as FCL_1 and FCL_2, respectively. MULTI.2.B has two parts, namely the model consisting of Fuzzy C-Means clustering to extract features followed by a multi-label classifier model based on fuzzy membership. These two parts will be denoted as FCM and Fuzzy_CLF, respectively, as mentioned in Section 3.2. Ablation experiments were performed by removing components of these model to understand their impact in the overall system. For these experiments the main classifier layer is substituted with a One-vs-the-rest classifier which fits one classifier per class. The base estimator for this classifier is taken as a support vector classifier (This classifier was designed using the scikit-learn library) . This classifier is denoted as Base_CLF.

The results from these experiments are given in Table 7. This table consists of F1-Scores for each of the seven labels and the macro-average F1-Score.

It is observed that the F1-Score for the label 'Unbalanced power relations' is the highest among all other labels, at 0.548. This value has been observed for the the MULTI.2 ablation MyRoberta + FCM + Base_CLF. The highest F1-Score for the label 'Shallow Solution' is 0.457 using the model MyRoberta + FCM + Fuzzy_CLF. The highest F1-Scores for the labels 'Presupposition', 'Metaphor' and 'Compassion' are observed using MULTI.1 with the CLS embedding from MyRoberta considered as an input to MULTI.1.B. The highest F1-Score for the labels 'Authority Voice' is observed for MyRoberta + FCL_1 + FCL_2. The highest F1-Score for the label 'the poorer, the merrier' is observed for the MULTI.2 ablation MyRoberta + Base_CLF. Overall best performance is observed for MULTI.1 with the CLS embedding from MyRoberta considered as an input to MULTI.1.B. It is noted that all the presented experiments perform better than the roberta-baseline.

6 Conclusion

In this paper, systems for the task of binary and multi-label classification for detection of PCL in text, have been proposed. For the binary classification task, the first proposed system uses an ensemble transformer-based language model architecture. The other system detailed in the present work, for binary classification is a fine-tuned transformer-based language model with some custom layers. The first system proposed for the task of multi-label classification combines outputs from a transformer-based model fine-tuned for multi-label classification, and uses the embeddings from this model as features for individual label-balanced XGBoost models. Another system for multi-label classification has also been discussed, which uses a transformer-based model fine-tuned for multi-label classification, and uses the outputs from this model as inputs to a fuzzy-membership based ensemble classifier.

The experiments were conducted on Google Colaboratory.

A Appendix: Hyperparameters for Further pre-training

The RoBERTa and XLNet models were further pre-trained on the text from the Train+Dev set, with the parameter setting given in Table 8. This pre-training was carried out using RobertaForMaskedLM (RoBERTa Model with a language modeling head on top) and XLNetLMHeadModel (XLNet Model with a language modeling head on top) for RoBERTa and XLNet models, respectively. The value of batch size was chosen based on computation specifications, and the values of learning rate and weight decay were chosen based on empirical results presented in Sun et al.. To tune the hyperparameter representing the number training steps, the Train subset is used for training and the Dev set is used for validation.

Experiment Setting	Value
Train steps	30000
Batch Size	64
Initial Learning Rate	2e-5
Weight Decay	0.1
Optimizer	AdamW
Learning Rate Scheduler	Cosine
Warm-up steps	10

Table 8: Experimental Setting for further pre-training

B Appendix: Attention Architecture

This is defined with a fully connected layer with input dimension as the size of the document embeddings of dimension $batch\ size \times sequence\ length \times embedding\ dimension$ from the previous layer, and output dimension taken as 512. This is followed by a Tanh activation and another fully connected layer with input dimension as 512, and output dimension as 1. A softmax activation is applied to this layer to get the weights corresponding to each token in the sequence. Using these weights a weighted sum of the document embeddings of the size which were an input to this layer, is calculated producing an output of size $batch\ size \times embedding\ dimension$.

C Appendix: Hyperparameters for XGBoost Classifiers

The seven XGBoost classifiers trained in System B use the hyperparameter values as given in Table 9. For the hyperparameters not mentioned in the table, their default values given in the Python implementation of XGBoost Classifier are used. In the table, the parameter n_estimators denotes the number of gradient boosted trees, eta indicates the learning rate, min_split_loss indicates the minimum loss reduction required to make a further partition on a leaf node of the tree, max_delta_step indicates the maximum delta step allowed to each leaf output, subsample indicates the subsample ratio of the training instances, reg_alpha denotes the L1 regularization term on weights, and tree_method denotes the tree construction algorithm used in XGBoost.

Parameter	Value
n_estimators	100
eta	0.5
min_split_loss	0.1
max_delta_step	2
subsample	0.6
reg_alpha	0.5
tree_method	gpu_hist
objective	binary:logistic

Table 9: XGBoost Classifier Parameters

D Appendix: MULTI.2.B Algorithm

The algorithm for MULTI.2.B is given in two parts, the model generation algorithm and the prediction algorithm, as given below.

D.1 Algorithm for Model Generation

1 MiniBatchKMeans (Sculley, 2010) clustering algorithm is applied to $\mathbf{X} = [X_{i,j}]_{l\times c}$ to obtain k clusters namely $(D_1, \cdots, D_k)$, resulting in $\Omega = [\omega_{i,j}]_{k\times l}$ where

$$\omega_{i,j} = \begin{cases} 1 & \text{, if the } j^{\text{th}}\text{document is in cluster } D_i \\ 0 & \text{, otherwise} \end{cases}$$

2 A degree of association $\zeta(i,j)$ of each cluster D_i with each feature f_j is calculated as average of the feature values of f_j over all the documents in cluster D_i i.e., if the indices of the samples in cluster D_i are $\{e_1^{(i)}, \cdots, e_{|D_i|}^{(i)}\}$, then,

$$\zeta(i,j) = \frac{\sum_{r=1}^{|D_i|} X_{e_r^{(i)},j}}{|D_i|}$$

3 Cluster D_i is modeled as a fuzzy set of labels, with membership of label c_r to D_i as $\mu_{D_i}(c_r)$, for $r = 1, 2, \cdots, p$, which is modeled as the proportion of occurrences of label c_r in the label set of each document in the cluster D_i. Thus,

$$\mu_{D_i}(c_r) = \frac{\sum_{s=1}^{l} \omega_{i,s} G_{s,r}}{\sum_{s=1}^{l} \omega_{i,s}}$$

where $\mathbf{G} = [G_{i,j}]_{l\times p}$ is defined as

$$\begin{bmatrix} \mathbf{Y}_1 & \mathbf{Y}_2 & \cdots & \mathbf{Y}_l \end{bmatrix}^T$$

$\mathbf{Y}_i = (Y_{i,1}, \cdots, Y_{i,p})$ is the label vector for the i^{th} sample where $Y_j = 1$ if the document has label j and $Y_j = 0$ otherwise.

D.2 Algorithm for Prediction

Given an input text the following steps are performed to compute its label set.

1 This text is passed as input to MULTI.2.A and the output from the first fully connected layer is sent to the trained Fuzzy C-Means clustering algorithm. The Fuzzy C-partition from this is denoted by $\mathbf{v} = (v_1, \cdots, v_c)$.

2 Using $\zeta(i,j)$, a vector $\mathbf{R} = (R_1, \cdots, R_k)$ is calculated as,

$$R_i = \frac{\sum_{j=1}^{c} v_j \zeta(i,j)}{\sum_{j=1}^{c} \zeta(i,j)}$$

Here R_i represents the weighted average of $(v_1, \cdots, v_c)$ with weights as the degree of association vector $(\zeta(i,1), \cdots, \zeta(i,c))$ corresponding to the i^{th} cluster.

3 Top s, $s \leq k$ clusters with highest R values, say $\{D_{\gamma_1}, D_{\gamma_2}, \cdots, D_{\gamma_s}\}$ are chosen and their fuzzy union (or fuzzy t-conorm) is considered. In this case the fuzzy t-conorm algebraic sum[8] is used.

[8] $u(a,b) = a + b - ab$

4 For a given threshold α, predicted set of labels is computed as $\{c_i | \mu_{D_{\gamma_1} \cup D_{\gamma_2} \cup \cdots, D_{\gamma_s}}(c_i) \geq \alpha\}$.

Abstract

Patronizing and Condescending Language (PCL) towards vulnerable communities in general media has been shown to have potentially harmful effects. Due to its subtlety and the good intentions behind its use, the audience is not aware of the language's toxicity. In this paper, we present our method for the SemEval-2022 Task4 titled "Patronizing and Condescending Language Detection". In Subtask A, a binary classification task, we introduce adversarial training based on Fast Gradient Method (FGM) and employ pre-trained model in a unified architecture. For Subtask B, framed as a multi-label classification problem, we utilize various improved multi-label cross-entropy loss functions and analyze the performance of our method. In the final evaluation, our system achieved official rankings of 17/79 and 16/49 on Subtask A and Subtask B, respectively. In addition, we explore the relationship between PCL and emotional polarity and intensity it contains. Our code is available on Github [1].

1 Introduction

Patronizing and Condescending Language (PCL) expresses a superior attitude towards vulnerable communities (e.g. women, refugees, poor families), and describes them or their situation in a charitable way that evokes feelings of compassion (Pérez-Almendros et al., 2022). Although it is generally used involuntarily and with good intentions, the use of PCL can potentially be very harmful, as it feeds stereotypes, routinizes discrimination and drives to greater exclusion. Due to the subtlety of PCL, PCL detection is difficult for both humans and NLP systems and has aroused broad attention.

To address the challenge of patronizing and condescending language detection in general media, Pérez-Almendros et al. (2022) introduce the Task 4 at SemEval-2022, and build a dataset with annotated paragraphs extracted from news articles in English. Given a paragraph, systems must predict whether it contains condescending language or not (Subtask A), and whether it contains any of the 7 subtypes identified in the PCL taxonomy (Subtask B).

For Subtask A, a binary classification task, we introduce adversarial training based on Fast Gradient Method (FGM) (Miyato et al., 2016), enhancing the robustness of the model. And in Subtask B, a multi-label classification problem, there is a long-tailed distribution of each label. To address the class imbalance problem, we utilize various improved multi-label cross-entropy loss functions: Focal loss (Lin et al., 2017), Class-balanced focal loss (Cui et al., 2019) and Distribution-balanced loss (Wu et al., 2020). We analyze the performance of our methods and demonstrate the contribution of each component of the architecture.

In addition to completing basic evaluation tasks, we also explore the relationship between PCL and emotional polarity and intensity it contains in official dataset. The experimental results demonstrate that the above two have relevance.

The structure of the paper is as follows: We first provide a brief overview of related research, and then introduce our proposed framework. Besides, experiments and evaluations as well as the analysis of results are given. Finally, we discuss the future directions of our work.

2 Related Work

Patronizing and condescending language has been studied extensively in sociolinguistics and the traits of PCL have been suggested by related research. PCL builds stereotypes (Fiske, 1993), which strengthen exclusion, discrimination, rumour spreading (Nolan and Mikami, 2013) and unbalanced power relations (Sap et al., 2019), relying on subtle language (Mendelsohn et al., 2020). It tends

[1] https://github.com/Nutpok/GUTS-at-SemEval-2022-Task-4.git

to avoid stating the reasons for deep-rooted societal problems by concealing those responsible and proposes temporary solutions (Chouliaraki, 2010), which oversimplify the core problems (Head, 2008). The abuse of PCL exacerbates the difficulty of improving the lives of disadvantaged groups (Nolan and Mikami, 2013) and dehumanizes minorities in news media (Mendelsohn et al., 2020). Due to its hazard, PCL is classified as a milder form of toxic speech (Dale et al., 2021).

The increasingly social issue caused by PCL has attracted considerable attention of researchers in the natural language processing (NLP) field. Wang and Potts (2019) introduced the task of condescension detection in direct communication and built a dataset with annotated social media messages. Pérez-Almendros et al. (2020) proposed Don't Patronize Me!, an annotated dataset with PCL, and demonstrated the effectiveness of the model for PCL detection (Kenton and Toutanova, 2019).

3 Methodology

3.1 Preliminaries

We utilize a transformer-based pre-trained language model (PLM), such as BERT and RoBERTa, to represent the input sentences. Each sentence $x = [CLS, t_1, t_2, ..., t_T, SEP]$ is embedded as $s \in R^{n \times d_{emb}}$, where n is the sequence length and d_{emb} is the dimension of the embedding. We add a softmax classifier on the sentence-level embedding, such as the final hidden state h_{CLS} of the $[CLS]$ in BERT:

$$p_i = softmax(Wh_{[CLS]}) \tag{1}$$

where $W \in \mathbb{R}^{C \times d_{emb}}$, and C denotes the number of classes.

3.2 Adversarial Training

Adversarial training (Goodfellow et al., 2015) is a effective regularization method for classifiers to improve robustness to small, approximately worst case perturbations. In SubtaskA, we introduce Fast Gradient Method (FGM) (Miyato et al., 2016), a novel approach in adversarial training, to improve the generalization ability of the model in PCL detection. Figure 1 shows the overall framework of our model.

According to FGM, we apply tiny perturbations to sentence embeddings rather than original input itself. The adversarial perturbation r_{adv} on s is defined as:

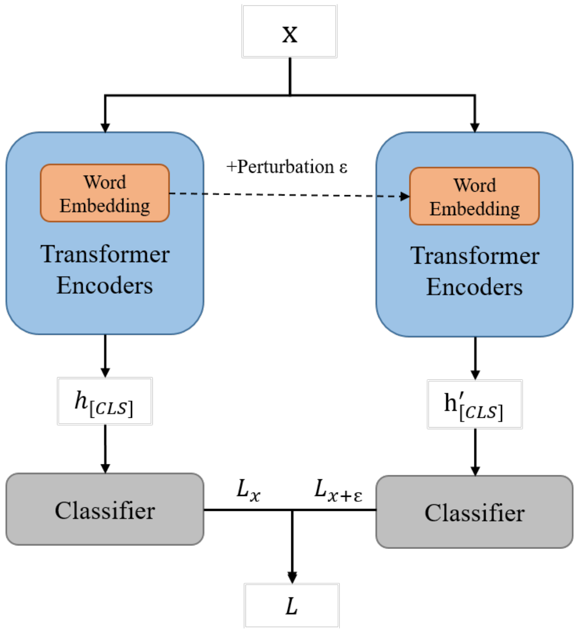

Figure 1: Model architecture for our proposed method in Subtask A.

$$r_{adv} = \epsilon \cdot g/\|g\|_2 \; where \; g = \nabla_s L(s, y) \tag{2}$$

where ϵ is a hyperparameter limiting the size of the adversarial perturbations.

To integrate the information trained from original and adversarial samples, we use an overall loss function as follows:

$$L = L(s, y) + L_{adv}(s + r_{adv}, y) \tag{3}$$

3.3 Balancing Methods

Subtask B becomes a challenging multi-label text classification task because of its long-tailed distribution of labels, each training sample $\{(x^1, y^1), \dots, (x^N, y^N)\}$ has a multi-label group $y^k = [y_1^k, \dots, y_C^k] \in \{0, 1\}^C$, and a classification result $z^k = [z_1^k, \dots, y_C^k]$. In this work, we use different balancing methods (Huang et al., 2021) re-weighting the binary cross entropy to address the class imbalance problem. And the sigmoid function is used for computing $p_i^k = \sigma(z_i^k)$. The codes of these several balanced loss functions are open source[2].

Focal Loss (FL) proposed by Lin et al. (2017) places a higher weight of loss on "hard-to-classify" instances, which are predicted with low probability. The FL can be formulated as follows:

$$L_{FL} = \begin{cases} -\alpha(1 - p_i^k)^\gamma \log(p_i^k) & if \; y_i^k = 1 \\ -\alpha(p_i^k)^\gamma \log(1 - p_i^k) & \text{otherwise} \end{cases} \tag{4}$$

[2]https://github.com/Roche/BalancedLossNLP

where $\gamma \geq 0$ is a non-negative tunable focusing parameter to differentiate between easy and difficult samples and $\alpha \in [0, 1]$ is a weighting factor to balance the training weights of positive and negative samples, p_i^k is the kth choice of p_i.

Class-balanced Focal Loss (CB) (Cui et al., 2019) re-balances the loss according to the effective number of samples for each class. Data sampling can be viewed as a random coverage problem, therefore we assign weights to the different classes based on the number of effective samples. The class-balanced term is defined as:

$$r_{CB} = \frac{1-\beta}{1-\beta^{n_i}} \tag{5}$$

where $\beta \in (0, 1)$ controls the effect of effective number of samples on marginal benefit. And we can use this term to re-weight focal loss:

$$L_{CB} = \begin{cases} -r_{CB}(1-p_i^k)^\gamma \log(p_i^k) & if\ y_i^k = 1 \\ -r_{CB}(p_i^k)^\gamma \log(1-p_i^k) & \text{otherwise} \end{cases} \tag{6}$$

Distribution-balanced loss (DB) Wu et al. (2020) present DBloss to overcome the additional imbalance caused by label co-occurrence upon resampling. In the case of single label, the resampling probability of each instance can be defined as: $P_i^C = \frac{1}{C}\frac{1}{n_i}$; while under multi-label conditions, the instance is repeatedly sampled by each positive class it contains, thus the resampled probability can be defined as $P^I = \frac{1}{C}\sum_{y_i^k=1}\frac{1}{n_i}$. And we can obtain a balancing term: $r_{DB} = P_i^C/P^I$. With a smooth function $\hat{r}_{DB} = \alpha + \sigma(\beta \times (r_{DB} - \mu))$, mapping the weight r_{DB} to a reasonable range, the re-balanced loss function is defined as:

$$L_{R-FL} = \begin{cases} -\hat{r}_{DB}(1-p_i^k)^\gamma \log(p_i^k) & if\ y_i^k = 1 \\ -\hat{r}_{DB}(p_i^k)^\gamma \log(1-p_i^k) & \text{otherwise} \end{cases} \tag{7}$$

To mitigate the over-suppression of negative labels, Wu et al. (2020) introduce a Negative Tolerant Regularization (**NTR**) in the loss function. NTR initializes a non-zero bias v_i as a threshold, and linearly scales the negative logits before the original loss is computed negative, together with a regularization parameter λ to constrain the gradient between 0 and 1. The distribution-balanced loss with NTR can be defined as:

$$L_{DB} = \begin{cases} -\hat{r}_{DB}(1-q_i^k)^\gamma \log(q_i^k) & if\ y_i^k = 1 \\ -\hat{r}_{DB}\frac{1}{\lambda}(q_i^k)^\gamma \log(1-q_i^k) & \text{otherwise} \end{cases} \tag{8}$$

where $q_i^k = \sigma(z_i^k - v_i)$ for positive instances and $q_i^k = \sigma(\lambda(z_i^k - v_i))$ for negative ones. Due to its strong applicability, NTR can also be utilized in Focal loss and DBloss to avoid over-suppression (Huang et al., 2021).

4 Experiments

4.1 Dataset and Evaluation

The dataset from the Task4 of SemEval2022 contains paragraphs about potentially vulnerable social groups[3]. The paragraphs have been extracted from the News on Web (NoW)[4] corpus (Davies, 2013). The total number of training set is 10469 and the final test set contains 2971 samples. The statistics of datasets are shown in Table 1 and the distribution of PCL categories is reported in Table 2.

Label	Samples	Proportion
PCL	993	9.49%
no PCL	9476	90.51%

Table 1: The distribution of labels in SubTaskA.

PCL Categories	Samples	Proportion
Unb. power rel.	716	6.84%
Shallow solu.	196	1.87%
Presupposition	224	2.14%
Authority voice.	230	2.20%
Metaphor	197	1.88%
Compassion	469	4.48%
The p., the mer.	40	0.04%

Table 2: The distribution of labels in SubTaskB.

To estimate the performance of the system, the organizers used different metrics for subtask A and B. In Subtask A, a binary classification task, F1 over the positive class is applied as evaluation measure, while for Subtask B, framed as a multilabel classification problem, results are evaluated based on the macro-average F1 of seven PCL categories.

4.2 Experimental Settings

We utilize Roberta-base (Liu et al., 2019) as the pretrained language model for representing the input paragraphs. The AdamW optimizer is used for model training. In evaluation period, we perform five-folds cross-validation on training set and evaluate the performance of our model using average metrics over five-folds. We keep the model parameters for optimal performance. In test phase, we

[3]https://github.com/Perez-AlmendrosC/dontpatronizeme
[4]https://www.english-corpora.org/now/

utilize each fold of the optimal model to predict on the offical test set and vote on the results to obtain the final predictions.

Specially, we implement our model with `transformers`[5] package. During the training phase, we evaluate the performance of the model every 200 steps and retain the parameters of the model that performed best on the validation set. The hyperparameters settings adopted are shown in Table 3. All models are trained on NVIDIA Geforce GTX 3090 GPU.

Hyperparameters	SubtaskA	SubtaskB
seed	1234	1234
epochs	5	15
batch size	32	8
learning rate	2e-4	2e-4
alpha	0.6	0.95
gamma	2	4
dropout	0.25	-

Table 3: The hyperparameters of the experiment.

4.3 Results and Discussions

The influence of adversarial training. Table 4 shows the influence of adversarial training in Subtask A. Based on the experimental results, we observe that the introduction of FGM can improve the detection capability of the model in both evaluation phase and test phase. It shows that adversarial training can improve the robustness of the model.

Evaluation phase	
Model	**F1(postive)**
RoBERTa	0.5699
RoBERTa+FGM	0.5785
Test phase	
Model	**F1(postive)**
RoBERTa	0.5545
RoBERTa+FGM	0.5790

Table 4: The performance of our model in Subtask A.

The influence of balancing methods. Table 5 shows the results of our framework trained with various loss functions in Subtask B. It is observed that the performance after introducing the balancing methods is significantly more superior than BCE, while the effect is further improved after employing NTR.

In the period of test, we choose two models with the best performance during the evaluation phase to predict the samples, which are trained with FL+NTR and CB+NTR, respectively. Moreover, the model trained with FL+NTR performs better in the final test set. It is because CB is more sensitive to the assumed sample space size β. If there is a significant difference between the training set and the label distribution of the test set, the ability of the model to address label imbalance will be reduced. In the follow-up work, we will conduct more experiments to observe the impact of parameters on hyperparameters.

Evaluation Phase	
Loss Function	**F1(macro)**
BCE	0.2923
FL	0.3662
DB	0.3767
CB	0.3776
FL+NTR	0.3917
CB+NTR	0.3922
Test Phase	
Loss Function	**F1(macro)**
FL+NTR	0.3700
CB+NTR	0.3537

Table 5: The performance in Subtask B.

5 Emotional Polarity and Intensity of PCL

In this section, we conduct a further analysis to explore the relevance between PCL and emotional polarity and intensity it contains.

We employ NLTK[6], a natural language processing toolkit, to determine the emotional features of a paragraph. For a given text, parser of NLTK returns a sentiment score in a interval of [-1,1], which determines if sample is positive or negative and shows emotional intensity. We divide the sentiment score into 5 levels, and the mapping relationships reflecting motional polarity and intensity are shown in Table 6 and Table 7.

Sentiment Score	Emotional Level
$[-1, -0.6]$	-2
$[-0.6, -0.2]$	-1
$[-0.2, 0.2]$	0
$[0.2, 0.6]$	1
$[0.6, 1]$	2

Table 6: Mapping between sentiment scores and emotional level of the polarity.

[5]https://huggingface.co/

[6]https://github.com/nltk/nltk

Sentiment Score	Emotional Level
$[-0.2, 0.2]$	0
$[0.2, 0.4] \cup [-0.4, -0.2]$	1
$[0.4, 0.6] \cup [-0.6, -0.4]$	2
$[0.6, 0.8] \cup [-0.8, -0.6]$	3
$[0.8, 1] \cup [-1, -0.8]$	4

Table 7: Mapping between sentiment scores and emotional level of the intensity.

We divide the training set into 5 subsets based on the sentiment level and calculate the number of samples. Then we count the proportion of paragraph containing PCL in each subset. The experimental result is reported in Figure 2 and 3.

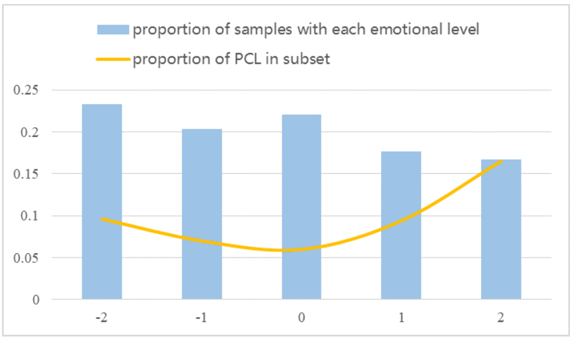

Figure 2: The emotional polarity level of PCL. Blue strip: proportion of samples with each level reflecting emotional polarity in the entire dataset, yellow line: proportion of PCL in subset with each emotional level.

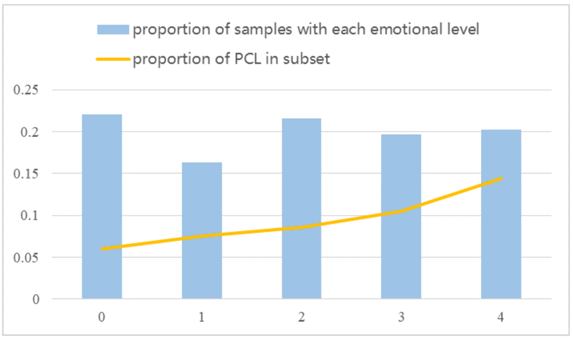

Figure 3: The emotional intensity level of PCL. Blue strip: proportion of samples with each level reflecting emotional intensity in the entire dataset, yellow line: proportion of PCL in subset with each emotional level.

From the results, we can observe that: a) The paragraph containing PCL is more likely to express positive emotions since the use of PCL is often with good intentions. b) Paragraphs with higher emotional intensity are more likely to contain PCL. This is because there are numerous excerpts of live speeches, speakers tend to express their opinions in a stronger tone, which is often condescending.

6 Conclusion and Future Work

In this work, we present our approach to the SemEval-2022 Task 4 to tackle the problem of patronizing and condescending language detection. We employ adversarial training and balancing methods for PCL classification with long-tailed class distribution and demonstrate the effectiveness of our methods.

Besides basic deep learning techniques, introducing multi-task learning in PCL detection, such as predicting the sentiment polarity of a paragraph, is also a problem worth discussing. We have found that PCL is associated with the emotional polarity and intensity of paragraphs. In the future, we will further explore the relationship between sentiment analysis and PCL detection and propose corresponding multitasking frameworks.

Abstract

This paper describes the system for the Semeval-2022 Task4 "Patronizing and Condescending Language Detection".An entity engages in Patronizing and Condescending Language(PCL) when its language use shows a superior attitude towards others or depicts them in a compassionate way. The task contains two parts. The first one is to identify whether the sentence is PCL, and the second one is to categorize PCL. Through experimental verification, the RoBERTa-based model will be used in our system. Respectively, for subtask 1, that is, to judge whether a sentence is PCL, the method of retraining the model with specific task data is adopted, and the method of splicing [CLS] and the keyword representation of the last three layers as the representation of the sentence; for subtask 2, that is, to judge the PCL type of the sentence, in addition to using the same method as task1, the method of selecting a special loss for Multi-label text classification is applied. We give a clear ablation experiment and give the effect of each method on the final result. Our project ranked 11th out of 79 teams participating in subtask 1 and 6th out of 49 teams participating in subtask 2.

1 Introduction

The effect of Patronizing and Condescending Language (PCL) towards vulnerable communities in the media is not always conscious and the intention of the author is often to help the person or group they refer to (e.g. by raising awareness or funds or moving the audience to action). However, these superior attitudes and discourse of pity can routinize discrimination and make it less visible. While there has been substantial work on modeling language that purposefully undermines others, the modeling of PCL is still an emergent area of study in NLP since PCL is the speaker's unconscious superior speaking attitude, the special word that causes PCL is subtle compared to the keywords in other natural language processing problems.

The authors decided to evaluate the questions separately. In Semeval-2022 task 4: Patronizing and Condescending Language Detection(Pérez-Almendros et al., 2022), the purpose of subtask 1 is to identify whether a sentence is PCL. In contrast, the goal of subtask 2 is to indicate the presence of PCL at the text span level, which detects the exact categories in the seven categories of PCL.In subtask 1, the method of using data set retraining to make the pre-trained language model learn the specific distribution of the data set, adding keywords to the input, and integrating five RoBERTa-based models, subtask 2 is to select k from 7 For classification tasks, task-specific loss calculation methods are designed. These methods will be explained in detail in the following sections.

2 Background

Research on PCL has been in various fields such as language studies (Margić, 2017), sociolinguistics (Giles et al., 1993), politics (Huckin, 2002) or medicine (Komrad, 1983). In recent years, natural language processing systems for recognizing PCL languages have also begun to emerge, for example, (Wang and Potts, 2019) introduced the task of modeling humility in direct communication from an NLP perspective, and developed a dataset of annotated social media messages. In the same year, (Sap et al., 2019) discuss the social and power implications behind the use of certain languages, an important concept in the imbalanced power relations that often arise in condescending treatment. But there has not been a standard in terms of accuracy and definition of PCL. Therefore, this article will first explain the definition of PCL and define some categories of the linguistic techniques used to express PCL.

2.1 What is PCL

Somebody is patronizing or condescending when their language denotes a superior attitude towards others, talks down to them, or describes them or their situation in a charitable way, raising a feeling of pity and compassion. For example,*People across Australia ordered pizzas to be delivered on Saturday night, with the ample leftovers donated to local homeless shelters.* is a sentence that contains PCL for the sentence conveys a superior attitude towards the homeless.

Patronizing and Condescending Language (PCL) is often involuntary and unconscious, and the authors using such language are usually trying to help communities in need by e.g., raising awareness, moving the audience to action, or standing for the rights of the under-represented. On the other hand, due to its subtlety, subjectivity, and the (generally) good intentions behind its use, the audience is often unaware of this diminishing treatment. But PCL can potentially be very harmful, as it feeds stereotypes, routinizes discrimination, and drives to greater exclusion.

PCL detection is difficult both for humans and NLP systems, due to its subtle nature, its subjectivity, and the fair amount of world knowledge and commonsense reasoning required to understand this kind of language. With this task, we expect to push the boundaries of this new challenge in the NLP community.

2.2 Categories of PCL

Our PCL taxonomy has been defined based on previous works on PCL. We consider the following categories:

Unbalanced power relations The author distances themselves from the community or the situation they are talking about and expresses the will, capacity or responsibility to help those in need. It is also present when the author entitles themselves to give something positive to others in a more vulnerable situation, especially when what the author concedes is a right which they do not have any authority to decide to give.

Shallow solution A simple and superficial charitable action by the privileged community is presented either as life-saving/life-changing for the unprivileged one or as a solution for a deep-rooted problem.

Presupposition When the author assumes a situation as certain without having all the information or generalizes their or somebody else's experience as a categorical truth without presenting a valid, trustworthy source for it (e.g. a research work or survey). The use of stereotypes or clichés is also considered to be an example of presupposition.

Authority voice When the author stands themselves as a spokesperson of the group, or ex-plains or advises the members of a community about the community itself or a specific situation they are living.

Metaphor They can conceal PCL, as they cast an idea in another light, making a comparison between unrelated concepts, often with the objective of depicting a certain situation in a softer way. For the annotation of this dataset, euphemisms are considered as an example of metaphors.

Compassion The author presents the vulnerable individual or community as needy, raising a feeling of pity and compassion from the audience towards them. It is commonly characterized by the use of flowery wording that does not provide information, but the author enjoys the detailed and poetic description of the vulnerability.

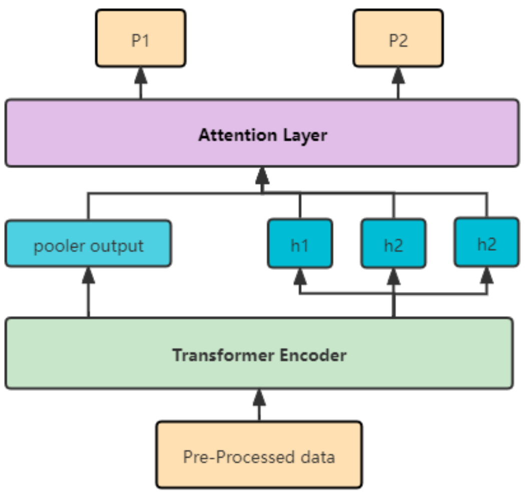
The poorer, the merrier The text is focused on the community, especially on how the vulnerability makes them better (e.g. stronger, happier, or more resilient) or how they share a positive attribute just for being part of a vulnerable community. People living in vulnerable situations have values to admire and learn from. The message expresses the idea of vulnerability as something beautiful o or poetic. We can think of the typical example of 'poor people are happier because they don't have material goods.

3 System description

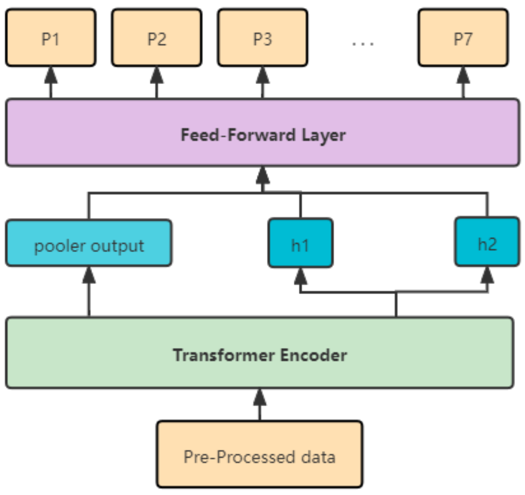
In subtask 1 and subtask 2, we ensemble several models to obtain the results, which are all in RoBERTa-Based architecture (Liu et al., 2019). RoBERTa learns an inner representation of the English language that can be used to extract features useful for downstream tasks. In subtask 1, we pretrain the model on task-specific data. In subtask 2, we utilize multi-label categorical cross-entropy loss to improve performance.

3.1 Data pre-processing

Data for both subtask 1 and subtask 2 contain important information such as the keyword of the sentence and country code. In subtask 1, We truncate the original text centered on the keyword and



(a) RoBERTa-Based architecture of subtask 1.



(b) RoBERTa-Based architecture of subtask 2.

Figure 1: RoBERTa-Based architecture. In our system, the transformer encoder is RoBERTa, the input is pre-processed data mentioned above, pooler output denotes the last layer hidden-state of the first token of the sequence (classification token), hN means hidden states of the keyword extracted during pre-processing, which are the output of the Nth layer from the bottom of the encoder. Attention Layer uses the attention mechanism and calculates attention scores of inputs as weights. FeedForward Layer consists of two linear layers and performs the nonlinear transformation. PN denotes the probability that the Nth label belongs to the sentence.

extract the keyword and its position in the sentence. Also, the article location of the sentence, the keyword of the sentence and the country of the sentence are added to the input as additional features to make the model learn more useful information. Noting that the given country names are in abbreviated form, we restore them to their full form. With this approach, the input formats are shown in Tabel 1. What's more, considering the label imbalance problem of subtask 1, we find the sentences containing PCL from the data in subtask 2 and merge them to form several new sentences as data augmentation.

In subtask 2, We collect different labels of the same sentence to form a single piece of data and use the same way as subtask 1 to pre-process the data. Finally, we lowercase the pre-processed text of both subtasks before they are tokenized.

3.2 Task-Adaptive pretraining

It is proved that Task-Adaptive pretraining can help improve the performance of downstream tasks (Gururangan et al., 2020). In order to make our model better learn the distribution of the data for this task, we pretrain RoBERTa-large model on unlabeled data from subtask 1 and subtask 2. For the same consideration, we process the pretraining data in the way mentioned in Section 3.1.

We apply masked language modeling to pretrain RoBERTa model and use dynamic masking according to the RoBERTa paper. Compared with the original model, the model pretrained in this way can improve the performance to a greater extent.

3.3 RoBERTa-Based architecture

We tried different pretrained models on two subtasks. In our experiments, models initialized with RoBERTa outperform other models. So we choose RoBERTa and pretrain it on task-specific data as our basic model.

Model of subtask 1 In subtask 1, our system uses ensembles of 5 models based on pretrained RoBERTa-Based architecture. As shown in Figure 1(a), the RoBERTa-Based architecture consists of two components: Transformer Encoder, Attention Layer.

First, we pre-process the data to carry more information and tokenize the input into a form accepted by the model. The transformer encoder then is used to extract context representation of the whole sentence. During pretraining, transformer-based language models always use inputs with special tokens(such as [CLS]), so we take out the

extra information	Original text	Pre-processed text
par_id: 1964 keyword: refugee country: my	hospitals fill as rohingya refugees shiver through winter.	from 1964, keyword: refugee, country: Malaysia, hospitals fill as rohingya refugees shiver through winter.
par_id: 4136 keyword: homeless country: za	durban 's homeless communities reconciliation lunch.	from 4136, keyword: homeless, country: South Africa, durban 's homeless communities reconciliation lunch.

Table 1: Examples of Pre-processed text, where "extra information" means additional information in the training data, "Original text" means the original sentence to be judged as PCL or not, "Pre-processed text" means the sentence after pre-processing.

last layer hidden-state of the first token of the sequence(named pooler output), which is the representation of "[CLS]", to obtain a vector representation of the whole sentence. Also, we extract the hidden-state of the keyword of the last three layers, as it is proved that high-level network of transformer encoder learns rich semantic information features(Jawahar et al., 2019).

After we get the pooler output and hidden states of the keyword of each sentence, the two representations are concatenated and fed into an attention layer. We utilize the self-attention mechanism to calculate attention scores as weights in order to make the model attend to essential information. Finally, perform a linear transformation to get reduced representations. The whole process for the model to get the classification results is as follows:

$$Attn(e) = Softmax(A(eW_1+b_1)W_2+b_2) \quad (1)$$

$$Out = (Attn(e) \cdot e)W_3 + b_3 \quad (2)$$

Where e denotes the concatenation of pooler output and the last three hidden states of the keyword of each sentence. A is the Gaussian Error Linear Unit (GELU) (Hendrycks and Gimpel, 2016) activation function, Out denotes the probabilities of sentence-level labels.

Model of subtask 2 In subtask 2, our system uses ensembles of 2 models based on pretrained RoBERTa-Based architecture. As shown in Figure 1(b), the RoBERTa-Based architecture consists of two components: Transformer Encoder, Feed-Forward Layer.

The pre-processed data is obtained by the same method as subtask 1. We also take out the pooler output of the encoder, Furthermore, through experiments, we find that the last two hidden layer outputs of the keyword in each sentence are more effective for this subtask. Then the two representations are concatenated and fed into the Feed-Forward Layer, which is a combination of multiple linear and nonlinear transformations. Finally, we get the probability of each PCL category implied in the sentence.

According to a previous work (Sun et al., 2020), we use the loss function called multi-label categorical cross-entropy. Considering that the task is a multi-label classification problem, a common implementation is to use sigmoid activation, and then turn it into n binary classification problems, using the sum of the cross-entropy of the binary classification as the loss. Supposing k target categories are selected from n candidate categories, when n $\gg$ k, this approach will face a serious class imbalance problem. Therefore, we try to extend softmax and cross-entropy to multi-label classification, which expects each target class score is not less than the score for each non-target class. Instead of turning multi-label classification into multiple binary classification problems, it becomes a pairwise comparison of target class scores and non-target class scores to avoid class imbalance phenomenon. In the implementation, the weight of each label is automatically balanced with the good properties of log-sum-exp. The calculation process of the loss is as follows:

$$log(1 + \sum_{i \in \Omega neg} e^{s_i}) + log(1 + \sum_{i \in \Omega pos} e^{-s_j}) \quad (3)$$

Where Ωneg is the set of negative labels and Ωpos is the set of positive labels. s_N is the score of the Nth label in the corresponding set. In our experiments, we find that using this loss function can help improve the model performance.

task		Train	Valid	Total

Table 2: Statistics of the dataset

4 Experiment

4.1 Dataset

We trained our models on SemEval-2022 Task 4 training data which is an annotated dataset with Patronizing and Condescending Language(PCL) towards vulnerable communities(Pérez-Almendros et al., 2020). The organizers not only annotated all text spans as containing PCL, but also provided PCL category labels, including a total of seven more fine-grained level categories. At last, there are 10469 marked data in total. The organizers of the competition have divided the data into training set and validation set using the split ratio 8:2. And each text contains an average of 232 tokens. Subtask 1 is a binary classification task, so the labels are just PCL and not PCL, but most of them contain PCL accounts for the majority resulting in imbalance between classes. Subtask 2 is a multi-label binary classification task that aims to predict which PCL categories these texts belong to. And The proportion of each category is more balanced. The statistics of these datasets are given in Table 2.

4.2 Metric

For Subtask 1, it is a binary classification task that will be evaluated using F1 value of the positive class. Subtask 2 is a multi-label classification task, which is evaluated by macro-F1. The calculation formula is as follows. The experimental results are all obtained by averaging three runs with different random initialization.

$$F1 = \frac{2 \times P \times R}{P + R} \tag{4}$$

$$Macro - F1 = \frac{1}{n} \sum_{s=1}^{n} F_z \tag{5}$$

4.3 Experiment Settings

After many experiments, the results show that the effect of using RoBERTa-large is the best and most stable. So at last, all models used in the end are all based on the RoBERTa-large. At the same time, the maximum length of the text is 512. We use Adam as the optimizer with a learning rate of 2e-5. We also use gradual warmup(Goyal et al., 2017) and cosine annealing schedule for learning rate. The coefficient of L2-regularization is 1e-5 and batch size is 32. All the experiments are done on 2 NVIDIA 3090 GPUs, and Limited by the size of GPU memory, we used gradient accumulation.

4.4 Results

For Subtask 1, we designed four models in total: (1)**RoBERTa-ft**: simply fine-tune RoBERTa-large model;(2) **RoBERTa-cls3**: extract the first hidden vector of the last three layers of RoBERTa model and cat them, then pass through a self-attention layer. At last, the hidden vector obtained by multiplying the softmax weight is classified through the linear layer to get predictions;(3) **RoBERTa-cls4**: similar with model1, The only difference is that this model extracts the first hidden vector of the last four layers. (4) **RoBERTa-key**: this model will take out the hidden vector corresponding to the keyword and splice it with the pooler-out vector, then pass through the linear layer to get predictions. For Subtask 2, we build two models at last, including: (1) **RoBERTa-ff**: cat the hidden vectors of the last two layers, and then spliced with pooler-out to pass through a feedforward layer. (2)**RoBERTa-att**: cat the hidden vectors of the last two layers, and then spliced with pooler-out to pass through an attention layer.

Table 3 shows the best F1 values of each model on the official Subtask 1 validation set. And Table 4 shows the F1 values of the above two models on each category and their average values in Subtask 2. For both Subtask 1 and Subtask 2, we set the maximum number of epochs to 10 and open early stop.

We can see from the data in the table that all of the considered methods clearly outperform the baseline. For Subtask 1, the RoBERTa-key achieves the best performance. We also try some other methods, such as extracting the last four hidden vectors of the model, calculating the average value or the maximum value, but their effect is not as good as the above methods. We think that

Method	**acc**	**F1**
baseline	-	0.5211
RoBERTa-ft	0.9254	0.6385
RoBERTa-cls3	0.9288	0.6410
RoBERTa-cls4	0.9303	0.6439
RoBERTa-key	0.9298	**0.6475**

+key-hidden	0.6127
+pre-train	0.6386
Last	**0.6475**

Table 5: Ablation results of our model

the keyword can be regarded as an object. For example, if the keyword is poor, the passage is to judge whether the author has an arrogant attitude towards the poor. Therefore, the hidden vector corresponding to the keyword contains more feature information and is very helpful for our judgment. At the same time, extracting the last few hidden vectors contains more information with different granularity. For Subtask 2, We also tried many other different structures, the RoBERTa-ff achieves the best performance we find after a lot of experiments.

4.5 Ablation

We used some stricks and methods in the competition, and we show the improvement effect of each method through the ablation experimental results on Subtask 1 in Table 5. It can be seen that the improvement brought by pre-training is the most significant which improves by more than two points. The second is to add a prefix template. In addition to these methods in the table, there are also slight improvements by some stricks such as resampling.

5 Conclusion

The paper describes our system at SemEval-2022 Task 4, which uses several different models based on RoBERTa. We used a series of methods such as pre-training, constructing prefix templates, and model fusion to achieve relatively good results. As we can see, using RoBERTa as the network backbone achieves better performance in this task. Also post-training and using the hidden vectors of the last few layers of RoBERTa can improve the effect. At the same time, we also tried FGM, focal loss and other methods, while none of them seemed to be beneficial for our task. Still, the F1 value is less than satisfactory, so we can see that identifying and categorizing Patronizing and Condescending Language are difficult challenges. In the future, we will consider using some external knowledge to help the judgment of the model.

Abstract

Patronizing and condescending language (PCL) is everywhere, but rarely is the focus on its use by media towards vulnerable communities. Accurately detecting PCL of this form is a difficult task due to limited labeled data and how subtle it can be. In this paper, we describe our system for detecting such language which was submitted to SemEval 2022 Task 4: Patronizing and Condescending Language Detection. Our approach uses an ensemble of pre-trained language models, data augmentation, and optimizing the threshold for detection. Experimental results on the evaluation dataset released by the competition hosts show that our work is reliably able to detect PCL, achieving an F1 score of 55.47% on the binary classification task and a macro F1 score of 36.25% on the fine-grained, multi-label detection task.

1 Introduction

Everyone has seen, experienced, and expressed patronizing and condescending language (PCL). Someone is patronizing or condescending when they communicate in a way that talks down to others, positions themselves in a superior position to the subjective group, or describes them in a charitable way in order to raise a feeling of compassion for the target person or group. Such language is seen frequently in social media or other mediums where hate is the norm. Many previous works have addressed offensive language and hate speech (Zampieri et al., 2019) (Basile et al., 2019) in such communities. However, until (Perez-Almendros et al., 2020) there has not been work in modeling PCL where 1) it is targeted towards vulnerable communities such as refugees or poor families 2) occurs in the *general media or news*. The authors note that this form of PCL is not usually meant to be harmful, and can often have good intentions, such as when the author is trying to raise awareness about an at-risk group. Yet, research in sociolinguistics has shown that regardless of the intent, PCL has negative effects on potential vulnerable communities such as perpetuating stereotypes, reinforcing societal misbehaviors, and oversimplifying deep-rooted problems. The authors of *Don't Patronize Me! An Annotated Dataset with Patronizing and Condescending Language towards Vulnerable Communities* originally proposed a new dataset to help in detecting such cases of PCL and are currently hosting a SemEval-2022 competition: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022).

In this paper we describe our contribution to both competition subtasks: binary and multi-label classification. Our final ensemble leverages many techniques including pre-trained language models, data augmentation, intermediate fine-tuning on related datasets, and optimizing the detection threshold to empirically maximize F1. For the binary task, our system achieves an F1 score of 55.47%, or 6.36% higher than a comparable RoBERTa-based baseline model. We achieve a macro F1 score of 36.25% on the multi-label task, or 25.84% higher than a similar RoBERTa baseline. These results show encouraging progress for the task of detecting fine-grained and linguistically subtle types of PCL, although there is still room for improvement.

2 Background

The Patronizing and Condescending Language Detection task contains two subtasks. In the first subtask, binary classification, the system is given a paragraph of text and it must predict if it contains *any* form of PCL. In the second subtask, multi-label classification, a system is given a paragraph of text and it must identify if it contains each of seven types of PCL (one paragraph can contain multiple categories of PCL).

2.1 Dataset

The binary classification task dataset contains 10,636 total labeled text samples that were selected

Text	Keyword	Country	Label
This wally of an MP just wants his name in the press , what has he ever achieved fro Southend , what did this idle wally do to get the scanner tuned on at the hospital ... zero ! He raised in parliament the fact that his was his mummies birthday , but forgot to mention the homeless families on our streets .	homeless	gb	3
Our life has completely changed from when he as an able-bodied young man running around 5000 miles an hour organising everyone . Now , he 's more disabled than anyone that he ever helped .	disabled	nz	4
The World Health Organization did not give a reason for the increase in deaths , but a provincial health official in Sindh said that the disease hit areas where poor families did not vaccinate their children .	poor-families	us	2
However , she said immigrant patients urgently need treatment and counselling from health-care providers who speak Punjabi or Hindi , and that 's what Roshni – which means light – will offer them.	immigrant	ca	1
In February 2015 , five of the men , aged 23 to 25 at the time , went to the station to protest the "" arbitrary and violent "" arrest of one of their friends from the Cova da Moura neighbourhood , known for its large population of immigrants from Cape Verde , a former Portuguese colony off Africa 's northwest coast .	immigrant	in	0

Table 1: Samples from the competition dataset

	Train	Validation	Test
Positive	683	111	199
Negative	6436	1145	1894

Table 2: Label distribution in train, validation and test splits for the binary classification subtask

from news stories from the News on the Web corpus (Davies, 2013). All the selected paragraphs are from news stories that were published between 2010 and 2018 from 20 English speaking countries. Each paragraph is assigned a label ranging from 0 (not containing PCL) to 4 (being highly patronizing or condescending). Each paragraph is also associated with one of ten keywords used to retrieve the text from the corpus. Samples from this dataset can be found in Table 1 and the distribution of positive and negative labels in each of our data splits can be found in Table 2.

The dataset for the multi-label classification task contains paragraphs from the binary classification task which were labeled as containing PCL. Each paragraph is further labeled with at least one of the seven classes: unbalanced power relations, shallow solution, presupposition, authority voice, metaphor, compassion, and the poorer, the merrier. Each is associated with a country-code and keyword as before. Additionally, each paragraph has the start and end spans of where in the paragraph the particular category of PCL is contained. Further background information about this dataset can be found in the paper published by the competition hosts (Perez-Almendros et al., 2020).

2.2 Baselines

Recent advances in natural language processing have enabled complex and subtle tasks to be solved by fine-tuning large, pre-trained language models (Kalyan et al., 2021). These models can also be fine-tuned on small datasets (such as only 1,000 samples) and while still achieving significant predictive power (Mosbach et al., 2020), or even with just a few samples (Brown et al., 2020). As such, the competition authors provided baseline results using a pre-trained RoBERTa model, one of the go-to models for fine-tuning for a classification task (Liu et al., 2019). They provide results of multiple baselines which help put into context the improvements made by the participating systems. For example, one such baseline is simply random guessing, or assigning each paragraph a random label with equal probability. In our work we build upon the RoBERTa baseline by applying techniques often used in machine learning. Namely, we use early stopping using a validation dataset and set hyperparameters according to best practices discussed by (Mosbach et al., 2020). We also will experiment with a host of NLP techniques including data augmentation and other language models.

3 Subtask 1: System Overview

Considering the challenge of the task and the scarcity of positive examples of PCL, our approach was to experiment with methods focused on enriching our small dataset, such as data augmentation and external datasets. We started with fine-tuning a pre-trained RoBERTa (Liu et al., 2019) model to use as a foundation. RoBERTa has been shown to be very powerful for a range of NLP tasks such as text classification, while also being straightforward to implement and train using libraries such as HuggingFace (Wolf et al., 2019). We use its architecture unchanged with pretrained weights downloaded from HuggingFace. We add a standard binary classification head on top of RoBERTa's pooled outputs. For preprocessing input into the model, we use HuggingFace's auto-tokenizer. In the following subsections, we detail the additional methods and modifications to the RoBERTa baseline. The models used in our final ensemble use a mix of these methods and the exact ensemble methodology is described in section 3.6.

3.1 Pre-trained Language Models

In addition to RoBERTa, we use MPNet (Song et al., 2020). This model inherits the pre-training advantages of both Masked Language Modeling (Devlin et al., 2018) and permuted language modeling (Yang et al., 2019) under a unified view which splits tokens in a sequence into non-predicted and predicted parts. Experimental results show that MPNet outperforms previous models like BERT, XLNet and RoBERTa by 4.8, 3.4 and 1.5 points respectively on GLUE tasks. In our work, we fine-tune MPNet using the hyperparameters suggested by the authors, which can be found in Appendix A.

3.2 Intermediate Fine-Tuning

We leverage several external data sources which are related to our task of PCL detection. (Phang et al., 2018) originally proposed *Supplementary Training on Intermediate Labeled Data Tasks* (STILTs), which we refer to as intermediate fine-tuning. They observed that by 1) starting from a pre-trained language model such as BERT, 2) further training it on an intermediate, *labeled* task, and 3) finally fine-tuned on the target task; improved final performance on a variety of NLP tasks. (Pruksachatkun et al., 2020) and (Vu et al., 2020) provide further insight into tasks that are well suited for intermediate fine-tuning. We used these insights a to develop four independent binary classification tasks on Stereoset (Nadeem et al., 2020), BiasCorp (Onabola et al., 2021), Social Bias Inference Corpus (SBIC) (Sap et al., 2020), and TalkDown (Wang and Potts, 2019) datasets, and used them for intermediate fine-tuning. Two of these tasks, SBIC and Biascorp, are used in our final ensemble, while the other two were left out due to having no performance uplift on our task's test set.

BiasCorp is a dataset containing about 43,000 labeled examples of racial bias from Fox News, BreitbartNews and YouTube. Each text has 3 bias ratings from 0 to 5 and corresponding annotator confidence scores from 1 to 10. To turn this into a binary classification task, we use a similar approach from their paper by first computing a confidence weighted score, and then we threshold this score where scores above 1 are labeled as positive examples.

The **Social Bias Inference Corpus** is a labeled dataset of over 125,000 examples of social media posts from Reddit, Twitter, and hate sites like Stormfront. For our binary classification task, we use the provided offensiveness rating of a post, and use a threshold of 0.3 for positive examples.

3.3 Sentence-Level Features

Transformers are generally able to vastly outperform regression on engineered features. However, in some text labeling tasks, such as essay scoring, it has been shown that engineered features can be used in tandem with Transformer output to improve performance (Uto et al., 2020). This can be achieved simply by concatenating a vector of features $\mathbf{f_n}$ to BERT's CLS vector. An extended classification head will now take the extended vector as input, and similarly project to the final prediction. The classification head, including the added weights, is trained along with the fine-tuning of BERT.

Our set of features was inspired by (Uto et al., 2020), but we excluded the readability metrics because they are not as relevant for our task. Specifically, for text sample $\mathbf{x_n}$, we calculate *the number of words, number of sentences, number of exclamation marks, question marks, and commas, average word length, average sentence length, the number of nouns, verbs, adjectives, and adverbs, and the number of stop words*. Each one of these values is used as a separate dimension of $\mathbf{f_n}$. We leveraged the spaCy Python library (Honnibal and Montani, 2017) to calculate these values. We also included the feature calculation as a data pre-processing step, since calculating the features at run-time would be too costly.

3.4 Original Labels

Simply collapsing the 0-4 label in the dataset to a binary value results in a loss of relevant information. To combat this, we translate each label to a *probability* of a sample containing PCL. Specifically, we perform the following mapping: 0 - 0.0, 1 - 0.25, 2 - 0.5, 3 - 0.75, 4 - 1.0. We refer to these probabilities as the *original labels*. We adapt our loss function for this reformulated learning setup by computing the binary cross-entropy loss between the predicted probability and the original label.

3.5 Backtranslation

Data augmentation for NLP tasks is becoming increasingly popular with a vast variety of existing techniques. Data augmentation refers to any strategy aimed at increasing the amount of data available for training, by only leveraging the existing training set or domain knowledge about the task (Feng et al., 2021). (Sennrich et al., 2015) is a model-based technique for data augmentation where the original text is translated into a desired language and then back to the original language to rephrase it. This process can introduce a different style of sentence for the same meaning. We have used French as our intermediate language for backtranslation on our data. To implement backtranslation for our task, we used the MarianMT model (Tiedemann and Thottingal, 2020) provided by HuggingFace to convert between French and English.

3.6 Ensemble Model

Ensembling is a technique that leverages multiple trained models to improve task performance on the test set. For our final ensemble of three independently trained models, we used a relatively simple approach. Given a set of models M and a test dataset D, let $\hat{y}_{ni}$ be M_i's estimate of the probability that text sample x_n is a positive sample. This value is taken directly from M_i's softmax layer output. Each label is then assigned a final positive probability of $\hat{y}_n = \frac{1}{|M|}\sum_{i=1}^{|M|}\hat{y}_{ni}$. We use this augmented softmax score to make the final prediction for each label in the test set.

3.7 Choosing an Empirically Optimal Threshold for F1 Score

The F1 score is the metric used for evaluation in the competition and it is defined as the harmonic mean of precision and recall:

$$F_1 = \frac{2 * precision * recall}{precision + recall}$$

Note that the output of our transformer models for binary classification is the softmax of a final linear layer. In order to compute the F1 score, those continuous outputs must be binarized. Typically, that is done via a simple transformation:

$$f(x, threshold) = \begin{cases} 1, & x \geq threshold \\ 0, & x < threshold \end{cases} \quad (1)$$

, where x is the softmaxed model output and threshold is a value commonly set to be 0.5. Since the model is optimized using cross entropy loss, it is unclear if 0.5 is the best threshold to use in order to maximize F1 score. Since the F1 score is a *harmonic mean*, we would like to balance precision and recall in order to achieve the highest score. Roughly, precision can be increased (and recall decreased) by increasing the threshold, and vice versa by decreasing the threshold.

In order to find the best threshold, we use a simple, brute force algorithm to determine the best threshold on the validation data set. The algorithm takes vectors y_true and y_out, which are the true binary labels and the normalized model output, respectively. For each model output, we treat it as a *possible threshold* and compute the F1 score using the true labels and y_out binarized via $f(y\_out,$ model output) (assume f operates on vectors). The algorithm outputs the threshold that achieved the highest F1 score.

Algorithm 1: Brute-force F1 Threshold

```
Input: y_true, y_out
best_score ← 0
best_threshold ← 0.5
for threshold in y_out do
    bin_y_out ← f(y_out, threshold)
    score ← f1_score(y_true, bin_y_out)
    if score > best_score then
        best_score ← score
        best_threshold ← threshold
return best_threshold
```

4 Subtask 2: System Overview

Our system for task 2, multi-label classification, adapts many of the techniques we used in the binary classification task. Similar to our task 1 system, we leverage RoBERTa as a base model for further fine-tuning. However, the target is now a vector of binary labels. Another way to view the problem is as 7 binary classification tasks, one for each category of PCL. Our final ensemble includes models treating the problem in this way, and also training one multi-label classifier directly. We also independently train a binary classification model to generate a prediction for each class using the same model setup from the binary task. In either case, the final ensemble of models was computed identically to the binary classification task by treating each category independently. The sigmoid function was applied to each model output before creating the ensemble.

4.1 Data Processing

The dataset for the multi-label classification task contains only paragraphs from the binary classification task which were labeled as containing PCL. This creates a disconnect between the data that would be seen during evaluation (i.e. there are samples without any category of PCL). To handle this discrepancy in data distributions, we take every non-PCL paragraph from the binary classification task dataset and add it to the multiclass dataset with a label vector of all 0s.

5 Experimental Setup

We start by splitting our dataset into a train and test set according to the split provided by the competition authors, which is 80% train and 20% test data. From the training split, we take 15% to use as a validation split. Table 2 shows the distribution of positive and negative labels within the train, validation and test splits.

Using our validation split, for each experiment, we perform a hyperparameter sweep by varying the peak learning rate $\in$ {3e-5, 2e-5, 1e-5, 5e-6}. We use early stopping where the model is evaluated at the end of each epoch, and if for 10 consecutive epochs performance does not improve, we stop training and save the model from the epoch with the highest valdiation F1 score. For final evaluation on the test set we use this model that achieved the highest F1 score on the validation set. We choose a batch size that maximizes GPU usage, and use the default maximum sequence length of each model. A listing of the full hyperparameters used can be found in Appendix A. Random seeds for Python, `numpy`, and `PyTorch` were fixed at 221 for all experiments.

For our final results and submission to the competition, we use the validation split for early stopping and train including the test dataset. All models were trained with a learning rate of 2e-5 unless otherwise noted. We submitted two identical systems, only differentiated by the random seed used. All

Binary	Description	P	R	F1
Model 1	RoBERTa, intermediate fine-tuning, features	67.95	47.75	56.08
Model 2	MPNet, original labels	65.95	55.85	60.48
Model 3	RoBERTa, features, backtranslation	61.11	49.55	54.73
Ensemble		62.04	60.36	61.19

Table 3: Subtask 1 - Validation split scores for each of our models that composed the final ensemble. The scores for each model use the default threshold, while the ensemble's threshold is optimal for the validation split.

Multi-label	Description	P	R	F1
Model 1	RoBERTa, features, backtranslation	42.90	30.52	35.01
Model 2	RoBERTa, backtranslation, LR=1e-5	46.53	36.18	39.13
B4MC	Binary model 1 for each category	2.51	100.0	4.83
Ensemble		49.38	35.72	40.50

Table 4: Subtask 2 - Validation split scores for each of our models that composed the final ensemble.

results shown in Tables 3 and 4 are the random seed that performed better.

Our experiments were run a system with the following hardware; GPU: NVIDIA RTX 3090, CPU: AMD 5950X, RAM: 64GB 3200Mhz, SSD: 4TB SATA.

6 Results

Submitted systems were evaluated on the F1 score (macro F1 score for the multi-label task). We built several models that each combine different methods. Observe that in Tables 3 and 4 each model has a varying degree of balance between precision and recall. This diversity in outcomes and methodology between individual models helps our final ensemble achieve better overall results than any individual model. Our best ensemble for subtask 1 placed 22nd out of 78 and our best ensemble for subtask 2 placed 18th out of 49.

For subtask 1, our best model on the validation split was the one that used MPNet as a base and used the original labels during training. Model 1 used RoBERTa as a base and was first trained using intermediate fine-tuning, before being trained on

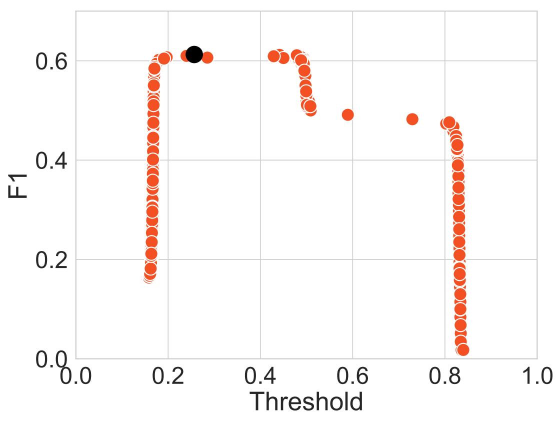

Figure 1: Plot of the resulting F1 score when using each validation softmax score (unbinarized) as the detection threshold.

the final dataset using sentence level features. Intermediate fine-tuning was done by first training using the SBIC task for 5 epochs, followed by training for 5 epochs on the Biascorp task. Each intermediate task was trained with a learning rate of 5e-6. Finally, model 3 used RoBERTa as a base and was trained with sentence level features and additional backtranslated samples.

For subtask 2, our best model used RoBERTa as a base and was trained with backtranslated samples and a learning rate of 1e-5. Model 1 was similar except it used sentence level features and our default hyperparameters found in Appendix A. Binary for multi-category (B4MC) was 7 individual models (one for each category), trained using the same methodology as our best binary model, model 1.

6.1 Thresholds

We use Algorithm 1 to find an optimal F1 threshold on the validation split in order to increase the F1 score for our final ensemble. Analysis of this optimization for our binary task ensemble is in Figure 1. Based on that plot, we set our prediction threshold to be 0.32, about in the middle of the range of thresholds that achieved the highest F1 scores. Notice that if we had picked a threshold of 0.5, we likely would have achieved a lower score due to the drop in scores around that mark.

We performed similar analysis for subtask 2. The thresholds we choose were 0.5, 0.31, 0.49, 0.27, 0.29, 0.21, and 0.4 for the categories unbalanced power relations, shallow solution, presupposition, authority voice, metaphor, compassion, and the poorer the merrier, respectively.

6.2 Error Analysis

To further analyze how our model compares to the baseline, we examine samples from the test set where 1) the baseline made an error, but our model made the correct prediction, and 2) where both the baseline and our model made the incorrect prediction. We examine false positives and false negatives in both cases.

In Table 5, we can see that the baseline's false negatives tend to be more poetic examples. They paint vivid, dramatic scenes, and use strong adjectives like "shocking" and "hopeless". This indicates that our model may have picked up on this poetic language signal as an indicator of PCL.

In the baseline's false positives, we see phrases that may be indicative of PCL, such as "in need of food", "treat men and women differently", and "being disabled". However, in context, these phrases are not condescending to the subjects of the statements. It's possible that the baseline was simply acting on the presence of these phrases, while our model was able to identify the lack of other supporting signals as evidence that the sentences were not PCL.

In Table 6, we can see where both the baseline and our model failed, where there are a variety of possible issues. The first two false negatives are only identifiable as PCL given their subtext (assuming the perspective of refugees and creating a division between disabled and non-disabled people), rather than obvious choices of words. While the third false positive uses flowery language (a possible PCL indicator), the identifying piece, "people from poor families have more perseverence...", uses a positive sentiment. The models seem to struggle with the "poorer the merrier" category, which this is an example of. It's possible that the model is overwhelmed with more negative sentiments from other categories so it tends to correlate that too strongly with PCL.

The false positives all use the kinds of words that seem to be common in the actual positive examples, such as "plight", "challenges", "disadvantaged", and "vulnerable". What the models seem to fail at is distinguishing between pointing out a group's disadvantage and using that disadvantage to patronize the group.

Overall, the models seem to be very active on words and phrases that might indicate PCL. While

Table 6: Samples where both the baseline and ensemble were incorrect.

our best model appears able to deal with these features in somewhat intelligent ways, the main downside is that it cannot place the samples in a global context. Simply using certain adjectives to describe a certain group of people does not necessarily make a statement condescending. It depends on exactly which adjectives, which group, and what other context is in the statement. As humans, we have two main advantages in this task: 1) we understand the struggles and stereotypes of disadvantaged groups, and 2) we also can perform deductive reasoning to determine the underlying meaning of a phrase. Possibly remedies for our model might be 1) providing many more examples, so it can build the kind of context needed to make these distinctions, and 2) to enhance the model with ways of reasoning about the problem.

7 Conclusion

We developed a system to detect patronizing and condescending language by media towards vulnerable communities. We combined a multitude of NLP techniques in our final ensemble. Our system leveraged backtranslation, sentence level features, intermediate fine-tuning, and pre-trained language models. We also proposed multiple training techniques and optimizing the F1 threshold. These improvements resulted in our system placing in the top 25% for subtask 1 and the top 40% for subtask 2.

Abstract

This paper describes a system built for the SemEval-2022 competition. As participants in Task 4: Patronizing and Condescending Language Detection, we implemented the text sentiment classification system for two subtasks in English. Both subtasks involve determining emotions; subtask 1 requires us to determine whether the text belongs to the PCL category (single-label classification), and subtask 2 requires us to determine to which PCL category the text belongs (multi-label classification). Our system is based on the bidirectional encoder representations from transformers (BERT) model. For the single-label classification, our system applies a BertForSequenceClassification model to classify the input text. For the multi-label classification, we use the fine-tuned BERT model to extract the sentiment score of the text and a fully connected layer to classify the text into the PCL categories. Our system achieved relatively good results on the competition's official leaderboard.

1 Introduction

Text classification is an area of natural language processing (NLP) that aims to classify text using certain features. Previous studies on text classification tasks used traditional machine learning methods, which require researchers to manually design features. Feature extraction methods such as term frequency–inverse document frequency (TF-IDF) (Hakim et al., 2014) and N-Gram (Cavnar et al., 1994) are used to extract features from original documents, and then the features are input into classifiers such as naive Bayes(Berrar, 2019), support vector machines (SVMs) (Hearst et al., 1998), and decision trees (Vens et al., 2008). Since the advent of deep learning, text classification tasks are achievable without manual extraction of text features. Researchers must simply pretreat the text and incorporate it into a deep learning model for training. For text classification using deep learning methods, the classification accuracy is often higher than that of traditional machine learning methods. With their continuous improvement, deep learning models, such as recurrent neural networks (RNNs)(Zaremba et al., 2014), multi-channel CNN-LSTM (Zhang et al., 2017),gate recurrent units (GRUs) (Rana, 2016), long short-term memory (LSTM) (Shi et al., 2015), bidirectional long short-term memory (Bi-LSTM) (Zhang et al., 2015), and attention-based Bi-LSTM (Zhang et al., 2018) networks, can be used to solve text classification problems. In recent years, bidirectional encoder representations from transformers (BERT) (Devlin et al., 2018), a new deep learning model, has achieved, or even surpassed, human performance in multiple tasks within the NLP domain, including text classification.

Task 4 of the SemEval-2022 consists of the following two subtasks.

- Subtask 1: identifying whether the sentence contains any kind of PCL.
- Subtask 2: identifying which types of PCL the sentence contains.

In this paper, we introduce a deep learning system for SemEval-2022 Task 4: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022). We applied the pretrained BERT model as the base model. This task contains two subtasks: single-label classification and multi-label classification. To accomplish both subtasks, we used fine-tuning methods on the base model with an additional classification layer. Our contributions are as follows:

- For the sentiment analysis task, we used the pretrained BERT model as the base model.
- To obtain the classification results, we added a fully connected layer at the end of the base model.

The remainder of this paper is organized as follows. Section 2 provides an overview of our system for the two subtasks. Section 3 presents the specific details of our system. Section 4 discusses the results of the experiments, and finally, we draw our conclusions in Section 5.

2 Overview

This section presents an overview of our system and experiments, consisting of the following steps:

1. The data processing step, in which we use text processing tools to clean the text content, such as removing HTML tags in the text.

2. The model training step, in which we build, train, and evaluate the model.

3. The result generating step, in which we evaluate the model and predict the results on the test dataset.

Task description. The two subtasks involved text sentiment analysis and classification. The difference between them is that subtask 1 only requires us to determine whether the text contains any kind of PCL. Subtask 2 is the multi-label classification task, and the data of subtask 2 are marked by a list of 0s and 1s, which indicate the type of linguistic techniques (Unbalanced_power_relations, Shallow_solution, Presupposition, Authority_voice, Metaphors, Compassion, The_poorer_the_merrier) used to express condescension.

2.1 Data processing

To use the original text as much as possible and reduce the impact of meaningless text on the model, we built text cleaning tools that can be used to remove redundant text from the original. In addition, to complete the text classification task, a special token is added to the front of the original sentence.
Preprocessing. The texts may have been retrieved from the Internet by an automated program and inevitably there will be some unnatural language in the text. Text processing tools, such as regular expressions and Beautiful Soup, are used to remove impurities, such as HTML tags and redundant punctuation, from the text. Because the original sentence cannot be used in the pretrained BERT model, a special token **[CLS]** is added to the front of the sentence, and the model receives the new sequence (with the added token) as input.

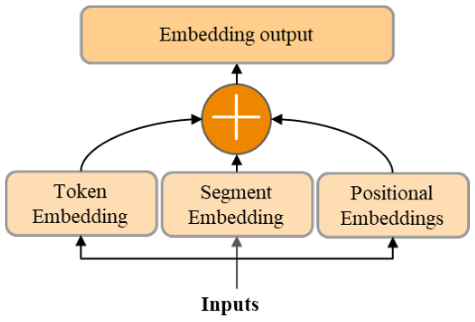

Figure 1: Embedding blocks

2.2 Deep learning models

In recent years, the use of deep learning for NLP text classification has become the most commonly adopted method in the industry. We used the pretrained BERT model to accomplish the tasks mentioned in the task description.
Bidirectional Encoder Representations from Transformers (BERT). As the name suggests, the BERT model is the encoder of the bidirectional transformer. BERT uses masked LM and next-sentence prediction to capture the representation at the word and sentence levels, respectively, and pretrains the model in a self-supervised manner.

Since the BERT model was proposed by Google in 2018, the entire field of NLP has entered a new stage. With BERT, we can easily fine-tune a pretrained model to achieve outstanding results that may even surpass human performance.

BERT consists of two main blocks: the embedding block and transformer encoder block, whose details are as follows.

1. **Embedding Block.** After preprocessing the original text, the output is fed to the embedding block, whose structure is shown in Figure 1.

   The embedding block has three embedding layers: the Token Embeddings, which convert each word into a fixed-dimensional vector similar to most deep learning models; Segment Embeddings, which distinguish between the two sentences; and Position Embeddings, which represent the position of each word in the sentence. These embedding layers transform the input text into a three-dimensional matrix $X \in R^{N \times n \times d}$, where N is the number of sentences in the text, n is the number of words in the sentence, and d is the dimension of the embedding vector.

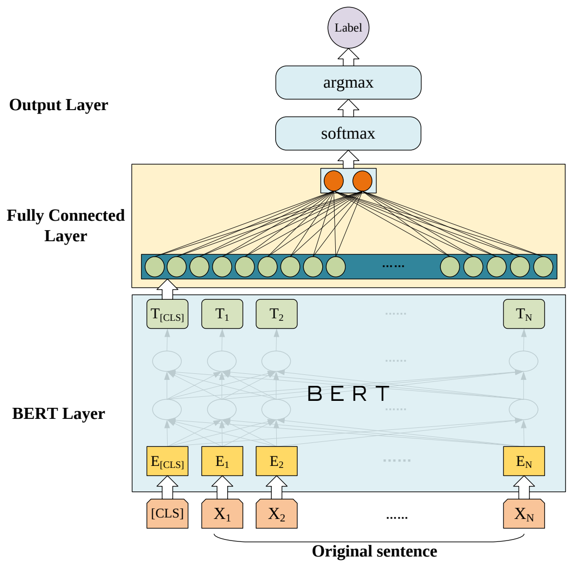

Figure 2: Single-label classification system

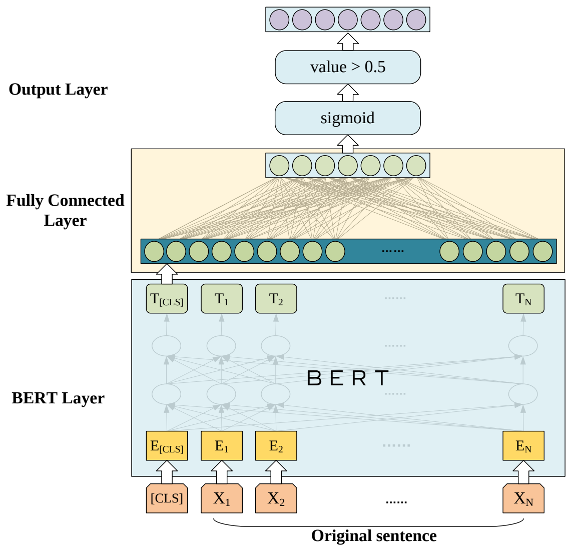

Figure 3: Multi-label classification system

2. **Encoder Block.** The encoder block comprises a series of transformer encoder blocks. Each transformer encoder block comprises two layers: the multi-head self-attention and feed-forward layers. The self-attention layer included in the encoder block of the transformer allows each word in the sentence to use the information of all other words in the sentence. The output of the current word does not need to depend on the output of the previous word, making the training well parallelized and greatly reducing the time to train the model. Because each word has a different impact on the sentence category, the attention mechanism can dynamically change the weight of each word.

3 Model Description

A pretrained BERT model is used to accomplish both subtasks with the two independent datasets. The details of the model built for these two subtasks are as follows.

3.1 Subtask 1: single-label classification

The architecture of the system built for subtask 1 has three different layers, as shown in Figure 2.

3.2 Subtask 2: multi-label classification

The system built for subtask 2 is similar to that for subtask 1, and the architecture of this system is only slightly different in the output layer. The structure is shown in Figure 3.

3.3 Details of the model architecture

BERT Layer. After preprocessing, the texts are input into the z BERT model, which contains the embedding and encoder blocks. Each word in the input sequence will output a fixed-dimensional (d) vector. In our BERT model (bert-based-uncased), d is 768.

Fully Connected Layer. The fully connected layer is used to convert a d-dimensional vector into a vector with the number of categories or labels as the dimension. In the text classification task, only the output of the first word, which is **[CLS]** at the BERT layer, is fed to the fully connected layer because it integrates the semantic information.

Output Layer. A matrix $X \in R^{N \times c}$ is output by the fully connected layer, in which N is the number of sentences and c is the number we manually set. In the single-label two-category classification task, it is set to 2, and the fully connected layer converts the 768-dimensional vector into a 2-dimensional vector. In the multi-label two-category classification task, it is set to the number of labels, 7, and the fully connected layer converts the 768-dimensional vector into a 7-dimensional vector.

To obtain the final result for the single-label classification task, the output of the fully connected layer is input into the *softmax* function to calculate the probability of the sentence belonging to the category, and the outcomes of the *softmax* function are fed to the *argmax* function to obtain the classification result.

$$class = \begin{cases} 0, value_0 \geq value_1, \\ 1, value_0 < value_1 \end{cases} \quad (1)$$

If the output value is 1, the sentence belongs to the label, that is, this sentence contains some kind of PCL; otherwise, the sentence does not contain any kind of PCL.

For the multi-label classification task, we input the result of the fully connected layer into a *sigmoid* function that maps each value in the output vector to a value between 0 and 1. Each value in the vector is then mapped to 0 or 1 according to the rounding rules.

$$label_i = \begin{cases} 0, label_i \leq 0.5, \\ 1, label_i > 0.5. \end{cases} \quad (2)$$

The output is a 7-dimensional vector that consists of 0 or 1. If the value is 1, the sentence used the technique corresponding to the vector element number to express the condescension.

3.4 Training and Hyperparameters

For these two classification tasks, we used the BCEwithLogits loss function and Adam (Kingma and Ba, 2017) optimizer to train both models. Both models use a stochastic gradient with mini-batches of size 16. The hyperparameters are as follows:

Hyperparameters The maximum input sequence length of the BERT model is 512, the dimension of word embeddings (d) is 768, the dropout ratio is 0.1 at each layer in the models, the learning rate is 1e-5, and the number of epochs is 15.

4 Experiment

Dataset. For the two subtasks, the corpus we used to train the model are from the competition(Pérez-Almendros et al., 2020), without other external data.

dontpatronizeme_pcl.tsv This dataset contains 10,469 paragraphs, and each paragraph is annotated with a label ranging from 0 to 4. In the single-label classification subtask, the original label annotated as either 0 or 1 is replaced with 0, and the other labels with 1.

dontpatronizeme_categories.tsv This dataset contains 993 unique paragraphs with a total of 2,760 instances of PCL. In the multi-label classification task, each paragraph is annotated with 7 labels ranging from 0 to 1.

Table 1: Subtask 1 result

Precision	Recall	F1_Score
0.5097	0.4132	0.4564

Table 2: Subtask 2 result

Label	Score
Unbalanced_Power_Relations	0.1600
Shallow_Solution	0.1245
Presupposition	0.0721
Authority_Voice	0.0968
Metaphor	0.0696
Compassion	0.1139
The_poorer_the_merrier	0.0385
Average	0.0965

Evaluation Methods. For subtask 1 (single-label classification), the competition metrics given by the competition organizer are precision, recall, and F1 score. For subtask 2 (multi-label classification), there are two competition metrics: prediction accuracy of each label and average prediction accuracy of all labels.

Results. The results of the two subtasks are shown in Tables 1 and 2.

For subtask 1, we ranked 42/81 in precision, 47/81 in recall, and 52/81 in F1 score.

For subtask 2, we ranked 35, 33, 35, 34, 33, 34, and 24 out of 81 for the seven labels: Unbalanced_power_relations, Shallow_solution, Presupposition, Authority_voice, Metaphors, Compassion, and The_poorer_the_merrier, respectively.

Experiments and Analysis. We used 80% of the training data as the training set and 20% of the training data as the validation set. We trained our model on the training set and used the validation set to evaluate the accuracy of the model. Our system achieved relatively good results on the competition's official leaderboard, which is inseparable from the excellence of the pretrained BERT model. The outstanding advantage of the pretrained model is that it can learn the language from a large amount of unlabeled data and then fine-tune on a small amount of labeled data. Thus, downstream tasks often lead to better learning of language and task-specific features.. Compared to traditional RNN and LSTM models, BERT can perform concurrently and simultaneously extract relational features of words in a sentence at several different levels, thus comprehensively reflecting the sentence semantics. Compared to word2vec, the meanings of words can also be obtained according to the context of the sentence, which would avoid ambiguity.

5 Conclusion

In this paper, we described our system, which is based on the pretrained BERT model, for the text classification task SemEval 2022 Task 4: Patronizing and Condescending Language Detection. We added a classification layer to the pretrained BERT model to address both subtasks. The results generated by the proposed system achieved a relatively good ranking. In the future, we hope to explore other models and methods in the sentiment analysis field.

Abstract

Patronizing and Condescending Language is an ever-present problem in our day-to-day lives. There has been a rise in patronizing language on social media platforms manifesting itself in various forms. This paper presents two performing deep learning algorithms and results for the "Task 4: Patronizing and Condescending Language Detection." of SemEval 2022. The task incorporates an English dataset containing sentences from social media from around the world. The paper focuses on data augmentation to boost results on various deep learning methods as BERT and LSTM Neural Network.

1 Introduction

Nowadays, Patronizing and Condescending Language (PCL) (Pérez-Almendros, Espinosa-Anke, and Schockaert 2022) is used to refer to a forced kindness that derives from a perceived superiority towards another person. A subtle form of bullying, being patronized can leave a person feeling infuriated and impotent.

It is a type of behaviour that cuts across generations. An older person can talk down to a younger colleague, but it can just as easily happen the other way around. Men can patronize women at work and vice versa. But what they have in common is power play, with one individual exerting their authority or seniority over another.

People could feel discriminated by condescending comments. Considering the relevance of equality and respect, and it is important to note that nobody should be treated in such a way as to feel intimidated or different. In SemEval-2022: Task 4 Subtask 1, participants must determine whether a phrase presents PCL or not.

The idea behind the proposed solution was to compare three models based on deep learning. The first model is a Long short-term memory (LSTM) neural network (Zhou et al. 2015). The second, a LSTM neural network with embedding pretrained layer. The third one uses BERT (Devlin et al. 2018). The latter yielded the best results. For all the models we have used data augmentation to balance the training dataset.

The F1-score in our final submission (BERT) was 0.4134 on the test dataset. Compared to the results of the winning team, the difference is not extremely large. Nevertheless, our model obtained a good result of accuracy (0.61) compared to other participants.

2 Background

This paper is focused on Subtask 1: Binary classification. The corpus provided to perform subtask 1 (Pérez-Almendros, Espinosa-Anke, and Schockaert 2020) was composed of 10473 documents with 6 features: "id", "doc id", "keyword", "country code", "text" and "label". The dataset was imbalanced with respect to the class "label". Out of 10473 rows, 9470 were from the negative class and 993 from the positive class. English data augmentation was applied to the original dataset to balance them (Shorten, Khoshgoftaar, and Furht 2021).

After being balanced with data augmentation, the rows of the dataset increased to 19401, 9926 (class 1) and 9470 (class 0). In order to train the three proposed models, we only used the "text" and "label" features. The csv file used follows this structure:

- text: "*The pope as well called on the congregation to reach out…*"
- label: *"1"*

3 Related work

In recent years, several people have been researching this topic. A few years ago, an experiment of the impact of age, race, and stereotypes on perceptions of language performance and patronizing speech was published (Atkinson and Sloan 2017). Indeed, a research of different types of behaviours in healthcare settings (as condescending language) was published to show the impact it has in the world (Felblinger 2009). This is a recent problem and there are significant challenges to be overcome.

4 System overview

4.1 Balancing data techniques

Imbalanced data refers to types of datasets where the target class has an uneven distribution of observations. Sometimes, when the records of a certain class outnumber the other class, our classifier may become biased towards the prediction.

Before considering whether to use balancing techniques, we analyzed the data provided and we trained the models with the original dataset to test the results.

For this purpose, we trained both LSTM neural network and BERT models. The results were as expected. Both models reached similar results. To summarize, they obtained an accuracy of 0.91 and a ROC curve of 0.66. Given the obtained results, we decided to apply some balancing techniques to the original dataset.

Random Under-sampling

Random Under-sampling (Prusa et al. 2015) is a technique to remove examples from the majority class. However, this approach can result in the loss of valuable information during model training. The original dataset was extremely imbalanced, so rows of negative class were removed to achieve a balanced dataset.

The new dataset created using this technique totaled 1986 rows, 993 for each class.

Data Augmentation

Due to the results obtained with the under-sampling method, data augmentation was used to balance the data. Among the most common data augmentation techniques, synonym substitution was used. The synonym augmenter (Wordnet, English) (Miller 1995) to create synonym phrases for the minority class was applied. An example of this kind of substitution is:

- Sentence: *"A quick fox jumps over the lazy dog"*
- Synonym sentence: *"A prompt dodger jumps over the lazy domestic dog"*

Finally, the balanced dataset had a distribution of 9926 (class 1) and 9470 (class 0).

Table 1 shows the results obtained after the application of the two balancing methods. As can be seen, data augmentation produced better results.

Model	**Under sampling**		**Data Augmentation**	
	Accuracy	**ROC Curve**	**Accuracy**	**ROC Curve**
LSTM Neural Network	0.73	0.73	**0.97**	**0.97**
LSTM Neural Network with embedding pretrained layer	0.70	0.70	0.96	0.96
BERT-base-uncased	0.81	0.81	**0.97**	**0.97**

Table 1: Results obtained using sampling techniques for balancing the dataset

4.2 Models

Based on LSTM Neural Networks and BERT, three different models were implemented.

LSTM Simple Neural Network

LSTM is a special type of recurrent neural network. The main feature of recurrent networks is that information can persist by introducing loops in the network diagram, so they can basically 'remember' previous states and use this information to decide what will be next.

The LSTM was composed of an embedding layer with a size of 200, two bidirectional LSTM layers, a dense layer, a drop layer and, finally, a dense layer with a sigmoid activation.

The parameters used to train the LSTM Neural Network were a batch size of 32 and 10 epochs. Indeed, early stopping was invoked to avoid over-training.

LSTM Simple Neural Network with pretrained embedding layer

A pretrained layer was added to the model described above using GloVe [1] (Pennington, Socher, and Manning 2014, 1532-1543). GloVe is a type of implementation of an inter-contextual model, so that each word that appears in training will have a single vector representation obtained by collapsing all the information available about this word with all its appearances in the data.

Some pretrained word vectors of different sizes were downloaded. Finally, we used a file with a size of 200d. Then we added a weight matrix to the first layer of the recurrent neural network.

BERT: Bidirectional Encoder Representations from Transformers

A BERT-based transformer was used to train our third model. In particular, the model implemented was "BERT-base-uncased", which consists of 12 transformer layers, 12 self-attention heads per layer, and a hidden size of 768.

A transformer (Vaswani et al. 2017), has an attention mechanism that learns contextual relations between words (or sub-words) in a text. In its vanilla form, transformer includes two separate mechanisms — an encoder that reads the text input and a decoder that produces a prediction for the task. Since BERT's goal is to generate a language model, only the encoder mechanism is necessary.

The model was fine-tuned with the balancing dataset. Before training, every word was set to lower case. The model was trained with a batch size of 32 and 5 epochs.

5 Experimental setup

To set up our models, some libraries were used. Some of them were "NLTK" (Wang and Hu 2021, 1041-1049), "Keras" [2], "TensorFlow" (Joseph, Nonsiri, and Monsakul 2021, 85-111), "Scikit-learn" (Hao and Ho 2019) and "Pandas" (Stepanek 2020).

To test whether the data was balanced, the original training dataset was used. Once the balancing method was decided, the training data was split into two parts – 80% for training and 20% for test, using a stratify approach.

The stratify parameter makes a split so that the proportion of values in the sample produced will be the same as the proportion of values provided for the parameter to stratify.

During the training phase, we evaluated our models with accuracy, ROC curve, precision, recall and F1-score measures.

Once the organizers provided the test data, the models with the original training dataset were trained without splitting.

6 Results

The two models submitted were LSTM Neural Network with pretrained embedding model and BERT-base-uncased. According to the official metrics (F1-score for the positive class), a result of 0.413 and 0.61 of accuracy was obtained. BERT-base-uncased reached the best results.

After training using under sampling and data augmentation methods, we concluded that data augmentation had the best results.

Table 2 shows a summary of the results obtained during the evaluation phase using data augmentation.

7 Conclusions

In this paper we present our approach and system description on Task 4 (Subtask 1) in SemEval 2022: Patronizing and Condescending Language

Model	Training			Test		
	Accuracy	ROC Curve	F1-score (class 1)	Accuracy	ROC Curve	F1-score (class 1)
LSTM Neural Network	0.97	0.97	0.98	0.95	0.95	0.94
LSTM Neural Network with embedding pretrained layer	0.96	0.96	0.97	0.96	0.96	0.97
BERT-base-uncased	0.96	0.96	0.96	0.96	0.96	0.95

Table 2: Results obtained during the evaluation phase using data augmentation

Detection towards communities in the media. The main aim was to develop three deep learning models using data augmentation to solve imbalanced problem of the original dataset. We implemented three different models. After training and analyzing each model, an F1-score of 0.41 in the evaluation process for class “1” was achieved. For future works, we think the models could be further improved by training with a bigger dataset or using more balancing techniques.

PiCkLe at SemEval-2022 Task 4: Boosting Pre-trained Language Models with Task Specific Metadata and Cost Sensitive Learning

Manan Suri
Netaji Subhas University of Technology
New Delhi, India
manan.suri.ug20@nsut.ac.in

Abstract

This paper describes our system for Task 4 of SemEval 2022: Patronizing and Condescending Language Detection. Patronizing and Condescending Language (PCL) refers to language used with respect to vulnerable communities that portrays them pitifully and is reflective of a sense of superiority. Task 4 involved binary classification (Subtask 1) and multi-label classification (Subtask 2) of Patronizing and Condescending Language (PCL). For our system, we experimented with fine-tuning different transformer-based pre-trained models including BERT, DistilBERT, RoBERTa and ALBERT. Further, we have used token separated metadata to improve our model by helping it contextualize different communities with respect to PCL. We faced the challenge of class imbalance, which we solved by experimenting with different class weighting schemes. Our models were effective in both subtasks, with the best performance coming out of models with Effective Number of Samples (ENS) class weighting and token separated metadata in both subtasks. For subtask 1 and subtask 2, our best models were finetuned BERT and RoBERTa models respectively.

1 Introduction

Patronizing and Condescending Language (PCL) in the context of vulnerable communities refers to language that portrays a sense of superiority or has a tendency to view communities with a pitiful and passionate lens. PCL works subtly and is intricately associated with the way that words and phrases are used. This makes it difficult to classify PCL as compared to overtly offensive language where the nature of words and phrases is clearly negative. Since the harms associated with PCL are not always evident, it is often used inadvertently by actors trying to help these communities. Recognising PCL is important because the expression of PCL leads to a paradigm where discrimination and injustices are routinised and made less visible (Ng, 2007). Use of PCL also feeds into stereotypes (Fiske, 1993), reinforces societal power dynamics and avoids deep-rooted societal problems, providing surface-level solutions for the same (Chouliaraki, 2010). Task 4 of SemEval 2022 (Pérez-Almendros et al., 2022) aims to identify PCL with Subtask 1 working towards binary classification and Subtask 2 working towards the multi-label classification of PCL.

Our strategy involves using state-of-the-art Pre-Trained Language Models (PLMs) and finetuning them for our specific task. We work with BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), DistilBERT (Sanh et al., 2019), ALBERT (Lan et al., 2019) as our models. Additionally, we design effective and simple approaches to optimize our models, by experimenting with different cost-sensitive class weighting methods and working with token separated metadata to enhance performance. With an increasing number of PLMs, each having millions of parameters and being computationally expensive to train, it is essential to make the right model choice. This paper provides a comprehensive analysis of the performance of different models. This can help determine baselines for similar text classification tasks. For model replicability, our code is available online.[1]

2 Background

2.1 Task Description

Patronizing and Condescending Language (PCL) refers to language which may seem kind or helpful but is reflective of a sense of superiority. SemEval 2020 Task 4: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022) had two subtasks that dealt with the identification of PCL and the categories used to express it. These were seen specifically in reference to communities

[1] https://github.com/MananSuri27/PatronisingAndCondescendingLanguage

	PCL	Non PCL	unb	sha	pre	aut	met	com	the
Training Set	794	7581	574	160	162	192	363	145	29
Development Set	199	1895	142	36	62	38	106	52	11

Table 1: Distribution of categories across the training and development set. The labels 'unb', 'sha', 'pre', 'aut', 'met', 'com' and 'the' refer to 'unbalanced power relations', 'shallow solution', 'presupposition', 'authority voice', 'metaphor', 'compassion', and 'the-poorer-the-merrier' respectively.

being identified as being vulnerable and having unfair treatment in the media.

- **Subtask 1:** Subtask 1 was binary classification, where given a paragraph the system was supposed to predict whether it contains any form of PCL. The basis of evaluation was F1 score on the positive class, PCL.
- **Subtask 2:** Subtask 2 was a multi-label classification task where given a paragraph, we were supposed to predict what categories of PCL the paragraph subscribes to. Pérez-Almendros et al. (2020) determined these categories based on previous works and their research on PCL. The 7 categories considered are 'unbalanced power relations' (unb), 'shallow solution' (sha), 'presupposition' (pre), 'authority voice' (auth), 'metaphor' (met), 'compassion' (com), and 'the-poorer-the-merrier' (the). The basis of evaluation was average F1 score across the given classes.

2.2 Data Description

This task is based on the Don't Patronize Me!(Pérez-Almendros et al., 2020) dataset by the task organizers. For this paper, we have considered the practice split offered by the organizers as the split between train and development set. The train, development and test set contain 8375, 2094 and 3831 rows of data respectively.

The paragraphs in this dataset have been selected from news stories and have been annotated with labels specifying whether they qualify as PCL and the categories of PCL that they belong to. The dataset includes additional information about the paragraphs— including the country of reference and the keyword. The keywords clarify the context of the paragraph. The included keywords are: 'disabled' (dis), 'homeless' (hom), 'hopeless' (hop), 'immigrant' (imm), 'in-need' (need), 'migrant' (mig), 'poor families' (poor), 'refugees' (ref), 'vulnerable' (vul) and 'women' (wom). The dataset includes reports from 20 countries.

Table 1 shows the distribution of labels in the train and dev set. We can observe that the distribution of classes is heavily imbalanced. In the training set, only 9.5% of the samples belong to the PCL class. Similarly, in the multi-label category, 72% of all samples with PCL have the class label of 'unb' for the training set.

3 System Overview

3.1 Finetuning Pre-trained Language Models (PLMs)

Pre-training in NLP is a technique that involves training general-purpose language representations through a large set of unannotated text data. It is beneficial for downstream tasks and avoids training a new model from scratch. Pre-training leads to a better generalization performance and helps in convergence on downstream tasks because it provides a better model initialisation. Most NLP datasets contain limited human-annotated samples, due to which there is a tendency to cause overfitting. Pre-training can be regarded as a kind of regularization, preventing overfitting on smaller datasets (Erhan et al., 2010). Pre-training models followed by fine-tuning them for downstream tasks has shown good performance on many NLP tasks (Dai and Le, 2015; Radford and Narasimhan, 2018; Peters et al., 2018).

Briefly discussing the PLMs we have used for this task:

BERT: BERT refers to Bidirectional Encoder Representations (Devlin et al., 2019). It uses bidirectional transformers (Vaswani et al., 2017) pre-trained using a combination of Masked Language Modeling (MLM) and Next Sentence Prediction (NSP). It learns deep bidirectional representations by jointly conditioning on both left and right context layers.

RoBERTa: RoBERTa refers to A Robustly Optimized BERT Pretraining Approach (Liu et al., 2019). It builds on BERT and modifies key hyperparameters, such as training with larger mini-batches and learning rates. RoBERTa also removes

Table 3: Subtask2: Category Classification; The performance of the PLMs we have considered: BERT, RoBERTa, DistilBERT and ALBERT on the dev set, with different class weighting techniques.These systems also included token separated metadata. The columns represent the F1 score for different classes and the average F1 score across all classes. The class weighting strategies (INS- Inverse Number of Samples, ISNS- Inverse of Square Root of Number of Samples, ENS- Effective Number of Samples) are discussed in section 3.2 .

the Next Sentence Training (NSP) objective in BERT.

DistilBERT: DistilBERT (Sanh et al., 2019) is a small, fast, cheap and light transformer based model trained by distilling BERT base. It has lesser parameters, and runs faster but still conserves a large proportion of BERT's performance. DistilBERT uses a triple loss combining language model, distillation and cosine distance losses to leverage the advantage gained by larger models during pre-training.

ALBERT: A Lite BERT for Self-supervised Learning of Language Representations (Lan et al., 2019) is a modification of BERT which efficiently allocates model capacity, reducing the training time and memory consumption. It reduces parameters by factorised embedding parameterization- where the embedding matrix is decomposed to a lower dimension and projected. Layer sharing across layers reduced redundancy. Inter-sentence coherence loss based on Sentence Order Prediction (SOP) is also employed by the model.

We finetuned the PLMs for both subtasks by stacking a dropout layer followed by a dense layer on top of the PLM model. The dropout layer before the dense classification layer is added for regularization. In Subtask 1 we use Sigmoid activation to predict binary labels. In Subtask 2 we use sigmoid activation in the final layer rather than softmax as it allows us to deal with non-exclusive labels. For BERT, DistilBERT and ALBERT we use the features of the [CLS] token and for RoBERTa the <s> token. The performance of the models along with the other strategies we have used is present in Table 2 and Table 3 for Subtask 1 and Subtask 2 respectively.

3.2 Utilising metadata

We have attempted to enrich the PLMs with additional metadata provided in context to the paragraphs in the task. In this setup, more data is available to the model. This is based on the idea that more meaningful data leads to better performance on classification. The same has been observed by other researchers who have experimented with including task-specific data in NLP (Ostendorff et al., 2019; Zhang et al., 2019).

Pérez-Almendros et al. (2020) included ten keywords related to potentially vulnerable communities that are widely covered in media and have had the propensity of receiving condescending treatment, namely: disabled, homeless, hopeless, immigrant, in need, migrant, poor families, refugee, vulnerable and women. Since PCL involves a subtle use of language, we believe that contextualizing whether a phrase is PCL also depends on the context of which community or situation is being referred to.

496 @@26214070 refugee hk 3
Hundreds of thousands of Rohingya refugees living in sprawling camps in Bangladesh are celebrating the Muslim holiday of Eid al-Adha, praying for better lives as they wonder if they'll ever again celebrate at their homes in Myanmar. People streamed into makeshift mosques in the camps, the children dressed in new clothing . Those who could afford it feasted on buffalo meat. Muslims often...

350 @@21894186 homeless lk 4
It can not be right to allow homes to sit empty while many struggle to find somewhere to live, others having to sleep rough on pavements during Christmas, hoping against hope, for some charity to provide shelter . The number left homeless and destitute is alarming not necessarily at Christmas ?

Table 4: Two examples from the dataset to get an intuitive sense of the advantage that using keyword might add to contextualise the paragraph. Both paragraphs describe *home*, but one in the context of *refugees* and the other in context of *homelessness*. The data included in the first row of each paragraph includes the serial number, paragraph ID, keyword, country and annotation.

To understand this, let us consider two examples (Table 4) from the dataset, where paragraphs with ID @@26214070 and @@21894186 are tagged with the keywords "refugee" and "homeless" respectively, and use the word "home" in different contexts. With the "refugee" tag, we are given to understand that "home" refers in a very specific way to a place in the actor's country of origin whereas in the "homeless" context, "home" refers to accommodation or the lack there-of. The purpose of including additional metadata thus was to add to the contextualizing abilities of the model.

We include the metadata by adding it to the input string itself as another sentence in itself; separating the metadata from the text with the [SEP] token in case of BERT, DistilBERT and ALBERT and the </s> token for RoBERTA.

Therefore, the input in case of BERT, DistilBERT and ALBERT looks like:

[CLS] keyword [SEP] paragraph [SEP],

and in the case of RoBERTa, looks like:

<s> keyword </s> paragraph </s>.

We make this system design choice based on the following ideas:

- The chosen PLMs are strong enough to learn how the metadata interacts with the input sequence, considering that we have enough training samples available.
- Using token separated metadata rather than concatenating another model reduces the number of additional parameters to be trained.
- Using the [SEP] and </s> tokens help us utilize the power of pre-training which wouldn't have been convenient if we defined new special tokens to separate the metadata instead of using the predefined special tokens.

Table 5 includes a comparison of the different models we have used, with and without the token separated metadata. For comparability, the same parameters including class weights are used for each model.

3.3 Cost Sensitive Learning

One of the challenges in the task was a heavy imbalance in the number of samples in the given classes in the training data. The positive class for the binary classification task (Subtask 1) was underrepresented where the number of samples with PCL was only around 9.5% of the training set. Similarly, subtask 2 which included multi-label classification had a large proportion of samples from only 2 classes- 'unb' and 'met' (72% and 45% of all samples with PCL respectively), and some classes such as 'the' were heavily underrepresented(3% of training samples with PCL). This varying distribution is a significant issue while training because it becomes a challenge for us to ensure that our model learns the characteristics of the minority classes as well.

Class imbalance is a common issue in many real-world datasets, and many techniques have been developed to mitigate this problem: changing the data (undersampling the majority class, oversampling the minority class, data augmentation by using synonyms or other such methods) or adjusting the model (like changing the performance metric). We found in our experiments that data manipulation techniques only provide a marginal performance boost, and the same has been observed by other researchers working on transformer-based models in text classification tasks (Tayyar Madabushi et al., 2019).

The technique that we have used is cost-sensitive learning (Elkan, 2001), which is based on the statistical concept of importance sampling. Importance sampling refers to weights being assigned to samples in a way that matches the given distribution of data. Mathematically, the loss function is modified to account for a multiplier that represents the weight of the class. This method doesn't modify the distribution of the imbalanced data directly.

For a single prediction x with a gold label of a given class, the loss function is then modified as:

$$loss(x, class) = weight[class]\Theta \qquad (1)$$

where Θ represents the original loss function.

This can be interpreted as adjusting the cost of misclassification of the given classes, practically increasing the cost for misclassification of an important class such as a minority class by assigning a larger weight to it.

We explored different cost weighting strategies which are discussed below. Table 6 describes the count as well as class weights of different cate-

	PCL	Non PCL	unb	sha	pre	aut	met	com	the
Count	794	7581	574	160	162	192	363	145	29

ISNS	297.22	96.19	1.91	165.55	164.52	151.12	109.91	173.90	388.85
ENS	11.85	2.80	16.30	20.32	20.22	19.01	16.68	21.18	64.27

Table 6: Count of different categories in the training set and the calculated weights according to the Inverse of Number of Samples (INS), Inverse of Square-root of Number of Samples(ISNS) and Effective Number of Samples (ENS) schemes.

gories for subtask 1(PCL, No PCL) and subtask 2 (unb, sha, pre, aut, met, com, the) according to the different weighting schemes we discuss below.

1. Inverse of Number of Samples (INS)

For finding the class weight for a given class, we simply take the inverse of the number of samples in the class. It is a simplistic way of ensuring that under-represented classes have a higher weight and classes with a large number of samples have a lower weight. INS class weighting can be described by the following equation:

$$weight[class] \propto \frac{1}{n_{class}} \tag{2}$$

where n_{class} is the number of samples in that class.

2. Inverse of Square Root of Number of Samples (ISNS)

The INS method increases the recall by decreasing the number of false negatives, we observed that because the weight of the majority class had been highly diminished, the precision is still low because of a higher number of false positives. The ISNS method mathematically is the inverse of the root of class frequency. Mathematically, this means that the class weights are larger numeric quantities here than in the INS method and more importantly, the problem of the weights of the majority class being highly diminished for our dataset is mitigated by this method. The ISNS class weighting strategy can be summarised by the following equation:

$$weight[class] \propto \frac{1}{\sqrt{n_{class}}} \tag{3}$$

where n_{class} is the number of samples in that class.

3. Effective Number of Samples (ENS)

A third class weighting strategy that we consider is the Effective Number of Samples (ENS) method which was described by Cui et al. (2019). The authors argue that as the number of samples of a class increases, the benefit added by each new sample will diminish. Instead of considering individual rows of data as singular points in the space,

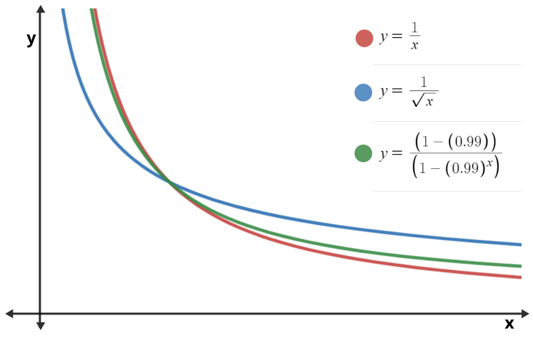

Figure 1: The plots of the mathematical functions that define INS, ISNS and ENS class weighting schemes. The actual class weight may involve additional constants.

this model considers them as small neighbouring regions, the effective number of samples is then calculated mathematically as the effective volume of samples, given by the simple formula:

$$ENS[class] = \frac{1-\beta^{n_{class}}}{1-\beta} \tag{4}$$

where β is a parameter that can take values as 0.9, 0.99, 0.999 and so on, ENS refers to the effective number of samples and n_{class} is the number of samples in the given class.

The weight of the class is then defined as being the inverse of the effective number of samples.

$$weight[class] \propto \frac{1-\beta}{1-\beta^{n_{class}}} \tag{5}$$

For a very high value of β , this class weight comes very close to the INS class weight.

Figure 1 is a graphical representation of the mathematical functions that define the class weights we have discussed above. The performance of the PLMs we have considered with different class weighting strategies can be seen in Table 2 and Table 3 (Subtask 1 and Subtask 2 respectively).

Table 7: PiCkLe's Results on the official leaderboard for subtask 1 and subtask 2.

4 Experimental Setup

To ensure comparability, all models are trained on the same train, dev and test split. Further, the train-dev splits are the same splits provided by the task organizers in the practice splits.

The models were developed on Keras[2] (Chollet et al., 2015), and implemented using the transformers library by HuggingFace[3] (Wolf et al., 2019). We experimented with learning rates of 1e-5,2e-5 and 5e-5 for all models, finding the best results at 2e-5. For all the models, we fixed the max length parameter at 256 tokens and the batch size parameter to 16. The finetuning for the models was performed on Google Colab GPU. We trained each model for 1-2 epochs and found the best results at 2 epochs. The value of β for ENS class weighting was taken as 0.9997 for Subtask 1 and 0.99 for Subtask 2 based on experiments with different values.

Class weighting was implemented using the *class_weight* parameter during model fitting. We used the Autotokenizer offered by HuggingFace's transformers library to tokenize our inputs. We implemented the token separated metadata by setting the *add_special_tokens* parameter of the tokenizer as True and using the *text_pair* parameter. We used the Adam (Kingma and Ba, 2014) optimiser by Keras. The loss function used is binary cross-entropy and categorical cross-entropy for Subtask 1 and Subtask 2 respectively.

5 Results and Analysis

Based on the performance of different PLMs with different configurations (Table 2 and Table 3) on the development set, for Subtask 1 we submitted a finetuned BERT model with ENS class weighting and token separated metadata. For Subtask 2 we submitted a finetuned RoBERTa model with ENS class weighting and token separated metadata.

Our results in the given subtasks on the test set are shown in Table 7 for subtask 1 and subtask 2. We have ranked 38 on subtask 1 with an F1 score of 0.513. For subtask 1, our best performing model on the test set is BERT with token separated metadata and ENS class weighting. This model performs better than the baseline RoBERTa model and falls in the top half of all the models entered into the competition. For subtask 2, our submitted model for the evaluation phase was RoBERTa with token separated metadata and ENS class weighting. This model seems to have performed very well on the development set however it has failed to give the same performance on the evaluation set. While we saw an average F1 of 0.419 on the development set, we get a lower F1 of 0.1515 on the evaluation set. This model still ranks 35 on the leaderboard and has performed better than the baseline model. Moreover, this model is amongst the top 20 models in terms of the F1 scores on 'the' class which was in the smallest proportion in the training set, showing how the cost-sensitive learning that we have performed has been effective in taking into account the minority classes.

While we recognise that our model has performed well for subtask 1, the model still lacks in terms of learning what exactly represents PCL. Recognising PCL is an inherently difficult task because of the subtle nature of the language used and the lack of an exact benchmark of what constitutes PCL. With further tuning of parameters and attempts at improving paragraph representations, we may improve the performance of our existing model.

For Subtask 2, on analysis, we believe that a possible issue with the chosen model for submission is that its performance on the development set is heavily biased by the distribution of labels in the training and development set. This is evident by

[2]https://keras.io/
[3]https://huggingface.co/docs/transformers/index

the fact that 'unb' which is in the highest proportion in Subtask 2 has a development F1 score of 0.838 on the 'unb' class (which also raises the average F1), signifying that a large number of samples have been correctly classified as 'unb' in the development set. We believe that since this model has a high tendency to classify samples as 'unb', it gained a high F1 for 'unb' on the development set where this class was statistically well represented with 71% of the samples with PCL having the class 'unb' in the development set, however, the same distribution may not present in the evaluation set revealing a pitfall of our model.

6 Conclusion

The task of predicting Patronizing and Condescending Language (PCL) is relatively new in the field of Natural Language Processing and comes with its challenges as discussed in this paper. We used a finetuning approach to build models to identify and classify PCL and explored the performance of various models as well as training variations and present them as a comparative in this paper. We explore techniques to deal with class imbalance, which is a rampant problem in real-world datasets by considering various class weighting techniques which work based on cost-sensitive learning. We also explore the idea of using metadata to optimize our model by adding a context that represents the target community or situation being referred to in a given paragraph.

In the future, we would like to explore other options that utilise the power of task-specific metadata. We would also like to work with other transformer-based models such as T5 (Raffel et al., 2019) and ELECTRA (Clark et al., 2020). We would also like to work on improving the ability of our model to recognise the subtle use of language which is embodied by PCL.

Acknowledgements

We would like to thank Dr Vijay Kumar Bohat and Aniruddha Chauhan for their support during writing this paper. We would also like to thank the organisers of SemEval-2022 for conducting this competition.

Abstract

This paper describes the system used by the Machine Learning Group of LTU in subtask 1 of the SemEval-2022 Task 4: Patronizing and Condescending Language (PCL) Detection. Our system consists of finetuning a pretrained Text-to-Text-Transfer Transformer (T5) and innovatively reducing its out-of-class predictions. The main contributions of this paper are 1) the description of the implementation details of the T5 model we used, 2) analysis of the successes & struggles of the model in this task, and 3) ablation studies beyond the official submission to ascertain the relative importance of data split. Our model achieves an F1 score of 0.5452 on the official test set.

Pérez-Almendros et al. (2020) introduced the dataset for the SemEval-2022 Task 4 (Pérez-Almendros et al., 2022)[1]. The dataset covers the English language. It is meant to support Natural Language Processing (NLP) models in identifying PCL towards vulnerable communities, such as poor families and refugees. The dataset is designed for 2 subtasks in the competition. Subtask 1 is a binary classification task of predicting the presence of PCL while subtask 2 is a multi-label classification task of predicting PCL categories. We address subtask 1 in this system paper.

PCL is an expression that depicts someone in a compassionate way or shows a superior attitude of the speaker (Pérez-Almendros et al., 2022). PCL identification is important because PCL has been shown to have harmful effects on vulnerable groups (Fox and Giles, 1996; Morris, 2007; Bell, 2013; Wang and Potts, 2019). This task of identifying and categorizing PCL is apparently more challenging than some other types of harmful language because it is subtle and generally used with good intentions (Wang and Potts, 2019; Gilda et al., 2022).

The main strategy of our system, to address the challenge, was to use a recent SoTA model (T5) in a simple, novel way to reduce out-of-class predictions. We discovered that our system achieves a relatively good performance on the task and PCL identification is a challenging task, due to its subtle nature. It achieved an F1 score of 0.5452 on the test set while the best score was 0.651. This made us rank 27 (66th percentile) out of 78 and we surpass the official RoBERTa baseline. We perform error analysis and ablation studies to evaluate the strengths and weaknesses of the model. We contribute the model checkpoint publicly on the HuggingFace hub[2] and the T5 code [3]

The rest of this paper is organized as follows. Section 1 gives a brief background of related work in PCL. Section 2 gives the system overview of what we used for the task. Section 3 describes the experimental setup for the task and the additional experiments beyond the official submission. Section 4 gives the tables of results and discusses relevant observations from the results. We share concluding remarks in section 5.

1 Background

Work on various sorts of harmful language in NLP has mostly concentrated on explicit aggressive and brazen phenomena (Pérez-Almendros et al., 2022). Scholars are striving to distinguish between harmful and unhealthy language by identifying the fundamental characteristics of unhealthy language. Price et al. (2020) proposed one of the most recent efforts in this regard. The research introduced a new dataset containing 44,000 comments with the unhealthy category sub-classified as either (1) hostile; (2) antagonistic, insulting, provocative or trolling; (3) dismissive; (4) condescending or patronizing; (5) sarcastic; and/or (6) an unfair generalisation. In their work, it is assumed that the language with a PCL tone will assume an attitude of superiority, implying that the other speak-

[1] semeval.github.io/SemEval2022/tasks

[2] huggingface.co/tosin/pcl_22

[3] github.com/tosingithub/pcl (after another competition)

ers/listeners are ignorant, naive, or unintelligent. In such scenarios, the language will usually imply that the other speaker should not be taken seriously.

Similarly, Morris (2007) explains the high likelihood of using PCL language when there is discussion between two persons with different mental health conditions. He demonstrated that patronizing language is common when a discussion occurred between a cashier with no cognitive issue and a customer who suffers from cognitive disability. Overall, PCL does not have an obvious negative or critical language and there is the challenge of limited, high-quality labelled data.

There have been different efforts at automatically detecting PCL. Wang and Potts (2019) showed that models with contextual representations are much better at identifying PCL and this bolstered the hypothesis that context is essential for PCL detection. They implemented the BERT model, which deploys a Transformer-based encoder architecture, on the TALKDOWN corpus they introduced. Both the base and large versions of the BERT model are implemented and evaluated over the new proposed corpus for balanced and imbalanced data. Price et al. (2020) added more context to their work by comparing the performance of BERT to human performance in order to better understand the model's performance. In their experiments, they observed that the BERT model detects PCL with a 78% accuracy, whereas the average over human annotators does so with a 72% accuracy. (Warholm, 2021) also finetuned a BERT model to classify the unhealthy comments in Norwegian data. This model was subjected to a variety of finetuning approaches to distinguish between condescending and non-condescending cases and in the binary classification subtask, the best accuracy was 0.862.

1.1 Data

"Don't patronize me" is an annotated dataset of PCL by (Pérez-Almendros et al., 2020) through crowdsourcing. It is a collection of texts which targets vulnerable communities. The dataset is extracted from News On Web (NoW) corpus[4], containing web articles from over 20 English-speaking countries. It contains 10,637 paragraphs. In addition to the words (*disabled, homeless, hopeless, immigrant, in need, migrant, poor families, refugee, vulnerable and women*) for identifying PCL for annotation in paragraphs, the following traits are also identified as indicators and used for acquiring the dataset:

- Words expressing feeling of pity towards the vulnerable community. For example: *god bless the victims , all those people and their poor families , and i feel so sorry but i want to tell them it was n't my son who did this , it was a different seifeddine*

- Words describing the vulnerable community as lacking certain privileges, knowledge or experience. For example: *After Vatican controversy, McDonald's helps feed homeless in Rome*

- Expressions that present members of the vulnerable community as victims. For example: *the biggest challenge is the no work policy . i think that refugees who come here , or asylum seekers , they 're unable to work and they have kids here – their kids are stateless . that 's really the cause of a lot of stress in the community*

The dataset was annotated by 3 expert annotators. It has two-level classification of PCL: binary classification used to determine if a paragraph has PCL or not, and then categorical label for those with PCL. The categorical classification has three higher-level categories: saviour, expert and poet. "Other" category is the final category to classify all paragraphs with PCL but that do not fit any of the previous categories. The saviour category represents text in which the author is in a privileged class as opposed to the target community. It has two subcategories: unbalanced power relations and Shallow solutions. The expert category is for text where the author is also in a privileged position and presents themselves as knowing better than the target group what their needs are. It also has two subcategories: presupposition and authority voice. The final category "Poet" is identified by how the author frames the community with a literary style writing. It has three subcategories: Metaphor, Compassion and The poorer the merrier.

2 System Overview

The T5 architecture (Raffel et al., 2020) is very similar to the originally proposed architecture of the Transformer by Vaswani et al. (2017). We use the pretrained base version of the model from the

[4]english-corpora.org/now/

HuggingFace hub (Wolf et al., 2020). Input sequence of tokens are mapped to embeddings and then passed to the encoder, which has alternating set of multi-head attention and feed-forward layers. The attention mechanism (Bahdanau et al., 2015) replaces each element of a sequence by a weighted average of the remaining sequence (Raffel et al., 2020). In addition to each self-attention layer of the decoder, there is the standard attention mechanism. As self-attention is order-independent, relative position embeddings are used in the architecture.

The training method (for both pretraining and finetuning) uses maximum likelihood objective (i.e. teacher forcing) and a cross entropy loss (Raffel et al., 2020). The model was pretrained on 34B tokens. Adam optimizer is used for optmization during finetuning. The model has 12 layers each in the encoder and decoder blocks and a total of 220M parameters (Raffel et al., 2020). When we refer to T5, we mean the base model, except where explicitly stated otherwise. The size of the model meant that a batch size of 64 or 32 required more memory than what is available on a single V100 GPU, so we lowered the batch size to 16. T5 takes a hyperparameter called a task prefix. We, hence, use 'classification: ' as the task prefix.

We introduced a correction to the out-of-class prediction of the model, as shown in the flow chart in Figure 1. Raffel et al. (2020) mentioned this issue as a possibility but they did not experience it. The issue appears to be because all the tasks the T5 model is trained on are framed as "text-to-text" before training. Hence, sometimes, the model might predict tokens seen during training but that do not belong to the category of classes in a classification task. This behaviour seems more common in the initial epochs of training and may not even occur sometimes. We further observed that replacing target labels with numbers and explicitly typecasting them as string reduces this occurrence, as the model becomes more stable with predictions.

We split 10% of the training set for validation (dev set) for both of our submissions to the competition. We explored different sizes, however, in further ablation studies, as explained in the next section. The 2 submissions of prediction files are based on 2 adaptive optimizers: Adam and AdamW (Loshchilov and Hutter, 2019). The predictions based on Adam had the better F1 score. Each experimental run was for 3 epochs and the model checkpoint with the lowest validation loss was saved and used to make prediction on the test set. The initial learning rate and scheduler for both submissions are 2e-4 and linear schedule with warmup, respectively.

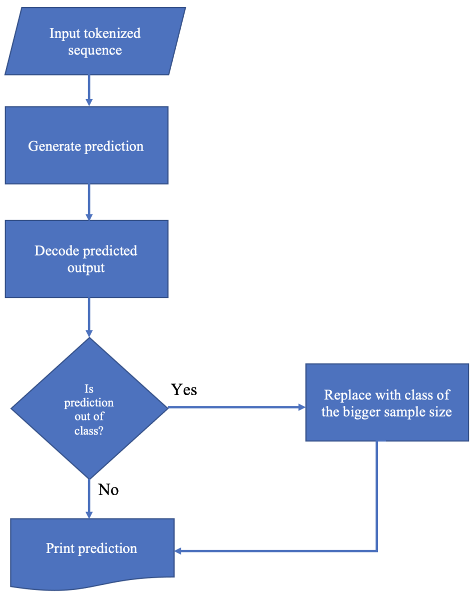

Figure 1: Flowchart of out-of-class code section for the T5 model during prediction.

3 Experimental Setup

All the experiments were conducted on a shared DGX-1 cluster of 8 × 32GB Nvidia V100 GPUs. The server runs on Ubuntu 18 OS and has 80 CPU cores. The experiments were conducted in a Python (3.6.9) virtual environment with the PyTorch framework (1.8.1+cu102). We use both the training & test data provided by Pérez-Almendros et al. (2020). Besides the 2 submissions of prediction files, we perform ablation studies over the training/dev set split ratio (95%/5%, 90%/10%, 85%/15%, and 80%/20%). The training set was shuffled before splitting each dev set. We evaluate all the models using macro F1 scores, precision (P) and recall (R). In the absence of the ground truth of the test set, we perform error analysis by constructing the confusion matrix on a split of the dev set (20%). Further to that, in order to have a basis of comparison of the T5 model's strengths and struggles with the official RoBERTa baseline, we removed the 10 examples provided in Table 5 by Pérez-Almendros et al. (2022) from the training set and concatenated them with the dev set before training and evaluation. The predictions of 9 of the samples are given in Table 3.

Evaluation of the available data, by code, before and after running the script provided by Pérez-Almendros et al. (2022) to categorize the labels into 0 (neg) and 1 (pos) (for subtask 1) reveals that there are a total of 10,469 samples. The script treated paragraphs with the original labels 0 and 1 as 0 (instances not containing PCL) and paragraphs with the original labels 2, 3 and 4 as 1 (instances containing PCL). After running the script, the following are obtained: 9,476 samples classified as 0 and 993 classified as 1 in the training set. The test set has 3,832 samples. Before training, the following preprocessing steps were applied to all splits of the data:

- Emails & URLs are removed.
- All the characters are made lowercase.
- Extra spaces are removed.
- Special characters such as hashtags(#) and emojis are removed.
- Numbers & IP addresses are removed.

4 Results and Discussion

Our model performed relatively well with an F1 score of 0.5452 in the official assessment. This made it rank 27 (the 66th percentile) out of the 78 scores. All the F1 scores we report are macro scores. Our model has 11% advantage over the RoBERTa baseline, which achieved 0.4911, as shown in Table 1. Indeed, our second submission, based on the AdamW optimizer, also performs better than the baseline, achieving an F1 score of 0.5282, precision and recall of 0.5976 and 0.4732, respectively. The T5 model may have performed even better in the official rankings but for the shortcoming we described in section 2. In ablation studies, as shown in Table 2, we observe that training/dev set split ratio affects the performance of the system. All the results are based on submissions to the official evaluation system[5]. Using 5% of the training set as the dev set gave the worst F1 score but we observe improvements as the size is increased, though not linearly. We observe a sharp rise in F1 score when we increase the split from 5% to 10% but the rate of increase falls for subsequent increases.

[5]competitions.codalab.org/competitions/34344

Model	Rank	P	R	F1
best	1	0.646	0.6562	0.651
T5 (ours)	27	0.5801	0.5142	0.5452
RoBERTa baseline	43	0.3935	0.653	0.4911
worst	78	0.1059	0.0284	0.0448

Table 1: Abridged official result ranking for subtask 1.

Model (dev split)	P	R	F1
T5 (5%)	0.0725	0.8643	0.1339
T5 (10%)	0.6725	0.3628	0.4713
T5 (15%)	0.6067	0.4574	0.5216
T5 (20%)	0.5818	0.5047	0.5405

Table 2: Ablation studies results on the test set for subtask 1. Hyperparameters are the same for all model modifications. The T5 (10%) model is retrained afresh like the others, to avoid test/dev set feedback because of the samples in table 3.

4.1 Error Analysis

Since the ground truth labels of the test set are not available, we perform error analysis on the dev set. The T5 (20%) model achieves an F1 score of 0.7405 on the dev set (20%). However, the confusion matrix, as depicted in Figure 2, reveals that the model predicted 0 (neg) correctly 96.4% of the time while struggling to make the correct predictions when it came to 1 (pos), making only 47.8% of predictions correctly. This is very likely due to data imbalance, as 90.5% of the total training set contains samples labeled as 0 (neg). Ways of mitigating this may include data augmentation, possibly in a similar strategy to that used by Sabry et al. (2022), where an autoregressive model was deployed (Adewumi et al., 2022). A more careful stratification of the data split may also be helpful in this case.

Pérez-Almendros et al. (2022) report that the models they considered struggled to detect certain categories of PCL. We observe a similar challenge though our model achieves a better performance than the official baseline. For example, our T5 (20%) model's predictions for the same examples shown by Pérez-Almendros et al. (2022) for subtask 1 reveal that our model correctly predicts 5 out of the 9 displayed in Table 3, unlike the 3 correct predictions out of the 10 by the official baseline. The reason the T5 (20%) may have misclassified 2 of the samples labeled 0 (neg) in Table 3 may be because of tokens such as *vulnerable patients* and *hopelessly*, since they belong to the keywords used for annotating paragraphs with PCL, as discussed

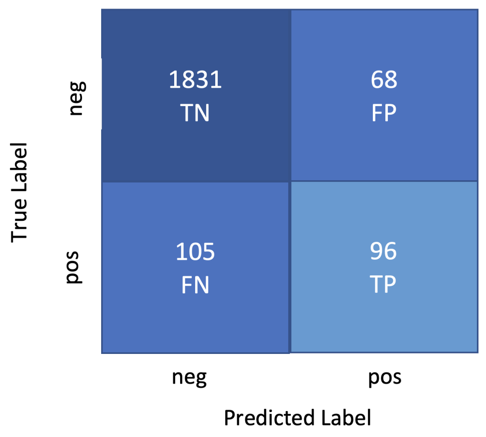

Figure 2: Confusion matrix of T5 (20%) on the dev set (20%). Macro F1 (0.7405): [0.9549 (neg) 0.5260 (pos)]

in section 1.

5 Conclusion

We describe the system involving the pretrained T5 model, which we use for our submission for the subtask 1 of the SemEval-2022 Task 4. We split 10% of the training set as dev set for hyperparameter evaluation in our official submission. Typecasting integer values, which represent classes, as string before feeding the T5 model and adjusting for out-of-class predictions improved the stability of the model in making predictions. Furthermore, in the post-competition phase, we performed ablation studies on the relative importance of dataset split by experimenting with different ratios of the training/dev set and showed what the model struggles with. Our results show that the encoder-decoder T5 model is competitive in this binary task and can obtain better performance with more hyperparameter tuning.

Xu at SemEval-2022 Task 4: Pre-BERT Neural Network Methods vs Post-BERT RoBERTa Approach for Patronizing and Condescending Language Detection

Jinghua Xu
University of Tübingen
jinghua.xu@student.uni-tuebingen.de

Abstract

This paper describes my participation in the SemEval-2022 Task 4: Patronizing and Condescending Language Detection. I participate in both subtasks: Patronizing and Condescending Language (PCL) Identification and Patronizing and Condescending Language Categorization, with the main focus put on subtask 1. The experiments compare pre-BERT neural network (NN) based systems against post-BERT pretrained language model RoBERTa. This research finds that NN-based systems in the experiments perform worse on the task compared to the pretrained language models. The top-performing RoBERTa system is ranked 26 out of 78 teams (F1-score: 54.64) in subtask 1, and 23 out of 49 teams (F1-score: 30.03) in subtask 2.

1 Introduction

An entity is considered to engage Patronizing and Condescending Language (PCL) when its language use presents a superior attitude towards others or depicts them in a compassionate way (Pérez-Almendros et al., 2020). Such language is often used toward vulnerable communities such as women, refugees, and homeless people. These unfair treatments of the vulnerable groups are believed to result in further exclusion and inequalities in society. Compared to other types of harmful language (e.g. hate speech), PCL is considered more subtle and unconscious. Given the negative effects of PCL on society and its subtle nature, enabling computers to identify and categorize PCL presents an interesting technical challenge to the NLP community.

This paper describes my participation in both subtasks of the SemEval-2022 Task 4: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022). Subtask 1, Patronizing and Condescending Language Identification is a binary text classification task to predict whether a given paragraph contains PCL or not. Subtask 2, Patronizing and Condescending Language Categorization is a multi-label classification task to identify the categories of a given paragraph according to the taxonomy defined in Pérez-Almendros et al. (2020), which categorizes PCL into 7 types: *1) Unbalanced power relations 2) Shallow solution 3) Presupposition 4) Authority voice 5) Metaphor 6) Compassion 7) The poorer, the merrier*. The dataset (Pérez-Almendros et al., 2020) contains annotated paragraphs in English, collected from news stories in 20 English-speaking countries.[1]

The focus of my experiments is primarily on subtask 1, meanwhile, this paper also proposes a solution to subtask 2. For subtask 1, the experiments compare pre-BERT neural network (NN) based systems including a majority voting system of NN models against pretrained language model RoBERTa. The experiments start with building individual NN models from the most basic artificial neural network (ANN) to long short-term memory network (LSTM) models following previous work on NN for text classification. It was found that the NN-based systems in the experiments perform worse on this task in comparison to the pretrained language models. The best-performing NN-based voting system could not outperform the RoBERTa baseline model. For subtask 2, this paper simply proposes a RoBERTa solution.

The code is released at: github.com/JINHXu/PCL-Detection-SemEval2022-task4.

2 Background

Numerous previous research had been conducted on the treatment of condescension and patronization. The studies range in various areas from so-

[1] 19 countries and Hong Kong: Australia, Bangladesh, Canada, Ghana, Ireland, India, Jamaica, Kenya, Sri, Lanka, Malaysia, Nigeria, NewZealand, Philipines, Pakistan, Singapore, Tanzania, UK, United States, South Africa, and the special administrative region of China, Hong Kong.

ciolinguistics (Irisawa et al., 1993) to medicine (Komrad, 1983). Whereas in the field of natural language processing, automatically identifying or categorizing PCL has been an understudied area. Most research on harmful language detection has focused on more explicit and aggressive topics such as hateful speech (MacAvaney et al., 2019), offensive language (Zampieri et al., 2019), and fake news (Conroy et al., 2015). Only in recent years, few in the research community have started to show interest in enabling computers to identify condescending language. Prior to this shared task, for instance, Wang and Potts (2019) proposed an annotated TalkDown corpus of condescending language from social media.

3 Dataset

The corpus used for this shared task, the Don't Patronize Me! dataset is described in Pérez-Almendros et al. (2020). The corpus consists of 10,637 paragraphs extracted from the News on Web (NoW) corpus (Davies, 2013). The paragraphs were selected according to 10 keywords related to potentially vulnerable communities (disabled, homeless, hopeless, immigrant, in need, migrant, poor families, refugee, vulnerable, and women). And for each keyword, a similar number of paragraphs were chosen for each of the 20 English-speaking countries.[2] Each paragraph is annotated with a true/false label indicating whether it contains PCL or not, and the ones that contain PCL are annotated with a category label. Each category label is a set of 7 binary predictions, each prediction indicates the existence of a specific type of PCL.

The dataset is highly imbalanced. The POS:NEG ratio is approximately 1:10, which poses a challenge to the predictive modeling process. In the experiments of this paper, various strategies were employed in order to deal with the imbalance in data. The following sections will describe these strategies in detail.

Additionally, the shared task provides a comparable 80/20 split of the training data for development. In the experiments of this paper, the same split was used to train models and generate predictions in the development stage.

[2]Except for Hong Kong, which is not a country.

4 Model

4.1 Preprocessing

In the preliminary experiments, it was found that preprocessing data by removing stop words decreases model performance. Thus in the following model training process, the text data are used as-is. Furthermore, in order to deal with data imbalance, various approaches including data oversampling, undersampling, and setting class weights were experimented with. The neural network models were found in preliminary experiments to work the best with the original data, with class weights set to 10:1 according to the POS:NEG ratio in data. Whereas the RoBERTa models present the best performance with oversampled data with default class weights.

4.2 Neural Network Models

The experiments start with exploring NN models for the binary text classification subtask. Previous work has shown that linear classic machine learning models such as Linear SVM (Suthaharan, 2016), Bernoulli Naive Bayes (Webb et al., 2010), and Logistic Regression (Wright, 1995) have advanced performance on binary text classification with proper feature engineering. This paper is, however, interested in exploring neural network solutions to the task, given the sufficient size of the dataset.

Neural network models have been regarded to be capable of achieving remarkable performance on text classification. In addition to the popular LSTM (Hochreiter and Schmidhuber, 1997) models, some basic ANN (McCulloch and Pitts, 1943) models have also been proved in previous work to perform well on the task of binary text classification. The experiments of this paper start with building individual NN models from the most basic ANN models to the more sophisticated LSTM models. Furthermore, in order to continue improving system performance from the individual models, a majority voting system that uses the predictions of both of the best-performing ANN and LSTM models was built.

4.2.1 Basic ANNs

Common basic ANN architectures for binary text classification tasks typically consist of an Embedding layer, a pooling layer of different types (average, minimum, maximum), and various dense layers. Following the previous work, the experiments start with building a baseline ANN model using a GloVe (Pennington et al., 2014) embedding layer for word representation, with a `GlobalAveragePooling1D` built on top of it, followed by a ReLU layer, and a sigmoid layer to generate predictions. In the preliminary experiments, various types of pooling were tried, and the model with the `GlobalAveragePooling1D` layer presented the best performance. The confidence threshold was initially set to 0.5, which resulted in low precision and high recall. Thus the threshold was gradually increased in experiments, with 0.7 found to generate the best predictions in the development stage.

In order to improve the ANN model from the baseline, more dense layers were added to the network gradually. Since there are no rules of thumb in building a neural network, the strategy employed in this experiment is to continue adding dense layers of tanh and ReLU to the baseline model before the output layer. The F-score reaches a peak value after two additional tanh layers with a ReLU layer in between were added to the baseline model. Adding more dense layers did not further help increase the model performance in the experiments.

4.2.2 LSTM

The LSTM model uses the same GloVe embedding layer for word representation, with a single layer of LSTM units (output dimension size 60) built on top of it. A `GlobalMaxPool1D` layer is built on top of the LSTM layer, followed by a ReLU layer, and a sigmoid layer to generate predictions. The dropout rate is set to 0.1. With the confidence threshold set to 0.5, relatively even precision and recall were obtained.

4.2.3 NN voting system

NN model performance can be unstable in each run, this was also confirmed in the experiments of this paper. In order to handle the instability, also to continue increasing system performance from the individual models, a majority voting system based on both NN models was built. The system considers the predictions of both the ANN and the LSTM models in two separate runs, which results in four votes in total. The systems prediction for each paragraph is then based on the majority vote of the four votes produced by both models in two runs.

All NN models in the experiments are implemented using `tensorflow.keras` (Chollet et al., 2015). During training, each model uses 10% of data for validation, with class weights set to 10:1 as mentioned in a previous section.

The hyperparameter tuning process in this experiment focuses on batch size and the number of training epochs. For each model, batch sizes of 16, 32, 64, 128, and training epochs of 10, 50, 100 were tried. All models present the best performance with the number of training epochs set to 50. The LSTM model works the best with training batch size of 128, and ANN models with 32.

4.3 Pretrained Language Model: RoBERTa

For both shared tasks, this paper proposes a RoBERTa (Liu et al., 2019) solution. RoBERTa is regarded as an improved pretraining procedure from BERT (Devlin et al., 2018), and it is able to match or exceed the performance of all post-BERT methods. All pre-trained language models in the experiments are implemented using the `simpletransformers` library (Rajapakse, 2019).

In subtask 1, the shared-task provides a baseline `roberta-base` model with default configurations, trained on undersampled data. On top of this work, I further tuned the hyperparameters (mainly the number of training epochs, in the search space: 1, 2, 3, 5, 10) and improved model configurations using manually oversampled/undersampled PCL data of various POS:NEG ratios, class weights for fine-tuning. In addition to the `roberta-base` model used in the baseline model, I also experimented with a number community models[3] alternative to `roberta-base`. Among the community models, the experiments mainly focus on BERT- and RoBERTa-based models for toxic language detection and sentiment analysis, given the similarity and relevance of the tasks to PCL detection. Appendix A lists the community models tried in the experiments. However, none of these community models in Appendix A turned out to work better than `roberta-base` in my experiments. I believe the models are too specialized in their own tasks (e.g. sentiment analysis, toxic language detection), therefore resulting in poor performance on the PCL detection task.

The best-performing model in the development stage is a `roberta-base` model, with the number of training epochs set to 1, maximum input sequence length increased to 500.[4] The data was

[3]A list of community models can be found on the website: huggingface.co/models.

[4]The longest paragraph in training data is of the length

balanced by manually repeating all positive data instances 9 times, and keeping the same number of negative data instances for training. The balanced dataset results in 8937 data instances of each class for training. In order to reduce training time, GPUs were used for model training and inference. All RoBERTa-related experiments were conducted on Google Colab.[5]

In subtask 2, the shared-task also provides a RoBERTa baseline model configured with `roberta-base` model, with default configurations. The baseline model is trained on undersampled data (794 positive data instances, 397 negative data instances). I simply increased the maximum input sequence length to 500 from the baseline model and oversampled data to obtain 7146 positive data instances and 7146 negative data instances for training.

5 Results

5.1 Subtask 1: PCL Detection

Model	Precision	Recall	F-score
ANN$^{\text{baseline}}$	32.63	39.19	35.61
ANN	36.50	46.23	40.79
LSTM	41.44	46.23	**43.70**
voting_NN	46.29	40.70	43.32
RoBERTa$^{\text{baseline}}$	40.98	50.25	45.14
RoBERTa-base	51.15	66.83	**57.95**
BERT-emotion	35.93	41.7	38.6
RoBERTa-toxic	37.5	66.33	47.91

Table 1: Model performance on development data.

Table 1 shows the precision, recall, and F1-score of the models in the development stage. Among the neural network systems, the LSTM model presents the most advanced performance with an F-score of 43.7. Meanwhile, the voting system has an F-score (43.32) only slightly lower than the LSTM model. The F-score of the ANN model is lower than the LSTM model, however, the performance gap is not huge. Nevertheless, the best-performing neural network based system LSTM does not outperform the RoBERTa baseline model.

The tuned RoBERTa-base model has the highest score of 57.8 among all systems in the development stage. As mentioned in a previous section, the community models pretrained on sentiment or toxicity language data present poor performance on the PCL data compared to the base model of RoBERTa.[6] Overall, for each model in the development stage, the difference between precision and recall is not vast, except for the tuned RoBERTa model and the toxicity model of RoBERTa.

Model	Precision	Recall	F-score
ANN$^{\text{baseline}}$	28.34	48.90	35.88
ANN	26.62	67.19	38.14
LSTM	38.31	50.16	43.44
voting_NN	48.50	40.69	**44.25**
RoBERTa$^{\text{baseline}}$	39.02	62.78	48.13
RoBERTa-base	46.19	66.88	**54.64**
BERT-emotion	36.54	35.96	36.25
RoBERTa-toxic	25.19	84.54	38.81

Table 2: Model performance on test data.

Table 2 presents model performance on the test data in the evaluation stage. It is notable that among the neural network models, the top-performing system on test data becomes the voting system (F-score: 44.25) instead of the LSTM model, which performs the best in the development stage. The F-score of the voting system in the evaluation stage is also higher than in the development stage. Nonetheless, as the top-performing neural network based system in the evaluation stage, the NN voting system presents an F-score still lower than that of the RoBERTa baseline model (F-score 48.13). Both the LSTM and the ANN model F-score decreased from in the development stage. While the baseline ANN model presents a similar F-score on the test data to that on the development data. In general, in the evaluation stage, the gap between precision and recall is rather big for both the ANN baseline and the ANN model, whereas it is small for the LSTM model and the NN voting system. By comparing the performance of the neural network based systems during the development stage to the evaluation stage, it can be seen that the performance of the ANN models is less stable compared to the LSTM and the voting system.

The tuned RoBERTa-base model is still the top performer among all models in the evaluation stage, with an F-score of 54.64. However, this score decreased from in the development stage. While for the RoBERTa baseline model, the F-score in the

between 400 and 500, in case of future longer data instances to predict on, the model's maximum input sequence length is set to 500.

[5]colab.research.google.com/

[6]Only the performance of two of the community models tried in the experiments are presented in the tables.

evaluation stage is higher than in the development stage. As for the two community models, their performance on test data is also worse than on the development data. Overall, every RoBERTa model shows higher recall than precision with a notable gap. This is also true for the ANN models as mentioned in the previous paragraph. These models produce more false positives than false negatives. While for the BERT-based emotional model, it shows similar precision and recall, although also a low F-score. In general, for every model in the evaluation stage except for the BERT model, the gap between precision and recall further increased from that in the development stage.

5.2 Subtask 2: PCL Categorization

F-score	RoBERTa$^{\text{baseline}}$	RoBERTa
Unb. power rel.	35.35	55.94
Shallow solu.	00.00	31.74
Presupposition	29.63	24.44
Authority voice.	00.00	19.35
Metaphor	00.00	23.88
Compassion	28.78	45.83
The p., the mer.	00.00	15.38
Average	13.40	30.94

Table 3: Model performance on development data.

Table 3 presents the per-class and average F-scores of the RoBERTa baseline model and the proposed RoBERTa model for subtask 2 in the development stage. The proposed RoBERTa model is able to produce a higher F-score for each class with the exception of the *Presupposition* category. Overall, the average F-score is improved from baseline by around 17%.

F-score	RoBERTa$^{\text{baseline}}$	RoBERTa
Unb. power rel.	35.35	54.38
Shallow solu.	00.00	47.06
Presupposition	16.67	26.92
Authority voice.	00.00	24.06
Metaphor	00.00	11.11
Compassion	20.87	46.72
The p., the mer.	00.00	00.00
Average	10.41	30.03

Table 4: Model performance on test data.

Table 4 presents the per-class and average F-scores of the RoBERTa baseline model and the proposed RoBERTa model for subtask 2 in the evaluation stage. As can be seen from the table, the proposed RoBERTa model increased the per-class F-score from the baseline model for each category except for only the *the poorer the merrier* class, for which neither the baseline model nor the proposed model is able to detect. The average F-score of the proposed model is also increased from that of the baseline model. However, the score slightly decreased in the evaluation stage from in the development stage.

6 Conclusion

The experiments of this paper compare some of the pre-BERT neural network based systems against the post-BERT pretrained language model RoBERTa. The experiments start with building individual NN models from the most basic ANN models to the more sophisticated LSTM models, and create a majority voting system based on the individual NN models. It was found that the NN-based systems in the experiments perform worse on the task compared to the RoBERTa baseline model. And the community models pretrained on relevant data such as sentiment and toxicity data turn out to be too specialized in their own task thus resulting in poor performance on the PCL data compared to the RoBERTa-base model.

This paper explores neural network models mainly the basic ANN and LSTM models. Future work should also consider convolutional neural networks (CNN) for PCL detection. In addition to the neural networks, I suggest also investigating classic machine learning models such as Logistic Regression, as well as indicative linguistic features of PCL for feature engineering. Furthermore, on top of the RoBERTa-base model, I propose to pretrain a RoBERTa model using the TalkDown corpus proposed in Wang and Potts (2019), and fine-tune the pretrained model using the PCL data. Finally, future work should run further error analysis of the models to improve performance.

Amsqr at SemEval-2022 Task 4: Towards AutoNLP via Meta-Learning and Adversarial Data Augmentation for PCL Detection

Alejandro Mosquera
Broadcom Corporation / 1320 Ridder Park Drive San Jose, 95131 California, USA
alejandro.mosquera@broadcom.com

Abstract

This paper describes the use of AutoNLP techniques applied to the detection of patronizing and condescending language (PCL) in a binary classification scenario. The proposed approach combines meta-learning, in order to identify the best performing combination of deep learning architectures, with the synthesis of adversarial training examples; thus boosting robustness and model generalization. A submission from this system was evaluated as part of the first subtask of SemEval 2022 - Task 4 and achieved an F1 score of 0.57%, which is 16 percentage points higher than the RoBERTa baseline provided by the organizers.

1 Introduction

The harmful use of language in social media can have negative and long-lasting effects such as exclusion and unfair treatment, specially when targeting vulnerable communities. For this reason, the detection of toxic, hateful and abusive comments has been the central topic of several workshops and tool evaluations, drawing a lot of attention from the Natural Language Processing (NLP) research community in the last years. However, while toxic language has a clear intent and is usually obvious to the reader, patronizing and condescending language (PCL) is more subtle and likely used in a subconscious manner even in traditional media (Perez Almendros et al., 2020). The aforementioned characteristics and its subjective nature makes PCL harder to identify than abusive comments by both humans (Sap et al., 2019) and NLP applications.

The continuously increasing taxonomies of language misuse poses new challenges to social media platforms, thus not only requiring more effort and cost in order to identify abuse across different languages and textual genres but also having to keep a balance between aggressive and conservative filtering strategies. On the one hand, users eventually devise ways of evading automatic content moderation (Gerrard, 2018), while on the other hand, policing that restricts freedom of speech can lead to distrust (Kirk and Schill, 2021). For these reasons, content filters usually rely on the latest advances in NLP research, dominated in the recent years by deep learning architectures. Despite the competitive scores achieved via transfer learning and models such as the Transformer (Vaswani et al., 2017) in this area, choosing and optimizing the right modeling framework for a given NLP task is still a non-trivial problem.

Automated Natural Language Processing (AutoNLP), the equivalent of Automated Machine Learning (AutoML) for NLP, is a relatively new field of study that aims to automate the iterative components of developing a NLP model given a specific input data and task without requiring any special domain expertise. By building upon existing concepts such as transfer learning, data augmentation and meta-learning the author hypothesizes that is possible to generate strong NLP baselines with minimal human interaction. An analysis of the results of the shared task 4 of SemEval-2022: Patronizing and Condescending Language Detection (Pérez-Almendros et al., 2022) shows that AutoNLP can be successfully applied to PCL classification, obtaining a 16% higher F1 score than the baseline provided by the task organizers.

This paper is organized as follows: In Section 2, the state of the art is reviewed. Further on, Section 3 describes the AutoNLP approach for PCL classification. Next, in Section 4, an in-depth discussion of the results obtained is described, and finally Section 5 concludes this research and outlines future work.

2 Related Work

There have been several research works on the detection of different types of harmful language, not only focused on the most explicit such as hate speech (Zampieri et al., 2019) (Garibo i Orts, 2019) but also more subtle usages such as condescending interactions (Wang and Potts, 2019) and social power implications (Sap et al., 2020). PCL towards vulnerable communities in news articles has also been characterized into 7 categories (Perez Almendros et al., 2020) used in order to label the most comprehensive PCL-annotated corpus to date: the Don't Patronize Me! (DPM) dataset, the official training resource for the shared task 4 of SemEval-2022: Patronizing and Condescending Language Detection.

3 AutoNLP for PCL

Deep neural network modeling techniques have inspired state of the art approaches in various domains, such as image classification and language modeling, thus dominating several benchmarks and shared tasks in the last years. For this reason, NLP applications relying on manually-crafted features have been less popular in comparison with deep learning (DL) architectures (Young et al., 2018), specially where extensive manual feature engineering is required to achieve a similar performance (Mosquera, 2021). However, since building a high-quality DL system for a specific task still relies on human expertise, AutoML offers a promising solution to this problem by automating most of the modeling steps (He et al., 2021).

In order to tackle an arbitrary NLP classification task, in this case PCL detection, a custom end to end AutoNLP solution has been designed and evaluated by using exclusively the DPM dataset provided by the organizers, off-the-shelf pre-trained models and without applying any special pre-processing or feature engineering besides standard tokenization. The main components of the system are described in the following section.

3.1 Adversarial Data Augmentation

Adversarial data augmentation can not only increase model robustness but also improve generalization by increasing the number of training samples (Shorten et al., 2021). This can be specially relevant when using neural networks, which tend to under-perform in a low-data regime (Antoniou et al., 2018). The different data augmentation strategies incorporated in the AutoNLP pipeline are as follows:

- **Backtranslation**: Transformation using TextAttack (Morris et al., 2020) that translates a PCL sentence into a random target language and translates it back to English.
- **Checklist**: TextAttack implementation of the Invariance Testing Method: Contraction, Extension, Changing Names, Number, Location (Ribeiro et al., 2020) applied to the positive class.
- **Wordnet**: Word swap by swapping synonyms in WordNet (Fellbaum, 1998) for PCL paragraphs.
- **Embedding**: Attack that replaces words with synonyms in the word embedding space (Mrkšić et al., 2016) for PCL texts.
- **Counterfactual**: Inspired by the concept of counterfactual augmentation (Kaushik et al., 2020), this manipulation only applies to text from the positive class which is augmented with random texts from the negative class. The resulting paragraph should still have a positive (PCL) label.
- **Shuffle**: Attack that shuffles words in a PCL paragraph.
- **Parrot**: Paraphrased PCL sentences generated with Parrot (Damodaran, 2021).
- **Pegasus**: PCL augmentation by generating paraphrases via conditional augmentation using Pegasus (Zhang et al., 2019).

3.2 Meta-learning

A common approach to meta-learning is stacked generalization (Wolpert, 1992), where a set q of base learners applied to a training set T_{train} : $\{(\tilde{X}_i, c_i)\}_{i=1}^{m}$ to produce q hypotheses $\{h_j\}_{j=1}^{q}$ is redefined into a new set T'_{train} by replacing each vector $\tilde{X}_i$ with the class predicted by each of the q hypothesis on $\tilde{X}_i$. T'_{train} is used as input to a set of meta-learners, producing a new set of hypotheses (Vilalta and Drissi, 2001).

While this approach has been successfully applied in several NLP tasks (Li and Zou, 2017) (Mosquera, 2020), an small variation that deals with skewed datasets and automatically sub-samples the majority class in each base learner (Chan and Stolfo, 1998) was considered instead for this challenge. In order to do this, a pool of 40 base learners was generated by randomly combining different data augmentation approaches, deep learning architectures via transfer learning and sub-sampling factors. Logistic regression was used as meta-learner in the second layer, with probability thresholds and hyper-parameters optimized via cross-validation.

Several pre-trained resources were used for fine-tuning with early stopping including BERT (Devlin et al., 2019), ELECTRA (Clark et al., 2020), GloVe (Pennington et al., 2014) embeddings with capsule networks (Frosst et al., 2018), RoBERTa (Liu et al., 2019) and XLNet (Yang et al., 2019). The number of optimal training epochs was determined via cross-validation. However, for cost mitigation purposes, no model was trained for longer than 10 epochs and most hyper-parameters were left with the default values.

3.3 Model Selection

The maximum relevance and minimum redundancy (MRMR) algorithm (Zhao et al., 2019) was applied as feature selection method, reducing the final number of base learners used by the meta-model to 8.

After analyzing the cross-validation results we can observe that base models fine-tuned with ELECTRA obtained the highest F1 scores. Likewise, the most successful data augmentation was the combination of the Checklist and Backtranslation methods. The final list of base learners, including their cross validation F1 score and logistic regression coefficient is shown in Table 1.

Model	Augmentations	F1	β
BERT	Checklist	0.52	**0.31**
ELECTRA	Checklist	**0.55**	0.25
ELECTRA	Checklist Backtranslation	**0.55**	0.17
ELECTRA	Checklist Backtranslation Embedding Counterfactual Wordnet	0.54	0.13
RoBERTa	Checklist Backtranslation	0.53	0.30
RoBERTa	Parrot	0.54	0.14
RoBERTa	Checklist Backtranslation Embedding	0.54	0.09
RoBERTa	Checklist Backtranslation Embedding Counterfactual Wordnet	0.53	0.13

Table 1: Final list of base learners selected via MRMR with their cross-validation score and regression coefficient estimated during the training phase.

4 Evaluation and Results

Final test set results obtained in the PCL classification task by the AutoML system (amsqr) and the winning submission (hudou) can be found in Table 2. The official RoBERTa baseline and the development set results are also included for comparison purposes.

Model	Precision	Recall	F1
hudou	**0.646**	**0.656**	**0.651**
amsqr (dev)	0.587	0.578	0.582
amsqr (test)	0.547	0.599	0.572
RoBERTa baseline	0.393	0.653	0.491

Table 2: PCL classification results.

The fact that only 42 out of 78 competing teams were able to beat the RoBERTa baseline provided by the task organizers highlights the difficulty of this competition. Besides the nature of the task, other challenging factors were the strong class imbalance and the considered evaluation metric, which required careful tuning of classification thresholds via cross-validation (Lipton et al., 2014). A post-competition analysis in Table 3 shows that the automatically chosen classification threshold of 0.26 during training was also optimal for the test set.

Threshold	Precision	Recall	F1
0.20	0.498	**0.656**	0.566
0.22	0.516	0.634	0.569
0.24	0.532	0.621	**0.573**
0.28	0.558	0.586	0.572
0.30	**0.566**	0.574	0.570

Table 3: Post-competition classification results in the test set for different probability thresholds.

5 Conclusion and Future Work

This paper describes the system developed for the PCL detection task of SemEval 2022. The author demonstrates that the selected AutoNLP approach can produce competitive results by leveraging meta-learning, adversarial data augmentation and pre-trained resources. Automatic hyper-parameter optimization and exploring different meta-learning algorithms are left to a future work.

SATLab at SemEval-2022 Task 4: Trying to Detect Patronizing and Condescending Language with only Character and Word N-grams

Yves Bestgen
Statistical Analysis of Text Laboratory (SATLab)
Université catholique de Louvain
Place Cardinal Mercier, 10 1348 Louvain-la-Neuve, Belgium
yves.bestgen@uclouvain.be

Abstract

A logistic regression model only fed with character and word n-grams is proposed for the SemEval-2022 Task 4 on Patronizing and Condescending Language Detection (PCL). It obtained an average level of performance, well above the performance of a system that tries to guess without using any knowledge about the task, but much lower than the best teams. To facilitate the interpretation of the performance scores, the F1 measure, the best level of performance of a system that tries to guess without using any knowledge is calculated and used to correct the F1 scores in the manner of a Kappa. As the proposed model is very similar to the one that performed well on a task requiring to automatically identify hate speech and offensive content, this paper confirms the difficulty of PCL detection.

1 Introduction

This paper presents the SATLab's participation in SemEval-2022 Task 4: Patronizing and Condescending Language Detection. It is a very recent task that aims at identifying passages in texts in which a person is condescending to a vulnerable community (Pérez-Almendros et al., 2020; Wang and Potts, 2019). The task organizers have proposed to identify this type of discourse in paragraphs extracted from news stories published in English-speaking media.

The Patronizing and Condescending Language (PCL) Detection task is part of the large family of tasks that aim at automatically identifying problematic language, whether in media or on social networks. Examples include the detection of hate speech and offensive content, fakenews and hyperpartisan news (Kiesel et al., 2019). The PCL challenge, however, differs from these cases in one important characteristic. As pointed out by (Pérez-Almendros et al., 2020), using PCL is not always conscious and the intention of its author is often positive. Nevertheless, PCL tends to indirectly demean the community in question and reinforce negative stereotypes about it. It is therefore important to develop procedures to identify it.

Recently, the SATLab performed well on a task requiring to automatically identify hate speech and offensive content in tweets using a classical supervised algorithm only fed with character n-grams (Bestgen, 2021b). It was especially effective for resource-poor languages (e.g., Marathi). For English, its performance ($F1 = 0.782$) was average, but nevertheless relatively close to the best team ($F1 = 0.831$) that used complementary resources, pre-trained embeddings and deep learning approaches. These performances suggest that the proposed approach could be a interesting baseline to evaluate the benefits of these more complex approaches.

The goal of SATLab's participation in the PCL detection task was to evaluate whether this finding can be generalized to this new task. A priori, one might think that the performance of the system should be significantly worse here for two reasons. First, this task seems to be much more difficult because of the complex language means of expression on which it relies and the considerable amount of world knowledge and common sense reasoning required to understand this type of language (Pérez-Almendros et al., 2020). Secondly, this task is only proposed for English, a language for which many additional resources are available.

The rest of this document presents the task (see Pérez-Almendros et al. (2022) for more details), the proposed system and the performances reached in the challenge.

2 Task

For this challenge, the organizers extracted paragraphs mentioning predefined vulnerable communities, such as *homeless people*, *migrants* or *poor families*, in news stories from various media in different countries, all in English. Each paragraph was annotated according to whether or not it contained one or more instances of PCL. Annotators were also asked to identify the type of PCLs present in a paragraph using seven categories.

On this materials, the SATLab participated in the two tasks proposed by the organizers. The first task consists in deciding whether a paragraph contains some kind of PCL or not. It is thus a classical binary decision task.

The second task is a fine categorization task in seven positive and one negative categories. The seven positive PCL categories are: *a)*[1] *Unbalanced power relations, b) Shallow solution, c) Presupposition, d) Authority voice, e) Metaphor, f) Compassion, g) The poorer, the merrier*. It is important to note that this categorization is non-exclusive: a single instance can be an example of two, three, four and even five categories. I treated this second problem as Task 1 and thus as seven independent binary problems, the predictions of the seven models being simply concatenated in the final submission. For this second task, the organizers also provided the precise position of the text areas that had been identified by the annotators as warranting the assignment of a given category. This information was not used.

The dataset provided by the organizers to develop the systems consisted of 10,469 instances (but one, id = @@16852855, contained no text). It was highly unbalanced for Task 1 with only 9.5% positive instances. The distribution was even more unbalanced in Task 2 since it contained the same proportion of negative cases. The most frequent positive category (a) represented 6.84% of the total instances and the least frequent only 0.38%.

For the system development phase, the organizers proposed a division of the paragraphs into a learning set (80%) and a development set. The test set used in the final evaluation of the systems, whose responses were therefore unknown, consisted of 3,832 paragraphs.

The measure of effectiveness chosen by the organizers was the F1-score on the positive category for Task 1 and the unweighted average of the F1-scores on the seven PCL categories for Task 2.

[1]The letters are used to identify these categories in Table 2 and 4.

Condition	Char	Word	Combi
F1	0.443	0.440	0.468

Table 1: Performance on the development set

3 System

The proposed system is adapted from the SATLab's participation at HASOC 2021. It is based on the following components.

3.1 Features

The only features used were character and word n-grams. These n-grams were extracted from the lowercased paragraphs. The character n-grams had a length between 1 and 7. The extracted word n-grams contained from 1 to 4 words. The tokenization provided in the materials was used. All n-grams present at least twice in the materials were extracted.

3.2 Weighting schema

BM25 (for Best Match 25) was used to weight the frequency of the features in each paragraph (Robertson and Zaragoza, 2009; Bestgen, 2021a). It is a kind of TF-IDF with specific choices for each of the two components, but above all it takes into account the length of the document. Its classical formula is:

$$\text{BM25} = \frac{tf}{tf + k_1 * (1 - b + b * \frac{dl}{dl - avg_{dl}})} \times \log \frac{N - df + 0.5}{df + 0.5} \quad (1)$$

in which tf refers to the frequency of the term in the paragraph, N is the number of paragraphs in the set, df the number of paragraphs that include the term, dl the length of the paragraph and avg_{dl} the average length of the paragraphs in the set. The parameter k_1 was set to 2 and b to 0.75.

3.3 Regularization

The feature values for each paragraph were regularized using the L2 norm.

3.4 Supervised learning procedure

These character and word n-grams were the only features provided to the supervised learning procedure: the L2-regularized logistic regression as implemented in the LIBLinear package (Fan et al., 2008). This procedure is extremely fast and very

Sub	P	T1	T2a	T2b	T2c	T2d	T2e	T2f	T2g
1	C	3.1	4.75	0.95	0.55	0.35	0.25	0.95	0.014
	w1	180	500	1,600	1,300	700	1,250	850	1,400
2	C	2	3.75	0.90	0.70	0.65	0.40	1.45	0.016
	w1	50	300	2,000	1,500	1,400	750	1,750	1,800

Table 2: Parameters for the two submissions for each task

simple to implement because it only requires the optimization of two parameters: the regularization parameter C and $-wi$ which allows to adjust this parameter C for the positive category, the one which has the most influence in the efficiency measure. It should be noted that during the development period of the system, tests were carried out with an approach much slower and much more complex to optimize: a gradient boosting decision tree as implemented in the LightGBM free software (Ke et al., 2017). But, this approach was abandoned because it did not improve the efficiency of the system.

3.5 Comparison to HASOC

The main difference between this system and the one used for HASOC 2021 is the addition of word n-gram. This decision was made during the development phase of the system, carried out on the basis of the division of the materials into a train set and development set as provided by the organizers. Table 1 shows the F1-scores on the positive category for the models based on each n-gram type and their combination. The parameters were optimized directly on the development set, which obviously raises the concern of overfit, but it can be assumed to be similar for each condition compared. As we can see, the two types of n-grams produce very similar performances and the combination brings a small benefit. The addition of word n-grams means that the system can no longer be considered completely language agnostic like the HASOC system, because it relies on the tokenization provided by the organizers and because a number of characters, such as punctuation marks, are removed.

4 Results

The system just described is identical for the two tasks, the only differences being in the parameters of the logistic regression which were optimized independently for each task and for each target category in Task 2. For the two final submissions, these parameters were optimized by a 5-fold cross-validation procedure applied to the combination of the training and development sets using several steps of exhaustive grid search.

Rank	Id	Prec.	Rec.	F1-Score
1	First	0.646	0.656	0.651
43	Baseline	0.394	0.653	0.491
54	SATLab	0.348	0.552	0.427

Table 3: Results for Task 1 (N = 79)

The parameters employed for each submission are given in Table 2. The parameters for the first submission were those that produced the best overall performance in the cross-validation experiments while those for the second submission corresponded to a model producing close performance, but in which the difference between precision and recall for the target categories was as small as possible.

As can be seen in this table, the parameter values are often very different in the two versions while the performance of the models was very close.

Tables 3 and 4 show the performance of the better of the two submissions on the test set, as provided by the organizers. For Task 1, submission 1 performed better while submission 2 performed better for Task 2. The differences between the two submissions for the two tasks are however very small, less than 0.005. These two tables also give the performance of the first team in the challenge as well as that of the Roberta-based Baseline proposed by the organizers.

The proposed system outperformed the Roberta-based Baseline in Task 2, but not in Task 1. It ranked in the middle of the participants at best, very far from the challenge winners. It is unfortunate (for the SATLab at least) that the task was not proposed in languages with less resources and precomputed embeddings, making the use of Deep Learning much more easier.

Rank	Id	a	b	c	d	e	f	g	Mean F1
1	First	0.656	0.529	0.369	0.407	0.359	0.492	0.471	0.469
24	SATLab	0.424	0.331	0.170	0.232	0.175	0.315	0.142	0.256
38	Baseline	0.354	0	0.167	0	0	0.209	0	0.104

Table 4: Results for Task 2 (N = 49)

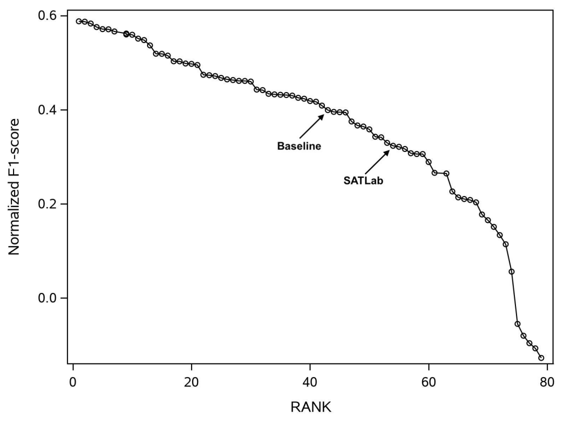

Figure 1: Corrected F1 for all teams in Task 1.

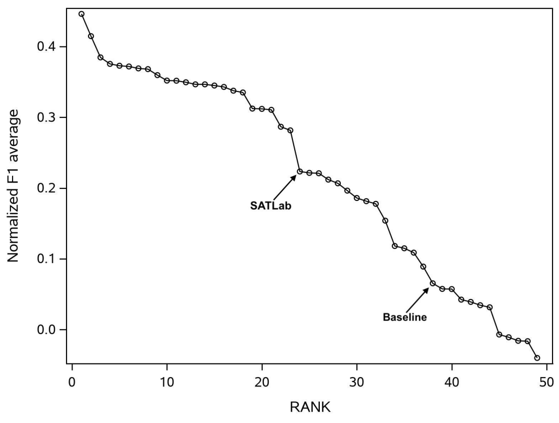

Figure 2: Corrected F1 for all teams in Task 2.

It is interesting to note that the performances obtained on the test set is only slightly lower than those obtained when optimizing the parameters by a cross-validation procedure on the training set. For task 1, this performance on the training set was only 0.03 higher and, on task 2, only 0.008. This suggests that the optimization did not produce an overfit.

The comparison of the system's performance to that of the best team for the seven categories (Table 4) shows that for none of the categories does the system manage to come close to this benchmark. The differences are always approximately 0.20, except *a) Unbalanced power relations*, which is by far the most frequent category, and for *g) The poorer, the merrier*, which is by far the rarest in the learning set, categories for which they are even higher. The more than limited effectiveness of the system does not seem to justify a detailed analysis of its errors.

While the F1-score has become the standard of evaluation for NLP categorization tasks, its interpretation is not obvious. One may wonder whether a Mean F1 of 0.256 (Task 2) represents a prediction of at least an acceptable value. A priori, this does not seem to be the case. On the other hand, the large differences in the frequency of the categories and the imbalance in favor of the negative category may explain the relatively low F1. One way to answer this question more objectively is to determine the best level of performance a system that tries to guess without using any knowledge about the task (Best Guess) can expect to achieve. Ansgar Grüne in his blog post available at https://inside.getyourguide.com/blog/2020/9/30/what-makes-a-good-f1-score shows[2] that in the case of a binary task this is the F1 obtained by a system that always predicts the positive category. If q is the actual proportion of instances belonging to this positive category,

$$\text{F1 Best Guess} = \frac{2q}{q+1}. \qquad (2)$$

This value can also be obtained by submitting the responses of a system that always predicts the positive category, the approach I used here since the challenge participants still ignore the proportion of each category in the test set. In the present challenge, this F1 Best Guess is 0.153 for Task 1 and 0.041 for Task 2. A system that would not exceed these values therefore does no better than a system that always predicts the positive category.

[2] I confirmed empirically this analysis on the task materials by means of a Monte-Carlo procedure in which the proportion of instances in the positive categories were varied between 0 and 1.

SATLab's performance is five times better than this baseline for Task 2, but less than three times better for Task 1. In absolute value, the gain compared to the Best Guess is 0.274 for Task 1 and 0.205 for Task 2. So the n-grams bring some information, but it is obvious that it is not enough to perform well in this task.

This best guest can also be used to correct participants' scores on the task using a formula derived from the Kappa coefficient proposed by Cohen (1960) to adjust the degree of agreement between two judges for agreement due to chance alone. The formula for this correction is:

$$\text{Normalized F1} = \frac{\text{System F1} - \text{F1 Best Guess}}{1 - \text{F1 Best Guess}}. \tag{3}$$

Figures 1 and 2 show the normalized performance of all teams on both tasks. The best system for task 1 achieved a corrected F1 slightly below 0.60. It thus performed 60 % of the way between doing nothing (i.e., the Best Guess) and a perfect performance. This again highlights the complexity of the task. The normalized F1 of the SATLab is only slightly higher than 0.30. For task 2, all the corrected performances are even worse. Figure 2 shows also that the SATLab normalized F1 is quite far from the team directly ahead of it.

5 Conclusion

The SATLab's proposed system for SemEval-2022 Task 4: Patronizing and Condescending Language Detection relies solely on the character and word n-grams present in the paragraphs to be categorized. It does not use any additional data and employs a classical supervised learning procedure (i.e., logistic regression). It obtained an average level of performance, well above the performance of a system that tries to guess without using any knowledge about the task, but much lower than the best teams.

Compared to the performance obtained in the HASOC task (Bestgen, 2021b) and in the detection of hyperpartisan news articles (Bestgen, 2019), this system is clearly further from these best teams. These results confirm, if it were necessary, the much greater difficulty of PCL detection compared to hate speech and offensive content identification (Pérez-Almendros et al., 2020, 2022). They thus suggest, unless other teams using a similar approach were more successful, that the use of much more complex approaches is essential for the PCL task.

Acknowledgements

The author wishes to thank the organizers of this shared task for putting together this valuable event and for their availability throughout the task. He is a Research Associate of the Fonds de la Recherche Scientifique - FNRS (Fédération Wallonie Bruxelles de Belgique).

Abstract

This work describes the development of different models to detect patronising and condescending language within extracts of news articles as part of the SemEval 2022 competition (Task-4). This work explores different models based on the pre-trained RoBERTa language model coupled with LSTM and CNN layers. The best models achieved 15th rank with an F1-score of 0.5924 for subtask-A and 12th in subtask-B with a macro-F1 score of 0.3763.

1 Introduction

The use of Patronising and Condescending Language (PCL) in text or speech can affect healthy communication channels adversely. The effect of PCL on the vulnerable sections of society have been widely studied. PCL acts as a catalyst for discriminatory behaviour (Mendelsohn et al., 2020) against various vulnerable groups. It has been observed to promote exclusion and discrimination among communities and provide a conducive environment for rumour spreading and misinformation (Nolan and Mikami, 2013). These negative effects of PCL are unaffected by the intent of the writer/speaker who might have unknowingly used PCL. These reasons provide a strong argument for developing methods that can identify and prevent unwanted use of PCL in news articles, blogs, and other pieces of text.

In subtask-A of the Patronizing and Condescending Language Detection task at Semeval-2022 (Pérez-Almendros et al., 2022), the goal is to develop a model which takes a sample text as an input and outputs a label indicating the presence or absence of PCL. In subtask-B, the model was required to identify the correct set of PCL categories. The model takes in a sample text as an input and return seven separate outputs each indicating the presence or absence of the pre-defined seven categories. The dataset for the task was shared by the task organisers in the English language. To tackle these tasks, RoBERTa based models were developed. Different variations of the models involved the use of feed-forward layers, LSTMs, CNN and their combinations. For subtask-A RoBERTa with LSTM, CNN and feed-forward layers outperformed all the other variations with an F1 score of 0.5924. In subtask-B RoBERTa with feed-forward layers got the best F1 score of 0.3763 as compared to the other variations. For subtask-A, this work achieved 15th rank in the leader board and 12th rank for subtask-B details of which are discussed in section 3.2.

2 Background

Identification and analysis of PCL in text is well explored in linguistics (Aggarwal and Zhai, 2012), politics (Huckin, 2002), sociolinguistics (Thapar-Björkert et al., 2016) and other fields. However, in NLP it is still heavily unexplored and starting to gain traction. In the past topics such as sentiment analysis (Feldman, 2013), offensive speech identification (Safaya et al., 2020) and fake news identification (Shu et al., 2017) have been significantly worked upon. One major roadblock in exploring PCL in the text is the lack of well structured and labelled dataset. Recently, some new work has been developed to tackle this issue. Wang et al. (Wang and Potts, 2019) developed a model for identifying the condescending language in Reddit threads and also developed an annotated dataset for the same.

2.1 Dataset

For training and development of the model presented in this work "The Don't Patronize Me!" dataset (Perez-Almendros et al., 2020) was used. The dataset contains paragraphs in the English language extracted from the News on Web (NoW) corpus. It comprises 10469 samples out of which 993 have been classified as positive samples, i.e. they contain PCL. The dataset categorizes PCL into 7 different sub-categories, namely, Unbalanced power relations (UPR), Shallow solution

Sentence	Keyword	Label
In September , Major Nottle set off on foot from Melbourne to Canberra to plead for a national solution to the homeless problem .	homeless	1
10:41am - Parents of children who died must get compensation , free medicine must be provided to poor families across UP : Ram Gopal Yadav	poor-families	1
Today , homeless women are still searching for the same thing . A place to sleep and be safe	homeless	0
For refugees begging for new life , Christmas sentiment is a luxury most of them could n't afford to expect under shadow of long-running conflicts	refugee	0

Table 1: Sample text and keyword pairs along with corresponding labels.

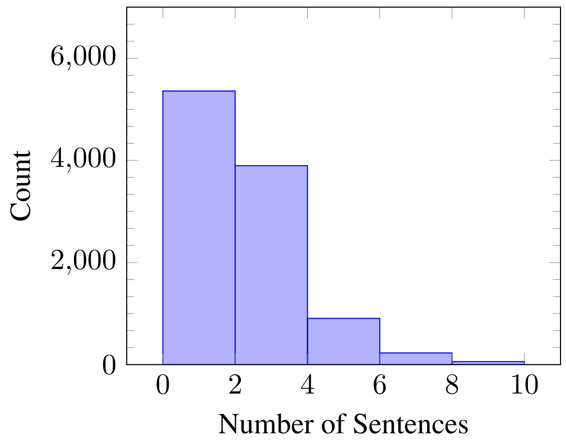

Figure 1: Distribution of the number of sentences per sample.

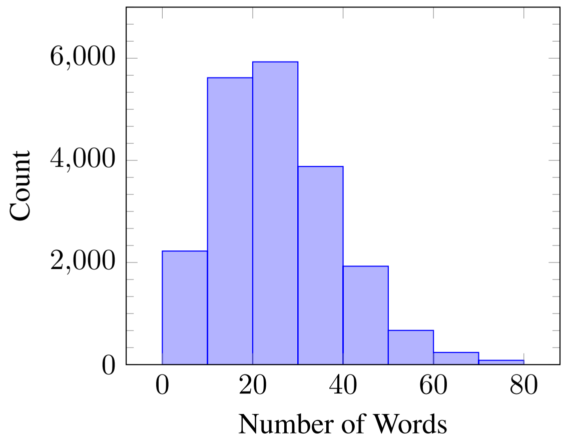

Figure 2: Distribution of the number of words per sentence in a sample.

(SSL), Presupposition (PS), Authority voice (AV), Metaphor (MTP), Compassion (CMP), The poorer - the merrier (PM). Each positive sample can belong to any combination of these categories. The distribution of each category out of all the positive samples is described in Figure 4.

For developing the models for subtask-A the dataset also provides binary labels (0 or 1) to signify the presence or absence of PCL in the text. Along with the paragraphs, the dataset includes the country of origin of the original article and keywords that occur in the paragraph under consideration. These keywords comprise the following, Disabled, Homeless, Hopeless, Immigrant, In need, Migrant, Poor Families, Refugee, Vulnerable and Women. These keywords are usually present in texts that concern the vulnerable sections of society (refer Table 1).

3 System Overview

This section describes the different model designs explored for Task A and Task B and the pre-processing techniques employed. Section 3.1 describes the pre-processing techniques and how they tackle the challenges offered by the dataset. The different models are described under section 3.2 along with a description of the different sub-components and the underlying intuition.

3.1 Data pre-processing

The "The Don't Patronize Me!" dataset offers primarily three major challenges, which are, low number of samples, high class imbalance and the low context in the textual data (smaller sentence length). To deal with high class-imbalance and lower number of samples data augmentation techniques, loss weighting strategies were adopted and to address the low context issue, keywords shared in the dataset were used to provide added context to the models.

3.1.1 Tokenisation

Each sample was tokenised using RoBERTa (Liu et al., 2019) tokenizer. To identify the optimal Tokenisation length analysis was done on the distribution of the number of a sentence per sample (Figure 1) and the distribution of the number of words for

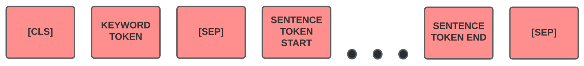

Figure 3: An example of tokenisation

each sentence (Figure 2). On analysing the two distributions length of 50 to 60 tokens seemed a viable candidate for Tokenisation operation. However, on further analysis, it was found that out of 993 positive samples, 193 (19.43 %) had more than 75 words. Thus, to prevent loss of information Tokenisation was done with a length of 100.

Each tokenised sentence was prepended with a tokenised keyword corresponding to that sample separated by the SEP token. Finally, the Tokenisation process was completed by adding a CLS and SEP token at the beginning and the end respectively (refer Figure 3).

3.1.2 Data augmentation

For data augmentation back-translation method was explored. Back-translation is the process of using a language model to translate a text from its parent language to another language, generally using a language model. The new text is then translated back to its parent language. This method introduces slight changes in the structures of the text while retaining the underlying context. This method has been shown to boost the performance of models trained over smaller datasets.(Sennrich et al., 2016). Helsinki-NLP models [1] were used to translate a sentence from English to French and back to English. Only 30 per cent (randomly sampled) of the positive samples from the dataset were back-translated.

3.1.3 Loss weighting

Initial exploratory analysis of the dataset has shown high class imbalance. To address this issue cost-sensitive re-weighting technique developed by Cui et al (Cui et al., 2019) and suggested by Jurkiewicz et al (Jurkiewicz et al., 2020) was adopted. The weighting factor for each class was identified as per the following definition:

$$(1-\beta)/(1-\beta^{n_i}) \tag{1}$$

where β is a hyper-parameter in [0,1), and n_i is the number of samples belonging to the class i. Using these weights the updated softmax cross-entropy loss is given as:

[1]https://huggingface.co/Helsinki-NLP

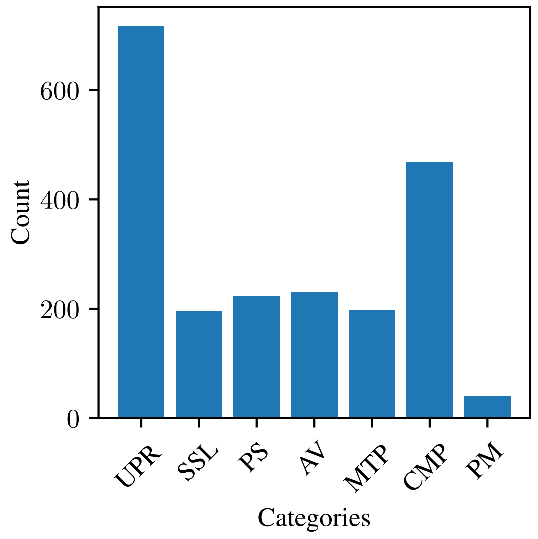

Figure 4: Number of samples for each of the seven PCL classes

Model	BASIC	AUG	WT
RB-FNN	**0.6177**	0.6301	0.6080
RB-BiLSTM	0.6140	**0.6305**	0.6258
RB-CNN	0.5879	0.5954	0.6037
RB-BLS-CNN	0.6059	0.6095	**0.6318**

Table 2: Analysis of the models trained under WT, AUG and BASIC setting for subtask-A

$$L(z,y)=\frac{1-\beta}{1-\beta^{n_i}}\log\left(\frac{\exp(z_y)}{\sum_{j=1}^{C}\exp(z_j)}\right) \tag{2}$$

where $z=[z_1,z_2,...,z_C]$ is the predicted output of the model for C classes and y being one of the possible class labels, i.e. $y \in C$

3.2 Model description

This work explores four different model designs. Each design includes RoBERTaLARGE (Liu et al., 2019) as it's base layer. The output of the last hidden state (shape = 106 X 1024) is then further fed down the network to get the final prediction. For subtask-A, all the models perform binary prediction (0 = no PCL, 1 = contains PCL) to identify if the input text contains PCL, while for subtask-B each model produces 7 binary predictions, one for each possible PCL category. The design of the four models remains the same for both tasks except for the number of outputs generated by them (Figure 5). Binary Cross-Entropy (BCE) loss was used for

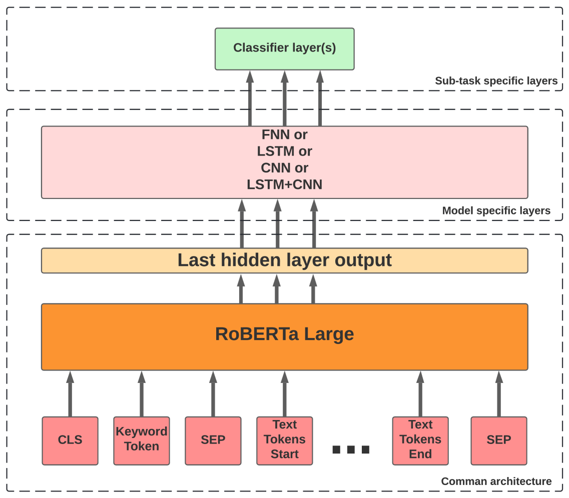

Figure 5: Generalised architecture of the models developed. For subtask-A classifier layers consist of single FNN with 2 units. For subtask-B classifier layers consist of 7 FNN layers each with 2 units.

all the outputs. Adam optimizer was utilized with a learning rate set to 1e-6 and epsilon at 1e-6.

3.2.1 RB-FNN

The model employs the use of two feed-forward layers added on top of $\text{RoBERTa}_{\text{LARGE}}$. The output of the last hidden layer is flattened and passed down the model. The initial feed-forward layer has 106 units. For subtask-A, the output of this hidden layer is passed on to a single feed-forward layer with 2 units for binary prediction, while for subtask-B the output is shared by seven feed-forward layers each with 2 units predicting the presence of each sub-category of PCL.

3.2.2 RB-BiLSTM

LSTM is a type of recurrent neural network (RNN) that allows the model to learn underlying features in temporal data without the added drawbacks of general RNN models such as exploding or vanishing gradients. LSTM allows the model to capture the long term dependencies in the data and identify the underlying temporal nature of the data(Tang et al., 2015). LSTMs have shown to achieve state of the art performance in different text classifications tasks (Tang et al., 2015) and (Li et al., 2020). Shi and Lin (Shi and Lin, 2019) also showed that using LSTM coupled with BERT can improve the performance compared to BERT by itself. For this model the output of the last hidden layer of $\text{RoBERTa}_{\text{LARGE}}$ model is fed into a Bi-Directional LSTM layer with 106 units. The output of the BiLSTM layer is then fed down to two FNN layers with 106 and 2 units respectively (subtask-A). For subtask-B, the output of the first FNN layer is fed to seven feed-forward layers each with 2 units.

3.2.3 RB-CNN

CNN based models have been shown to perform well for various text classification problems (Chen, 2015) (Safaya et al., 2020). CNN layers are able to capture the semantic relationships within the textual data and given the structured nature of the embeddings obtained from $\text{RoBERTa}_{\text{LARGE}}$ model it seemed beneficial to use CNN layers to extract the hierarchical features within the data (Rodrigues Makiuchi et al., 2019). In this model, the last layer embeddings of the $\text{RoBERTa}_{\text{LARGE}}$ model are fed to two CNN layers coupled with a max-pooling layer. The first CNN layer comprises 64 10X10 filters with stride 1 and the second layer comprises 32 5X5 filters with stride 1. After each CNN layer, a two-dimensional max-pooling operation is done with a shape of 2X2. The output of the last max-pooling operation is fed to an FNN layer with 106 units which is followed by an FNN layer with 2 units (subtask-A). For subtask-B, the output of this FNN layer is fed to seven feed-forward layers each with 2 units.

3.2.4 RB-BLS-CNN

To get the model to learn both temporal and hierarchical features within the data a hybrid model was developed employing both LSTM and CNN layers. This model is created as an amalgamation of the RB-BiLSTM and RB-CNN models. The last layer $\text{RoBERTa}_{\text{LARGE}}$ embeddings are fed to an LSTM layer with 106 units. The output of the LSTM layer is then further fed to the CNN architecture defined in the RB-CNN model. The final FNN layer with 106 units is then further fed to a single FNN layer with 2 units for subtask-A and to seven separate FNN layers each with 2 units for subtask-B.

4 Experimental setup

To gauge the effect of data augmentation and loss weighting techniques on the performance of models for each subtask four experiments were carried out (Table 6). The goal was to identify how both the techniques interacted with each other and to find the right combination for each subtask. For each experiment, the model was trained on 80 per cent of the data as the training set and 20 per cent

Model	Macro F1	UPR F1	SSL F1	PS F1	AV F1	MTP F1	CMP F1	PM F1
Baseline	0.1041	0.3535	0	0.1667	0	0	0.2087	0
RB-FNN	**0.3763**	**0.5969**	**0.4578**	**0.3333**	**0.2178**	**0.3043**	**0.536**	**0.1875**

Table 3: F1 score comparison on evaluation dataset for subtask-B between the RoBERTa baseline shared by task organisers and the RB-FNN under AUG experimental settings.

Model	F1 score	Precision	Recall
Baseline	0.4911	0.3935	0.653
RB-BLS-CNN	**0.5924**	**0.5357**	**0.6625**

Table 4: F1 score comparison on evaluation dataset for subtask-A between the RoBERTa baseline shared by task organisers and the RB-BLS-CNN under WT experimental settings.

Exp	Augment	Loss Weighting
BASIC	No	No
AUG	Yes	No
WT	No	Yes
AUG+WT	Yes	Yes

Table 6: Different experiments carried out on each model.

Model	BASIC	AUG	WT
RB-FNN	**0.4054**	**0.4082**	0.3158
RB-BiLSTM	0.3643	0.3818	0.2880
RB-CNN	0.3594	0.3903	**0.3180**
RB-BLS-CNN	0.3599	0.3519	0.2871

Table 5: Analysis of the models trained under WT, AUG and BASIC setting for subtask-B

as the validation set. The 80-20 split shared by the task organisers was used. F1 score for subtask-A and macro F1 score for subtask-B were chosen by the task organisers as the criteria to identify the best performing model, thus the same was used to evaluate the performance of different models created for the two subtasks under different experimental settings. For each experiment, training was done for 20 epochs with a batch size of 8. The best version of the model from each experiment was used to generate predictions for the evaluation dataset.

5 Results

For subtask-A RB-BLS-CNN under WT experiment achieved the highest F1 score of 0.5924 with a precision of 0.5357 and recall of 0.6625 on the evaluation dataset. While on the validation dataset the same model received an F1 score of 0.6318 with a precision of 0.5685 and recall of 0.7109.

For subtask-B RB-FNN performed best out of all the models under the AUG experimental settings. The model achieved a macro F1 score of 0.4006 on the validation dataset and 0.3763 on the evaluation dataset.

The minute difference in the F1 scores of the best models for the evaluation dataset and the validation dataset shows that the model did not overfit during the training phase despite a large number of training epochs.

The effect on class re-weighting (refer 3.1.3) and data augmentation was also explored (refer Table 2 and Table 5). It was found that for subtask-A a majority of the four models received a boost in the F1 score when class re-weighting was applied as compared to the BASIC experimental setting. However, this trend was absent for all the models of subtask-B. Rather class-weighting had a detrimental effect on the models for subtask-B as shown in Table 5. The low number of samples for each of the seven sub-classes coupled with the added complexity of the task as compared to subtask-A could have been the underlying cause behind this observation.

Similarly, the effect of data augmentation on model performance was also explored (refer to Table 2 and Table 5). For subtask-A, all the different models received a boost as compared to the models without augmented data. The same trend persisted for the majority of models trained for subtask-B.

Another interesting find in subtask-B was the significantly poor performance of the LSTM and CNN based models as compared to the vanilla RoBERTa model i.e. RB-FNN. This is not in line with the trend observed for the models in subtask-A (Table 2). The reason for this result could be similar to the unexpected trend observed for the models of subtask-B in class re-weighting experiments. Especially for LSTM based models as a large number of samples are required to train models that employ LSTMs in their design.

	UPR	SSL	PS	AV	MTP	CMP	PM
Precision	**0.6076**	0.3684	**0.5667**	**0.3428**	**0.5652**	**0.6521**	**0.6666**
Recall	0.5563	**0.3889**	0.2741	0.3157	0.25	0.4245	0.1818

Table 7: Precision and Recall values for RB-FNN model under AUG experimental settings on test data.

6 Conclusion

This work explored the design and training of different RoBERTa based models for PCL detection in text. The added benefits of using CNN and LSTM layers along with RoBERTa in boosting model performance was also shown. This work also explored the effects of using back translation as a data augmentation technique along with a class re-weighting technique to deal with low sample size and high class imbalance. Finally, the challenges offered by the models under different problem statements were explored which gives a deeper insight into the impacts of different design methodologies. The best models achieved 15th and 12th rank for subtask-A and subtask-B respectively.

Future work can include expanding the dataset with more data as the current dataset includes 10469 samples. Also, the original article can be provided against each sample which can be fed to the model as added context. This added context should significantly boost model performance.

Abstract

This paper presents a combination of data augmentation methods to boost the performance of state-of-the-art transformer-based language models for Patronizing and Condescending Language (PCL) detection and multi-label PCL classification tasks. These tasks are inherently different from sentiment analysis because positive/negative hidden attitudes in the context will not necessarily be considered positive/negative for PCL tasks. The oblation study observes that the imbalance degree of PCL dataset is in the extreme range. This paper presents a modified version of sentence paraphrasing deep learning model (PEGASUS) to tackle the limitation of maximum sequence length. The proposed algorithm has no specific maximum input length to paraphrase sequences. Our augmented under-represented class of annotated data achieved competitive results among top-16 SemEval-2022 participants. This paper's approaches rely on fine-tuning pretrained *RoBERTa* and *GPT3* models such as *Davinci* and *Curie* engines with extra-enriched PCL dataset. Furthermore, we discuss Few-Shot learning technique to overcome the limitation of low-resource NLP problems.[1]

Keywords: Natural Language Processing, Transformers, Data Augmentation, RoBERTa, GPT-3, Curie and Davinci Engines.

1 Introduction

Natural Language Understanding (NLU) and Interpretation (NLI) is a branch of Natural Language Processing (NLP) in Artificial Intelligence (AI), which involves understanding and analyzing human language in-depth. Recent advances in Deep Neural Networks (DNNs) have enabled NLP research scientists to achieve state-of-the-art results for tasks that were extremely difficult, if not impossible Devlin et al. (2019), Lan et al. (2020). However, understanding human emotions, reactions, and uncovering hidden insights from unstructured text data such as news stories channel is still challenging.

Language attitudes and intentions extracting in response to the support for the marginalized and vulnerable communities is one of the emergent NLP applications. Patronizing and condescending language (PCL) is a type of behavior that projects a sense of superiority to vulnerable populations Pérez-Almendros et al. (2020). Furthermore, biases and discrimination can result from patronizing attitudes, causing some people to feel unfairly treated, inadequate, unintelligent, and possibly infuriated Saeedi et al. (2021).

Since raw text data extracting from web is a common data collection method, language models can learn different forms of harmful language Heidari and Jones (2020). The PCL understanding is inherently different from sentiment analysis because positive/negative hidden attitudes in the context will not necessarily be considered positive/negative for PCL tasks. It is difficult due to the fair amount of world knowledge and commonsense reasoning required to understand this kind of language Saeedi et al. (2020). The fine-grained idea of PCL detection towards vulnerable communities was presented by Pérez-Almendros et al. (2022). They evaluated baseline results of NLP techniques to detect the presence of PCL and classify PCL types at the text span level.

In this paper, we describe systems participating in the SemEval-2022, PCL detection competition, multiple tasks of language interpretation. The competition is divided into binary classification and multi-label categorization tasks. Data quality analysis led us to explore several NLP data augmentation techniques and state-of-the-art DNN architectures for these challenging tasks. Our attempts to improve the performance of previous

Figure 1: PCL data for binary and multi-label classification problems. Labels 0 and 1 are corresponding to not containing and containing PCL, respectively. "Authority voice" is the PCL category of paragraph. Training model on combined features as the concatenation of keyword and paragraph with RoBERTa separation token "`</s>`".

efforts ranked us 16 among 79 NLP research teams with very competitive results on the PCL detection task. Our system's performance achieved 80% and 58% F1-score on the training and test datasets, respectively. In comparison, the winning system's F1-score was 65%. Also, the in-depth dataset analysis revealed multi-label classification techniques commonly confused in the PCL categorization task.

This paper is organized as follows. In Section 2, we introduce two PCL tasks, an in-depth analysis of their datasets, and the challenges of these tasks. In Section 3, we describe our different strategies to tackle discovered challenges of data quality. Next, we explored text augmentation methods to fine-tune the Transformer-based model for each individual task. In Section 4, we discuss our applied models, the experimental setup for fine-tuning models, and their performance. Finally, we conclude the paper in Section 5.

2 Tasks Definition and Dataset Analysis

As discussed, PCL competition consists of two classification tasks, each focused on the different objectives of PCL towards underprivileged communities. Figure 1 shows samples of data, their salient features, and annotated labels in training set for both tasks. The first task aims to classify a paragraph that contains PCL as an act of appearing kind or helpful but internally feeling superior to others. The second task is the investigation of the text categorization problem, where each PCL-containing paragraph may belong to several PCL categories[2].

2.1 Data Analysis of Binary Classification

For the PCL binary classification task, we had access to 10469 human-labeled paragraphs for training our models. Two annotators consider their disagreement on borderline cases as not containing PCL. Our exploratory data analysis reveals not containing PCL paragraphs with label '0' make up a large proportion of dataset (90.4%), and target class '1' as containing PCL is the minority class.

The imbalance degree of PCL binary classification dataset can be measured in moderate to extreme range Leevy et al. (2018). The highly imbalanced data would be problematic because models are mostly trained on non-PCL data and will not learn enough from the PCL samples. In this case, a non-PCL outcome is almost always predicted by the trained model. Our experiment shows models yield inaccurate results, see Section 4.

To combat imbalanced training data and misleading classification results, we investigate several techniques in Section 3. Furthermore, this problem is highly challenging because the nature of PCL detection is different from other domains, such as hate speech, inappropriate and fake content detection.

[2]Seven categories for different traits of PCL: Unbalanced power relations (unb), Shallow solution (shal), Presupposition (pre), Authority voice (aut), Metaphor (met), Compassion (com), The poorer, The merrier (merr).

Words that might have positive connotations in sentiment analysis will not necessarily be considered positive in PCL.

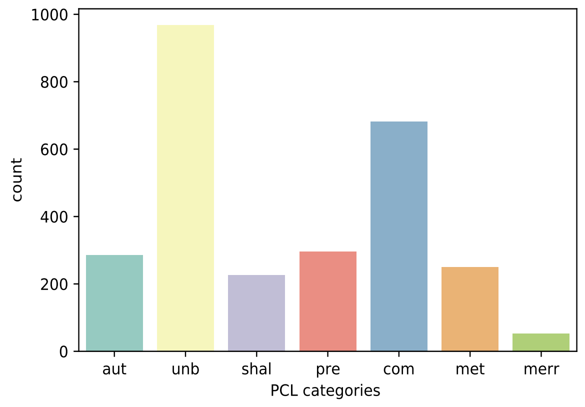

Figure 2: Imbalanced data representation. This chart illustrates the number of observations per PCL category is not equally distributed because in the first task not containing PCL class can obviously discriminate the minority class.

2.2 Data Analysis of Multi-label Classification

For identifying PCL types, the number of manually labeled samples in the datasets is 2760, including all PCL positive data from the previous task. Each text span within the containing PCL paragraph can represent one or more PCL categories.

We were challenged to build a multi-label deep learning model capable of detecting different types of PCL. The unevenly distributed labels, also in the case of multi-label classification, could be problematic. Figure 2 illustrates the number of paragraphs associated with "unb" and "com" are the dominant categories. In Sections 3, we present different methods to combat these challenges, and we describe our efforts of training model on the proper distribution to handle imbalanced dataset in Section 4.

3 Tackling Data Imbalance

Taken together, these challenges led us to approach skewed class proportion problems in the PCL dataset with various Data Augmentation (DA) techniques in NLP Wei and Zou (2019). Like many other NLP techniques, DA is not an exact science, and understanding both dataset and task is essential. We conducted an ablation study to measure the impact of DA on the performance of the system.

We aimed to enhance the size of dataset to reduce the side effect of data imbalance. Before trying text augmentation methods, we preprocessed the data by removing HTML-tags and non-alphabetic characters. Then, we expanded English language contractions, e.g., from "you've" to "you have." The following subsections explain our DA methods.

3.1 Synonym Replacement

Synonym Replacement (SR) is a simple operation that randomly chooses some non-stop words from the sentence and replaces them with one of their synonyms chosen at random. We applied *wordnet* database from *nltk* library to identify synonyms of a given word within the paragraph Miller (1995). As SR is a lightweight and efficient way of performing DA, we tried to replace 1 to 3 words at a time to create diverse PCL samples. Table 1 illustrates scores achieved by training $RoBERTa_{Large}$ model on the augmented dataset. Regardless of the approach taken, the model performance did not spike as expected. As shown later, this approach has been mixed with other text augmentation methods in training models.

3.2 Oversampling

Since containing PCL samples are underrepresented, we considered oversampling (OS) Paduraru and Breaban (2019). Oversampling randomly duplicates data in the minority class by a factor of 8 and adds them to the PCL training dataset, so the number of samples in each class becomes almost equal. The performance of the training pre-trained model with augmented training data by far exceeded the baseline result. (See Table 1)

3.3 Back Translation

We applied back translation (BT) to treat the problem of underrepresented class and boost model performance. In this case, we used a powerful augmenter method of BT in *nlpaug* library and *FairSeqMachineTranslation* Wang et al. (2020) model from *HuggingFace* [3] Transformers. The aim was to generate more PCL samples and then train model on the true distribution. BT translates all PCL samples from English to German, then translates the previously translated text back into the source language. We reused our best-performing model on OS and SR methods. However, later experiments showed that this technique led the model heavily to overfit the augmented training data (Figure 3).

[3] https://huggingface.co/docs/transformers/model_doc/fsmt

Note that we did no model validation using augmented data but did training with a mixture of OS, SR, and BT approaches. Although the improvement offered by BT is not so intelligible, statistical analysis is remarkable. The results are shown in Table 1.

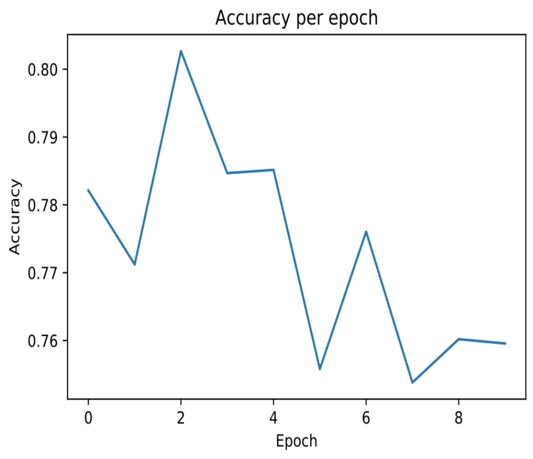

Figure 3: 80% F1-score was achieved at epoch 3. We can see a clear sign of overfitting after this epoch.

3.4 PEGASUS Paraphrasing

Paraphrase generation was the last effort in DA. Paraphrase generation models (in an encoder-decoder form) learn to reconstruct the input using different words and retaining the same meaning while paraphrasing. Paraphrasing can act as a regularizer and reduce the overfitting during the training process Fu et al. (2020).

To leverage PCL dataset efficiently, we performed paragraph paraphrasing along with SR to come up with a less imbalanced dataset. PEGASUS (Pre-training with Extracted Gap-sentences for Abstractive Summarization) Zhang et al. (2020) is a self-supervised Transformer model that masks important sentences from the input and then generates them as one output sequence from the remaining sentences.

The original PEGASUS is limited by the length of text and does truncation on long texts input. The maximum length of PCL paragraphs is 5493 tokens, while the longest input of original PEGASUS model can be 60 tokens. Therefore, we need to handle the limitation of Transformers on the size of the text while training Liu et al. (2019). We proposed an algorithm, multi-sentence PEGASUS, to modify PEGASUS model for arbitrarily long document paraphrasing. This algorithm separates each paragraph into sentences, and then multi-sentence PEGASUS generates ten paraphrased sentences from each individual sentence. The main challenge is to retrieve the original paragraph, because the number of paraphrased sentences for each paragraph was different due to different number of sentences in each sample data. This algorithm can concatenate paraphrased sentences to get the original paragraph in efficient time (The implementation is available at our GitHub). Multi-sentence PEGASUS generates a new dataset containing PCL paragraph over ten times larger than the original containing PCL training data. The following example is a containing PCL data and its corresponding paraphrased context:

Original Paragraph: Shepherding in America has always been an immigrant's job, too dirty, too cold and too lonely for anyone with options.

PEGASUS Paraphrased: In America, shepherding has always been an immigrant's job, dirty, cold, and lonely.

After multi-sentence PEGASUS paraphrasing, two words in each generated text are replaced by their respective synonyms from *wordnet* corpus. The hyper-parameters values for PEGASUS model have been selected by trial and error. We set a number of times the model searches for the most optimal follow-up word within the text to 10 and played with the parameter that regulates the chances of appearance of high/low probability words.

4 Model Description

Our system is based on pre-trained transformers models on the augmented PCL dataset. We focused on exploiting superior performance of *RoBERTa* and *GPT3* models.

4.1 Fine-tuning RoBERTa

To simulate the baseline result, we first did regular fine-tuning *RoBERTa* for each PCL task on the concatenated features of dataset (keyword and paragraph). Submitted systems on the SemEval-2022 leaderboard were evaluated on the F1-score metric. The (73%) F1-score was achieved by training the model with parameter values of $1e-5, 2, 400$ for learning rate, number of epochs, and warm-up steps, respectively while the baseline is 70.63% (See Table 1).

For the next step, we fine-tuned *RoBERTa* on the augmented datasets via each method mentioned

Models	Original Dataset	SR	OS	BT	Peg	SR/Peg	SR/OS/BT/Peg
Task1 $RoBERTa_{Large}$	73%	73%	79%	73%	76%	77%	81%
Task2 $RoBERTa_{Large}$	32%						57%

Hyper-parameters	LR	WS	Epoch
	{1e-5, 5e-6}	{400, 800, 3000, 4000}	{1, 2, 4, 8, 10}

Models	labels	precision	recall	f1-score	support	accuracy
Task1 $GPT3/Curie$	0	61%	22%	32%	50	
	1	52%	86%	65%	50	54%
Task1 $GPT3/Davinci$	0	58%	30%	39%	50	
	1	53%	78%	63%	50	54%

Table 1: Peg stands for PEGASUS paraphrasing. The training *RoBERTa* on the extra enriched dataset (SR/OS/BT/Peg) outperforms other DA methods. The learning process is controlled by setting hyper-parameters (Learning Rate (LR), Warm-up Steps (WS), and Number of Epochs) in the defined range. *GPT3* model with *Davinci* and *Curie* engines yield good performance with small subset of PCL training dataset. Support parameter indicates the number of queries which is the same for both models. 100 queries in total, and 50 queries for each label.

in Section 3, separately. Moreover, we took pre-trained *RoBERTa* and retrained on the extra enriched PCL dataset, which was boosted by a combination of three DA previously explained methods. Same as regular fine-tuning *RoBERTa*, we fed concatenation of keyword and paragraph with $RoBERTa$ special token "</s>" to the model and hyper-parameters are defined in Table 1. Augmented PCL dataset with SR and BT methods led to lower performance of our system compared to a mix of all described DA approaches. Using all DA methods together boosted the model performance to 81%. Figure 3 shows the accuracy of the model in each epoch, and it hits 81% F1-score at epoch 3, and then model start overfitting later. Our system trained and evaluated on the training dataset.

For multi-label classification, the trained *RoBERTa* model on the extra enriched dataset outperformed (57%) the same model trained on the original dataset (32%). However, the model's performance on the test dataset released in the post-evaluation phase was not the same. It is worth mentioning that the F1-average of the winning system (46%) for multi-lable classification task was not better than the random guess model.

4.2 GPT-3 Davinci and Curie

Limitation in the amount of available labeled data can be rectified with Few-Shot Learning technique by providing a few examples at inference time with a large language model. OpenAI *GPT3* Brown et al. (2020) language model uses this technique and also can be applied to PCL binary classification task. *GPT3* has been trained on a huge text dataset from the open internet with billions of parameters.

In this scheme, we considered two offered models of *GPT3* with different capabilities and price points. *Davinci* is the most capable in understanding the intent of a text, the motives of characters, and also the expensive engine. Also, *Curie* is quite faster and lower cost than *Davinci* and capable of tasks like sentiment classification.

We tried both models with Few-Shot learning technique by feeding the model a small amount of PCL training data (with an equal number of labels) as a prompt. The labeled examples were uploaded as a JSON file to OpenAI API for the purpose of classification. *Davinci* and *Curie* leverage a few labeled sets of examples without fine-tuning and enable to understand previously unseen data. We queried the model with a subset of training data to predict the most likely label for each query. In fact, *Davinci* and *Curie* engine classify specified queries using provided labeled data in a JSON file. These engines first search over the labeled data to select the most relevant for a particular query. Our implemented code is publicly available [4].

Table 1 illustrates the performance of *Davinci* and *Curie* models. OpenAI *GPT3* prices are per tokens. Therefore, we just prompted *Davinci* and *Curie* by 1000 and 200 labeled data, respectively. They were evaluated on F1-score with 100 queries of even class distribution. Surprisingly, both models perform well without hyper-parameter tuning and on just a few examples of PCL. *Davinci*'s performance was the same as *Curie*'s result but with

[4]https://github.com/daniel-saeedi/PCL_Detection_SemEval2022

five times fewer labeled examples. OpenAI API offers the ability to fine-tune their model on the desired task, which is quite costly and time-intensive. An interesting future research direction can be exploring GPT3 applications for PCL detection and multi-label classification tasks, regardless of the cost to train the model.

5 Conclusion

This paper presented a system description for PCL detection and multi-label categorization tasks. Our exploratory data analysis revealed annotated PCL dataset is highly imbalanced. We enhanced data quality with a combination of data augmentation methods. We presented a modified version of sentence paraphrasing deep learning model, Multi-sentence PEGASUS, to tackle the limitation of maximum sequence length. The proposed algorithm has no specific maximum input length to paraphrase sequences. We evaluated the performance of the large pre-trained RoBERTa model on the extra enriched PCL dataset. We boosted the baseline performance and achieved competitive results among the top-16 SemEval-2022 participants. Furthermore, we tried two models of GPT3, *Davinci* and *Curie* with Few-Shot learning technique. Our investigation showed both models perform well without hyper-parameter tuning and on just a few examples of PCL. We believe these tasks have many potentials and challenges to further improve current results.

Abstract

This paper details our implementations for finding Patronizing and Condescending Language in texts, as part of the SemEval Workshop Task 4. We have used a variety of methods from simple machine learning algorithms applied on bag of words, all the way to BERT models, in order to solve the binary classification and the multi-label multi-class classification.

1 Introduction

The Patronizing and Condescending Language Detection Task (Pérez-Almendros et al., 2022) is based on the paper Don't Patronize Me! (P'erez-Almendros et al., 2020), which is an annotated Dataset with Patronizing and Condescending Language Towards Vulnerable Communities.

The aim of this task is to identify PCL, and to categorize the language used to express it, specifically when referring to communities identified as being vulnerable to unfair treatment in the media.

Participants were provided with sentences in context (paragraphs), extracted from news articles, in which one or several predefined vulnerable communities are mentioned. The challenge is divided into two subtasks.

1. Subtask 1: Binary classification. Given a paragraph, a system must predict whether or not it contains any form of PCL.
2. Subtask 2: Given a paragraph, a system must identify which PCL categories express the condescension. The PCL taxonomy was defined based on previous works on PCL (i.e. Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier.)

2 Background

The dataset used for this SemEval 2022 task was Don't Patronize Me! (P'erez-Almendros et al., 2020), which contains a suite of sentences that mention some vulnerable communities and published in media in a lot of English speaking countries. The paragraphs were manually annotated to show 1) whether the text contains any kind of PCL, and 2) if it contains PCL, what linguistic techniques (categories) are used to express the condescension. The paragraphs, according to (P'erez-Almendros et al., 2020), were extracted from News on Web (NoW) corpus (Davies, 2013), being annotated by three expert annotators, with backgrounds in communication, media and data science.

The dataset for subtask 1 (binary classification) contained a number of 10.636 paragraphs and 2.792 instances were used for the categories classification subtask.

In Figure 1, it can be seen that for the first subtask, there are almost 1000 texts that contain PCL. This means that the dataset is highly imbalanced and this problem needs to be addressed.

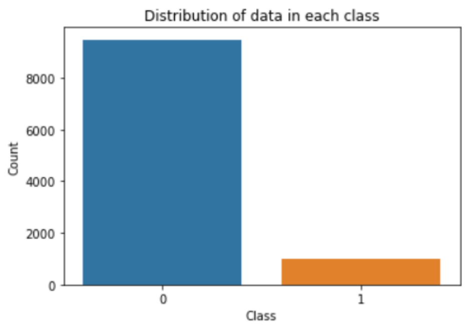

Figure 1: Classes Distribution for Binary Classification problem (Subtask 1)

For task 2, the paragraphs from task 1 are split according to the type of PCL speech category into sentences, resulting in 950 samples.

3 System Overview

1. Subtask 1 (Binary Classification)

   Because the dataset was very imbalanced, we tried different approaches in order to make it balanced:

- Adding a class weight to the models used. In this approach, we computed a metric in which we obtained a class weight according to the imbalance of the dataset. Through this method, we gave some different weights to both the majority and minority classes. This whole process had the purpose to penalize the miss classification made by the minority class by setting a higher class weight and at the same time, reducing the weight for the majority class.
- Using oversampling methods and special ensemble techniques. In this approach, we used methods like SMOTE (Synthetic Minority Over-sampling Technique) (Chawla et al., 2002), Adasyn (Adaptive Synthetic) (He et al., 2008), SVM-SMOTE (Mathew et al., 2015) and SPE (Self-Paced Ensemble) (Liu et al., 2020) that performs strictly balanced under-sampling in each iteration, being very efficient computationally.
- Augmenting the data. Because we notice so little data for label 1, we decided to collect hate speech datasets from Kaggle[1] and add the positive texts into our dataset in order to balance the classes frequency, obtaining a total of 6372 from 795 initial texts with label 1. We will notice in the results section that this collection and generation of new dataset did not provide good results.

The dataset was preprocessed. The preprocessing consisted in: clearing the special characters, lowercasing, tokenization, stopwords removal, removing the words shorter than 3 characters. Then, the resulted (and clean) dataset was split into two preprocessed types: lemmatized cleaned dataset and stemmed cleaned dataset. These two datasets were generated in order to make some comparison between those two techniques and to see which provided the best results.

To extract features from text, we have used TF-IDF (Sammut and Webb, 2010), Keras Tokenizer[2], Word2Vec with Skip-Gram (Mikolov et al., 2013) and, finally, Bert Tokenizer provided by Hugging Face (Wolf et al., 2019).

We have also used a variety of models such as Neural Networks with 3 dense layers, Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) with 64 and 128 neurons with dropout of 0.1 as well, basic Machine Learning algorithms like Logistic Regression, Random Forest, Support Vector Machines as XGBoost. In the end, we decided to try BERT embeddings and a BERT classification model, BertForSequenceClassification [3], that contains a single linear classification layer on top and that provided the best results after all of the other approaches.

Another approach, called "Text shards" made use of the subtask related to multi-class classification as well. For an average text that contains PCL, only some small pieces of them are actually PCL and the rest of the text are not. The assumption is that this confuses the model, because a combination of PCL and non-PCL is labeled as PCL. To address this, the following approach is used:

- negative examples are left as they are
- each positive example is replaced with the actual pieces of PCL inside it that we can get from the categories file
- the positive examples obtained this way are added with the negative examples to obtain a training dataset
- all the sentences are cleaned of characters that are not letters and the words in each sentence are lemmatized
- a Tensorflow Hub pretrained model called Universal Sentence Encoder (Cer et al., 2018) is trained on it
- for each text that we want to predict, we first use the model on the whole text to get an initial label
- a window (of the size of the average length of a cleaned PCL fragment * 2) is slided through the text and the model is used to predict that particular substring. If it is labeled as PCL, then we consider the whole text as PCL.

2. Subtask 2 (Multi-label Multi-class Classification)

[1]Hate Speech datasets
[2]Tokenizer method brought by Keras
[3]Bert for Sequence Classification

Considering the fact that the vocabulary of the is English is large, we have tried to leverage the power of pretrained language models. Therefore we have chosen 3 BERT-based models which were pretrained for hate speech detection and sentiment analysis. The BERT models also provided a tokenizer which split the sentences into tokens and appended the required tokens. The BERT models are used from the transformers library (Wolf et al., 2019).

- BERT (Devlin et al., 2018) Uncased
- BERT Multilingual Uncased
- BERT HateXplain (Mathew et al., 2020): This model was trained to classify text as Hate speech, Offensive or Normal. It was trained on Gab, Twitter and Humain Rationale;
- Distil BERT : This model is a version of Distilled BERT finetuned on the Twitter dataset;
- Distil BERT Multilingual Cased (Sanh et al., 2019)
- Distill RoBERTa : This model is a version of Distilled RoBERTa finetuned on the Twitter dataset;

In the paper describing the dataset (P'erez-Almendros et al., 2020), the authors group the categories into 3 General categories.

(a) The saviour: Unbalanced power relations and Shallow relations
(b) The Expert: Presupposition and Authority voice
(c) The Poet: Compassion, Metaphor and The poorer the merrier

From this idea, we tried to train the models to predict those 3 categories, and save the hidden features to a fixed latent space. Then these learned features can be used when training the model to predict the required 7 sub-classes.

Along with those BERT-based model, we also tried to implement models based on Word2Vec (Mikolov et al., 2013) (trained on "Google News") and Machine Learning algorithms based on TF-IDF and BOW:

- LSTM Word2Vec Embeddings (Staudemeyer and Morris, 2019)
- BiLSTM Word2Vec Embeddings (Huang et al., 2015)
- RNN Word2Vec Embeddings (Sherstinsky, 2020)
- SVM TF-IDF
- RandomForest TF-IDF

We also dabbled with the thought of training our own Word2Vec, in order to create a model specialized on hate speech. However we decided against this idea, due to the lack of usable datasets and the computational resources required for this task.

4 Results

1. Subtask 1 (Binary Classification)

   Since we experimented with various techniques and approaches, we decided to split the results based on the experiments made.

   (a) Deep Learning / Machine Learning for Imbalanced and Oversampled dataset
   In table 1, we can notice the results provided by classical Machine Learning algorithms and 3-layer Neural Networks (512, 256 and 128 layers with ReLU activation and using class weight for providing accurate performance in terms of data imbalance) on 4 types of datasets: the original dataset (without proceeding to class balance, but using class weights for controlling the class weights), Random Forest with Self-Paced Ensemble Bootstrap technique (SPE), SMOTE and SVM-SMOTE.
   Logistic Regression gave solid results on all variations of the datasets, providing an *f1_score* of 0.35 on lemmatized dataset and 0.38 on stemmed validation dataset. Neural Networks provided as well good results, but did not manage to obtain the performance of Logistic Regression. We could infer from the tables that Logistic Regression gave the best performance on stemmed dataset.

   (b) Keras Tokenizer & Word2Vec Embeddings + LSTM neural network
   Another experiment that we conducted was the use of Keras Tokenizer and Word2Vec in order to extract the embeddings from the texts. We then applied

Approach \ Dataset	Simple	SPE	SMOTE	SVM-SMOTE
Neural Networks	0.27	-	0.2823	0.3187
Logistic Regression	**0.34**	-	**0.35**	**0.35**
Random Forest	0.067	0.31	0.19	0.16
Support Vector Machines	0.27	-	0.10	0.14
XGBoost	0.15	-	0.23	0.24

(a) Results on Imbalanced and Oversampled Lemmatized dataset

Approach \ Dataset	Simple	SPE	SMOTE	SVM-SMOTE
Neural Networks	0.2698	-	0.289	0.3166
Logistic Regression	**0.35**	-	**0.38**	**0.37**
Random Forest	0.038	0.31	0.21	0.13
Support Vector Machines	0.27	-	0.14	0.20
XGBoost	0.17	-	0.23	0.24

(b) Results on Imbalanced and Oversampled Stemmed dataset

Table 1: Results on Imbalanced and Oversampled Lemmatized & Stemmed dataset. The results are in terms of *f1_score*.

Approach \ Dataset	Augmented dataset
Neural Networks	0.2155
Logistic Regression	0.23
U.S.E. + 2 dense layers	**0.2316**

Table 2: Results on Augmented dataset.

two LSTM models: one with 64 neurons and the other one with 128 neurons.

The results of these two models on both Lemmatized & Stemmed datasets with two variations of created embeddings (Keras Tokenizer and Word2Vec) are provided in table 3. LSTM with 64 neurons provided best results on the datasets that were using the default Tokenizer from Keras, with an f1_score of almost 27% on Lemmatized dataset and 32& on Stemmed dataset. Word2Vec did not seem to provide good results in combination with LSTM networks.

(c) Data augmentation

As we discussed in the previous section, we augmented the data by using the positive texts from different hate speech datasets from Kaggle and adding to our dataset. We then applied TF-IDF vectorizer with 5000 features and fed the embeddings into a 3-layer Neural Network (512, 256 and 128 neurons) and to a Logistic Regression model. Another method used was Universal Sentence Encoder (U.S.E. annotated in table) + 2 dense layers of 128 and 64 neurons.

The results are present in table 2. We can infer that the third method provided the best results, but still insufficient to reach the level and performance of Logistic Regression from (a).

(d) BERT Transformers + BertForSequenceClassification

For Bert Transformers, we obtained a performance of **0.5074**, the best result provided among all of the other models and techniques. This performance was obtained by using Bert Tokenizer for encoding the entire texts, calculating the class weight and providing it to a BERT-base-uncased model with AdamW as optimizer (learning rate of $2e-5$) and 3 epochs for training. The total training time took 2 hours.

(e) Text shards

For "Text shards" approach, we obtained an F1 score of 0.3117.

Overall, for the first subtask, we obtained the best performance using BERT Transformers and fine-tuning a BERT model with an F1 score of 0.5074. The second best-performing algorithm was, surprisingly, Logistic Regression, that provided 0.38 on SMOTE oversampled dataset.

2. Subtask 2 (Multi-label Multi-class Classification)

(a) BERT models approach for classification across 7 classes. Table 4a shows that the model was able to learn only two of the classes. The best model, DistilBERT, obtains F1 score of 0.34.

Approach \ Dataset	Keras Tokenizer	Word2Vec
LSTM (64 neurons)	**0.2693**	0.2109
LSTM (128 neurons)	**0.2317**	0.2308

(a) Results on Lemmatized dataset with class weight

Approach \ Dataset	Keras Tokenizer	Word2Vec
LSTM (64 neurons)	**0.3213**	**0.2093**
LSTM (128 neurons)	0.2789	0.2412

(b) Results on Stemmed dataset with class weight

Table 3: Results on Lemmatized & Stemmed datasets using Keras Tokenizer and Word2Vec as word embeddings. The results are in terms of *f1_score*.

Model \ Class	Unb	Sha	Pre	Aut	Met	Com	Mer	Mean
BERT	0.82	0.0	0.0	0.0	0.0	0.0	0.64	0.21
DistilRoBERTa	0.83	0.0	0.0	0.0	0.0	0.0	0.59	0.20
DistilBERT	0.82	0.0	0.0	0.0	0.66	0.08	0.0	**0.34**

(a) Results of transformers trained directly on 7 classes

Model \ Sub-classes	*Expert*	Aut	Pre	*Saviour*	Sha	Unb	*Poet*	Com	Mer	Met	Mean
BERT	0.44	0.0	0.0	0.85	0.0	0.84	0.69	0.0	0.0	0.59	0.20
DistilRoBERTa	0.54	0.0	0.0	0.85	0.0	0.84	0.69	0.11	0.0	0.65	0.22
DistilBERT	0.42	0.0	0.40	0.75	0.0	0.81	0.61	0.0	0.0	0.67	**0.26**
DistilBERTMLC	0.36	0.0	0.0	0.86	0.0	0.83	0.60	0.0	0.0	0.52	0.19

(b) Results of transformers that were trained on 3 general classes, then finetuned for the desired 7 classes

Table 4: Transformer Results

(b) The general class approach is detailed in table 4b, where the general classes are italicized. It shows that the general classes were learned, but when using the pretrained models and fine-tuning on the specific classes, some of previously learned features are lost. The best results it obtained yet again by the DistilBERT model with an F1 score of .26.

5 Conclusion

In this paper, we presented our solution to the problem posed by SemEval 2022 Task 4: Patronizing and Condescending Language Detection. We applied various methods, including the application of Word Embedings (Bag of Words, Word2Vec, BERT), tokenization, oversampling/undersampling of the datasets.

In the binary classification problem, the approach that gave the best result on the validation dataset was BERT transformers combined with BERT for Sequence Classification, obtaining 0.50 as F1 score, followed by Logistic Regression applied on stemmed SMOTE dataset with a performance of 0.38.

In the multi classification multi label task, the number of labels proved to be a challenge. The results overall are low and the models were only able to learn only a few classes. The general class approach also proved to be inefficient. Perhaps a more suitable approach would be to build more complex models and use models that do not rely on specific pretrained approaches.

Some recommendations for future work could be to have a better approach and introduce more linguistic insight in the approach.

Acknowledgements

We would like to thank our supervisor Ana-Sabina Uban for the guidance and throughout the development of the project.

Abstract

This paper narrates the work of the team Amrita_CEN for the shared task on Patronizing and Condescending Language Detection at SemEval 2022. We implemented machine learning algorithms such as Support Vector Machine (SVM), Logistic regression, Naive Bayes, XG Boost and Random Forest for modelling the tasks. At the same time, we also applied a feature engineering method to solve the class imbalance problem with respect to training data. Among all the models, the logistic regression model outperformed all other models and we have submitted results based upon the same.

1 Introduction

Discriminatory language on the social media is lately creating hostile environment towards the vulnerable communities especially women and minorities. These are reflected in day to day conversations happening on popular social media sites. It is a high time now to build a technological solution to counter the discrimination against vulnerable communities. Here in this task, we consider one such issue known as "Patronizing and Condescending Language (PCL) Detection". When someone's language conveys a pompous attitude toward others or portrays them or their circumstances in a compassionate manner, eliciting feelings of sympathy and compassion, they are patronising or condescending. This is why it is important to develop a computational model to predict whether there is patronizing content in social media or not (Pérez-Almendros et al., 2020). This challenge can be solved by the applying Natural Language Processing (NLP) concepts. The Social media platforms reaches a huge audience, which might contribute to increased exclusion and inequity among vulnerable groups. Despite the fact that harmful language behaviour (such as hate speech, abusive language, fake news, rumour propagation, or disinformation) (Sreelakshmi et al., 2020), (Sreelakshmi et al., 2021) has been extensively investigated in NLP, PCL has remained a neglected field of research.

We implemented seven machine learning models which include three classical machine learning algorithms and four ensemble models: Support Vector Machine (SVM), Logistic regression, Naive Bayes, XG Boost and Random Forest for modelling the tasks (Soman et al., 2009), (Premjith et al., 2019), (Premjith and Kp, 2020). The class imbalance problem was dealt by a minority oversampling technique called SMOTE and comparative analysis of our algorithm was done by various evaluation metrics such as precision, recall and F1 score.

The remaining parts of the paper are described as follows: Section 2 contains dataset description along with works related to that. Section 3 describes the system overview. Section 4 explains the experimental setup. Section 5 discusses result and the paper is concluded in Section 6.

2 Related works

This section provides a brief review of the literature published for the detection of various offensive and abusive contents pertained to violence, cyberbullying etc. shared on the social media.

Adithya et.al (Bohra et al., 2018) analysed the hate speech data in code-mixed form and proposed classification models for the detection. They created a dataset consisting of Hindi-English code-mixed tweets. Machine learning algorithms like SVM, Random forest were used for the classification of tweets into different categories. Conroy et.al (Rubin et al., 2016) reported the problem of fake news detection in their paper and their study offered a classification of different types of truthfulness evaluation methods that fall into two categories: linguistic cue with machine learning and network analysis approaches. Zampieri et al (Zampieri et al., 2019) predicted the nature and victim of offensive content shared on social media. They used the Offensive Language Identification Dataset (OLID) for the analysis. They compared the performance of different machine learning models on this dataset. Wang and Potts (Wang and Potts, 2019) used a corpus called TALKDOWN for detecting the condescension in a text by incorporating the context. The dataset consist of annotated social media messages. They explored the issue of modelling condescension in direct communication from an NLP perspective. They used BERT-based models for developing the baseline models.

3 Task and Data Description

3.1 Task1

The competition mainly consisted of 2 sub tasks (Pérez-Almendros et al., 2022). The objective of the subtask 1 is to develop a model, which could predict whether a given paragraph contain condescension or not, which is a binary classification problem. The dataset used for subtask 1 consists of 10469 paragraphs. Each of the paragraphs describes the people belonging to vulnerable social categories. It contains excerpts from news items from 20 English-speaking nations that feature at least one of the following terms relating to potentially weaker sections of the society: vulnerable or women, refugee, hopeless, migrant, immigrant, in need, homeless, poor families, disabled, with Patronizing and Condescending Language (PCL) comments.

3.2 Task2

The objective of the subtask 2 is to develop a model, which could predict whether a given paragraph comes under any of the top 7 PCL taxonomies namely, Unbalanced power relations, Shallow solution, Presupposition, Authority voice, Metaphor, Compassion, The poorer, the merrier, which is a multi-label classification problem. The dataset used for subtask 2 consists of 993 paragraphs. Each of the paragraphs describes the people belonging to vulnerable social categories. It contains excerpts from news items from 20 English-speaking nations that feature at least one of the following terms relating to potentially weaker sections of the society: vulnerable or women, refugee, hopeless, migrant, immigrant, in need, homeless, poor families, disabled, with Patronizing and Condescending Language (PCL) comments.

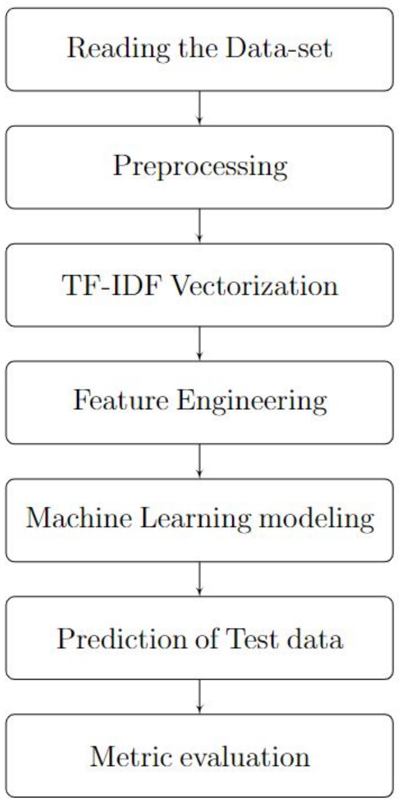

Figure 1: Flowgraph of the methodology

4 System Overview

This section discusses the procedure followed for developing models for each subtasks in completion. Figure 1 represents the block diagram of the workflow of the methodology.

This section explains the steps followed for developing models for the PCL shared tasks.

4.1 Preprocessing

Initially, we cleaned the data by removing stopwords, URLs and special characters. The cleaned texts were tokenized and lemmatized to obtain the root form of the word. It helped to reduce the vocabulary in the corpus, which further reduce the dimension of the sentence vector obtained using Term Frequency-Inverse Document Frequency (TF-IDF) vectorizer algorithm.

4.2 Feature Engineering

We represented the textual data as vectors using TF-IDF for the further processing. In addition to that, we employed SMOTE (SMOTE: Synthetic Minority Over-sampling Technique) (Chawla et al., 2002), an oversampling algorithm to address the problem of class imbalance in the data. The

SMOTE algorithms synthetically generates random data for the minority classes to increase the size of the minority classes. It is done by selecting one or more of random k-nearest neighbour for each minority instances. We employed SMOTE after converting texts into vector using Term Frequency-Inverse Document Frequency vectorizer algorithm.

4.3 Machine Learning modelling

The dataset for subtask 1 consists of total 10469 instances and for subtask 2 it is 993 instances. We considered a train-test split ratio of 80:20. The parameter stratify was used for the purpose of making a split so that the share of values in the sample produced will be the equal to the proportion of values provide to parameter stratify. For prediction, we have a total of 2094 test instances in which 1895 belongs to class 0 and 199 belonging to class 1 in subtask 1 and 198 test instances. For logistic regression model, hyper parameter tuning was done using sklearn's GridSearchCV function [1]. The parameters that was given for tuning was penalty $=l1, l2$ and value of $C = array([0.01, 0.1, 1, 10, 100])$. After hyperparameter tuning using GridSearchCV, the best parameters were found to be $C(regularization\_term) = 10$ and $Penalty = l2$. For subtask 2, we set the class_weight hyperpaameter to be 'Balanced'. To predict the multi-label output, we used the 'MultiOutputClassifier' function from Scikit-learn [2]. For models other than logistic regression, we used default parameters available in Scikit-learn for classification.

4.4 Evaluation

The evaluation measures used for this work were macro average F1,precision and recall. Recall is ratio of correct positive predictions to the total number of positives and Precision is ratio of correct positive predictions to the total number of positive predictions. F1 score is the harmonic mean of precision and recall. Macro average is defined as the average of precision, recall, F1 score on different classes.

5 Results

In both the sub tasks we used three classical ML models and four ensemble techniques for classification. The three ML models were logistic regression ,SVM and DecisionTreeClassifier and the ensemble techniques were Bagging classifier, Random forest, GradientBoost and XGBoost. Validation dataset was used to get a comparative analysis of our algorithm. In this analysis we used evaluation metrics such as precision, recall and F1 score. The official evaluation metric was F1 score for positive class for subtask 1. For the validation dataset an F1 score of 0.41 was achieved for positive class and in case of test dataset an F1 score of 0.39 was obtained and our final rank for subtask 1 in the competition was 60. For subtask 2 we got a macro_average F1 score of 0.45 during the post evaluation phase.

Model	Recall	Precision	F1
Log Reg	0.73	0.64	0.66
SVM	0.53	0.75	0.53
Dec Tree	0.57	0.57	0.57
Bagging	0.54	0.61	0.55
Random For	0.51	0.64	0.49
GradBoost	0.53	0.75	0.54
XGBoost	0.56	0.68	0.58

Table 1: Comparitive analysis of our ML models for subtask 1 considering macro averages

Model	Recall	Precision	F1
Log Reg	0.48	0.45	0.45
SVM	0.30	0.58	0.32
Dec Tree	0.35	0.36	0.35
Bagging	0.29	0.41	0.33
Random For	0.27	0.56	0.31
GradBoost	0.28	0.45	0.32
XGBoost	0.33	0.47	0.36

Table 2: Comparitive analysis of our ML models for subtask 2 considering macro averages

From the Tables 1 and 2 we can clearly see that the macro F1 score of Logistic regression stood out among all the other models. Moreover the execution time for logistic regression was less compared to other models especially the ensemble techniques. Hence this model was used for the final prediction of the test dataset.

6 Conclusion

This paper narrates the work of Amrita_CEN with respect to SemEval 2022 Task 4 competition named " Patronizing and Condescending Language Detection ". A total of seven machine learning algorithms were used which include three classical ML models and four ensemble techniques. The problem

[1]GridSearchCV: `https://rb.gy/lajkio`
[2]MultiOutputClassifier: `https://rb.gy/52vpax`

of class imbalance was dealt with minority oversampling technique called SMOTE. Considering macro F1 score for both the sub tasks, logistic regression performed the best and the results were submitted using the same model. Coming to the future work, implementation using deep learning and BERT approaches can give better results compared to classical machine learning models.

7 Acknowledgements

With the invaluable guidance of our faculty Dr Sowmya V, this work and the research has been feasible. Her constant guidance, attitude of perfection and passion of detailing were an inspiration and helped us to achieve our objective.

Abstract

This paper describes our submissions to SemEval-2022 subtask 4-A - "Patronizing and Condescending Language Detection: Binary Classification". We developed different models for this subtask. We applied 11 supervised machine learning methods and 9 pre-processing methods. Our best submission was a model we built with BertForSequenceClassification. Our experiments indicate that pre-processing stage is a must for a successful model. The dataset for Subtask 1 is highly imbalanced. The F1-scores on the oversampled imbalanced training dataset were higher than the results on the original training dataset.

1 Introduction

The explosion of social media in recent years also enables an increasing the number of patronizing and condescending language (PCL). Patronizing language is best described as expressions that are agreeable and show kindness to a person or group in a condescending manner, indicating that the person or group is inferior (McCune and Matthews, 1978).

The discourse of condescension has three main characteristics: (1) It does not contain anything openly critical or negative, and often contains insincere praise; (2) it assumes a difference in status and worth between the writer and the person who wrote about him; and (3) this assumed difference is disputed by the listener (Huckin, 2002).

PCL can harm individuals or groups of people and may cause harmful effects on society. Therefore, it is important to develop efficient computerized systems capable of detecting PCL (Lo and Wei, 2006).

PCL detection is not a simple problem because it requires understanding the context of the situation, the relevant culture, and indirect clues. In social media texts, the problem is harder due to the different levels of ambiguities in natural language and the noisy nature of such texts.

In contrast to the offensive language or hate speech detection field, where there has been relatively an extensive research (e.g., Basile et al., 2019; Zampieri et al., 2019; Zampieri et al., 2020), PCL is still a relatively new and open field of study in Natural language processing (NLP) and machine learning (ML) (Pérez-Almendros et al., 2020).

Pérez-Almendros et al. (2020) introduced the Don't Patronize Me! Dataset. This dataset contains paragraphs extracted from news stories, which have been annotated to indicate the presence of PCL at the text span level.

This paper describes our research and participation in subtask 4-A for patronism detection in posts written in English. The full description of task 4 in general and 4-A, in particular, is given in Perez-Almendros et al. (2022).

The structure of the rest of the paper is as follows. Section 2 introduces a background concerning patronism detection, text pre-processing, and TC with imbalanced classes. Section 3 describes subtask 4-A and its training dataset. In Section 4, we present the submitted models and their experimental results. Section 5 summarizes and suggests ideas for future research.

2 Related Work

Various NLP methods have been applied in the detection of several types of harmful language such as offensive language or hate speech detection (Basile et al., 2019; Zampieri et al., 2019; Zampieri et al., 2020). Previous NLP tasks have generally focused on explicit, aggressive, and flagrant phenomena such as fake news detection (Conroy et al., 2015).

During the last three years, several studies on PCL have appeared. Wang and Potts (2019) introduced the task of modeling condescension and developed an annotated dataset of social media messages. Sap et al. (2019) discussed various implications behind certain uses of language. Mendelsohn et al. (2020) analyzed, from a computational linguistics viewpoint, how language has dehumanized minorities in media news.

2.1 Text preprocessing

Text preprocessing is an important step of TC in general and in social text documents in particular. Classification of text dataset that has not been carefully cleaned or preprocessed might lead to misleading results.

HaCohen-Kerner et al. (2019) investigated the impact of all possible combinations of six preprocessing methods (spelling correction, HTML tag removal, converting uppercase letters into lowercase letters, punctuation mark removal, reduction of repeated characters, and stopword removal) on TC in three benchmark mental disorder datasets. In another study, HaCohen-Kerner et al. (2020) explored the influence of various combinations of the same six basic preprocessing methods on TC in four general benchmark text corpora using a bag-of-words representation. The general conclusion was that it is always advisable to perform an extensive and systematic variety of preprocessing methods because it contributes to improving TC accuracy.

2.2 Text classification with imbalanced classes

The problem with TC with imbalanced classes is that there are too few examples of the minority class to effectively learn a good predictive TC model. There are various methods to cope with this problem (e.g., Liu et al., 2004). The main idea is to change the dataset until a more balanced distribution is reached. Two well-known sampling methods that enable such a change are oversampling and undersampling (e.g., Yap et al., 2014). Random oversampling means randomly duplicating examples in the minority class. Random undersampling means randomly deleting examples in the majority class.

An additional frequent method is to generate synthetic samples, which means randomly sampling the attributes from instances in the minority class (Zhu et al., 2017). There are several algorithms that support the generation of synthetic samples. The most popular one is called the Synthetic Minority Over-sampling Technique (SMOTE) (Chawla, 2002). This method is an oversampling method that creates synthetic samples from the minor class instead of creating copies. This method selects two or more similar instances and perturbs an instance one attribute at a time by a random amount within the difference to the similar instances.

Other possible methods are to try a variety of different types of machine learning (ML) methods in general and penalized variants of these methods that charge an additional cost on the model for making classification mistakes on the minority class during training.

Readers interested in expanding and deepening the topic of solutions to TC with imbalanced classes are referred to the following articles (Chawla et al., 2002; He and Ma, 2013; Krawczyk, 2016; Brownlee, 2020).

3 Task and Training Dataset Description

We only participated in subtask 4-A - “Patronizing and Condescending Language Detection: Binary Classification", which deals with the classification of each post as a patronizing or condescending language (PCL) or not in the English language. Table 1 presents various statistical details about the data set.

	not patronize	is patronize	total
Documents	9,476	993	10,469
% Docs	90.5	9.5	100
words	453,690	53,245	506,935
characters	2,514,890	286,435	2,801,325
avg word per doc	47.87	53.62	50.745
avg chars per doc	265.39	288.45	276.92
words std	32.77	28.62	30.695
chars std	158.36	175.52	166.94

Table 1: Details of the training set.

The analysis of the details presented in Table 1 shows that the dataset is highly imbalanced with a ratio of about 91:9 (not patronize: is patronize). We changed this rate to 77:23 by the creation of new partial 'patronized' posts extracted from various posts that belong to different categories of positive patronized labels available from TASK 6-2 (multi-label classification). We also evaluated an equal split (50:50) by duplication of the patronized sentences. However, the experimental results using the equal split lead to results that were lower than the results using unequal ratios. All the python code lines used for improving the ratio, preprocessing methods, and the different models are available on Github at https://github.com/meyrow/pcl-detection-task4-semeval2022.

4 The Submitted Models and Experimental Results

We applied 11 supervised ML methods to the training dataset. Seven of them were classical ML methods: Random Forest (RF), K Nearest Neighbours (KNN), Support Vector Classifier (SVC), XGBoost Classifier, Logistic Regression (LR), Decision Tree (DT), Naive Bayes (NB), and four of them were deep learning (DL) methods: Bert, DistilBert, Roberta, and Albert.

In our various models, we applied nine sub-types of preprocessing methods: remove newlines, remove HTML Tags, remove Links, remove White spaces, remove accented characters, conversion to lower-case, reduce repeated characters, and punctuations, expand contractions, and remove special characters.

These methods were applied using the following tools and information sources:

- The Python 3.7.3 programming language[1].
- Scikit-learn – a Python library for ML methods[2].
- Numpy – a Python library that provides fast algebraic calculous processing, especially for multidimensional objects[3].

In our experiments, we tried to find the best combination of ML method, preprocessing methods, and oversampling methods. The training set was split into 80:20 train: test and the training test was using 90 percent in every epoch to train and 10 percent of the training set was used for validation.

Figure 1 presents training and validation loss curves of our BERT model with 20 epochs showung that training and validation continuously improved themselves. We noticed that a gap between training and validation began to grow, therefore we had to stop the model after 20 epochs, otherwise, the model will be overfitted. Figures 2 and 3 present the confusion matrices of our BERT model with 20 epochs and the decision tree model, respectively. The confusion matrix of both models demonstrates that the dataset is imbalanced as shown in Table 1. We also noticed that the ratio of 77:23 after improving the original dataset is close to the ratio shown in the confusion matrix. That indicates that our models are well trained. To select the best model we compared the F1-score.

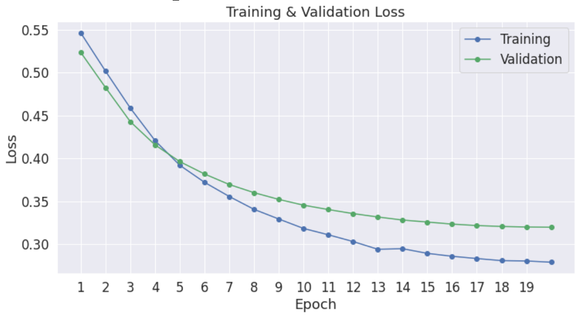

Figure 1: Training and validation loss curves of our BERT model with 20 epochs.

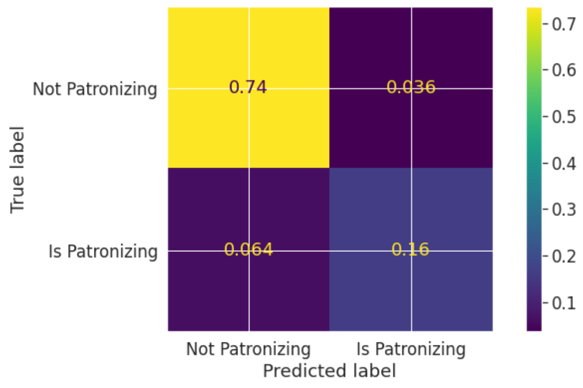

Figure 2: Confusion matrix of our BERT model with 20 epochs.

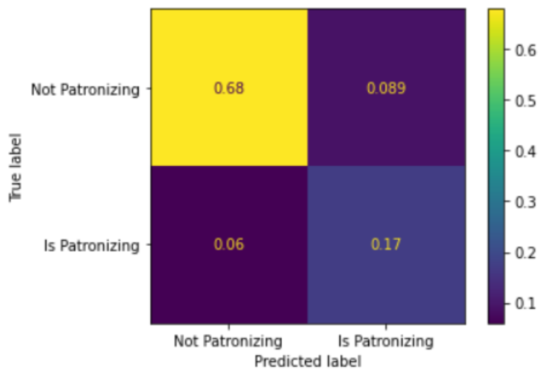

Figure 3: Confusion matrix of our Decision Tree model.

[1] https://www.python.org/downloads/release/python-373/

[2] https://scikit-learn.org/stable/index.html

[3] https://numpy.org

Our best submission was a model called Matan-bert that we built using a function called BertForSequenceClassification. This BERT model includes 768 layers. Its values of the learning rate, epsilon, number of epochs, and batch size were 2e-7, 1e-8, 20, and 16, respectively. This model was ranked the 62nd position. Its F1-score over the PCL class, precision, and recall results are 0.377, 0.3536, and 0.4038, respectively.

Table 2 presents the results of the submitted models. The F1-score over the PCL class on the training dataset of our best model was 0. 77 while the F1-score over the PCL class on the test dataset of our best model was only 0.377. Currently, the posts' labels of the test dataset are unknown. Therefore, we do not have any definite explanation(s) for such a large decrease in the results. Possible explanations might be: (1) The training dataset is different in its balance rate than the balance rate of the competition test dataset and (2) the content of a relatively high number of news items in the competition test dataset is fundamentally different from the content of the news in the training dataset.

Our code is available on Github at https://github.com/meyrow/pcl-detection-task4-semeval2022. Our models are available for reproducibility with comments that explain the code and parameters such as epsilon, learning rate batch, and epochs.

5 Conclusions and Future Research

In this paper, we describe our submissions to subtask 4-A of the SemEval-2022 contest. We submitted the models that achieved the best results while trying to choose two models that applied different supervised learning methods.

Future research ideas include (1) Acronym disambiguation that will extend and enrich the social text and might enable better classification (e.g., HaCohen-Kerner et al., 2008; HaCohen-Kerner et al., 2010A); (2) use of skip character n- to overcome problems such as noise and sparse data (HaCohen-Kerner et al., 2017); (3) use of stylistic feature sets (HaCohen-Kerner et al., 2010B) and key phrases that can be extracted from text files (HaCohen-Kerner et al., 2007).

Model Name	split mode	ML Method	Features	F1-score over the PCL class on the training dataset	F1-score over the PCL class on the test dataset
Matan_bert	80:20	BertForSequence Classification	Layers: 768 Learning rate: 2e-7 Epsilon: 1e-8 Epochs: 20 Batch-size: 16	0.77	0.377
Matan_ Decision_Tree	70:30	Decision Tree	criterion= 'entropy' random_state = 0	0.7	was not published

ULFRI at SemEval-2022 Task 4: Leveraging uncertainty and additional knowledge for patronizing and condescending language detection

Matej Klemen   **Marko Robnik-Šikonja**
University of Ljubljana, Faculty of Computer and Information Science
Večna pot 113, Ljubljana, Slovenia
{matej.klemen, marko.robnik}@fri.uni-lj.si

Abstract

We describe the ULFRI system used in the Subtask 1 of SemEval-2022 Task 4 Patronizing and condescending language detection. Our models are based on the RoBERTa model, modified in two ways: (1) by injecting additional knowledge (coreferences, named entities, dependency relations, and sentiment) and (2) by leveraging the task uncertainty by using soft labels, Monte Carlo dropout, and threshold optimization. We find that the injection of additional knowledge is not helpful but the uncertainty management mechanisms lead to small but consistent improvements. Our final system based on these findings achieves $F_1 = 0.575$ in the online evaluation, ranking 19th out of 78 systems.

1 Introduction

Despite invaluable contributions to the society, the internet can also serve as an infrastructure for a rapid spread of hurtful language, in part due to the anonymity it commonly provides (Burnap and Williams, 2015). The spread of such language can have a serious impact on individuals, such as the increased development of mental health problems in children (Munro, 2011). To prevent this, the society has to establish moderation mechanisms. Fully manual content moderation is infeasible both due to the large scale of the web as well as the possible negative psychological effects on human moderators (Arsht and Etcovitch, 2018). Much attention has been devoted to the automatic detection of offensive language within the field of natural language processing (NLP). Some examples include the detection of hate speech (Davidson et al., 2017), toxic language (Pavlopoulos et al., 2021), and cyberbullying (Dadvar et al., 2013), which use a relatively explicit form of hurtful language (Waseem et al., 2017). In contrast, patronizing and condescending language (PCL) is more implicit in nature. PCL can roughly be described as an expression of a superior attitude towards others, possibly unconsciously. Perez Almendros et al. (2020) have shown that large language models are able to detect PCL to a various degree, but consistently better than random guessing or a machine learning approach using the bag-of-words representation. Based on that, the authors propose SemEval-2022 Task 4 (Pérez-Almendros et al., 2022), which aims to encourage further research and improvements in the detection of PCL.

We present our attempts at modeling PCL, based on the RoBERTa model (Liu et al., 2019) and following two main lines:

1. **Injection of additional knowledge**. We experiment with the injection of additional knowledge on coreferences, named entities, dependency relations, and sentiment.

2. **Leveraging uncertainty present in the task**. We experiment with the use of soft labels in the form of the target label probability distribution, and with the Monte Carlo dropout as a means for more accurate estimation of the label posterior probability (Gal and Ghahramani, 2016).

Our first set of modifications aims to guide the model to better follow the definition of PCL. The additional coreference and named entity knowledge may help the model to focus on detecting an imbalance between entities in the text, while the dependency relations and sentiment knowledge may help the model discover more subtle linguistic patterns used in PCL. We inject different forms of knowledge as the second input sequence to the model, combining it with the primary text representation during training of the PCL detector. This is motivated by the Factored Transformer (Armengol-Estapé et al., 2021).

The second set of modifications aims to capture the subjectivity and uncertainty that is inherently present in the task and is reflected in the annotator disagreement. This is motivated by the data perspectivism paradigm (Basile et al., 2021) which argues the disagreements are not necessarily errors.

We participate in Subtask 1, and our best model ranks 19th out of 78 systems[1]. In our analysis, we find that (1) injection of additional knowledge does not increase the F_1 score significantly and (2) leveraging uncertainty in the task leads to small but consistent increase in the F_1 score.

The remainder of the paper is structured as follows. In Section 2, we describe the details of the task. In Section 3, we describe our approach, and analyze its performance in Section 4. In Section 5, we summarize our work and provide ideas for further work.

2 Task Description

Given an updated version of the *Don't Patronize Me!* dataset (Perez Almendros et al., 2020), the goal of SemEval-2022 Task 4 Subtask 1 is the detection of patronizing and condescending language (PCL). The provided dataset consists of 10 469 paragraphs annotated by three annotators: two were tasked with annotating the examples as not containing PCL (0), containing PCL (2), or borderline (1). The third annotator resolved *complete* disagreements, i.e. examples annotated as $\{0, 2\}$ by the two annotators. The annotations are aggregated into a five-point fine-grained class y_F:

- $y_F = 0$ if both annotators assigned the label 0,
- $y_F = 1$ if one annotator assigned the label 0 and the other assigned 1,
- $y_F = 2$ if both annotators assigned the label 1,
- $y_F = 3$ if one annotator assigned the label 2 and the other assigned 1,
- $y_F = 4$ if both annotators assigned the label 1.

We provide the distribution of these fine-grained class labels in Figure 1. For the task evaluation, the fine-grained five label class is binarized into a coarse-grained class y_C, where $y_C = 1$ if $y_F \in \{2, 3, 4\}$, and $y_C = 0$ otherwise. Although the final evaluation uses binary labels, the fine-grained labels can provide additional information in the form of label uncertainty. We leverage this information in one of our modifications, described next.

[1]Our code is available at `https://github.com/matejklemen/pcl-detection-semeval2022t4`.

3 Methods

In this section, we describe our methodology. First, we describe RoBERTa, which we use as the baseline model. Then, we describe how additional knowledge is injected into the model in Section 3.2. In Section 3.3 we describe how we leverage the task uncertainty in our model.

3.1 RoBERTa

RoBERTa (Liu et al., 2019) is a robustly optimized BERT model (Devlin et al., 2019), composed of multiple transformer layers that use the self-attention mechanism to construct a text representation. It is first pre-trained on a general corpus using the masked language modeling objective, after which it can be fine-tuned for a downstream task. Motivated by its strong performance on the PCL detection task shown by Perez Almendros et al. (2020), we use the RoBERTa$_{\text{BASE}}$ model as a baseline.

3.2 Knowledge injection

We inject various types of additional knowledge through a secondary aligned input sequence containing additional knowledge in the form of special tokens. The procedure is shown in Figure 2 for one type of additional knowledge. Using RoBERTa, we independently obtain two representations and combine them using a learned weighted linear combination to obtain a single representation. Lastly, a linear layer transforms the representation into label

scores. The individual sequence representations correspond to the output of the last layer for the <s> token in each sequence.

We experiment with four different types of additional knowledge, one at a time: coreferences (obtained using neuralcoref[2]), sentiment (obtained using SentiWordNet (Esuli and Sebastiani, 2006)), named entities, and dependency relations (obtained using Stanza (Qi et al., 2020)). We provide additional preprocessing details and the used tagsets in Appendix A.

As our modification requires embedding two input sequences instead of one, the memory requirement during training is doubled, and the batch size has to be halved. To minimize differences due to a halved batch size, we accumulate gradients over two half-sized batches before updating the parameters.

3.3 Leveraging uncertainty

We experiment with two ways to leverage the task uncertainty. The first approach trains a model on soft instead of hard (one-hot encoded) labels. We show the comparison between hard and soft labels in Table 1. As described in Section 2 each example is annotated twice. We assign each annotation a probability of the example containing PCL: 0.0 if the annotation is 0, 1.0 if it is 2, and 0.5 if it is 1 (borderline). To obtain the final soft labels, we then take the mean of the two annotations. In this way, we transform a five-class problem into a binary one while approximately preserving information about label differences. Additionally, we potentially avoid issues when a label has few training examples.

[2]https://github.com/huggingface/neuralcoref

Table 1: Conversion scheme from fine-grained annotations into hard and soft binary target vector.

Label type	Fine-grained annotation (y_F)	Binary target vector
hard	0, 1	[1.00, 0.00]
	2, 3, 4	[0.00, 1.00]
soft	0	[1.00, 0.00]
	1	[0.75, 0.25]
	2	[0.50, 0.50]
	3	[0.25, 0.75]
	4	[0.00, 1.00]

The second approach uses the Monte Carlo dropout (MCD) (Gal and Ghahramani, 2016) to sample the label distribution during the prediction phase. Instead of determining the target label using a single prediction, we obtain multiple non-deterministic predictions while applying dropout (Srivastava et al., 2014), and then aggregate them into a single prediction (in our case, using the mean) (Miok et al., 2022).

Both modifications transform the target label probability distribution, so using the PCL probability threshold of 0.5 may no longer be suitable. For this reason, we also experiment with the decision threshold optimization, i.e. we select the threshold based on the validation set F_1 score.

4 Evaluation

In this section, we evaluate our methodology and compare it to the baseline. We start by describing the experimental settings in Section 4.1, and continue with the results in Section 4.2.

4.1 Experimental settings

We select the hyperparameters for the training of RoBERTa using the validation set F_1 score in preliminary experiments on a single 80%:10%:10% split into the training, validation and testing set. In our main experiments, we use the learning rate 10^{-5}, maximum sequence length of 158, and batch size of 48. The latter two were selected in a way to allow training on an 11GB GPU.

In the evaluation, we use 10-fold cross validation and report the means across folds. In each cross validation iteration, we use 10% of the training set for tuning and early stopping. Following the official evaluation, we use three metrics: precision, recall, and F_1 score for the positive (PCL) label. To improve clarity, we only report the mean F_1 score throughout this section, and provide other metrics and standard deviations of the results in Appendix B. We statistically test the differences in F_1 score between pairs of models using the Wilcoxon signed-rank test (Wilcoxon, 1945). The same test is applied to the difference between groups of models, where one group uses and one group does not use certain modification (e.g., soft labels). In all cases, we use a confidence level $\alpha = 0.01$ to determine the significance of the differences.

For the online evaluation, we retrain the model using the best parameters on a 90%:10% split into a training and validation set.

4.2 Results

Table 2 shows the F_1 scores of our enhanced models in comparison to the RoBERTa$_{\mathrm{BASE}}$ baseline. We interpret the results below, starting with knowledge-enhanced models in Section 4.2.1 and models leveraging uncertainty in Section 4.2.2.

4.2.1 Knowledge-enhanced models

We first only consider the knowledge injection in isolation, i.e. the scores for each type of knowledge in Table 2a.

We can observe that the addition of knowledge about coreferences ($F_1 = 0.575$), named entities ($F_1 = 0.563$), and dependency relations ($F_1 = 0.567$) increases the performance over the baseline ($F_1 = 0.556$). However, none of the increases are statistically significant due to the variance in performance across the folds.

4.2.2 Knowledge- and uncertainty-enhanced models

Next, we consider the effect of leveraging uncertainty both on the base model as well as the knowledge-enhanced models, i.e. analyze the full results in Table 2. Unless stated otherwise, we compare the modified models with their respective base model without the discussed modifications (i.e. not necessarily always against the roberta-base model without MCD).

The first observation is that training the models on soft instead of hard labels in most cases improves the F_1 score both when not using MCD and when using MCD. Using soft labels increases the

Table 2: Results of the base models and their modifications. The best score in each table is displayed in bold.

(a) Results without MCD.

+ opt. thresh.	0.569	0.577

F_1 score for 13 models and makes no difference for 2 models (named entity and dependency relation enhanced models using 10 MCD rounds). The differences are statistically significant.

Optimizing the threshold after training on soft labels improves the F_1 score for 14 models: for 13 models, the improvement over baseline is larger than without threshold optimization. The only exception where the F_1 score decreases is the coreference enhanced model without MCD, which could be due to overfitting the threshold to the tuning set. Optimizing the threshold after training on hard labels has a mixed effect. For models without MCD, it consistently leads to equivalent or lower F_1 scores compared to the baseline model without the optimized threshold. On the other hand, the threshold optimization leads to the statistically significant increase in the F_1 score for models with MCD. Concretely, it increases the F_1 score for 9 models and decreases it for 1 model.

Using MCD on its own is not helpful. Without also training the model on soft labels or optimizing the threshold, it decreases the F_1 score for all 10 models in comparison to the respective models not using MCD. However, as described previously, using MCD in combination with either or both of these mechanisms mostly leads to an increase in F_1 score.

Lastly, using more MCD rounds starts to bring a diminishing increase in the F_1 score after a certain point. Concretely, using 50 instead of 10 MCD rounds leads to only a small additional increase in F_1 score.

The best F_1 score is achieved by the model without additional knowledge, trained on soft labels, using 50 MCD rounds and the threshold optimization. This model achieves the F_1 score of 0.586 (+0.030 over the baseline) in the offline evaluation, and the F_1 score 0.575 on the official online test set.
