From the results it is clear that our zero-shot approach did not yield any effective results. This may be a result of several factors. Mikolov et al. (2013b) were able to leverage a simple mapping strategy between word embeddings created from large monolingual datasets in order to fill the gaps in translation dictionaries. Given the poor results of this experiment, it seems unlikely that this same strategy can effectively capture the complex relationship between target and source language word vectors in a way that is useful for sentiment analysis. This is likely due to the different purposes of the mapping strategy in each approach. In Mikolov et al. (2013b), the success of this technique depended largely on using a small subset of the vocabulary and pairing it with other approaches. In our approach, however, all of the weight of correctly classifying a phrase fell on the accuracy of the mapping scheme. Therefore, it seems that any error in the mapping resulted in the propagation of error during classification.

Another problem that arose is that there were some words whose vector representation always appeared as the nearest neighbor of many other words, although they were not semantically similar with any of them. This problem is known as *hubness* and is an intrinsic problem with high-dimensional vector space. Our work seems to confirm the research of Lazaridou et al. (2015) and Georgiana Dinu et al. (2015), who showed that hubness is compounded when trying to create a linear mapping between two sets of word embeddings.

Bilingual Word Embeddings

The next set of experiments required the use of parallel sentences to create bilingual word embeddings (**BWEs**). Following the work of Luong et al. (2015), we created bilingual word embeddings using the Bilingual Skip-gram algorithm, which uses the Skip-gram model (Mikolov et al., 2013a) with an added bilingual objective. This algorithm creates vector representations in which words that appear in parallel sentences have similar representations. We used the Bilingual Skip-gram algorithm to train English and Spanish word vectors on the Europarl corpus (Koehn, 2005) and the corpus of parallel sentences in the hotel domain used in the work of Lambert (2015). We created the alignment using 3 iterations of the Berkley Aligner[6]. We then created 300 dimensional vectors with a window of 5 words, 10 negative samples and ran the algorithm for 3 epochs. This process gave us two sets of word embeddings in which words that often appear in parallel sentences have similar vector representations.

To train our classifier, we used our learned English embeddings and take the average of the vectors in each opinion unit in the English train set. We performed the same procedure with the learned Spanish embeddings and the Spanish test set. The results are shown in Table 4.

The results given by the bilingual word embeddings are not optimal, but are promising enough to warrant more research. There are problems with bilingual word embeddings which would need to be addressed in order to improve their usefulness for CLSC. First, there is the problem of ambiguity that affects all word embeddings. One way to correct this problem would be to disambiguate the word

[5]The monolingual English test set does not have the same examples as the Spanish one.

[6]https://code.google.com/archive/p/berkleyaligner/

senses prior to creating the word embeddings. Cheng et al. (2014) show that this technique improves the performance of distributional models for learning compositional models of meaning and it may improve the performance for sentiment analysis as well.

Secondly, due to the fact that they have similar distributions, antonyms are often given similar vector representations. This is not a problem for POS-taggers or parsers, but it is detrimental to sentiment analysis systems based on word embeddings because these words have opposing polarities and should therefore have different vector representations. To remedy this, one could add a classification task in the problem formulation that would better separate these antonyms into differing vector spaces (Tang et al., 2014). Another option is to decompose the word vectors into interpretable subspaces, train them to differentiate for a certain property, and use only these spaces as features (Rothe and Schütze, 2016).

Stacked Denoising Autoencoders

Following the work of Zhou et al. (2016) we trained a stacked bilingual denoising autoencoder (**SDBA**) on parallel sentences from the Europarl corpus. This approach aims to encode the parallel sentences into a common latent space. Given a vocabulary of length n, the autoencoder maps the sentences, which are represented as n-dimensional one-hot vectors, to a lower dimensional representation. These representations are then used to reconstruct the original sentences. In order to keep the autoencoder from simply learning the identity function, the lower dimensional representation of one of the sentences is corrupted, which causes the autoencoder to look for discriminative features to help reconstruct the original sentences. In this way, the autoencoder learns to find a lower dimensional representation that encodes as much information as possible needed to reconstruct the bilingual sentences.

We created source and target language autoencoders with 1000 hidden units, which were then mapped to 500 hidden units. The corruption level was set to 0.5. The 500 source and 500 target hidden units were then concatenated and normalized to unit length and fed to the bilingual autoencoder, again with the corruption level set to 0.5. After the autoencoder had been trained, we could use the learned weights to force any of our data into a latent bilingual space.

We then created our training data by mapping the opinion units from the English train set to this lower dimensional latent representation, which was a 500 dimensional vector. We trained a classifier on the mapped English training set. We tested on the similarly mapped Spanish test set. The results are shown in Table 4.

The stacked denoising autoencoder approach gave reasonably good results, despite the fact that it was designed for sentence-level CLSA. There are still ways which we could adapt this approach to aspect-based CLSA. By using word alignment, we could split sentences into parallel or pseudo-parallel n-grams and train the autoencoder with this data. This may improve its performance at aspect-level.

Statistical Machine Translation

For the final experiment we used statistical machine translation as a means of bridging the gap between languages. We compared Google Translate[7], a highly developed SMT system, as well as Constrained SMT (see section 2.2). First, we trained our monolingual English classifier and used Google Translate to create our cross-lingual test set. In this case, we translated only the opinionated phrases. This technique has the disadvantage that translation is done without context. We compared this with the Constrained SMT approach in Lambert (2015). This technique allows us to translate the opinion units in context, but without reordering or scrambling them. The language model used in this approach was trained with hotel domain data. All of this improved the quality of translation and resulted in more accurate CLSC results.

Finally, we trained our classifier on unigram features from the monolingual English training set. We created test sets by translating the Spanish test data with each SMT system. The results are shown in Table 4.

The constrained SMT approach is the most accurate approach and shows that, given a more refined treatment of less parallel data, one can achieve CLSA systems which are comparable to monolingual ones. It is interesting that Google Translate has a better BLEU score than constrained SMT[8], but the

[7] http://translate.google.com/

[8] Google Translate scores a 48.6 BLEU in English-Spanish true-case, versus 45.3 for constrained SMT.

performance on the classification task was lower. It also showed poorer results than the bilingual stacked denoising autoencoder.

Equal amounts of parallel data

Each of the previous experiments rely on different amounts of parallel data for optimal performance. Since we are interested in their performance on under-resourced languages, we ran all experiments again with the minimal amount of parallel data (measured at 15.9M English words). The results shown in Table 4 show that, despite a general decrease in precision, recall and F1, the performance of bilingual word embeddings remains stable with less data. The stacked denoising autoencoder, however, performs poorly with this amount of data.

4 Results

	English	Spanish	Zero-shot	Const. SMT	BWEs	SBDA	Google SMT
Parallel Data	-	-	4518	15.9M	15.9M	15.9M	-
Precision	-	-	.453	.779	.49	.254	-
Recall	-	-	.310	.758	.468	.4	-
F1 Score	-	-	.351	.755	.473	.338	-
Accuracy	-	-	48%	75.76%	62%	55%	-
Parallel Data	0	0	4518	15.9M	49M	49M	?
Precision	.824	.803	.517	.779	.632	.682	.670
Recall	.822	.809	.503	.758	.598	.590	.568
F1 Score	.820	.800	.434	.755	.567	.633	.615
Accuracy	82.22%	80.86%	50.25%	75.76%	59.76%	74.5%	72.81%

Table 4: Results of Crosslingual Experiments: Precision, recall and F1 are the weighted averages of all classes. The amount of parallel data is measure in the number of English tokens used in training the transfer method.

5 Discussion

Role of Parallel Data

It is interesting to see that there is not a direct correlation between the amount of parallel data used and the results. Constrained SMT uses less data than bilingual word embeddings or stacked denoising autoencoders and still outperforms both. However, this approach uses higher quality, in-domain data as well as tuning parameters which adapt it to this domain. The trend within representation and distributional approaches has been to use larger and larger datasets , but these results seem to suggest that using smaller, task-specific in-domain datasets which are automatically discovered from larger datasets may be key in improving performance in CLSC.

Representation

Besides using the average of the vectors in the opinion unit as a representation, we also experimented with summation and using Long Short-term Memory networks (LSTMs) as a way to deal with the different lengths of the opinion units for our vector-based methods. Although it lacks a strong theoretical motivation, summation is often used in distributional semantics as a baseline for combining vectors (Giorgiana Dinu and Baroni, 2014). Summation led to results that were slightly worse than averaging. This is likely due to the fact that longer opinion units result in vectors which are a magnitude larger than shorter opinion units. We discuss LSTMs below.

Classifiers

Apart from the SVM classifiers used in all experiments, we conducted further experiments using deep feed-forward networks during the zero-shot and bilingual word embeddings experiments. We used the

DAN model (Iyyer et al., 2015), with three hidden layers of 300 dimensions. This model performed better on the zero-shot learning experiments, but similar to SVMs on all other experiments.

We also experimented with an LSTM with a 400 dimensional hidden layer. The final state of the LSTM is used to output a softmax probability over the four classes. The results, however, were not competitive with the SVM for zero-shot learning or bilingual word embeddings. We believe the loss of information during transfer did not allow the LSTM to detect the same features during testing that it found while training. We also suspect that the dataset was not large enough to train an LSTM easily. This may limit the usefulness of LSTMs in cross-lingual settings where the dataset used to train the model is small. Given larger training sets, this effect may decrease.

6 Conclusion and Future Work

We have presented a comparison of aspect-based CLSA approaches using different amounts of parallel data. The results show that a simple zero-shot learning approach is currently ineffective for CLSA. We show that distributional vector representations are more promising and produce results that are comparable to simple SMT baselines, but still require more research.

In future work, we plan to investigate the role of prior disambiguation and ways to add sentiment-specific information to bilingual word embeddings. We believe this will make bilingual word embeddings more useful for aspect-based CLSA. Another approach that could improve the performance is to use ensemble classification, where we combine SMT and word vector information. Finally, we will extend these techniques to Catalan and Basque.

Abstract

Emotions in code-switching text can be expressed in either monolingual or bilingual forms. However, relatively little research has placed emphasis on code-switching text. The challenges of this task include the exploration both monolingual and bilingual information of each post and capturing the informative words from the code-switching context. To address these challenges, we propose a Bilingual Attention Network (BAN) model to aggregate the monolingual and bilingual informative words to form vectors from the document representation, and integrate the attention vectors to predict the emotion. The experiments show the effectiveness of the proposed model. Visualization of the attention layers illustrates that the model selects informative words qualitatively.

1 Introduction

Microblogs such as Twitter and Facebook have gained tremendous popularity in the past decade, they often contain extremely current, even breaking, information about world events. However, the writing style of microblogs tends to be quite colloquial and nonstandard, unlike the style found in more traditional, edited genres (Li et al., 2015; Vo and Zhang, 2015). In addition, authors from multi-lingual communities tend to write code-switching posts frequently (Ling et al., 2013; Wang et al., 2015). These pose challenges for automatic emotion prediction tasks.

There has been some previous research focusing on both emotion analysis (Pang et al., 2002; Lee et al., 2014) and code-switching text analysis (Solorio and Liu, 2008; Ling et al., 2013; Jamatia et al., 2015). However, little research has focused on predicting emotion in code-switching text. Different from monolingual emotion prediction, the emotion in code-switching posts can be expressed in either monolingual or bilingual forms. In this study, we focus on Chinese and English mixed code-switching text from Chinese social media. Although Chinese is the major language, it has been shown that English words are critical for emotion expression (20.1% posts express emotion through English text). E1 - E4 show four examples of code-switching posts that contain both Chinese and English words.

E 1. 玩了一下午轮滑**so happy** ！
(I went rollerblading the whole afternoon, **so happy**!)

E 2. 开学以来，浮躁的情绪。不安稳的心态。确实该自己检讨一下了。。。**sigh** ~
(I have been grumpy and emotional since the first day of school, unstable mindset too. It's really time to self-evaluate ... **sigh**.)

E 3. 上了一天的课，嗓子**hold**不住了啊。
(I have been teaching the whole day, my throat **can't take it anymore**.)

E 4. 早起直接飙酒，喝多上车回校，回校一睁眼过站，多么**happy**的一天。
(I drank too much in the morning. I got drunk and went back to school by bus, and I missed my stop. Such a **happy** day.)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1624–1634, Osaka, Japan, December 11-17 2016.

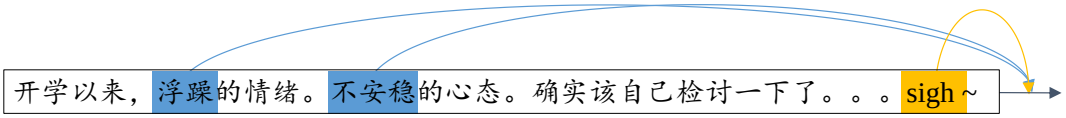

Figure 1: Example of attention mechanism result on E2.

These examples show that it is much more difficult to detect emotions in code-switching text than in the monolingual one, since emotions in code-switching posts can be expressed in either one or two languages. Take E2 for example, the sadness emotion is expressed by both Chinese and English text, and the mention of explicit emotion in English is triggered by the Chinese text. The sadness emotion of E3 is expressed by the mixed Chinese and English phrase "hold 不住". In addition, not all the words in the post are useful for predicting emotion, and the importance of words is highly context-dependent. For example in E2, only the words "浮躁" (*grumpy*) and "sigh" can be used to indicate the sadness emotion, yet the word "happy" in E4 indicates the opposite emotion without the context. Hence, the question how to explore both monolingual and bilingual information of each post post, and how to the informative words and phrases from the code-switching context are what constitute the challenging part.

To address the above challenges, we propose a Bilingual Attention Network (BAN) model to capture informative monolingual and bilingual emotion representations in the code-switching text. The attention mechanism (Bahdanau et al., 2014; Rocktäschel et al., 2015) used to aggregate the representation of informative words into a vector for emotion prediction, provides insight into which words contribute to the classification decision. In addition, a bilingual attention network is used to capture informative words from both monolingual and bilingual context. In particular, we first construct a document representation through a neural network model. Secondly, we project the document representation into three attention vectors by aggregating the representation of the informative words from both monolingual and bilingual context. Finally, a full-connected layer is used to integrate the three attention vectors and predict the emotion.

Our primary contribution is multi-lingual context sensitivity. The model considers both monolingual context and bilingual context, which allow the model to pay relevant attention to informative monolingual and bilingual words, respectively, when constructing relevant document representation. For example, consider the example in Figure 1. We can find that the informative Chinese and English words, such as "浮躁" (*grumpy*) and "sigh", have much more influence to the final decision. The key difference to previous work is that our system uses context to discover when a sequence of tokens is relevant rather than simply filtering for sequences of tokens, taken out of context. Evaluation shows the effectiveness of our proposed BAN model with both monolingual and bilingual information.

2 Related Works

2.1 Emotion Analysis

Over the last decade, there has been much work exploring various aspects of emotion analysis (Wiebe et al., 2005). While most focused on analyzing emotions in monolingual text. Some of these studies emotion lexicon building, for example, Rao et al. (2012) automatically built a word-emotion mapping dictionary for social emotion detection, Yang et al. (2014) proposed a novel emotion-aware topic model to build a domain-specific lexicon. For emotion classification, Liu et al. (2013) used a co-training framework to infer the news from readers' comments and writers' emotions collectively. Wen and Wan (2014) used class sequential rules for emotion classification of microblog texts by regarding each post as a data sequence. Li et al. (2015) proposed a factor graph based framework to incorporate both label and context dependency for emotion classification.

Deep neural networks have been proved effectiveness for many NLP tasks, including sentiment and emotion analysis (Vo and Zhang, 2015; Zhang et al., 2015). dos Santos and Gatti (2014) proposed a character-based deep convolutional neural network to predict sentiment of short text. Tang et al. (2015) proposed a neural network model to learn vector-based document representation. Zhang et al. (2015)

employed a neural network based CRFs for extracting opinion targets on open domains. Most of the previous studies focused on monolingual text, while our proposed bilingual attention network model focuses on exploring the monolingual and bilingual information collectively, and we also propose a new architecture to capture informative words from monolingual and bilingual contexts with attention mechanisms.

2.2 Research on Code-switching and Bilingual Text

Code-switched documents have received considerable attention in the NLP community (Adel et al., 2013; Garrette et al., 2015). Several studies have focused on code-switching identification and analysis, including mining translations in code-switched documents (Ling et al., 2013), predicting code-switched points (Solorio and Liu, 2008), identifying code-switched tokens (Lignos and Marcus, 2013), adding code-switched support to language models (Li and Fung, 2012), and POS tagging for code-switching text (Jamatia et al., 2015). There is relatively little work focus on predicting emotion in code-switching text. Wang et al. (2015) proposed a machine translation based approach to predict emotion in code-switching text with various external resources. Our approach departs from the previous work that we model the task by considering monolingual and bilingual information in both lexical and document level with neural network model and attention mechanism, while previous research only focused on lexical-level bilingual information. In addition, we do not use any external resource, such as bilingual and sentiment dictionary, to train our model.

More remotely connected, multilingual natural language processing has attracted increasing attention in the computational linguistic community due to its broad real-world applications. Relevant studies have been reported in various natural language processing tasks, such as parsing (Burkett and Klein, 2008), information retrieval (Gao et al., 2009), text classification (Amini et al., 2010), and so on. There are a number of studies on predicting sentiment polarity through multilingual text. Wan (2009) incorporated unlabeled data in the target language into classifier with co-training to improve classification performance. Wei and Pal (2010) regarded cross-lingual sentiment classification as a domain adaptation task and applied structural correspondence learning (SCL) to tackle this problem. Their approach achieves a better performance than the co-training algorithm. More recently, Meng et al. (2012) employed the parallel corpus for cross-lingual sentiment classification. They explored the case when no labeled data is available in the parallel corpus. However, such multi-lingual models do not explicitly consider code-switching, since their data sets are always parallel corpus. As the two languages are mixed in the code-switching text without parallel, code-switching corpus is more difficult to process.

3 Bilingual Attention Network

Given a post X with T words ($X =< w_1, w_2, ..., w_T >$), where each word w_t is represented with a K-dimensional embedding (Mikolov et al., 2013), our goal is to predict emotions for each post. Formally, for the post X with the emotion e, we need an objective integer variable y ($y \in \{0, 1\}$) to define if the emotion e is expressed in the post or not. Note that, we have five emotions in our emotion scheme[1], and we build the binary classifier to predict each emotion of the post individually.

There are three phases for predicting code-switched emotion using our bilingual attention network. Firstly, we use a long short-term memory network to build a document representation for each post. Secondly, we project the document representation into three vectors by aggregating the representation of the informative words from both monolingual and bilingual context. Note that, the attention vectors from monolingual context only consider the corresponding monolingual words from the document representation, and the vectors from bilingual context consider all the words from the document representation. Thirdly, a full-connected layer is used to integrate the three attention vectors, and predict the emotion with softmax function. The overall architecture of the Bilingual Attention Network (BAN) is shown in Figure 2.

[1]The emotions includes, *happiness*, *sadness*, *anger*, *fear*, and *surprise*. Please refer to Section 4.1 for more details.

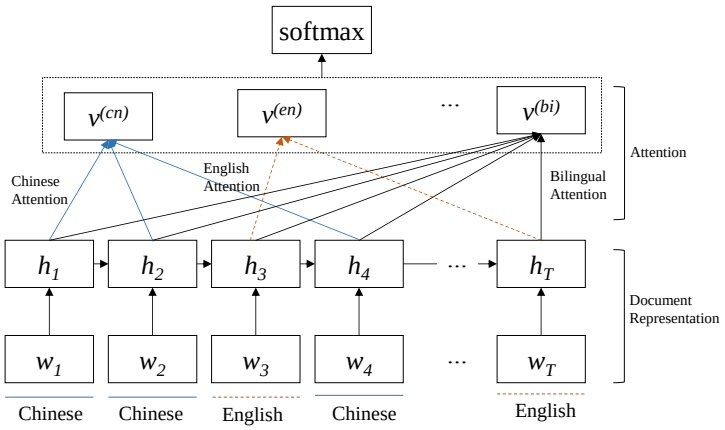

Figure 2: Overview of the bilingual attention network.

3.1 Document Representation

A Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997) is used to obtain the document representation of each post. LSTM models a recurrent state transform sequence from a input sequence $\{x_1, x_2, ..., x_t\}$ of the post to a hidden state sequence $\{h_1, h_2, ..., h_t\}$. A LSTM represents each time step with an input, a memory and a output gate, denoted as i_t, f_t and o_t respectively. There are numerous variations to the LSTM model, and we choose one for which the hidden state h_t for each time-step t is given by:

$$i_t = \sigma(W^{(i)}x_t + U^{(i)}h_{i-1} + b^{(i)}) \tag{1}$$

$$f_t = \sigma(W^{(f)}x_t + U^{(f)}h_{t-1} + b^{(f)}) \tag{2}$$

$$o_t = \sigma(W^{(o)}x_t + U^{(o)}h_{t-1} + b^{(o)}) \tag{3}$$

$$u_t = \tanh(W^{(u)} + U^{(u)}h_{t-1} + b^{(u)}) \tag{4}$$

$$c_t = i_t \odot u_t + f_t \odot c_{t-1} \tag{5}$$

$$h_t = o_t \odot \tanh(c_t) \tag{6}$$

where σ denotes the sigmoid function. After the LSTM process, we obtain an **annotation** h_t for a given word w_t.

3.2 Attention Mechanism

Not all words contribute equally to the representation of the meaning. Hence, we introduce an attention mechanism (Bahdanau et al., 2014; Yang et al., 2016) to extract the words that are important to the meaning of the post, and aggregate the representation of those informative words to form a vector. Since emotion can be expressed in either one or two languages in code-switching text, we build the vectors from monolingual and bilingual contexts respectively. For the monolingual case, we build two vectors $v^{(cn)}$ and $v^{(en)}$ to capture informative information from the Chinese and English contexts separately. For the bilingual case, we construct a vector $v^{(bi)}$ to capture the salient words from the mixed text.

Bilingual Attention. We use an attention function to aggregate the representation of the salient words to form the bilingual attention vector $v^{(bi)}$. Specifically,

$$u_t^{(bi)} = \tanh(W^{(bi)}h_t^{(bi)} + b^{(bi)}) \tag{7}$$

$$\alpha_t^{(bi)} = \frac{\exp(u_t^{(bi)\mathrm{T}}u^{(bi)})}{\sum_t \exp(u_t^{(bi)\mathrm{T}}u^{(bi)})} \tag{8}$$

$$v^{(bi)} = \sum_t \alpha_t^{(bi)}h_t^{(bi)} \tag{9}$$

In the above equations, we first feed the bilingual word annotations $h_t^{(bi)}$ through a one-layer perceptron to get $u_t^{(bi)}$ as a hidden representation of $h_t^{(bi)}$ (Eq. 7), and then measure the importance of the word by measuring the similarity of $u_t^{(bi)}$ with a word-level context vector $u^{(bi)}$ obtaining a normalized importance weight α_t (Eq. 8). After that, we compute the bilingual attention vector v^{bi} as a weighted sum of the word annotations based on the weight (Eq. 9). The context vector $u^{(bi)}$ can be seen as a high-level informative representation of the words in memory networks (Kumar et al., 2015). The word context vector $u^{(bi)}$ are randomly initialized and jointly learned during the training process.

Monolingual Attention. To reward to the most relevant words from the two monolingual contexts for emotion classification, we again use an attention functions on the monolingual context to measure their importance.

$$u_t^{(mo)} = \tanh(W^{(mo)} h_t^{(mo)} + b^{(mo)}) \tag{10}$$

$$\alpha_t^{(mo)} = \frac{\exp(u_t^{(mo)\mathrm{T}} u^{(mo)})}{\sum_t \exp(u_t^{(mo)\mathrm{T}} u^{(mo)})} \tag{11}$$

$$v^{(mo)} = \sum_t \alpha_t^{(mo)} h_t^{(mo)} \tag{12}$$

Since we only consider monolingual contexts, the input of attention function is the annotation h_t of Chinese or English words respectively. When Chinese is used as the monolingual context, $v^{(cn)}$ equals $v^{(mo)}$ in Eq. 12. and $v^{(cn)}$ equals $v^{(mo)}$ when considering English as the monolingual context.

3.3 Prediction

The monolingual vector ($v^{(cn)}$, $v^{(en)}$) and bilingual vector ($v^{(bi)}$) with the attention mechanism mentioned above are concatenated into a single vector $F = [v^{(cn)}, v^{(en)}, v^{(bi)}]$. We then use a softmax classifier to predict the label y give the inputs X. The classifier takes the feature vector $f \in F$ as input:

$$\widehat{p}_\theta(y|X) = \mathrm{softmax}(W^{(s)} f + b^{(s)}) \tag{13}$$

$$\widehat{y} = \arg\max_y \widehat{p}_\theta(y|X) \tag{14}$$

Training cost function is the negative log-likelihood of the true class labels $y^{(k)}$ at each labeled node ($k \in \{0, 1\}$):

$$J(\theta) = -\frac{1}{2} \sum_{k=0}^{1} \log \widehat{p}_\theta(y^{(k)}|X^{(k)}) + \frac{\lambda}{2} ||\theta||_2^2 \tag{15}$$

where the superscript k indicates the k^{th} labeled node, and λ is an L2 regularization hyperparameter.

We apply online training, where model parameters are optimized by using Adagrad (Duchi et al., 2011). In order to avoid over-fitting, dropout (Hinton et al., 2012) is used to the word embedding with a ratio of 0.2. For LSTM models, we empirically set size of the hidden layer is 32. We train the word embedding using the *Skip-gram* algorithm[2].

4 Experiments

4.1 Dataset and Statistics

We focus on emotion prediction in code-switching text which is defined as text that contains more than one language ("code"). We use Chinese and English code-switching posts for experimental study, and the data set is taken from Weibo.com, one of the popular Chinese social media websites. Our dataset is collected and annotated by Wang et al. (2015). Following their setting, five basic emotions are defined as candidate emotions, namely *happiness*, *sadness*, *fear*, *anger* and *surprise*. After removing those posts containing noise and advertisements, there are 3,530 posts express emotions.

[2] https://code.google.com/p/word2vec/

Emotion	Chinese	English	Both
Happiness	0.670	0.127	0.203
Sadness	0.835	0.046	0.119
Anger	0.706	0.068	0.226
Fear	0.901	0.026	0.073
Surprise	0.883	0.055	0.062

Table 1: Joint distribution of emotion and causal situations.

Emotions can be expressed through the two languages separately or collectively, and we focus four types of causal situations for each emotion, namely, *None*, *English*, *Chinese*, and *Both*. *None* means that the post does not contain any corresponding emotions (E5). *Chinese* means that the emotion is expressed through the Chinese text only (E6). *English* means that the emotion is expressed through the English text only (E1). *Both* means that the emotions of the post are expressed through both Chinese and English text (E2).

The joint distribution between emotions and caused situations is illustrated in Table 1. Each cell presents the conditional probability $p(l_j|e_i)$ of the emotion e_i based on the situation l_j. From the table, we can find that, most of emotional posts are expressed through Chinese text due to Chinese being the major language. Although English text contains relatively fewer words in each post, 20.1% of emotional posts are expressed through English. It indicates that English is of vital importance to emotion expression even in code-switching contexts dominated by Chinese. And more notably, 13.7% emotional posts are conducted in both Chinese and English. It indicates that Chinese and English text would be influenced by each other, and the bilingual context would also be effective for predicting emotion in code-switching text.

E 5. 还木有看《起风了》，**mark**一下，还有《虞美人盛开的山坡》。
(I've never seen the "Kaze tachinu" and "Kokuriko-zaka kara", **mark** as a note.)

E 6. 静静坐下来看别人**show**啦。刚刚在节目里看到妈咪和弟的视频真的很意外！
(I sat down quietly to watch someone else's **show**. To my surprise, both my mother and brother appeared on the programme.)

4.2 Experiment Setting

After constructing the dataset, we randomly selected half of the annotated posts as the training data and the other half as the testing data. We use FudanNLP[3] for Chinese word segmentation and adopt the F1-Measure (F1.) to evaluate the performance of emotion prediction.

4.3 Baselines

Our first group of experiments is to investigate whether our proposed approach improves emotion prediction in code-switching text compared with state-of-the-art monolingual emotion prediction methods. For fair comparison, the following models are implemented.

- *Term-Counting (TC)* counts the Chinese and English emotional cue words for each post to predict the emotion (Tunery, 2002).
- *SVM* is the basic model which uses all the Chinese and English text of each post as features[4], we consider bag-of-words as features.
- *BLP-BS* is proposed by Wang et al., (2015), employs a Bipartite graph based Label Propagation framework with lexical level Bilingual and Sentimental information. We re-implement their approach.

[3] https://github.com/FudanNLP/fnlp
[4] SVM^{light} is used as the implementation for the SVM classifier, http://svmlight.joachims.org

Emotion	TC	SVM	BLP-BS	LSTM	BAN
Happiness	0.258	0.591	0.638	0.662	0.678
Sadness	0.207	0.573	0.628	0.614	0.634
Anger	0.194	0.677	0.700	0.659	0.728
Fear	0.187	0.719	0.693	0.700	0.728
Surprise	0.211	0.548	0.560	0.575	0.594
Average	0.211	0.622	0.645	0.642	0.672

Table 2: Comparison with baselines.

	CN	EN	All	Comb
LSTM	0.627	0.579	0.642	0.656
Attention	0.635	0.590	0.663	0.672

Table 3: Influence of Different Factors.

- *LSTM* uses the mixed code-switching text as the input to train a basic LSTM model, using the last hidden state vector h_n directly for emotion prediction. This services as a neural network baseline without different monolingual and bilingual context.

- *BAN* is our proposed model, which uses attention to capture the informative words from both monolingual and bilingual context.

Table 2 shows the experimental results. From the table we can find that, 1) the performance of Term-counting is unacceptable since many emotions are expressed implicitly and the importance of words is highly context-dependent. 2) Since the neural network model can capture richer features automatically, LSTM outperforms the bag-of-word SVM model in most emotions. 3) Our proposed BAN model significantly outperforms all other approaches (p-value < 0.01). This indicates the effectiveness of attention mechanism from bilingual and monolingual context, compared to learning the monolingual information. Moreover, as BAN outperforms the BLP-BS model, it shows that our proposed model can automatically capture more valuable information. Note that, BLP-BS use many external resources, such as bilingual and sentimental dictionary, while our proposed model does not use any external resources.

4.4 Influence of Different Factors

Table 3 shows the influence of different factors on our proposed model. *LSTM* represents use basic LSTM as the prediction model, and *Attention* represents the LSTM model with attention. *CN* means only considering the Chinese text of each post as input, *EN* means only considering English text, *All* means using the mixed code-switching text as input. Specificlly, *LSTM-Comb* means merge the output of LSTM-CN, LSTM-EN and LSTM-All into the full connected layer, and then get the prediction results with softmax function, and *Attention-Comb* is same as the proposed BAN model that integrate both monolingual and bilingual attention mechanisms from the document representation.

The table shows us that 1) as the English is the minor language in our corpus, the results of LSTM-EN and Attention-EN are relatively weak. 2) the model using mixed code-switching text (*All*) always outperforms the model using the monolingual text individually, indicating the bilingual information is more useful than mere monolingual information. 3) Exploring monolingual and bilingual information collectively, the LSTM-Comb model can improve the accuracy over the basic LSTM model. It indicates both monolingual (i.e., Chinese and English) and bilingual texts are useful for predicting emotion in code-switching text. 4) By aggregating the representation of the informative words, the attention-based model always outperform the traditional LSTM model. 5) Our model Attention-Comb (BAN) that further utilizes attention mechanism to capture the informative words from both monolingual and bilingual context can outperforms the previous models.

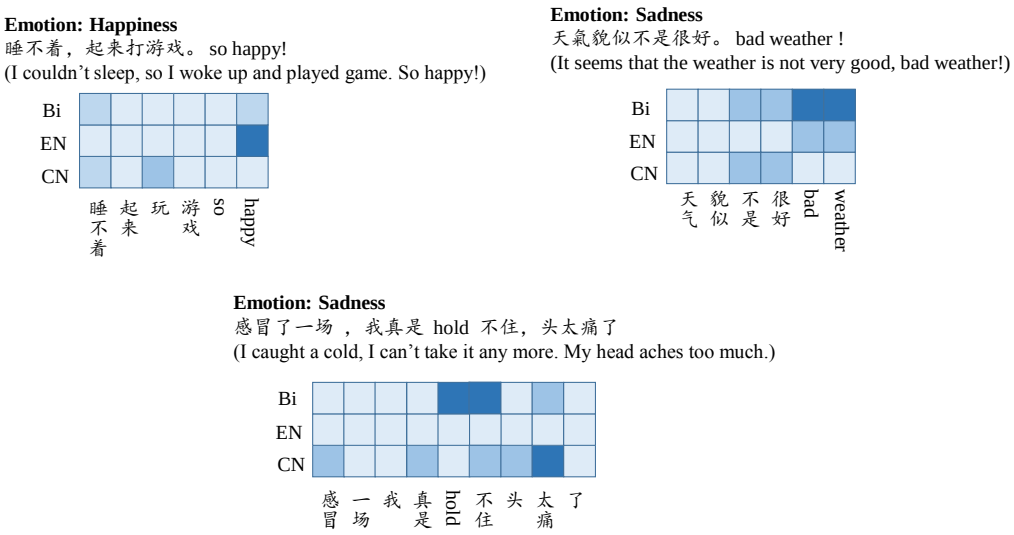

Figure 3: Example attention results.

4.5 Visualization of Attention

In order to validate that our model is able to select informative words in a post, we visualize the attention layers for several posts from our corpus in Figures 3 . Blue denotes the word weight. Since we have three attention mechanisms for monolingual and bilingual context, the first blue line denote the word weight for bilingual attention, and the other two lines denote the word weight for the Chinese and English attention respectively.

The figure shows that our model can select the words carrying strong sentiment signals such "happy", "bad", and "很好"(*very good*). In addition, since different attention functions consider different contexts, the monolingual attention functions always select the monolingual sentimental words with corresponding language such as, "happy", and "很好"(*very good*). The bilingual attention function can select mixed sentimental phrases, such as "hold不住" (*can't hold any more*). The joint attention mechanism can also deal with complex contexts. For example, in the first case, the weight of the sadness emotional word "睡不着" (*couldn't sleep*) is high with Chinese attention function, although the emotion of the whole post is happiness. However, by considering the English and bilingual attention functions, we can find the weight of word "happy" is higher than " 睡不着" (*couldn't sleep*), and it can lead us to the correct emotion.

5 Conclusion

In this paper, we addressed a novel yet important task, namely emotion detection in code-switching text. The challenges include that we need to consider both monolingual and bilingual information, and we need to extract the salient words from both monolingual and bilingual contexts. To address these challenges, a bilingual attention network model is proposed to capture the representations of monolingual and bilingual information in the code-switching text respectively. A LSTM model is used to construct the document-level representation of each post, and attention mechanism is used to capture the informative words from both monolingual and bilingual contexts. Empirical studies demonstrated that our model can significantly outperform several strong baselines.

Abstract

Most neural network models for document classification on social media focus on text information to the neglect of other information on these platforms. In this paper, we classify post stance on social media channels and develop UTCNN, a neural network model that incorporates user tastes, topic tastes, and user comments on posts. UTCNN not only works on social media texts, but also analyzes texts in forums and message boards. Experiments performed on Chinese Facebook data and English online debate forum data show that UTCNN achieves a 0.755 macro-average f-score for supportive, neutral, and unsupportive stance classes on Facebook data, which is significantly better than models in which either user, topic, or comment information is withheld. This model design greatly mitigates the lack of data for the minor class without the use of oversampling. In addition, UTCNN yields a 0.842 accuracy on English online debate forum data, which also significantly outperforms results from previous work as well as other deep learning models, showing that UTCNN performs well regardless of language or platform.

1 Introduction

Deep neural networks have been widely used in text classification and have achieved promising results (Lai et al., 2015; Ren et al., 2016; Huang et al., 2016). Most focus on content information and use models such as convolutional neural networks (CNN) (Kim, 2014) or recursive neural networks (Socher et al., 2013). However, for user-generated posts on social media like Facebook or Twitter, there is more information that should not be ignored. On social media platforms, a user can act either as the author of a post or as a reader who expresses his or her comments about the post.

In this paper, we classify posts taking into account post authorship, likes, topics, and comments. In particular, users and their "likes" hold strong potential for text mining. For example, given a set of posts that are related to a specific topic, a user's likes and dislikes provide clues for stance labeling. From a user point of view, users with positive attitudes toward the issue leave positive comments on the posts with praise or even just the post's content; from a post point of view, positive posts attract users who hold positive stances. We also investigate the influence of topics: different topics are associated with different stance labeling tendencies and word usage. For example we discuss women's rights and unwanted babies on the topic of abortion, but we criticize medicine usage or crime when on the topic of marijuana (Hasan and Ng, 2014). Even for posts on a specific topic like nuclear power, a variety of arguments are raised: green energy, radiation, air pollution, and so on. As for comments, we treat them as additional text information. The arguments in the comments and the commenters (the users who leave the comments) provide hints on the post's content and further facilitate stance classification.

In this paper, we propose the user-topic-comment neural network (UTCNN), a deep learning model that utilizes user, topic, and comment information. We attempt to learn user and topic representations which encode user interactions and topic influences to further enhance text classification, and we also incorporate comment information. We evaluate this model on a post stance classification task on forum-style social media platforms. The contributions of this paper are as follows: 1. We propose UTCNN,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1635–1645, Osaka, Japan, December 11-17 2016.

a neural network for text in modern social media channels as well as legacy social media, forums, and message boards — anywhere that reveals users, their tastes, as well as their replies to posts. 2. When classifying social media post stances, we leverage users, including authors and likers. User embeddings can be generated even for users who have never posted anything. 3. We incorporate a topic model to automatically assign topics to each post in a single topic dataset. 4. We show that overall, the proposed method achieves the highest performance in all instances, and that all of the information extracted, whether users, topics, or comments, still has its contributions.

2 Related Work

2.1 Extra-Linguistic Features for Stance Classification

In this paper we aim to use text as well as other features to see how they complement each other in a deep learning model. In the stance classification domain, previous work has showed that text features are limited, suggesting that adding extra-linguistic constraints could improve performance (Bansal et al., 2008; Hasan and Ng, 2013a; Walker et al., 2012). For example, Hasan and Ng as well as Thomas et al. require that posts written by the same author have the same stance (Hasan and Ng, 2013b; Thomas et al., 2006). The addition of this constraint yields accuracy improvements of 1–7% for some models and datasets. Hasan and Ng later added user-interaction constraints and ideology constraints (Hasan and Ng, 2013a): the former models the relationship among posts in a sequence of replies and the latter models inter-topic relationships, e.g., users who oppose abortion could be conservative and thus are likely to oppose gay rights.

For work focusing on online forum text, since posts are linked through user replies, sequential labeling methods have been used to model relationships between posts. For example, Hasan and Ng use hidden Markov models (HMMs) to model dependent relationships to the preceding post (Hasan and Ng, 2013b); Burfoot et al. use iterative classification to repeatedly generate new estimates based on the current state of knowledge (Burfoot et al., 2011); Sridhar et al. use probabilistic soft logic (PSL) to model reply links via collaborative filtering (Sridhar et al., 2015). In the Facebook dataset we study, we use comments instead of reply links. However, as the ultimate goal in this paper is predicting not comment stance but post stance, we treat comments as extra information for use in predicting post stance.

2.2 Deep Learning on Extra-Linguistic Features

In recent years neural network models have been applied to document sentiment classification (Socher et al., 2012; Socher et al., 2013; Kalchbrenner et al., 2014; Johnson and Zhang, 2015; Huang et al., 2016). Text features can be used in deep networks to capture text semantics or sentiment. For example, Dong et al. use an adaptive layer in a recursive neural network for target-dependent Twitter sentiment analysis, where targets are topics such as *windows 7* or *taylor swift* (Dong et al., 2014a; Dong et al., 2014b); recursive neural tensor networks (RNTNs) utilize sentence parse trees to capture sentence-level sentiment for movie reviews (Socher et al., 2013); Le and Mikolov predict sentiment by using paragraph vectors to model each paragraph as a continuous representation (Le and Mikolov, 2014). They show that performance can thus be improved by more delicate text models.

Others have suggested using extra-linguistic features to improve the deep learning model. The user-word composition vector model (UWCVM) (Tang et al., 2015b) is inspired by the possibility that the strength of sentiment words is user-specific; to capture this they add user embeddings in their model. In UPNN, a later extension, they further add a product-word composition as product embeddings, arguing that products can also show different tendencies of being rated or reviewed (Tang et al., 2015a). Their addition of user information yielded 2–10% improvements in accuracy as compared to the above-mentioned RNTN and paragraph vector methods. We also seek to inject user information into the neural network model. In comparison to the research of Tang et al. on sentiment classification for product reviews, the difference is two-fold. First, we take into account multiple users (one author and potentially many likers) for one post, whereas only one user (the reviewer) is involved in a review. Second, we add comment information to provide more features for post stance classification. None of these two factors have been considered previously in a deep learning model for text stance classification. Therefore, we

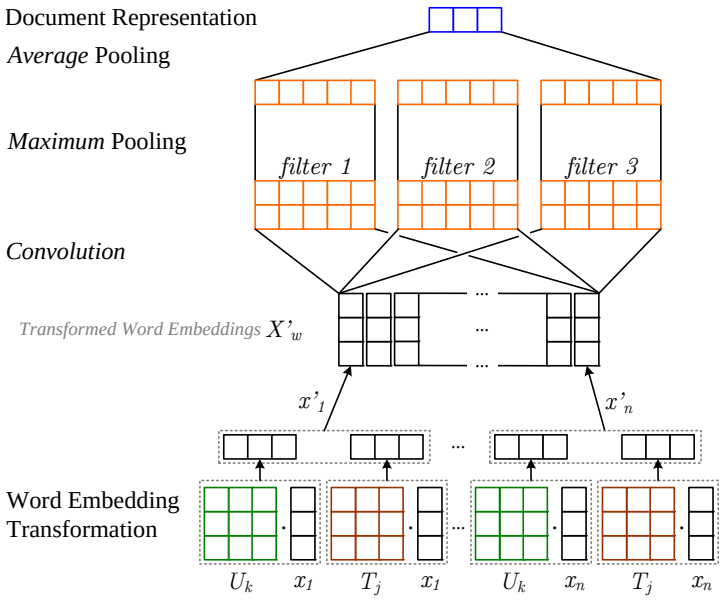

Figure 1: Document composition in a convolutional neural network with three convolutional filters and user- and topic-dependent semantic transformations. Respectively, x_w is the word embedding of word w, x'_w is the word embedding of word w after transformation, U_k and T_j are user and topic matrix embeddings for user k and topic j.

propose UTCNN, which generates and utilizes user embeddings for all users — even for those who have not authored any posts — and incorporates comments to further improve performance.

3 Method

In this section, we first describe CNN-based document composition, which captures user- and topic-dependent document-level semantic representation from word representations. Then we show how to add comment information to construct the user-topic-comment neural network (UTCNN).

3.1 User- and Topic-dependent Document Composition

As shown in Figure 1, we use a general CNN (Kim, 2014) and two semantic transformations for document composition [1] . We are given a document with an engaged user k, a topic j, and its composite n words, each word w of which is associated with a word embedding $x_w \in \mathbb{R}^d$ where d is the vector dimension. For each word embedding x_w, we apply two dot operations as shown in Equation 1:

$$x'_w = [U_k \cdot x_w; T_j \cdot x_w] \tag{1}$$

where $U_k \in \mathbb{R}^{d_u \times d}$ models the user reading preference for certain semantics, and $T_j \in \mathbb{R}^{d_t \times d}$ models the topic semantics; d_u and d_t are the dimensions of transformed user and topic embeddings respectively. We use U_k to model semantically what each user prefers to read and/or write, and use T_j to model the semantics of each topic. The dot operation of U_k and x_w transforms the global representation x_w to a user-dependent representation. Likewise, the dot operation of T_j and x_w transforms x_w to a topic-dependent representation.

After the two dot operations on x_w, we have user-dependent and topic-dependent word vectors $U_k \cdot x_w$ and $T_j \cdot x_w$, which are concatenated to form a user- and topic-dependent word vector x'_w. Then the transformed word embeddings $X'_w = [x'_1; x'_2; ...; x'_n]$ are used as the CNN input. Here we apply three convolutional layers on the concatenated transformed word embeddings $x'_c = [x'_m; x'_{m+1}; ...; x'_{m+l_{cf}-1}] \in \mathbb{R}^{d \cdot l_{cf}}$:

$$h_{cf} = f\left(W_{cf} \cdot x'_c + b_{cf}\right) \tag{2}$$

[1] Here by saying *document*, we mean the user-generated content in a post or a comment.

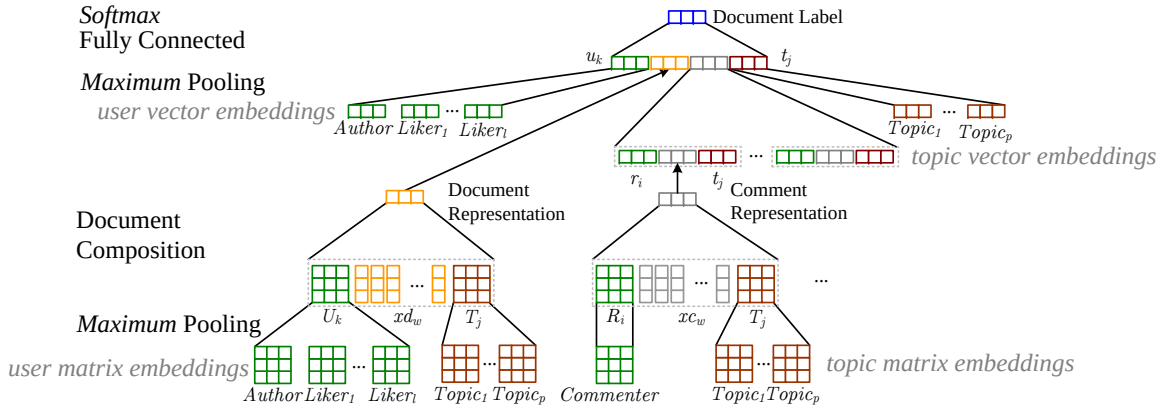

Figure 2: The UTCNN model. Assuming one post author, l likers and p topics, xd_w is the word embedding of word w in the document; xc_w is the word embedding of word w in the comments; U_k and u_k are the moderator matrix and vector embedding for moderator k; T_j and t_j are the topic matrix and vector embedding for topic j; R_i and r_i are the commenter matrix and vector embedding for commenter i. For simplicity we do not explicitly plot the topic vector embedding part for comments, but it does include a maximum pooling layer as with documents.

where m is the index of words; f is a non-linear activation function (we use $\tanh$[2]); $W_{cf} \in \mathbb{R}^{len \times d \cdot l_{cf}}$ is the convolutional filter with input length $d \cdot l_{cf}$ and output length len, where l_{cf} is the window size of the convolutional operation; and h_{cf} and b_{cf} are the output and bias of the convolution layer cf, respectively. In our experiments, the three window sizes l_{cf} in the three convolution layers are one, two, and three, encoding unigram, bigram, and trigram semantics accordingly.

After the convolutional layer, we add a maximum pooling layer among convolutional outputs to obtain the unigram, bigram, and trigram *n*-gram representations. This is succeeded by an average pooling layer for an element-wise average of the three maximized convolution outputs.

3.2 UTCNN Model Description

Figure 2 illustrates the UTCNN model. As more than one user may interact with a given post, we first add a maximum pooling layer after the user matrix embedding layer and user vector embedding layer to form a moderator matrix embedding U_k and a moderator vector embedding u_k for moderator k respectively, where U_k is used for the semantic transformation in the document composition process, as mentioned in the previous section. The term *moderator* here is to denote the pseudo user who provides the overall semantic/sentiment of all the engaged users for one document. The embedding u_k models the moderator stance preference, that is, the pattern of the revealed user stance: whether a user is willing to show his preference, whether a user likes to show impartiality with neutral statements and reasonable arguments, or just wants to show strong support for one stance. Ideally, the latent user stance is modeled by u_k for each user. Likewise, for topic information, a maximum pooling layer is added after the topic matrix embedding layer and topic vector embedding layer to form a joint topic matrix embedding T_j and a joint topic vector embedding t_j for topic j respectively, where T_j models the semantic transformation of topic j as in users and t_j models the topic stance tendency. The latent topic stance is also modeled by t_j for each topic.

As for comments, we view them as short documents with authors only but without likers nor their own comments[3]. Therefore we apply document composition on comments although here users are commenters (users who comment). It is noticed that the word embeddings x_w for the same word in the posts and comments are the same, but after being transformed to x'_w in the document composition process

[2]Some papers suggest using $ReLU$ as the activation function in deep CNNs with many layers. Nevertheless, we use $\tanh$ as the activation function, as our model is moderately deep and empirically we found the impact to be limited.

[3]Recently Facebook released a function allowing likes and comments on comments, but it was not available during the time we collected data. However, UTCNN works on this richer data, as comments are treated as posts under this framework.

Dataset	FBFans				CreateDebate

Uns	7.6%	5.2%	**61.3**%

Table 2: Distribution of like behavior.

shown in Figure 1, they might become different because of their different engaged users. The output comment representation together with the commenter vector embedding r_i and topic vector embedding t_j are concatenated and a maximum pooling layer is added to select the most important feature for comments. Instead of requiring that the comment stance agree with the post, UTCNN simply extracts the most important features of the comment contents; they could be helpful, whether they show obvious agreement or disagreement. Therefore when combining comment information here, the maximum pooling layer is more appropriate than other pooling or merging layers. Indeed, we believe this is one reason for UTCNN's performance gains.

Finally, the pooled comment representation, together with user vector embedding u_k, topic vector embedding t_j, and document representation are fed to a fully connected network, and softmax is applied to yield the final stance label prediction for the post.

4 Experiment

We start with the experimental dataset and then describe the training process as well as the implementation of the baselines. We also implement several variations to reveal the effects of features: authors, likers, comment, and commenters. In the results section we compare our model with related work.

4.1 Dataset

We tested the proposed UTCNN on two different datasets: FBFans and CreateDebate. FBFans is a privately-owned[4], single-topic, Chinese, unbalanced, social media dataset, and CreateDebate is a public, multiple-topic, English, balanced, forum dataset. Results using these two datasets show the applicability and superiority for different topics, languages, data distributions, and platforms.

The FBFans dataset contains data from anti-nuclear-power Chinese Facebook fan groups from September 2013 to August 2014, including posts and their author and liker IDs. There are a total of 2,496 authors, 505,137 likers, 33,686 commenters, and 505,412 unique users. Two annotators were asked to take into account only the post content to label the stance of the posts in the whole dataset as *supportive*, *neutral*, or *unsupportive* (hereafter denoted as *Sup*, *Neu*, and *Uns*). *Sup*/*Uns* posts were those in support of or against anti-reconstruction; *Neu* posts were those evincing a neutral standpoint on the topic, or were irrelevant. Raw agreement between annotators is 0.91, indicating high agreement. Specifically, Cohen's Kappa for *Neu* and not *Neu* labeling is 0.58 (moderate), and for *Sup* or *Uns* labeling is

[4]Currently not released due to copyright and privacy issues.

0.84 (almost perfect). Posts with inconsistent labels were filtered out, and the development and testing sets were randomly selected from what was left. Posts in the development and testing sets involved at least one user who appeared in the training set. The number of posts for each stance is shown on the left-hand side of Table 1. About twenty percent of the posts were labeled with a stance, and the number of supportive (*Sup*) posts was much larger than that of the unsupportive (*Uns*) ones: this is thus highly skewed data, which complicates stance classification. On average, 161.1 users were involved in one post. The maximum was 23,297 and the minimum was one (the author). For comments, on average there were 3 comments per post. The maximum was 1,092 and the minimum was zero.

To test whether the assumption of this paper – posts attract users who hold the same stance to like them – is reliable, we examine the likes from authors of different stances. Posts in FBFans dataset are used for this analysis. We calculate the like statistics of each distinct author from these 32,595 posts. As the numbers of authors in the *Sup*, *Neu* and *Uns* stances are largely imbalanced, these numbers are normalized by the number of users of each stance. Table 4 shows the results. Posts with stances (i.e., not neutral) attract users of the same stance. Neutral posts also attract both supportive and neutral users, like what we observe in supportive posts, but just the neutral posts can attract even more neutral likers. These results do suggest that users prefer posts of the same stance, or at least posts of no obvious stance which might cause annoyance when reading, and hence support the user modeling in our approach.

The CreateDebate dataset was collected from an English online debate forum[5] discussing four topics: abortion (ABO), gay rights (GAY), Obama (OBA), and marijuana (MAR). The posts are annotated as *for* (F) and *against* (A). Replies to posts in this dataset are also labeled with stance and hence use the same data format as posts. The labeling results are shown in the right-hand side of Table 1. We observe that the dataset is more balanced than the FBFans dataset. In addition, there are 977 unique users in the dataset. To compare with Hasan and Ng's work, we conducted five-fold cross-validation and present the annotation results as the average number of all folds (Hasan and Ng, 2013b; Hasan and Ng, 2014).

The FBFans dataset has more integrated functions than the CreateDebate dataset; thus our model can utilize all linguistic and extra-linguistic features. For the CreateDebate dataset, on the other hand, the like and comment features are not available (as there is a stance label for each reply, replies are evaluated as posts as other previous work) but we still implemented our model using the content, author, and topic information.

4.2 Settings

In the UTCNN training process, cross-entropy was used as the loss function and *AdaGrad* as the optimizer. For FBFans dataset, we learned the 50-dimensional word embeddings on the whole dataset using GloVe[6] (Pennington et al., 2014) to capture the word semantics; for CreateDebate dataset we used the publicly available English 50-dimensional word embeddings, pre-trained also using GloVe. These word embeddings were fixed in the training process. The learning rate was set to 0.03. All user and topic embeddings were randomly initialized in the range of [-0.1 0.1]. Matrix embeddings for users and topics were sized at 250 (5×50); vector embeddings for users and topics were set to length 10.

We applied the LDA topic model (Blei et al., 2003) on the FBFans dataset to determine the latent topics with which to build topic embeddings, as there is only one general known topic: nuclear power plants. We learned 100 latent topics and assigned the top three topics for each post. For the CreateDebate dataset, which itself constitutes four topics, the topic labels for posts were used directly without additionally applying LDA.

For the FBFans data we report class-based f-scores as well as the macro-average f-score (F_1^{SNU}) shown in equation 3.

$$F_1^{SNU} = 2 \cdot \frac{P^{SNU} \cdot R^{SNU}}{P^{SNU} + R^{SNU}} \tag{3}$$

*UTCNN (full) results are statistically significant (p-value < 0.005) with respect to all other methods except for UTCNN shared user embedding.

where P^{SNU} and R^{SNU} are the average precision and recall of the three class. We adopted the macro-average f-score as the evaluation metric for the overall performance because (1) the experimental dataset is severely imbalanced, which is common for contentious issues; and (2) for stance classification, content in minor-class posts is usually more important for further applications. For the CreateDebate dataset, accuracy was adopted as the evaluation metric to compare the results with related work (Hasan and Ng, 2013a; Hasan and Ng, 2013b; Sridhar et al., 2015).

4.3 Baselines

We pit our model against the following baselines: 1) SVM with unigram, bigram, and trigram features, which is a standard yet rather strong classifier for text features; 2) SVM with average word embedding, where a document is represented as a continuous representation by averaging the embeddings of the composite words; 3) SVM with average transformed word embeddings (the $x'w$ in equation 1), where a document is represented as a continuous representation by averaging the transformed embeddings of the composite words; 4) two mature deep learning models on text classification, CNN (Kim, 2014) and Recurrent Convolutional Neural Networks (RCNN) (Lai et al., 2015), where the hyperparameters are based on their work; 5) the above SVM and deep learning models with comment information; 6) UTCNN without user information, representing a pure-text CNN model where we use the same user matrix and user embeddings U_k and u_k for each user; 7) UTCNN without the LDA model, representing how UTCNN works with a single-topic dataset; 8) UTCNN without comments, in which the model predicts the stance label given only user and topic information. All these models were trained on the training set, and parameters as well as the SVM kernel selections (linear or RBF) were fine-tuned on the development set. Also, we adopt oversampling on SVMs, CNN and RCNN because the FBFans dataset is highly imbalanced.

4.4 Results on FBFans Dataset

In Table 3 we show the results of UTCNN and the baselines on the FBFans dataset. Here Majority yields good performance on *Neu* since FBFans is highly biased to the neutral class. The SVM models

perform well on *Sup* and *Neu* but perform poorly for *Uns*, showing that content information in itself is insufficient to predict stance labels, especially for the minor class. With the transformed word embedding feature, SVM can achieve comparable performance as SVM with *n*-gram feature. However, the much fewer feature dimension of the transformed word embedding makes SVM with word embeddings a more efficient choice for modeling the large scale social media dataset. For the CNN and RCNN models, they perform slightly better than most of the SVM models but still, the content information is insufficient to achieve a good performance on the *Uns* posts. As to adding comment information to these models, since the commenters do not always hold the same stance as the author, simply adding comments and post contents together merely adds noise to the model.

Among all UTCNN variations, we find that user information is most important, followed by topic and comment information. UTCNN without user information shows results similar to SVMs — it does well for *Sup* and *Neu* but detects no *Uns*. Its best f-scores on both *Sup* and *Neu* among all methods show that with enough training data, content-based models can perform well; at the same time, the lack of user information results in too few clues for minor-class posts to either predict their stance directly or link them to other users and posts for improved performance. The 17.5% improvement when adding user information suggests that user information is especially useful when the dataset is highly imbalanced. All models that consider user information predict the minority class successfully. UCTNN without topic information works well but achieves lower performance than the full UTCNN model. The 4.9% performance gain brought by LDA shows that although it is satisfactory for single topic datasets, adding that latent topics still benefits performance: even when we are discussing the same topic, we use different arguments and supporting evidence. Lastly, we get 4.8% improvement when adding comment information and it achieves comparable performance to UTCNN without topic information, which shows that comments also benefit performance. For platforms where user IDs are pixelated or otherwise hidden, adding comments to a text model still improves performance. In its integration of user, content, and comment information, the full UTCNN produces the highest f-scores on all *Sup*, *Neu*, and *Uns* stances among models that predict the *Uns* class, and the highest macro-average f-score overall. This shows its ability to balance a biased dataset and supports our claim that UTCNN successfully bridges content and user, topic, and comment information for stance classification on social media text. Another merit of UTCNN is that it does not require a balanced training data. This is supported by its outperforming other models though no oversampling technique is applied to the UTCNN related experiments as shown in this paper. Thus we can conclude that the user information provides strong clues and it is still rich even in the minority class.

We also investigate the semantic difference when a user acts as an author/liker or a commenter. We evaluated a variation in which all embeddings from the same user were forced to be identical (this is the UTCNN shared user embedding setting in Table 3). This setting yielded only a 2.5% improvement over the model without comments, which is not statistically significant. However, when separating authors/likers and commenters embeddings (i.e., the UTCNN full model), we achieved much greater improvements (4.8%). We attribute this result to the tendency of users to use different wording for different roles (for instance author vs commenter). This is observed when the user, acting as an author, attempts to support her argument against nuclear power by using improvements in solar power; when acting as a commenter, though, she interacts with post contents by criticizing past politicians who supported nuclear power or by arguing that the proposed evacuation plan in case of a nuclear accident is ridiculous. Based on this finding, in the final UTCNN setting we train two user matrix embeddings for one user: one for the author/liker role and the other for the commenter role.

4.5 Results on CreateDebate Dataset

Table 4 shows the results of UTCNN, baselines as we implemented on the FBFans datset and related work on the CreateDebate dataset. We do not adopt oversampling on these models because the CreateDebate dataset is almost balanced. In previous work, integer linear programming (ILP) or linear-chain conditional random fields (CRFs) were proposed to integrate text features, author, ideology, and user-interaction constraints, where text features are unigram, bigram, and POS-dependencies; the author

*UTCNN results were statistically significant (p-value < 0.001) with respect to other UTCNN settings.

constraint tends to require that posts from the same author for the same topic hold the same stance; the ideology constraint aims to capture inferences between topics for the same author; the user-interaction constraint models relationships among posts via user interactions such as replies (Hasan and Ng, 2013a; Hasan and Ng, 2013b).

The SVM with n-gram or average word embedding feature performs just similar to the majority. However, with the transformed word embedding, it achieves superior results. It shows that the learned user and topic embeddings really capture the user and topic semantics. This finding is not so obvious in the FBFans dataset and it might be due to the unfavorable data skewness for SVM. As for CNN and RCNN, they perform slightly better than most SVMs as we found in Table 3 for FBFans.

Compared to the ILP (Hasan and Ng, 2013a) and CRF (Hasan and Ng, 2013b) methods, the UTCNN user embeddings encode author and user-interaction constraints, where the ideology constraint is modeled by the topic embeddings and text features are modeled by the CNN. The significant improvement achieved by UTCNN suggests the latent representations are more effective than overt model constraints.

The PSL model (Sridhar et al., 2015) jointly labels both author and post stance using probabilistic soft logic (PSL) (Bach et al., 2015) by considering text features and reply links between authors and posts as in Hasan and Ng's work. Table 4 reports the result of their best AD setting, which represents the full joint stance/disagreement collective model on posts and is hence more relevant to UTCNN. In contrast to their model, the UTCNN user embeddings represent relationships between authors, but UTCNN models do not utilize link information between posts. Though the PSL model has the advantage of being able to jointly label the stances of authors and posts, its performance on posts is lower than the that for the ILP or CRF models. UTCNN significantly outperforms these models on posts and has the potential to predict user stances through the generated user embeddings.

For the CreateDebate dataset, we also evaluated performance when not using topic embeddings or user embeddings; as replies in this dataset are viewed as posts, the setting without comment embeddings is not available. Table 4 shows the same findings as Table 3: the 21% improvement in accuracy demonstrates that user information is the most vital. This finding also supports the results in the related work: user constraints are useful and can yield 11.2% improvement in accuracy (Hasan and Ng, 2013a). Further considering topic information yields 3.4% improvement, suggesting that knowing the subject of debates provides useful information. In sum, Table 3 together with Table 4 show that UTCNN achieves promising performance regardless of topic, language, data distribution, and platform.

5 Conclusion

We have proposed UTCNN, a neural network model that incorporates user, topic, content and comment information for stance classification on social media texts. UTCNN learns user embeddings for all users with minimum active degree, i.e., one post or one like. Topic information obtained from the topic model or the pre-defined labels further improves the UTCNN model. In addition, comment information provides additional clues for stance classification. We have shown that UTCNN achieves promising and balanced results. In the future we plan to explore the effectiveness of the UTCNN user embeddings for author stance classification.

Abstract

Human languages have multiple strategies that allow us to discriminate objects in a vast variety of contexts. Colours have been extensively studied from this point of view. In particular, previous research in artificial language evolution has shown how artificial languages may emerge based on specific strategies to distinguish colours. Still, it has not been shown how several strategies of diverse complexity can be autonomously managed by artificial agents . We propose an intrinsic motivation system that allows agents in a population to create a shared artificial language and progressively increase its expressive power. Our results show that with such a system agents successfully regulate their language development, which indicates a relation between population size and consistency in the emergent communicative systems.

1 Introduction

Over the past two decades, language evolution studies have attracted the attention of researchers working on domains such as biology, anthropology, artificial life or linguistics. This multitude of perspectives provides a rich variety of techniques on how to address this issue, including including agent-based modelling, which consists in studying the emergence and evolution of *artificial languages*, i.e. human-like communicative systems, in a population of artificial agents through recurrent peer-to-peer interactions (Smith et al., 2003; Steels, 2012). Results using this approach have shed light on the emergence of spatial relations (Spranger, 2013), case systems (van Trijp, 2013), colour categories (Bleys, 2010) or syntax (Garcia-Casademont and Steels, 2016).

In most of these experiments the control of the complexity relies on the experimenter, who carefully selects the stages of the experiment, constraining the language development. Insights from different models dealing with complexity come from research in AI and robotics, where a number of studies where a number of studies tried to specify how agents regulate the complexity of their actions in an autonomous way. Several models have been proposed, including error reduction (Andry et al., 2001), prediction (Marshall et al., 2004), interest (Merrick and Maher, 2009) or curiosity (Oudeyer et al., 2007).

These systems have been deeply inspired by psychological studies on the role of *motivation* (see Graham (1996) for an overview). According to Ryan and Deci (2000), motivation can be defined as "to be *moved* to do something". Psychologists further distinguish two types of motivation, depending on the reasons to perform an action: *extrinsic*, when the interest relies on the outcome of the action, or *intrinsic*, when the action itself results inherently enjoyable. Both types of motivation can incite to take part in the same activity. For example, a tennis player can work on improving her slice shots because she wants to win her next tournament or because she enjoys improving her technique.

This paper presents a simulation experiment to study how a population provided with the *Autotelic principle* (2004), a computational motivation system inspired on the *Flow theory* (1990), is able to self-organize and extend the expressive power of a shared communication system for the continuous domain of colour. Agents play a language game[1] and they use this motivation system to decide on the complexity

[1]Interested readers in the methodology used in this experiment to study the emergence of artificial language are referred to Steels (2012).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1646–1656, Osaka, Japan, December 11-17 2016.

of both the context of the interaction and the utterances they formulate and comprehend.

In the next section of the paper, we describe Flow Theory and an operational computational version, the Autotelic Principle, that allow agents to autonomously regulate their development. Section 3 briefly reviews artificial language evolution research on the domain of colour, the case study in which the motivational system is tested. Section 4 presents the experiment design in detail: how agents interact, the different communicative tasks, how the context of interactions is chosen and the different operational mechanisms agents use to emerge and align a shared communicative system. Finally, sections 5 and 6 presents the experimental results and conclusions.

2 Flow theory and architecture

Csíkszentmihályi wanted to understand what moves people to be absorbed in complex activities that do not provide an external reward, such as rock climbing, painting or sculpting. He found that the reason was that participants found these activities inherently enjoyable. He called these activities *autotelic*, as the motivational driving force (*telos*) comes from the individual itself (*auto*).

Based on these observations he developed the *Flow theory* (1990). Autotelic activities can be explained based on the relation of two dimensions (Figure 1a): *challenge*, a certain task to be done, and *skill*, the abilities that a person has to tackle that task. This relation accounts for the range of different mental states that people experience when they are involved in an autotelic activity: *boredom*, when the skills are too high for the current challenge, *anxiety*, when the challenge is too difficult given the current skills, and *flow*, when there is a balance between both. He identified the latest as the optimal state of experience. This state provides the best scenario for further enlarging their skills. As a consequence, the state of flow is in in continuous motion, as skills evolve over time. Participants seek to stay in flow state, therefore becoming self-motivated.

Inspired by the work of Csíkszentmihályi, Steels (2004) proposed the *Autotelic principle*, an operational version of the Flow theory to provide artificial agents with a system to self-regulate their development. As in the Flow theory, the balance between challenge and skills acts as the motivational driving force in agents. Agents use this relation to identify their internal state (*boredom*, *anxiety* or *flow*) and consequently react to it increasing or decreasing their challenges.

2.1 Challenge management

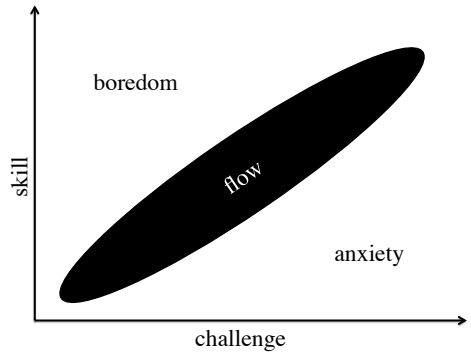
The principle establishes two different phases, *operational* and *shake-up*. The first one corresponds to the state of flow: agents explore a particular challenge and try to develop the abilities required to cope with it. The latest is reached when agents are either in a state of anxiety or boredom. It acts as a trigger to adjust the challenge to be addressed in order to look for a more balanced challenge-skills relation. In case of boredom a more demanding challenge should be attempted. In contrast, a more accessible challenge should be tackled in an anxiety state.

Challenges are characterised as a set of parameters: given a multi-dimensional parameter space P, a challenge p_i is defined as a vector $< p_{i,1}, p_{i,2}, ..., p_{i,n} >$, where $p_{i,j}$ corresponds to the value of the parameter j in the challenge i. Agents are able to generate more complex or manageable challenges by changing the specific configuration of a challenge. The space of possible challenges depends on the number of parameters of the set and the different values each parameter can have.

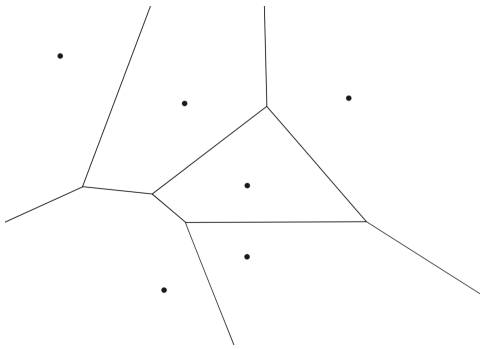
2.2 Skill evaluation

Agents indirectly measure their skills based on their performance. Each challenge is monitored with a value in the range [0,1] where 1 represents optimal performance for that task. This value is used to compute the *confidence* an agent has in its skill level to accomplish a particular challenge. A confidence value of 1 is interpreted as boredom as it indicates that the agent has acquired the skills to handle the current task. On the other hand, a steady value of 0 is interpreted as anxiety as it shows that the agent is not succeeding in expanding its abilities to cope with the actual challenge.

After each interaction, the confidence on the current challenge is updated taking into account the individual competences of the agent and the outcome of the interaction. When the interaction is a



(a) Flow theory



(b) Visual representation of the partition of the colour space into basic colour categories

Figure 1: According to Csíkszentmihályi (Figure 1a), individuals enter a state of *flow* when they correctly balance their skills against the selected challenges when performing particular activities. A mismatch of this balance may lead to anxiety (i.e. the challenge is too big) or boredom (i.e. the challenge is too easy). Figure 1b illustrates the division of the colour space into basic categories. Image extracted from Bleys (2010).

success, the confidence value is updated as follows: $conf_i = conf_{i-1} + \delta increase$, where $conf_i$ and $conf_{i-1}$ are the current and previous confidence values and $\delta increase$ is set to 0.005. On the contrary, when the outcome of an interaction is a failure the confidence value is updated in this way: $conf_i = conf_{i-1} - \delta decrease + ind_{comp}$, where $\delta decrease$ is set to 0.02 and ind_{comp} is the value in the range [0,0.015] that corresponds to the evaluation of the individual competences of the agent.

This motivation system has been used before in experiments of language emergence in discrete domains (Steels and Wellens, 2007; Cornudella et al., 2015). The work presented here differs from previous experiments in that it tests the autotelic principle in a continuous domain. In this experiment agents need to self-organize a communicative system but also agree on the meanings associated with their lexicons: colours are no longer discrete values but rather points in a three dimensional feature space and membership prototypes are values in the range [0,1].

3 A case study on colour

Research on the domain of colour has been of great interest to a lot of researchers, due to the differences observed in how colours are described in human languages (Berlin and Kay, 1969). It is commonly accepted that a *colour space*, the space of colours that can be perceived, is organised in different *colour categories*, subsets of this space (Figure 1b). *Colour prototypes* are the best representation of a particular colour category in a colour space (Rosch, 1973). Formally, a colour space is composed of a set of colour prototypes $\{c_1, c_2, ..., c_n\}$. Given the colour prototype c_k, its associated cell R_k, which determines the associated colour category, contains every point whose distance to c_k is shorter or equal to the distance to any other prototype c_i.

Although the research in this domain is extensive, most studies have focused on the use of single terms to describe colours. Experiments by Simpson and Tarrant (1991) and Lin et al. (2001) showed that only 15% of colour samples were described using a single colour term when human subjects were asked to describe colour samples without any restriction. These results provide evidence to the fact that usually people prefer to express more information about the colours they are describing instead of only employing single terms.

Colour has been of particular interest to researchers working on artificial language evolution. The majority of models have focused on the emergence of single colour terms (Steels et al., 2005; Belpaeme and Bleys, 2007; Baronchelli et al., 2010; Baronchelli et al., 2015), but some attempts to model more complex descriptions also exist. In this respect, the most advanced contribution is the work of Bleys (2009; 2009; 2012). In his doctoral thesis (2010) different *language strategies*, a particular method to express one area of meaning, are explained and studied. These language strategies are then tested on

artificial language evolution experiments, showing how these models can emerge and be learned by a population of artificial agents.

4 Experiment

In this section the design of the experiment is explained: the particular language game agents play, the different communicative challenges of the experiment, how the contexts of interactions are determined and the operational mechanisms agents use to develop and align their language. The experiment is implemented in Babel2[2], a multi-agent experiment framework (Loetzsch et al., 2008).

4.1 Language Game

The experiment consists in recurrent communicative interactions in a population of artificial agents equipped with the autotelic principle situated in a particular context. In every interaction a randomly selected pair of agents is picked from the population. One of them assumes the role of *speaker* and the other the role of *hearer*. The goal of the interacting agents is to communicate about one colour sample from the context.

The specific language game that agents play is called multi-word guessing game. The speaker selects the context of the interaction, based on the challenge it is currently addressing, and randomly picks a colour sample as topic[3]. When the speaker is able to discriminatingly conceptualise the topic into a meaning predicate it uses its language component to formulate an utterance which is transmitted as text to the hearer. The hearer tries to comprehend the utterance and constructs hypotheses about the topic. If the hearer has only one hypothesis, it points to the interpreted topic.

If the hypothesis corresponds to the topic, the speaker gives positive feedback and the interaction ends. On the other hand, if the hypothesis does not correspond to it, the speaker gives negative feedback to the hearer and points to the intended topic. When the hearer has no or multiple hypotheses it signs to the speaker that it could not identify the topic. The speaker then gives feedback by pointing to the intended topic. The interaction is a success only when the hearer has one hypothesis about the topic that corresponds with the topic selected by the speaker. Otherwise, the result of the interaction is a failure.

4.2 Challenges

Agents can use different language strategies to communicate about colour samples. These strategies are identified as the three communicative challenges of the experiment and were previously analysed in Bleys (2010): *basic colour*, *graded membership* and *graded category combination*[4]. A parameter *level* is associated to each challenge, according to its complexity. Agents use this parameter to move between challenges, depending on their internal state. Agents are able to perform three operations on the colour space: add a colour prototype, compute the distance between a colour sample and its closer colour prototype (Figure 2a) and transform the colour space towards a colour prototype (Figure 2b).

In the basic colour strategy a single term is used to describe a colour sample. Agents use this term to refer to the closest colour prototype. An example for English would be to use a term as “green” to describe a colour sample. In the experiment, agents are initialised with an empty vocabulary and colour space. This means that they need to converge both on a classification of the colour space into colour prototypes and on the terms associated to each colour prototype.

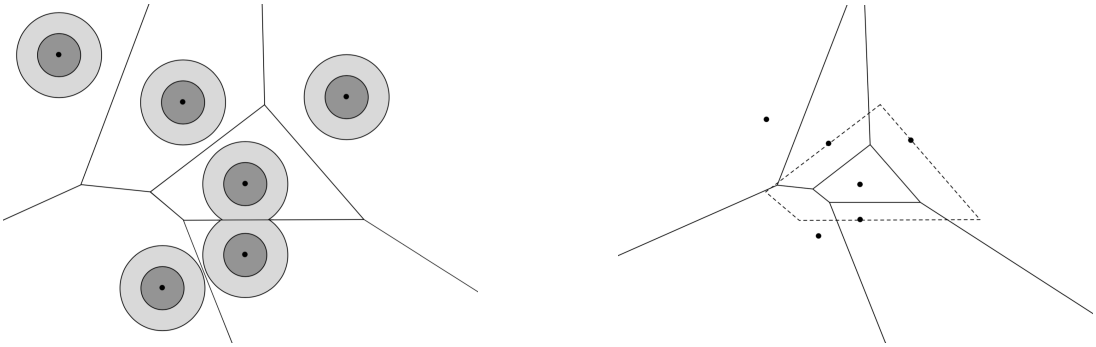
The graded membership strategy characterises a colour sample by expressing both the closest colour prototype and the distance between the colour sample to it. This strategy is observed, for instance, in English, where it is possible to describe a colour sample by combining a basic colour term with adverbs such as “very” or the postfix “-ish”, as in “very blue” or “greenish”. When addressing this challenge, agents also need to agree on both the membership prototypes and the terms associated with them.

Lastly, the graded category combination strategy describes a colour sample by referring to two colour and one membership prototypes. Agents first identify the closest colour prototype to the colour sample

[2]Babel2 is available as open-source software at `www.emergent-languages.org`.

[3]Interested readers in the impact of active selection of the topic are pointed to Schueller and Oudeyer (2015).

[4]The language strategies used in this paper have been replicated from Bleys (2010), who granted us access to the original implementation.



(a) Graded membership operation

(b) Category combination operation

Figure 2: Visual representation of available operations. In a graded membership operation (Figure 2a) the distance between the colour sample and the closer colour prototype is computed. In a category combination operation (Figure 2b) the colour space is transformed towards the main colour prototype of the colour sample in order to perform a second classification. Images extracted from Bleys (2010).

and transform the colour space towards that prototype. Agents classify again the colour sample on the transformed colour space, obtaining a second colour prototype[5]. Finally, they express how close the colour sample is to the identified colour prototype in the transformed colour space using a graded membership term. "Very dark green" or "blueish purple" are examples of this strategy in English.

The complexity of a communicative task is determined by its number of *cognitive operations*: algorithms that encode a particular cognitive function used in conceptualisation and interpretation. This number differs among the different challenges and is used to determine its level. Moreover, more complex colour descriptions can reuse skills developed on earlier stages.

4.3 Context

The world consist of 268 different colour samples in the CIE 1967 $L^*A^*B^*$ colour space. Colour samples are represented in three dimensions: the L^* dimension represents lightness, the A^* dimension roughly redness-greenness and the B^* approximately yellowness-blueness. The difference between two colour samples is determined by their Euclidean distance. The world contains the focal colours and the consensus samples[6] for English and colour samples created when combining two focal colours in different percentages: 25%, 45%, 55% and 75%, respectively.

(a) Example of a context for the basic colour challenge

(b) Example of a context for the graded membership challenge

(c) Example of a context for the graded category combination challenge

Figure 3: Example of the different contexts speakers can create, depending on their current challenge.

In each interaction the speaker selects the context, which is a subset of the colour samples present in the world. It chooses both the size of the context and the different colour samples that are part of it. The choice depends on the current challenge of the speaker. In the basic colour challenge the context is created by randomly picking three focal colours of English. In the graded membership challenge the speaker chooses five random samples from the consensus samples for English. Finally, in the graded category combination challenge the speaker picks six colour samples that correspond to the combination of two focal colours for English. Figure 3 provides an example of each context.

[5]In the experiment agents can classify the colour sample to the same colour prototype twice, before and after transforming the colour space. For instance, they can create utterances as "blueish blue" if the colour sample is very close to a certain colour prototype.

[6]Colour samples that were consistently named in English by all participants. See Sturges & Whitfield (1995).

4.4 Operational mechanisms

Agents create and learn *constructions*, which can be seen as form-meaning pairs. Constructions are stored in the *construction inventory* of the agent, which defines its vocabulary and grammar. Agents make use of their construction inventory to *formulate*, verbalise a conceptualised meaning, and *comprehend*, extract the meaning representation of an input utterance. Agents start the experiment with an empty vocabulary and enlarge it using different *diagnostics*, used to identify problems during an interaction, and *repairs*, processes to solve diagnosed problems.

Invention: the speaker cannot find a discriminating colour or membership prototype in formulation, caused by the lack of a relevant colour or membership prototype.

- *Diagnostic*: the speaker cannot come up with a discriminative conceptualization of the topic.
- *Repair for lack of relevant colour prototype*: the speaker creates a colour prototype C and sets the colour sample of the topic as its colour prototype. Additionally, the speaker invents a new term t for the colour prototype and creates a new construction relating C with t.
- *Repair for lack of relevant membership prototype*: the speaker creates a new membership prototype M and sets its value to the distance between the colour sample and the prototype of its closest colour category. Additionally, the speaker invents a new term t for the membership prototype and creates a new lexical construction relating M with t.

Adoption: the hearer cannot identify the topic due to an unknown word t, which can refer to either a colour or a membership prototype.

- *Diagnostic*: the hearer encounters an unknown word in the input utterance.
- *Repair for unknown word that refers to a colour prototype*: the hearer uses the feedback from the speaker to create a colour prototype C with the colour sample of the topic as its colour prototype. Additionally, the hearer creates a new construction relating C with t.
- *Repair for unknown word that refers to a membership prototype*: the hearer uses the feedback from the speaker to create a new membership prototype M and sets its value to the distance between the colour sample and the prototype of its closest colour category. Additionally, the hearer creates a new lexical construction relating M with t.

Moreover, agents can also create and learn *grammatical constructions*. These constructions allow agents to express meaning predicates not captured by lexical constructions and restrict the ambiguity of multi-word sentences by imposing form constraints.

4.5 Alignment

In the previous subsection we have introduced *adoption*, which allows hearers to learn new word-meaning associations for both colour and membership prototypes. When adopting an unknown word agents have to decide between adding the observed colour or membership prototype as a new prototype to their inventory or associate the unknown word to an existing one. The decision is based on how close the observed prototype is from the closest prototype in the inventory. A new prototype will be added when the Euclidean distance between both prototypes is bigger than 0.05. When the hearer associates the word to an already existing prototype it introduces competition in its construction inventory, as at least two constructions refer to the same prototype. For instance, the terms “blue” and “azul” would be competitors if they are associated to the same colour prototype.

Agents are provided with a mechanism called *alignment* to manage the competition between constructions in their construction inventory. Each construction has a score with a value between 0.0 and 1.0, and is initialized at 0.5. Scores are used by agents to decide which constructions apply to express one meaning, selecting the one with the highest score. After each interaction the scores of the constructions of the interacting agents are updated using an alignment method called *lateral inhibition* (De Vylder and

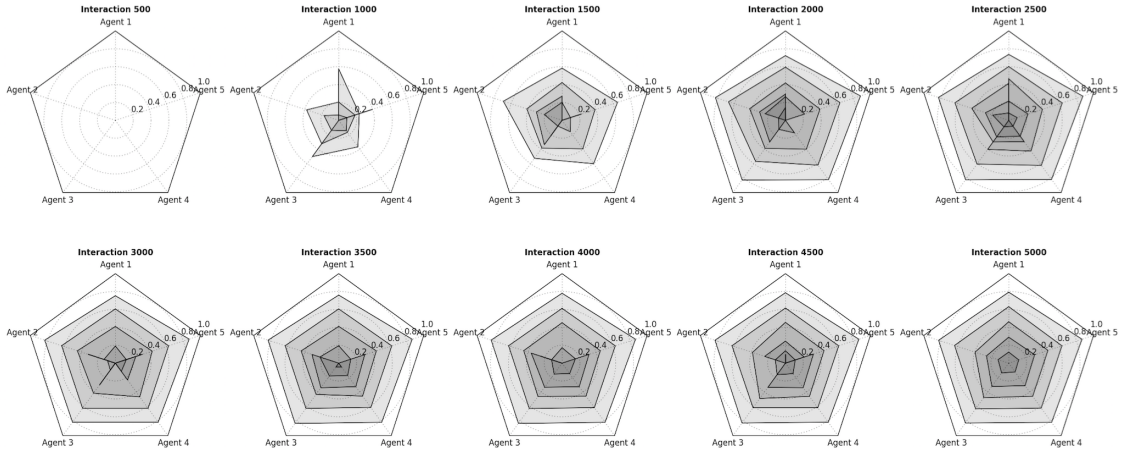


Figure 4: Example of the alignment of membership prototypes for a population of 5 agents. Initially each agent has different prototype values. After each successful interaction the involved membership values of the interacting agents are adjusted. At the end of the simulation the population converges to similar prototypes.

Tuyls, 2006). When a construction has reached a score of 0.0 is removed from the construction inventory of the agent.

Alignment takes into account the outcome of the interaction (i.e. communicative success or failure) to update the scores of the constructions. In a successful interaction both speaker and hearer increase the constructions used by a score $\delta_{increase}$ and punish their competing constructions by a score of $\delta_{decrease}$. If the result of the interaction is a failure, the speaker punishes the constructions used by a score of $\delta_{decrease}$. In the experiment both $\delta_{increase}$ and $\delta_{decrease}$ are set to 0.1.

Agents also align their prototypes. After a successful interaction that involved a membership prototype *M*, both speaker and hearer update the value m associated to that prototype as follows: $m_i = m_{i-1} - \delta rate(m_{i-1} - act_i)$, where m_i and m_{i-1} are the current and previous values of M and act_i the activation of the topic. In the experiment $\delta rate$ is set to 0.05. Figure 4 illustrates the alignment of membership prototypes in a population of five agents.

5 Experimental results

All experimental results have been tested on ten runs, to ensure the consistency of the results. In each trial agents start with an empty construction inventory and colour and membership inventories. The following measures are reported:

- *Communicative success* measures the average performance of the population in the communicative task. When the communication is successful a value of 1.0 is recorded, 0.0 otherwise.
- *Alignment success* measures the average cohesion of the construction inventory on the population. A value of 1.0 is recorded when there was communicative success and both agents would use the same constructions to refer to the topic of that interaction, 0.0 otherwise.
- *Lexical stability* measures the average scores of lexical constructions of the population. A value of 1.0 means that all lexical constructions on each agent have the maximum score.
- *Confidence in challenge* measures the average confidence that the population has for a certain challenge level. It has a value between 0.0 and 1.0.

The resulting dynamics of the experiment with a population of ten agents are shown in Figure 5. Agents start addressing the first challenge, on which the population has to create and coordinate their

construction inventory for basic colour terms. Agents gain confidence for this challenge fast, as both the communicative success and the confidence value for the first challenge rapidly increase. An abrupt drop occurs around interaction 2000, when agents start to reach maximum confidence. As it corresponds to the internal state of boredom, agents enter in the shake-up phase and move to the second challenge. In the course of the second challenge agents are exposed to a bigger diversity of contexts, which makes the alignment of membership prototypes and its associated lexical constructions more difficult. This is also reflected in the evolution of lexical stability, as the average score of lexical constructions drops despite the fact that agents are converging to an optimal lexicon for basic colour terms.

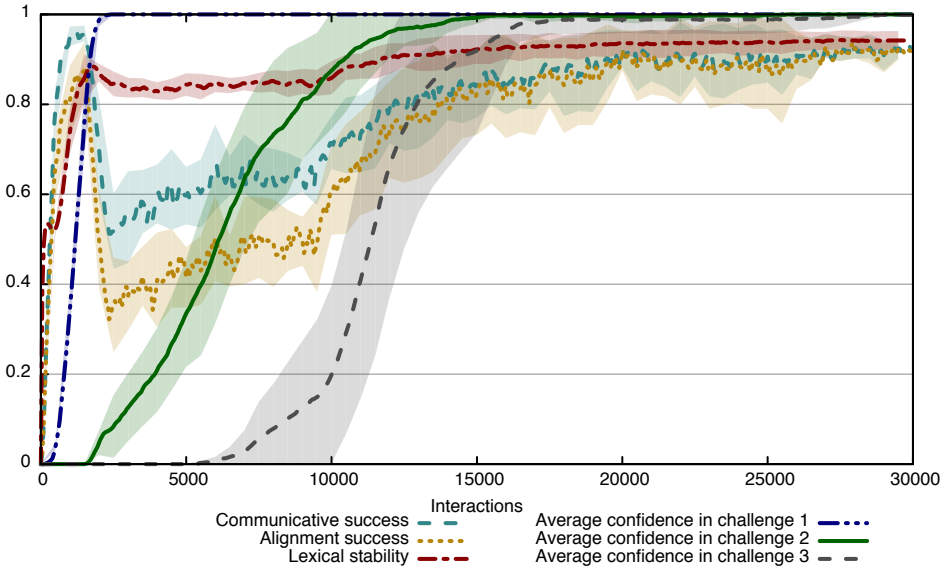

Figure 5: Resulting dynamics of the experiment for a population of 10 agents averaged over 10 runs of 30000 interactions. By the end of the simulation all agents in the population reach a steady communicative success value above 90% and maximum confidence for the three challenges. Error bars represent the maximum and minimum across the different experimental runs.

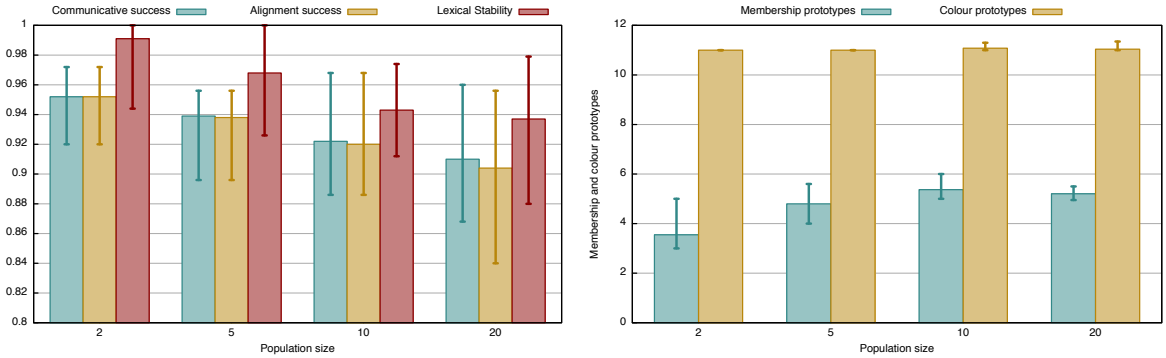
An overlap between the second and third challenge starts approximately at interaction 5000 where a fraction of the population has already reached maximum confidence for the second challenge. At this point agents identify their internal state as boredom and are motivated to attempt the third challenge. Communication success progressively improves as population succeeds in aligning their construction inventory and membership prototypes. As a consequence of this alignment, alignment success also increases and reaches the same value as communicative success. By interaction 30000 all agents in the population have reached maximum confidence for the three challenges and a steady communicative success value above 90%.

Bleys (2010) showed that agents using these strategies cannot come up with a discriminative conceptualisation in certain situations, which explains why the population does not reach a 100% communicative success even when all agents have reached the highest confidence score for all challenges. However, lexical stability settles to a value around 95%, which means that not all lexical constructions in the population have a score of 1.0. This is caused by different membership categories no longer used but still in the lexicon of some agents. Therefore, population has not fully converged to a minimal lexicon, although they manage to communicate successfully in most contexts.

We have studied the relation between lexical stability and communicative success by testing the same configuration on different populations. Figure 6a presents the resulting communicative success, alignment and lexical stability for a population of two, five, ten and twenty agents (3000, 10000, 50000 and 150000 interactions, respectively). Results show a slight reduction of communicative success as population size increases. More importantly, a little discrepancy between communicative success and alignment is observed in bigger populations. This gap occurs because in some interactions agents prefer distinct

discriminative conceptualisations for certain topics. In other words, different prototypes are triggered as more accurate conceptualisations of the topic in a particular context and therefore agents select different terms to describe the same colour sample.



(a) Resulting communicative success, alignment and lexical stability for different population sizes averaged over 10 runs.

(b) Resulting membership and colour categories for different population sizes averaged over 10 runs.

Figure 6: Effect of population size. Figure 6a presents the resulting communicative success, alignment and lexical stability scores in a population of two, five, ten and twenty agents. The scale on the Y-axis is set to the range [0.8,1]. Figure 6b displays the average membership and colour prototypes for the same populations.

This effect can be explained by the fact that bigger populations converge to systems with more membership prototypes (Figure 6b). An increased number of membership prototypes requires more time to align: this helps prototypes which are not spread over the population to stay longer in individual inventories as they are less used. The decrease in communicative success is therefore explained by (a) a lower alignment of agents' construction inventories and membership prototypes and (b) longer presence of non spread membership prototypes among the population that are used in conceptualisation. These results suggest that smaller populations could be able to arise more consistent communicative systems for the domain of colour.

6 Conclusions

In this paper we have studied how a population of agents provided with a motivation system to regulate their complexity is able to develop an artificial language of increasing expressive power to refer to colours. Agents using this system develop to their construction inventory in three progressive stages: they first (a) converge on a language for colour prototypes and then extend its expressive power by (b) developing categories to express degrees of similarity between a colour sample and a colour prototype and (c) combining colour prototypes.

The results obtained show that a population of agents equipped with an architecture of flow successfully manages to progressively develop its communicative skills when trying to remain in a state of flow. Moreover, simulations with different population sizes show that bigger populations converge to systems with more membership prototypes on average.

Acknowledgements

This research was conducted at and funded by the Sony Computer Science Laboratory Paris. Miquel Cornudella is partially supported by a CIFRE grant (agreement no. 2013/0730). We would like to thank those who provided help and feedback, particularly Paul Van Eecke, and three anonymous referees for very constructive remarks after a careful reading of the manuscript. Special thanks go to Joris Bleys, who granted us access to the original implementation of the language strategies used in his experiments.

Predicting the Evocation Relation between Lexicalized Concepts

Abstract

Evocation is a directed yet weighted semantic relationship between lexicalized concepts. Although evocation relations are considered potentially useful in several semantic NLP tasks, the prediction of the evocation relation between an arbitrary pair of concepts remains difficult, since evocation relationships cover a broader range of semantic relations rooted in human perception and experience. This paper presents a supervised learning approach to predict the strength (by regression) and to determine the directionality (by classification) of the evocation relation that might hold between a pair of lexicalized concepts. Empirical results that were obtained by investigating useful features are shown, indicating that a combination of the proposed features largely outperformed individual baselines, and also suggesting that *semantic relational vectors* computed from existing semantic vectors for lexicalized concepts were indeed effective for both the prediction of strength and the determination of directionality.

1 Introduction

Evocation, defined as the extent to which one concept (the *source* concept, s) brings to mind another (the *target* concept, t), is a directed yet weighted semantic relationship between semantic units (Boyd-Graber et al., 2006). As in the previous work (Boyd-Graber et al., 2006; Ma, 2013), the present work also considers evocation to be a semantic relationship between lexicalized concepts, rather than a relation between words. The weight of an evocation relation instance should measure the strength of the directed association from s to t, which we cannot directly observe nor compute from corpora.

Although evocation relations are potentially useful in several semantic NLP tasks, such as the measurement of textual similarity/relatedness and the lexical chaining in discourse, the prediction of the evocation relation between an arbitrary pair of concepts remains more difficult than measuring conventional similarities (synonymy, as well as hyponymy/hypernymy) or relatednesses (further including antonymy, meronymy/holonymy, as well as predicate-argument relations and maybe more), since evocation relationships cover a far broader range of semantic relationships (Cramer, 2008). Besides, as Ma (2013) argues, some types of evocation relations might be rooted in human perception and experience, implying that the acquisition of evocation relations solely from textual corpora is rather difficult, as they are the outcome of already accomplished activities of language production.

To the best of our knowledge, this paper is the first to present a supervised learning approach to predict the strength of an evocation as a regression task, and to determine the directionality as a classification task. We utilize Princeton WordNet (PWN) (Fellbaum, 1998) as the inventory of lexicalized concepts (synsets). Our empirical results show that combining a range of features is effective as intended, and that the *semantic relational vectors* (detailed in section 3.2.3) computed from existing semantic vectors for word senses and lexicalized concepts are indeed effective for both the prediction of strength and the determination of directionality. This definitely highlights the effectiveness of the semantic vectors derived for WordNet lexemes and synsets (Rothe and Schütze, 2015) (henceforth, Autoextend lexeme/synset semantic vector) that were utilized in the present work.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1657–1668, Osaka, Japan, December 11-17 2016.

The proposed method (section 3) utilizes several types of features: their effectiveness was examined by a series of experiments that employed the strength data provided by (Boyd-Graber et al., 2006) (PWN evocation data), and the directionality data made available by (Ma, 2013) (Ma's evocationNet data) (section 2). Although the empirical results (section 4) we obtained were rather promising, there remains considerable room for improvement. Thus, the paper concludes with possible future directions (section 6) after a brief review of some related research (section 5).

2 Evocation Relationship and the Resources

Evocation is the outcome of a kind of psychological phenomenon rooted in human perception and experience (Ma, 2013). This strongly implies that human-rated resources are required to uncover the underlying psycholinguistic mechanisms and to develop a computational mechanism to predict the evocation relationship between an arbitrary pair of lexicalized concepts.

To date, two resources have been publicized to facilitate research associated with the evocation relationship: one is the Princeton WordNet (PWN) evocation dataset (Boyd-Graber et al., 2006) that collects human ratings of the evocation strength; the other is Ma's evocationNet dataset (Ma, 2013) that provides directionality judgments.

2.1 PWN evocation dataset

The PWN evocation dataset[1] is a collection of ratings of evocation strength for 119,652 PWN synset pairs (Boyd-Graber et al., 2006). Each synset pair was judged by at least three raters, where each rating ranges between 0 and 100. We simply averaged the ratings in this work. As the synset pairs had been *randomly* selected from the *core synsets*, two thirds of them (80,343) are rated as zero, which means "no evocation." The mean and the standard deviation of the ratings greater than zero are 8.389 and 12.00, respectively, showing that the evocation strengths vary considerably.

For example, for some of the positively rated synset pairs (39,309), the evocation from `prize.n.01` to `honor.n.02` records the highest strength of 100.0, whereas that from `critical.a.04` to `obstruct.v.01` shows the lowest, namely 0.0625. Figure 1 further displays the distribution of the positive evocation ratings while binning them into five classes: $\{b0 : r > 0, b1 : r \geq 1, b25 : r \geq 25, b50 : r \geq 50, b75 : r \geq 75\}$.

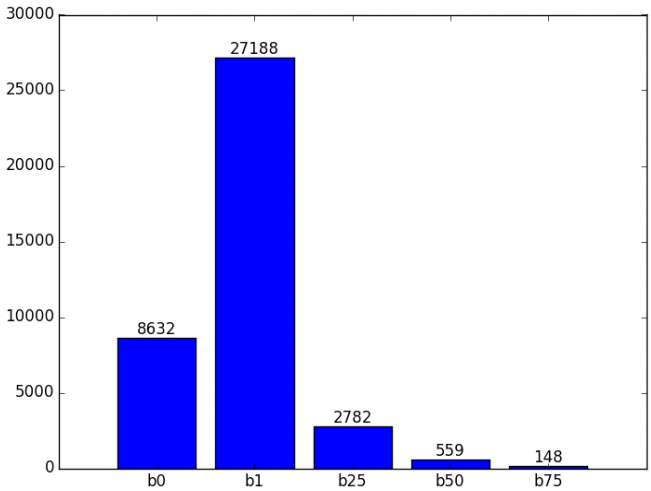

Figure 1: Distribution of the evocation ratings in the PWN evocation data.

Reports from as early as in (Boyd-Graber et al., 2006) showed that major similarity measures could not reproduce the evocation ratings well: the best result reported in the literature was as low as $\rho = 0.131$ (ρ:

[1] `http://wordnet.cs.princeton.edu/downloads.html`

Directionality	Count
$x \rightarrow y$ (outbound)	172,126
$x \leftarrow y$ (inbound)	123,147
$x \leftrightarrow y$ (bidirectional)	43,459
no-evocation (original)	9,715
no-evocation (incorporated from PWN)	90,058
Total	428,790

Table 1: Distribution of the directionality categories in Ma's evocationNet dataset (augmented by PWN Evocation data).

the Spearman correlation coefficient), which was achieved with semantic vectors derived by applying the Latent Semantic Analysis (LSA) method (Deerwester et al., 1990) toward the British National Corpus. Remind here, however, that the work (Boyd-Graber et al., 2006) did not intend to develop a method to predict evocation strengths, rather their intention was to explore a different type of semantic relationship that could be incorporated into PWN.

2.2 Ma's evocationNet dataset

Ma (2013) presented a method to create a dataset of concept pairs that are in evocation relation, and she publicized the dataset, which we refer to as Ma's evocationNet[2]. This dataset provides directionality annotations for a number of PWN synset pairs, but not their evocation strength ratings. She created this dataset by converting the word-based association data given in *The University of South Florida Free Word Association Norms* (Nelson et al., 2004) into *word sense*-based data by first applying an automatic word sense disambiguation process, and then a manual verification process. Because of this creation process, Ma's evocationNet dataset contains a number of duplications in the synset-level, but we did not exclude these duplicated data in the present research.

The dataset consists of 13,975 files from which we extracted 348,447 synset pairs. Each of the files is designated by a pair consisting of a word and a synset. As a simple example, the content of the file named `banana{banana.n.01}.txt` (for word: banana, synset: `banana.n.01`) is given below, showing this synset `banana.n.01` (*food* sense) is linked to the synsets `apple.n.01` as well as `orange.n.01` and `orange.n.02`, whereas it is co-linked with the synset `banana.n.02` (*plant* sense).

```
apple {apple.n.01}++
orange {orange.n.01}++
oranges {orange.n.01}++
banana {banana.n.02}+=
```

That is, the symbol '++' denotes an outbound link, whereas '+=' indicates a bidirectional link. Other categories that appeared in the dataset are: '+-' (inbound) and '==' (no evocation).

Table 1 counts the frequencies of the directionality categories. As displayed in the table, Ma's original dataset contains a relatively small number of "no-evocation" instances that causes the problem of skewed distribution. Thus, as a remedy, we added the synset pairs of which the evocation strength was rated as zero in the PWN dataset to this category, finally giving us a data set of 428,790 synset pairs.

3 Supervised Learning Approach

3.1 Machine-Learning Frameworks

Since the psychological mechanism underlying evocation or association is not yet well understood (De Deyne and Storms, 2015), it is natural to use an exploratory approach to build a computational method that exploits potentially effective features obtained from several resources. As detailed in the

[2] `http://kettle.ubiq.cs.cmu.edu/~xm/DataSet/webpage/evocationNet/`

previous section, the data for evocation strength are numerical ratings, and the data for evocation directionality are discrete categories. We therefore naturally defined the prediction of evocation strength as a regression task, and the determination of evocation direction as a classification task.

We adopt a supervised machine-learning approach, and compare a feed-forward neural network (NN) with the Random Forest™(RF) algorithm as the basic learning framework. Since the submitted paper is not intended as a contribution to the machine-learning field, we simply applied straightforward or off-the-shelf classifiers/regressors in the experiments. The hyperparameters were determined through a series of pre-experiments.

Neural Network: We adopted simple perceptron with two hidden layers, both for the regression task and the classification task. We applied *dropout* and employed *ReLu* as the activation functions. *Mean squared error* and *Adam algorithm* were utilized for the optimization in the regression tasks. Almost the same architecture was adopted for the classification tasks, where *softmax cross entropy* was adopted as the error function, and the number of nodes in the output layer was equal to the number of classes (that is, four). We utilized a Python-based framework known as chainer[3] for the implementation.

Random Forest: We employed another Python-based framework named scikit-learn[4] for the Random Forest classifiers and regressors. The hyperparameters we used were similar to the default parameters of the system, except that the number of estimators was boosted to 125 from the default of 10.

3.2 Features

We integrate potentially effective features, which can be divided into the following three groups.

3.2.1 Similarity/relatedness features

Even for an asymmetric semantic relationship such as evocation, *symmetric* similarity/relatedness would provide a certain *bias* or *basis* (De Deyne et al., 2013). With this motivation, we utilize four similarity/relatedness features as shown below. Note here that (c) and (d) are synset-based, whereas (a) and (b) are word-based. We were able to incorporate these word-based similarities, as the utilized data explicitly specify the focused word for each of the synsets. In addition, notice that (b) and (d) rely on distributed representation vectors, whereas (a) and (c) do not.

- (a) $ldaSim$ provides the cosine similarity between the word vectors created by applying the Latent Dirichlet Allocation (LDA) algorithm (Hoffman et al., 2010). We trained an LDA model from the enwik9 Wikipedia corpus[5] while using the gensim[6] Python library for topic modeling. The dimensionality of the vectors is 300, which is the same as the vectors employed by (b) and (d).

- (b) $w2vSim$ provides the cosine similarity between Word2Vec-induced word embedding vectors (Mikolov et al., 2013a). We used the pre-trained 300-dimensional vectors available at Google's Word2Vec site[7]. Note that these vectors were created by applying the continuous bag-of-words (CBOW) model.

- (c) $wupSim$ computes Wu-Palmer similarity (Budanitsky and Hirst, 2006) defined by the formula shown below: here, $depth(s)$ gives the depth of node s from the root; $lcs(s,t)$ computes the least common subsumer node of s and t. Wu-Palmer similarity is convenient in the sense that the similarity ranges $0 < wupSim(s,t) \leq 1$. To cope with cross-POS evocation relations, we assumed a virtual root node that integrates PWN's POS-oriented subtrees.

$$wupSim(s,t) = \frac{2 \times depth(lcs(s,t))}{depth(s) + depth(t)}$$

[3] http://chainer.org/
[4] http://scikit-learn.org/
[5] http://mattmahoney.net/dc/text.html
[6] https://radimrehurek.com/gensim/
[7] https://code.google.com/p/word2vec/

- (d) $autoexSim$ provides the cosine similarity between Autoextend synset semantic vectors. These 300-dimensional vectors were created by the method proposed in (Rothe and Schütze, 2015), and made available on the author's site[8]. Recall that these vectors were induced by using the same Word2Vec CBOW embedding vectors described above. We adopt the Autoextend method, since it conveniently utilizes the semantic-relational structure that resides in an existing lexical-semantic resource (in this case, PWN), while exploiting ready-made word embedding vectors.

3.2.2 Lexical resource features

Lexical resources, such as PWN, can be utilized as a precious source of features. In the present work, we employed the three features listed below. Note that all of these features have been incorporated in expectation of contributing to capturing some *asymmetric* aspects of evocation relationships.

- $posSem$ is introduced to dictate some of the fundamental attributes of the query synset pair. It concatenates the feature vector of the source concept with that of the target concept in this order. Each feature vector for a concept consists of a *1-of-k* encoding of the part-of-speech sub-vector (five dimensions, corresponding to: *a*, *s*, *n*, *r*, and *v*) and a 45-dimensional sub-vector for the coarse-level semantic classification. This eventually provides us with a 100-dimensional ($(5 + 45) \times 2$) vector to represent the query synset pair. As for the labels of the coarse-level semantic classes, we utilize the names of the lexicographer files in PWN, such as `noun.artifact`, `noun.process`, and `verb.motion`.

- $lexNW$ attempts to dictate the difference in graph-theoretic *influence* of the source/target concepts in the underlying PWN lexical-semantic network. The rationale behind this is: the evocation relation from a less important concept to a weighty concept may be more likely than in the reverse direction. More specifically, we compute the betweenness and load centralities (Barthélemy, 2004) for each synset node, and dispose the values in the order of source concept and target concept, resulting in a four-dimensional vector for the query synset pair.

  The betweenness centrality $bc(v)$ defined by the formula below measures the influence of the designated node in terms of network flow. In the formula, $npaths(a, b, c)$ counts the number of the shortest paths from a through c to b. The load centrality also assesses the importance of a node by using load distribution.

$$bc(v) = \sum_{s \neq v \neq t} \frac{npaths(s, t, v)}{npaths(s, t, *)}$$

  We computed these graph-theoretic metrics simply by using the NetworkX[9] Python library for processing complex networks.

- $dirRel$ also exploits the network structure of PWN, attempting to mimic the notion of *feature inclusion*: "an object with many features is judged as less similar to a sparser object than vice versa" (Gawron, 2014). In the present work, sets of neighboring concept nodes in the lexical-semantic network are considered as features.

  Figure 2 illustrates the notion of $dirRel(s, t, k)$, suggesting that this measure is associated with paths connecting s to t. In the present work, we set $k = 3$ as it performed best in the preliminary experiments. Note that this means that we considered the semantic paths in PWN of which the length is at most six as effective features.

  The defining formula shown below simply quantifies the overlap in *k*-neighbor nodes in the PWN lexical-semantic network, in which $nb(x, k)$ denotes the set of *k*-neighbor nodes of node x.

$$dirRel(s, t, k) = \frac{|nb(s, k) \cap nb(t, k)|}{|nb(s, k)|}$$

[8] `http://www.cis.lmu.de/~sascha/AutoExtend/embeddings.zip`
[9] `https://networkx.github.io/`

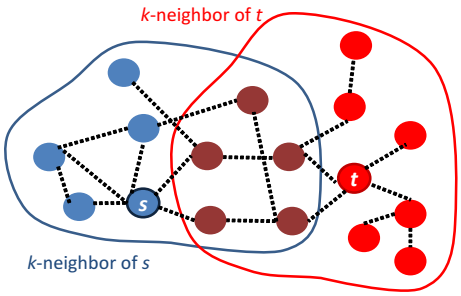

Figure 2: Notion of $dirRel(s, t, k), k = 2$.

Notice that this formula is a version of the well-known Tversky index $TI(X, Y)$ (Tversky, 1977) (where $\alpha = 1$ and $\beta = 0$), which dictates the asymmetric similarity of two given sets, X and Y.

$$TI(X, Y) = \frac{|X \cap Y|}{|X \cap Y| + \alpha|X - Y| + \beta|Y - X|}$$

3.2.3 Semantic relational vectors

One of the prominent advantages introduced by distributional word embedding vectors is the tendency: "all pairs of words sharing a particular relation are related by the same constant (vector) *offset*" (Mikolov et al., 2013b). Following this result, a number of research groups have tried to capture the characteristics of a semantic relationship from the offset vectors. Among them, for example, (Fu et al., 2014) successfully learned the hypernymy relationship by estimating the projection matrices that map words to the hypernyms.

Although it is not clear whether a similar approach would be effective for potentially complex semantic relationships such as evocation, we, in the present work, incorporated the offset semantic vectors $relVec(s, t)$ (referred to as *semantic relational vectors* in this research) as a vectorial feature. That is, we concatenated the obtained 300-dimensional relational vector with the vector obtained from other features described so far.

$relVec(s, t)$ could be defined as follows, provided an adequate semantic path from s to t is given by $path(s, t)$ that sequences edges. Here, each edge from a to b may carry a lexical-semantic relation r, and it could be associated with a relation weight $w(r)$.

$$relVec(s, t) = \sum_{(a,b,r) \in path(s,t)} w(r)(semVec(b) - semVec(a))$$

This formula can be simplified as follows by assuming a uniform relation weight ($w(r) = 1, \forall r$). This means that we see *an evocation relation as a short cut of a potential path* in the lexical-semantic network.

$$relVec(s, t) = semVec(t) - semVec(s)$$

In the formula, $SemVec(x)$ basically denotes the Autoextend synset semantic vector for synset x, but, as detailed in the experimental section, we experimentally altered it to other types of vectors.

4 Experiments and the Results

We assessed the proposed framework and investigated the effectiveness of the proposed features by conducting a series of experiments, where a five-fold cross-validation was employed in each of the experimental settings. The performances are measured by computing the Pearson (r) and Spearman (ρ) correlation coefficients between the gold data and the predictions for the regression tasks[10], and by the standard Precision/Recall/F1/Accuracy measures for the classification tasks, respectively. The results achieved by the combination of the proposed features were compared with each individual baseline case. Additionally we performed ablation tests in order to assess the importance of each feature.

[10]We included these two correlation measures, although we realized that the relative ordering captured by the Spearman was more adequate to compare.

4.1 Results: Prediction of strength

The whole combination of the proposed features yielded the best results of $r = 0.4391; \rho = 0.4000$ with NN, which significantly outperformed the results with RF, $r = 0.3695; \rho = 0.3291$. Thus, in the following, we only discuss the results achieved by NN.

Table 2 displays the strength prediction results in r and ρ, where each foo indicates an individual baseline with feature foo. Table 3 additionally displays the results of ablation tests, where each $-foo$ indicates the ablated feature foo. Both tables show two baseline results: one is the figure shown in (Boyd-Graber et al., 2006); the other is the result achieved by a simple baseline which uniformly assigns the average strength (2.756) computed from the entire PWN Evocation dataset.

Feature	r	ρ
All	**0.4391**	**0.4000**
$ldaSim$	0.1559	0.1441
$w2vSim$	0.2472	0.1841
$wupSim$	0.0907	0.0663
$autoexSim$	0.2395	0.1924
$posSem$	0.2442	0.2489
$lexNW$	0.1379	0.1211
$dirRel$	0.0839	0.0622
$relVec$	**0.2931**	**0.2763**
(Boyd-Graber et al., 2006)	NA	0.131
$Average$	0.0	NA

Table 2: Results: Prediction of evocation strength (individual features).

Feature	r	ρ
All	**0.4391**	**0.4000**
$-ldaSim$	0.4378	0.3994
$-w2vSim$	0.4370	0.3991
$-wupSim$	0.4387	0.3997
$-autoexSim$	0.4333	0.3962
$-posSem$	0.4269	0.3837
$-lexNW$	0.4379	0.3999
$-dirRel$	0.4385	0.4000
$-relVec$	**0.3959**	**0.3534**
(Boyd-Graber et al., 2006)	NA	0.131
$Average$	0.0	NA

Table 3: Results: Prediction of evocation strength (ablation tests).

The results listed in Table 2 and Table 3 can be summarized as follows.

- None of the individual baseline features could outperform the feature combination case *All*.
- The semantic relatedness measures based on distributed representation ($w2vSim$ and $autoexSym$) performed relatively well, suggesting that distributed representation of meaning would be promising. Besides, it is shown that even asymmetric evocation relationships could be somewhat recovered by symmetric semantic relatedness.
- A further effective feature was $relVec$, which in this case is a vector computed from the corresponding Autoextend semantic synset vectors. This definitely highlights the effectiveness of distributed representation at the concept level.
- Surprisingly, $posSem$, which essentially is a sparse representation of a synset pair, was a useful feature by itself, implying that characterization at a coarse semantic level could capture some aspects of evocation relationships.
- The contributions of $lexNW$ and $dirRel$, unfortunately, were not remarkable as expected. Indeed, $dirRel$ might have suffered from the relatively sparse connective structure of PWN.

4.2 Results: Determination of directionality

The combination of all the proposed features yielded 0.8703 in total accuracy with RF, which is considerably more accurate than 0.7642 with NN. Thus, in the following, we only discuss the RF results[11].

Table 4 displays the results of the directionality determination for the overall classification accuracy with individual features, whereas Table 5 displays additional results of the ablation test. The tables also

[11]The results are markedly different from the tendency observed in the regression results, where NN is superior to RF. Although, in general, RF algorithms are said to not perform well in regression tasks, this difference should be further examined.

list the accuracy figures obtained by two baselines: *Most frequent* always assigns the most frequent label (*outbound*), whereas *Random* randomly assigns a directionality label while observing the distribution shown in Table 1.

Feature	Accuracy

Random	0.2860

Table 5: Results: Determination of evocation directionality (ablation tests).

The results in Table 4 and Table 5 can be summarized as follows.

- Similar to the strength prediction problem, the semantic relational vectors $relVec$ played the most significant role: Without this feature, the accuracy drops by almost 17%. This clearly indicates that the semantic offset vectors are also useful in this classification task.
- Most of the individual features, including the asymmetric features ($posSem$ and $dirRel$) did not perform well by themselves. However, somewhat surprisingly, the graph-theoretic metric $lexNW$ played a greater role by itself (Accuracy=0.7084), implying that this simple NW-based metric could capture some aspect of the directionality of evocation relationships.
- On the contrary, contributions of the similarity/relatedness features are not very prominent even comparing to the random baseline. This might be however reasonable, given that these similarity/relatedness measures are innately symmetric.

Table 6 breaks down the results for the *All* feature case. It shows that the performance is generally good, but that distinguishing "no-evocation" from the other features is rather difficult. We may need to incorporate features that explicitly model some *irrelevancy* between the concept pair.

Directionality	Precision	Recall	F1
outbound	0.8311	0.9272	0.8765
inbound	0.9008	0.8029	0.8491
bidirectional	0.9600	0.9992	0.9792
no-evocation	0.8716	0.7913	0.8295

Table 6: Breakdown of the results for *All* features (Accuracy=0.8703).

4.3 Results: Types of semantic relational vectors

It is now evident that semantic relational vectors can be employed as a highly effective feature in both task types, suggesting that the characteristics of semantic relations, even though they are largely vague relationships such as evocations, can be captured to some extent by offset semantic vectors. The results reported thus far were achieved by utilizing Autoextend synset semantic vectors. However, alternatives

Vector type	r	ρ	Accuracy
synset	0.4391	0.4000	**0.8703**
w2v	**0.4551**	**0.4158**	0.7535
lexeme	0.4267	0.3880	0.7636

Table 7: Comparison of relational vector types.

would be possible: Word2Vec embedding vectors and the Autoextend lexeme semantic vectors can be assayed.

Table 7 thus compares the results when the type of semantic relational vector was altered. The most prominent observation in this table is: the synset-based relational vectors are far more effective than other types of vectors in the directionality classification task (0.8703 compared to around 0.76 in accuracy). This may indicate that a concept-level representation is more adequate in the classification task, which essentially is a coarser-level task compared to the strength prediction task. On the other hand, the strength prediction task may benefit from word-oriented features, as $relVec(w2v)$ produced the most accurate results (although the differences are subtle).

Interestingly however, the in-between representation $relVec(lexeme)$ failed to perform better than any of these. Although the reason should be further examined, it might reflect the mechanism of Autoextend that employs auto-encoders having the layer of lexemes as the middle layer.

5 Related Work

Among the efforts to enrich wordnets, similar to the work of (Boyd-Graber et al., 2006; Ma, 2013) are (Nikolova et al., 2012) and (Lebani and Pianta, 2012): The former, in the context of ViVA project, populated PWN with evocation links collected by using a crowd sourcing service, which may help people with anomic aphasia to navigate among words and concepts; the latter also extended PWN, but with more semantically relevant feature descriptions acquired from human subjects. Note also that these two projects may share the purpose: assisting people with verbal disorders.

Although there is a scarcity of research into a computational mechanism for predicting evocation relationships, some related research can be found in the areas of psycholinguistic semantic association and asymmetric semantic relatedness. Among a number of psychological/cognitive research studies on mental lexicons (Maki et al., 2004; De Deyne et al., 2013; De Deyne and Storms, 2015), De Deyne and Storms (2015) argue that "the entire set of connections between a pair of words in a large network of knowledge may determine the associative strength between them." Although the $dirRel$ feature proposed in this paper partly reflects this indication (since it virtually considers multiple short paths between the synsets), we could probe the network structures of the underlying lexical-semantic resources even further.

Since an evocation relation is a type of asymmetric semantic relation between lexicalized concepts, it is naturally associated with the issue of asymmetric similarities (Tversky, 1977). As already mentioned in this paper, the central notion behind the asymmetric similarity/relatedness is *feature inclusion*. In particular, (Kotlerman et al., 2010) and (Gawron, 2014) make use of dependency parses acquired from textual corpora as features. These features could potentially also be effective in predicting the evocation relations in part.

In addition to these areas, the use of semantic relational vectors (offset semantic vectors) (Fu et al., 2014; Bollegala et al., 2015; Necsulescu et al., 2015; Vylomova et al., 2016) would be worth pursuing further, as the present results strongly insist that these vectors could be an effective source of features. Our preliminary attempts (not discussed in this paper) to simply cluster the set of offset vectors into groups, however, have been proven ineffective in the present task. This may confirm that an evocation relation may be a composite of elementary semantic relations (Boyd-Graber et al., 2006). In this regard, we would need to further explore the semantic relational vectors, while considering the semantic paths connecting the source and target concepts in lexical-semantic networks. Presumably, deciding the edge weight $w(r)$ for each lexical-semantic relation type in the formula given in 3.2.3 would be a key to this issue. A closely related approach found in the literature is the "bag-of-edges" approach (Shwartz et al.,

2015) for automatically selecting an optimized subset of resource relations in a structured resource, given a target lexical inference task.

6 Concluding Remarks

This paper proposed a supervised learning approach to predict the strength and to determine the directionality of the evocation relation between lexicalized concepts. The empirical results evidently showed that the combination of the proposed features largely outperformed the individual baselines, and insisted that the *semantic relational vectors* computed from existing semantic synset embedding vectors (Rothe and Schütze, 2015) are quite useful in both tasks.

Although the achieved performances ($\rho \approx 0.42$ in regression; $Accuracy \approx 0.87$ in classification) are substantially superior to the figures reported in the literature, they could be further improved by applying more sophisticated machine learning frameworks. Once we get better performance figures, the proposed mechanism could be utilized with semantic NLP downstream applications, such as the measurement of textual similarity/relatedness and the lexical chaining in discourse.

Possible research directions for breakthroughs are (at least) threefold. First, we could explore more appropriate representations for words/lexemes/lexicalized-concepts. Although we proved in this research that the AutoExtend vectors were excellent, other approaches might be more effective. Among the possibilities we are interested in are the incorporation of perceptual features such as those acquired from images (Silberer and Lapata, 2014; Kiela and Bottou, 2014), as some evocation relationships might be rooted in human perception.

Second, we should incorporate more relational features. In particular, asymmetric similarity features that can be acquired from corpora (Kotlerman et al., 2010; Gawron, 2014) would be beneficial, as some of the evocation relations are rather direct asymmetric relations, such as hypernymy and meronymy. To facilitate this line of research, we would start with error analysis of the present results.

Finally, but not least important, we can exploit rich but latent information from a range of semantic resources, such as those with a networked structure; not necessarily limited to PWN. As an evocation relation could be considered as a shortcut for some longer semantic/conceptual association chains, paths in the semantic networks that link the source and target concepts could be utilized as a useful source of features.

Collecting and Exploring Everyday Language for Predicting Psycholinguistic Properties of Words

Gustavo Henrique Paetzold and **Lucia Specia**
Department of Computer Science
University of Sheffield, UK

Abstract

Exploring language usage through frequency analysis in large corpora is a defining feature in most recent work in corpus and computational linguistics. From a psycholinguistic perspective, however, the corpora used in these contributions are often not representative of language usage: they are either domain-specific, limited in size, or extracted from unreliable sources. In an effort to address this limitation, we introduce SubIMDB, a corpus of everyday language spoken text we created which contains over 225 million words. The corpus was extracted from 38,102 subtitles of family, comedy and children movies and series, and is the first sizeable structured corpus of subtitles made available. Our experiments show that word frequency norms extracted from this corpus are more effective than those from well-known norms such as Kucera-Francis, HAL and $\text{SUBTLEX}_{\text{us}}$ in predicting various psycholinguistic properties of words, such as lexical decision times, familiarity, age of acquisition and simplicity. We also provide evidence that contradict the long-standing assumption that the ideal size for a corpus can be determined solely based on how well its word frequencies correlate with lexical decision times.

1 Introduction

Large corpora of text are certainly one of the most fundamental resources in the field of Computational Linguistics. In Psycholinguistics, it has been long established that word frequencies from corpora play a very important role in cognitive processes. Brysbaert and New (2009) points out that frequently occurring words are often much more easily perceived, recalled and associated than rare words (Balota and Chumbley, 1984; Rayner and Duffy, 1986). In Text Simplification, researchers have found a strong relationship between frequencies and word simplicity (Devlin and Tait, 1998).

An inherent limitation of work based on word frequency analysis is that the type of resource used as a corpus is often built for a specific communication purpose, such as news (Burgess and Livesay, 1998). This is however not representative of everyday language usage, particularly from a psycholinguistic perspective. The other extreme of the spectrum features resources compiled from user-generated content, such as micro-blogs. However, these resources often suffer from grammar errors and misspellings, excessive use of acronyms and shortenings, partly due to the constrains of the publication means (e.g. limited number of characters) (Pak and Paroubek, 2010).

This is particularly concerning given that previous research has shown that the source from which a corpus was extracted is one of its most important defining traits. For example, the experiments of Brysbaert and New (2009) and Shardlow (2013) reveal that frequencies from spoken text have a much stronger correlation with psycholinguistic word properties than those from other sources. Their findings greatly highlight the potential of spoken language text, but there are very few examples of resources of this kind available for English. $\text{SUBTLEX}_{\text{us}}$ is a notable exception: it contains texts extracted from 8,388 subtitles of American movies, and is freely available for download. The OpenSubtitles2016 corpus (Lison and Tiedemann, 2016) is another example, featuring sentences extracted from numerous subtitle files aligned at sentence level across 60 languages.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1669–1679, Osaka, Japan, December 11-17 2016.

However, since the subtitles in these corpora are not restricted with respect to genre or domain, their proficiency in capturing everyday language can also be limited. Movies and series span from lighthearted productions for toddlers to historic dramas targeting older audiences, with very distinct vocabulary used. In this paper, we explore the use of everyday language corpora in psycholinguistic applications. In an effort to address the lack of reliable everyday language corpora for English, we create SubIMDB, the first structured corpus of subtitles in the literature. SubIMDB is composed of subtitles of movies and series written for the "average audience", and can be downloaded in useful formats. In the sections that follow, we describe the resources and procedures used to build SubIMDB, and evaluate its performance in various tasks.

2 Building SubIMDB

Our goal in creating SubIMDB was to compile and provide freely a large, structured corpus of everyday language. As a data type, we chose subtitles of movies and series, since they are available for dozens of languages. Another advantage of using subtitles as opposed to, for example, chat logs or podcast transcripts, is that movies and series are subject to production standards, and hence the subtitles created for them tend to be composed of linguistically correct constructs.

2.1 Acquiring Subtitles

To create a reliable corpus of subtitles one must take into account that movies and series can be of many different genres, and may target very distinct audiences. The compilation of $\text{SUBTLEX}_{\text{us}}$ involved the download of 8,388 subtitles of U.S films and series released between 1900-2007, with no restriction with respect to genre. We took a different approach when creating SubIMDB. We use OpenSubtitles[1] as a data source. One can download subtitles from their API by providing with a production's unique IMDb[2] identifier.

As the first step in creating SubIMDB, we queried the IMDb platform searching for identifiers of six types of content: family movies, family series, comedy movies, comedy series, movies for children and series for children. We chose these genres because productions of this kind tend to target viewers of either young or all ages, and hence tend to use accessible language. Our hypothesis is that word usage statistics from this type of content correlate better with psycholinguistic properties of words, such as lexical decision times and age of acquisition.

To obtain the identifiers, we used the IMDb engine[3] to search for and parse all pages under the family and comedy feature film pages, as well as the ones under the family and comedy series categories. Since IMDb does not contain a category specific for children movies and series, we resorted to 15 movies and series lists created by IMDb users to obtain them. In total, we obtained the IMDb identifiers of 9,709 family movies, 8,008 family series, 66,411 comedy movies, 24,776 comedy series, 745 children movies and 124 children series.

We then queried the online OpenSubtitles API for each of these 109,773 IMDb identifiers. Surprisingly, we were only able to find subtitles for 12,618 movies and series. On the other hand, since series are comprised of various episodes, we downloaded subtitles for each episode of every season available in OpenSubtitles. A total of 38,102 subtitles were collected in this way.

2.2 Processing Subtitles

In order to make their content more easily accessible, we first tokenized all lines in the subtitles and removed any HTML tags. A filtering algorithm was then applied to discard subtitle lines which:

1. **Refer to metadata or timing indicators**: These lines do not contain meaningful information.

2. **Have more than 80 characters**: In most cases, lines with close to or more than 80 characters are composed of sequences of random spurious characters.

Size	HF	LF	All
10M	$\mathbf{-0.393}$	-0.391	-0.576
20M	-0.393	-0.433	-0.601
30M	-0.392	-0.454	-0.613
40M	-0.390	-0.471	-0.624
50M	-0.391	-0.465	-0.620

Size	HF	LF	All
60M	-0.390	-0.468	-0.622
70M	-0.390	-0.469	-0.622
80M	-0.391	-0.470	-0.623
90M	-0.392	-0.470	-0.623
100M	-0.392	$\mathbf{-0.471}$	$\mathbf{-0.624}$

Table 1: Pearson correlation of decision times and high and low frequency words per corpus size.

3. **Have at least one word with more than 15 characters**: Lines with unusually long words tend to be incorrectly formatted sentences.

4. **Contain advertisement**: These lines refer to credits attributed to the creators of the subtitles in question. Some examples of expressions targeted are "synched by" and "opensubtitles.org".

The resulting corpus contains 225,847,810 words in 38,643,849 lines, which is 4.5 times bigger than $\text{SUBTLEX}_{\text{us}}$.

2.3 Reliability Assessment

One of the most popular strategies for frequency norm quality assessment is to evaluate how well they predict lexical decision times. A very popular task in the field of Psycholinguistics, *lexical decision*, also known as *lexical reaction time*, refers to the process of deciding whether or not a given sequence of characters is a real word of the language in question (Balota et al., 2007). Previous work has measured the time taken by subjects to make such a decision for certain words, then used correlation metrics to assess how well their frequencies can predict them (Balota et al., 2004; Van Heuven et al., 2014; Vega et al., 2011; Brysbaert and New, 2009). In this section, we evaluate the reliability of SubIMDB by replicating some of the lexical decision experiments of Brysbaert and New (2009) and Burgess and Livesay (1998).

Brysbaert and New (2009) reveal that the size of a spoken text corpus plays a role in its utility. In general, but not always, larger corpora tend to capture psycholinguistic properties of words more effectively, given that they tend to feature a broader vocabulary and a wider array of distinct contexts from which to extract word usage statistics. But going beyond the "the bigger, the better" assumption, Burgess and Livesay (1998) propose that the ideal corpus size depends on the frequency of the words which one aims to predict the lexical decision times for.

To replicate their experiments, we first sample SubIMDB in portions containing 10 to 100 million words from sentences selected at random. As our test set, we use the MRC psycholinguistic Database (Coltheart, 1981), which provides lexical decision times for 40,468 words. Like in (Brysbaert and New, 2009), we consider only the subset of 38,130 lowercase words in order to avoid most abbreviations and proper nouns.

We split these 38,130 words in two sets: high and low frequency words. A word is considered high frequency (HF) if it is among the 1% most frequently occurring words in SubIMDB, otherwise, it is considered low frequency (LF). This methodology resembles that of Burgess and Livesay (1998). The Pearson correlation between word frequencies and lexical decision times for each corpus size are presented in Table 1.

The scores support the hypothesis in (Burgess and Livesay, 1998): the Pearson correlation for high frequency words peaks at 10 million words, while the correlation for low frequency words continuously grows from 10 to 100 million words. The increase in corpus size reflects positively on the overall performance of SubIMDB for all words, contradicting the results obtained by Brysbaert and New (2009), which suggest that a corpus does not need to have more than 16 million words in order to be cost effective.

As discussed in (Hauk and Pulvermüller, 2004), word length can also influence lexical decision times. Intuitively, one would expect to take longer to read a ten character word than a three character word, for example. Inspecting the word frequencies from SubIMDB, we found that larger words tend to benefit from larger corpora. Table 2 shows the Pearson correlation scores with lexical decision times obtained by SubIMDB samples in different sizes with respect to word length in characters.

Table 2: Pearson correlation of decision times and word size per corpus size. Columns represent word length, rows represent corpus size, and cells depict Pearson correlation scores.

Table 2 shows that the scores for long words tend to require larger corpora. This could be explained by the hypothesis of Burgess and Livesay (1998), since the words' length and frequency in SubIMDB are inversely proportional. As illustrated in the second row of the table, shorter words occur much more frequently than longer words in SubIMDB.

Our findings also agree with the ones of Brysbaert and New (2009), who observed that, contrary to norms obtained from news articles and web content, spoken language text norms are better at predicting lexical decision times for shorter words. Notice that, while the correlation for shorter words tend to peak around -0.6, the correlation for longer words peaks around -0.5. This also applies to words with lengths beyond 9 characters: at around 15 characters, correlation values peak around -0.3.

Table 3 shows Pearson correlation scores for the HAL (Burgess and Livesay, 1998) and SubIMDB corpora with respect to word length. Unlike SubIMDB, the HAL corpus is composed of news articles. Much like what is observed in (Brysbaert and New, 2009), while the SubIMDB norm considerably outperforms HAL for words with 2-4 characters, the HAL corpus gives more reliable norms for words with 5+ characters. The reason behind SubIMDB's disadvantage with longer words is explained by the fact that words with 2-4 characters compose 80% of SubIMDB's content. Although this observation may seem puzzling at first, it can be easily explainable. Take, for an example, the sentences "what have you done?" and "what do you mean?". Both these sentences are composed entirely of words between two and four characters, and occur very frequently in SubIMDB. Other notable examples are "come on", "I got to go now" and "have a good one". This difference between HAL and SubIMDB suggests that combining frequency norms from different sources could be a good way of creating even more reliable norms.

Table 3: Correlation comparison between frequencies and decision times on a word size basis. The last line indicates a statistically significant difference with SubIMDB given $p < 0.1$ (•), $p < 0.01$ (••) or $p < 0.001$ (• • •) (F-test).

In sections to come, we compare the performance of SubIMDB and numerous other corpora in various psycholinguistic tasks.

3 Predicting Lexical Decision Times

In this experiment we assess how well frequencies from different sets of SubIMDB subtitles fair against other well-known corpora in how they correlate with lexical decision times. For this experiment, we extracted word frequencies from various SubIMDB subcorpora, as shown in Table 4.

All SubIMDB (SubIMDB)	All Comedy content (SubCOM)	Comedy movies (SubCOM-M)
All movies (SubMOV)	All children content (SubCHI)	Comedy series (SubCOM-S)
All series (SubSER)	Family movies (SubFAM-M)	Children movies (SubCHI-M)
All Family content (SubFAM)	Family series (SubFAM-S)	Children series (SubCHI-S)

Table 4: Subcorpora from SubIMDB used to predict lexical decision times

We compare ours to six frequency norms:

- **KF**: Oldest and most widely used frequency norm, calculated over the Brown corpus (Rudell, 1993; Francis and Kucera, 1979).
- **HAL**: *Hyperspace Analogue to Language* word frequency norm, calculated over the HAL corpus, which contains over 131 million words from Usenet newsgroups (Burgess and Livesay, 1998).
- **Wiki**: Word frequencies from Wikipedia, with 97 million words (Kauchak, 2013).
- **SimpleWiki**: Word frequencies from Simple Wikipedia, with 9 million words (Kauchak, 2013).
- **SUBTLEX**: Word frequencies from $\text{SUBTLEX}_{\text{us}}$, with 51 million words (Brysbaert and New, 2009).
- **Open2016**: Word frequencies from OpenSubtitles2016, with 2 billion words (Lison and Tiedemann, 2016).

We regularise all norms using Equation 1, in which f is the frequency norm value of a word w. This transformation has shown to best represent the relationship between word frequencies and lexical decision times (Balota et al., 2004).

$$norm(f(w)) = \log_{10}(f(w) + 1) \tag{1}$$

We use the same lexical decision dataset from our previous experiments as our test set. The results in Table 5 reveal that, while SubIMDB in its entirety yields the highest Spearman (ρ) correlation scores, the SubMOV corpus, which contains only subtitles of movies, yields the highest Pearson (r) correlation. F-tests show a statistically significant difference between frequencies from SubIMDB and all other corpora.

Norm	Size	ρ	r	F-test

Table 5: Lexical decision prediction correlation scores. The last column indicates a statistically significant difference with SubIMDB given $p<0.1$ (•), $p<0.01$ (••) or $p<0.001$ (•••) (F-test).

Unlike what was reported in (Brysbaert and New, 2009), the HAL norm achieved lower correlation scores than the SUBTLEX norm, despite the fact that the HAL corpus is twice as large as $\text{SUBTLEX}_{\text{us}}$. This contrast highlights the potential of spoken language corpora in lexical decision prediction.

Our results also indicate a poor performance for the Kucera-Francis coefficient. Despite its use in numerous previous contributions (Burgess and Livesay, 1998; Zevin and Seidenberg, 2002; Brysbaert and New, 2009), more modern resources proved more effective. We believe this is caused by the fact that these coefficients are calculated from a corpus that is very small when compared to the other resources presented in this paper.

4 Predicting Psycholinguistic Properties

In addition to lexical decision times, other psycholinguistic properties of words have been studied in terms of their correlation with frequency norms (Paetzold and Specia, 2016a). In this experiment, we evaluate how well the norms described in Section 3 correlate with four psycholinguistic properties extracted from the MRC psycholinguistic Database:

- **Familiarity**: Available for 9,392 words – frequency with which a word is seen, heard or used daily.
- **Age of Acquisition**: Available for 3,503 words – age at which a word is learned.
- **Concreteness**: Available for 8,228 words – how "palpable" the object the word refers to is.
- **Imagery**: Available for 9,240 words – intensity with which a word arouses images.

The results in Table 6 reveal that SubFAM-M (family movies) performs better than all other norms in predicting age of acquisition and concreteness, although it is 117 times smaller than OpenSubtitles2016 (Open2016). F-tests reveal a statistically significant difference between SubIMDB and all other corpora.

		Age of Acquisition		Familiarity		Concreteness		Imagery

Table 6: Pearson correlation of norms with respect to psycholinguistic properties. Columns following correlation scores indicate a statistically significant difference with SubIMDB given $p<0.1$ (•), $p<0.01$ (••) or $p<0.001$ (•••) (F-test).

Perhaps most surprising is the performance of the SubIMDB subset of children movies (SubCHI-M) in predicting age of acquisition. Despite its small size, its performance is still much superior than almost

all corpora, including OpenSubtitles2016, which is over 250 times larger. Comparing word frequencies from SubCHI-M with the ones in OpenSubtitles2016, we found interesting differences. Table 7 shows the most over and underrepresented words in SubCHI-M based on percentages of variance with respect to OpenSubtitles2016.

It can be noticed that while overrepresented words ("turtles", "hedgehog", etc.) are mostly innocent in nature, underrepresented words describe mostly sexual and/or thought-provoking concepts ("vagina", "abortion", etc.). These differences reveal that, although subtitle corpora may share traits in general, the domain from which the subtitles are extracted plays an important role. This highlights the often disregarded advantages of a structured, raw text subtitle corpora like the one we collected here. By making subtitles available in their raw form along with metadata about their source of origin, future research can explore different ways of building the ideal corpus for a given task, e.g. by employing clever subtitle selection and filtering techniques.

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**
Over	hoagy	flintstone	turtles	potter	fantasia	hedgehog	hiccup	dialogue
Under	vagina	abortion	cartel	intercourse	rapist	overdose	porn	pimp

Table 7: Representation contrast between the SubCHI-M and OpenSubtitles2016 corpora.

Inspecting our data, we also found further evidence that, unlike what was found by Brysbaert and New (2009), it is unfeasible to predict the ideal size of a corpus by simply looking at frequency correlation with lexical decision times. Table 8 illustrates Pearson correlation scores of different SubIMDB sample sizes for all aforementioned psycholinguistic properties. The correlation scores all behave differently: while familiarity benefits from larger corpora, the remaining properties do not.

	Age of Acquisition		Familiarity		Concreteness		Imagery

5 Predicting Simplicity

Everyday language corpora can also be useful in predicting word simplicity. In this experiment, we evaluate how well SubIMDB fairs against other corpora when employed as a solution to Lexical Simplification.

As our test set, we use the one from the English Lexical Simplification task of SemEval 2012, which contains 1,710 instances composed of a sentence, a target word, and candidate substitutions ranked by simplicity. This dataset has been widely used and hence allows the comparison of SubIMDB against state-of-the-art solutions for the task. For evaluation, we use Spearman (r) and Pearson (ρ) correlation, as well as the TRank metric proposed by Specia et al. (2012), which measures the rate with which a candidate substitution with the highest gold rank i.e. the simplest, was ranked first by the system.

We compare the performance of all frequency norms described in Section 3 to Google 1T, a corpus composed of over 1 trillion words (Evert, 2010), and the winner system in the SemEval 2012 task, which

Table 9: Correlation and TRank scores for frequency norms with respect to simplicity. The fifth column indicates a statistically significant difference with SubIMDB given $p<0.1$ (•), $p<0.01$ (••) or $p<0.001$ (•••) (F-test).

employs a Support Vector Machine ranker that uses a wide array of features (Jauhar and Specia, 2012). The results in Table 9[4] reveal that SubIMDB outperforms all baselines, including Google 1T and the former state-of-the-art for the task in TRank. Nonetheless, some SubIMDB subcorpora are even more effective than using our corpus in its entirety, despite being much smaller.

Work in Text Simplification has, however, explored more than single-word frequency norms, considering for example raw n-gram frequencies and language model probabilities (Horn et al., 2014; Baeza-Yates et al., 2015; Paetzold and Specia, 2016b). Table 10 shows TRank scores obtained on the SemEval 2012 task when using 3-gram and 5-gram raw frequencies and language model probabilities extracted from various corpora. The 3-grams and 5-grams consist in a candidate substitution surrounded by one and two tokens, respectively. For probabilities, we trained 5-gram language models using SRILM (Stolcke, 2002). For the Kucera-Francis (KF) norms we use the Brown corpus (Francis and Kucera, 1979). The HAL corpus is not available for download and hence it could not be tested here.

Table 10 shows that single word frequencies are more effective than both 3-grams or 5-grams in the SemEval 2012 task. We believe that the reason for this lies in the fact that almost all candidate substitutions in each instance of the dataset perfectly fit the context in which the target word was found, both with respect to grammaticality and meaning preservation. This setup disregards the need to account for context, which hence makes the use of n-grams less crucial. Since the representative sparsity of a corpus inherently grows as sequences of words become longer, n-grams with $n \geq 1$ are consequently much less reliable than single-word frequencies for this task in particular. This hypothesis is also supported by the fact that 3-gram frequencies achieved considerably higher scores than 5-gram frequencies.

Nonetheless, there is a clear advantage to using language model probabilities as opposed to raw frequencies for larger n-grams, since language models employ sophisticated smoothing techniques to reduce issues due to sparsity. These findings highlight again how important it is for corpora to be released in raw format to make it possible to train language models.

6 Conclusions

In this paper we presented a study on the application of everyday language corpora in the prediction of psycholinguistic properties of words. For our experiments, we created SubIMDB: a large structured corpus of subtitles of movies and series for the average audience. It contains 38,102 subtitles, each individually annotated with metadata about the movie or series for which they were created. Altogether, our corpus has 225,847,810 words in 38,643,849 lines, which is 4.5 times larger than the widely used $\text{SUBTLEX}_{\text{us}}$ corpus (Brysbaert and New, 2009).

We found that word frequencies from SubIMDB capture lexical decision times more effectively than various other frequency norms. Additionally, we found that using only certain types of subtitles can yield

[4]Specia et al. (2012) only provides results for TRank.

Table 10: TRank scores for n-grams. Columns following TRank scores indicate a statistically significant difference with SubIMDB given $p < 0.1$ (●), $p < 0.01$ (●●) or $p < 0.001$ (●●●) (F-test).

noticeable increase in performance. The same was observed for the prediction of other psycholinguistic properties, such as age of acquisition.

Our experiments provided evidence to support (Burgess and Livesay, 1998)'s hypothesis, which states that the ideal size of a corpus depends on the overall frequency of the words which one aims to predict lexical decision times for. Nonetheless, our results also reveal that, unlike what is claimed by Brysbaert and New (2009), one should not attempt to quantify the ideal corpus size based solely on correlation scores with lexical decision times.

Finally, we found that in English Lexical Simplification both word frequencies and language model probabilities from SubIMDB outperform the ones extracted from all other corpora available, as well as the state-of-the-art method for the task. Through these findings, we hope to encourage other researchers to collect and release corpora in more flexible, useful forms rather than simply providing with pre-computed single-word frequency counts.

In future work, we aim to add other types of subtitles to SubIMDB and to study smarter subtitle selection and filtering strategies. We also intend to study the use of other types of spoken text corpora, such as tweets and conversations from Facebook (Herdağdelen and Marelli, 2016), in improving the performance of Natural Language Processing tasks. We released the SubIMDB corpus in both raw form, containing subtitles individually annotated with metadata, and in compiled form. Both versions are freely available for download at `http://ghpaetzold.github.io/subimdb`.

Using Argument Mining to Assess the Argumentation Quality of Essays

Henning Wachsmuth, Khalid Al-Khatib, and Benno Stein
Faculty of Media, Bauhaus-Universität Weimar, Germany
{henning.wachsmuth,khalid.alkhatib,benno.stein}@uni-weimar.de

Abstract

Argument mining aims to determine the argumentative structure of texts. Although it is said to be crucial for future applications such as writing support systems, the benefit of its output has rarely been evaluated. This paper puts the analysis of the output into the focus. In particular, we investigate to what extent the mined structure can be leveraged to assess the argumentation quality of persuasive essays. We find insightful statistical patterns in the structure of essays. From these, we derive novel features that we evaluate in four argumentation-related essay scoring tasks. Our results reveal the benefit of argument mining for assessing argumentation quality. Among others, we improve the state of the art in scoring an essay's organization and its argument strength.

1 Introduction

Argument mining aims to determine the argumentative structure of natural language texts. Usually, this structure is composed of different types of argumentative discourse units, such as premises and conclusions, that together form one or more arguments in favor of or against some thesis.

One of the main proposed downstream applications of argument mining is writing support including automated grading, which will extend the capabilities of massive open online courses (MOOCs), thereby contributing to unlimited access and participation in education. To aid argumentative writing, we envision a writing support system to proceed in three major steps: (1) The *mining* of argumentative structure, (2) the *assessment* of specific quality dimensions based on the mined structure, and (3) the *synthesis* of suggestions for quality improvements. Figure 1 visualizes the resulting process. Several approaches to the mining step have been developed and evaluated in terms of the effectiveness of the mined structure. So far, however, the benefit of this structure remains largely unexplored (see Section 2 for details).

This paper puts the assessment step into the focus. We ask if, to what extent, and how the output of argument mining can be leveraged to assess the argumentation quality of a text. In particular, we consider these questions for persuasive student essays. Such an essay seeks to justify a thesis on a given topic via a composition of arguments. Different quality dimensions related to argumentation have been studied for persuasive essays, such as the clarity of the justified thesis (Persing and Ng, 2013). Also, argument mining has already been performed effectively on persuasive essays (Stab and Gurevych, 2014b).

We build on the outlined research in that we use argument mining to assess an essay's argumentation quality. First, we adapt a state-of-the-art approach for mining argumentative discourse units (Section 3). Then, we apply the approach to all essays from the International Corpus of Learner English (Granger et al., 2009) in order to analyze their argumentative structure. We find statistically reliable patterns that yield insights into how students argue in essays. From these, we derive novel solely structure-oriented features for machine learning (Section 4). Finally, we tackle essay scoring for four argumentation-related quality dimensions: organization, thesis clarity, prompt adherence, and argument strength. In systematic experiments, we compare our features to strong baselines and to the state of the art (Section 5). The observed results provide clear evidence for the impact of argumentative structure on argumentation quality: Our features consistently do best among all structure-oriented approaches. Moreover, we outperform the state of the art of scoring the organization and the argument strength of persuasive essays.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1680–1691, Osaka, Japan, December 11-17 2016.

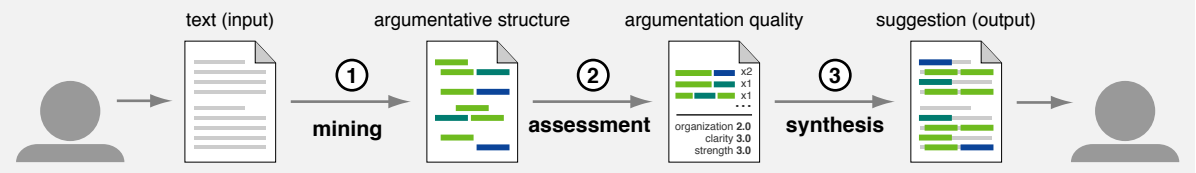

Figure 1: The three major steps of the envisioned process of writing support systems.

Contributions Altogether, with this paper we provide the following contributions to research:

1. We examine the use of argument mining for assessing argumentation quality for the first time.
2. We reveal common patterns in the argumentative structure of persuasive essays statistically.
3. We provide the new state of the art approach to two argumentation-related essay scoring tasks.

2 Related Work

Several approaches to argument mining have been introduced, often grounded in argumentation theory: Matching the argumentation schemes of Walton et al. (2008), Mochales and Moens (2011) model each argument in legal cases as a conclusion with a set of premises. Based on (Freeman, 2011), Peldszus and Stede (2015) capture support and attack relations between argumentative discourse units of microtexts. Habernal and Gurevych (2015) adapt the fine-grained argument model of Toulmin (1958) for web texts. As detailed in Section 3, we rely on the essay-oriented model of Stab and Gurevych (2014a). For us, mining is a preprocessing step only, though. For statistical reliability, we restrict our view to the units of arguments. Like Moens et al. (2007), we classify units on the sentence level, but we consider four different unit types. This results in a sequential structure comparable to argumentative zones (Teufel et al., 2009). The latter have also been exploited for downstream applications (Contractor et al., 2012).

Our focus is the *analysis* of argumentative structure. Related structures have been analyzed before: To measure text coherence, Feng et al. (2014) build on discourse structure (Mann and Thompson, 1988), which is connected but not equivalent to argumentative structure (Peldszus and Stede, 2013). Faulkner (2014) classifies the stance of essays using argument representations derived from dependency parse trees. For essay scoring, Persing et al. (2010) detect the discourse function of each paragraph in an essay in order to align the resulting function sequence with known function sequences. Similarly, we capture a review's overall structure in (Wachsmuth et al., 2014a) by comparing the local sentiment flow in the review to a set of common flow patterns that are learned through clustering. In (Wachsmuth et al., 2015), we further abstract the flows to optimize their domain generality in global sentiment analysis. Discourse structure, discourse functions, and sentiment flows serve as baselines in our experiments in Section 5. Unlike all mentioned approaches, however, we analyze the output of argument mining.

In particular, we use the mined structure to assess argumentation quality. While there is no common definition of such quality, Blair (2012) specifies the goals of relevance, acceptability, and sufficiency for arguments. To find accepted arguments in debate portals, Cabrio and Villata (2012) analyze attack relations between arguments based on the framework of Dung (1995). Rinott et al. (2015) detect three types of evidence in Wikipedia articles, and Boltužić and Šnajder (2015) seek for the prominent arguments in online debates. Here, we are not interested in the quality of single arguments but rather in the quality of a complete argumentation, namely, the argumentation found in a persuasive essay.

We target quality dimensions of persuasive essays that are directly related to argumentation: organization (Persing et al., 2010), thesis clarity (Persing and Ng, 2013), prompt adherence (Persing and Ng, 2014), and argument strength (Persing and Ng, 2015). In all four publications, sophisticated features are engineered to address a respective essay scoring task. The argument strength approach adopts ideas from the approach of Stab and Gurevych (2014b), but it finds structure heuristically only and, thus, does not perform argument mining. In the paper at hand, we fill this gap, i.e., we exploit the output of an argument mining approach trained on ground-truth data to assess the four quality dimensions.

In general, numerous approaches exist that assess essay quality. Classical essay scoring often focuses on grammar, vocabulary, and similar (Dikli, 2006), partly employing structural features like discourse markers (Burstein et al., 1998). In contrast, Song et al. (2014) study whether essays comply with critical

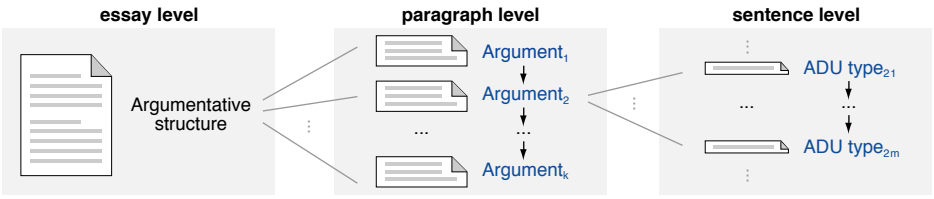

Figure 2: Application-oriented model of the argumentative structure of essays. Each paragraph is seen as an argument, defined as a sequence of sentence-level ADU types $\in \{$*Thesis, Conclusion, Premise, None*$\}$.

questions of an applied argumentation scheme. On manual annotations, they find correlations between an essay's score and the number of answered questions. Closer to our work, Ong et al. (2014) analyze argumentative discourse units found with a simple heuristic algorithm. And Ghosh et al. (2016) even derive features from argument mining, although they hardly exploit structure. Either way, all these approaches assign overall essay scores only, leaving unclear to what extent argumentation quality is captured.

3 Mining Argumentative Structure

This paper does *not* aim at new approaches to argument mining. Still, the effectiveness of mining as well as the underlying argumentation model directly affect the analysis of argumentative structure. Therefore, we summarize our mining approach in the following.[1]

3.1 An Application-Oriented Model of Argumentative Structure

We focus on the argumentative structures of persuasive student essays. Such an essay states and justifies a thesis on some topic that is introduced by a given prompt. To capture an essay's structure, we build on the work of Stab and Gurevych (2014a) who presented both an argumentation model for persuasive essays and an annotated corpus. By training a mining approach on this corpus, we expect to minimize the usual out-of-domain effectiveness drop (Blitzer et al., 2008), when using the approach on other essays.

Stab and Gurevych (2014a) distinguish four types of argumentative discourse units (called ADUs from here on) within essays: *Thesis*, *Conclusion*, *Premise*, and *None*.[2] The authors define an ADU loosely as a statement covering an entire sentence or less. Each conclusion in an essay supports or attacks a thesis, and each premise supports or attacks a thesis, conclusion, or other premise. Implicitly, these relations specify the essay's arguments. In their corpus, less than 15% of all relations are attacks.

For our purposes, we simplify the model of Stab and Gurevych (2014b) in two respects: (1) We define each sentence in an essay to correspond to exactly one ADU. Thereby, we avoid the need to segment essays into ADUs.[3] (2) We define each paragraph in an essay to correspond to exactly one argument. Thereby, we avoid the need to identify relations between ADUs. As a result, we represent the argumentative structure of an essay as a sequence of arguments and each argument as a sequence of ADU types. Figure 2 sketches this application-oriented model.

The justification for our simplification is twofold: (1) We aim to capture argumentative structure only on an abstraction level that allows assessing argumentation quality. Abstraction reduces the search space of argument structures to explore, which benefits pattern recognition, but it also takes away information. While the right level is unknown, we hypothesize that students largely organize essays sequentially. This is in line with our previous research (Wachsmuth et al., 2015). (2) For successful pattern recognition, we need to mine argumentative structure effectively. Therefore, we omit potentially helpful structure such as attack relations, as all available data seems insufficient for reliably training respective approaches.

3.2 Approach

For tokenization, sentence splitting, and paragraph splitting, we apply our own algorithms from previous work (Wachsmuth, 2015), while we use the TreeTagger for part-of-speech tagging (Schmid, 1995). Given the sentences and paragraphs of an essay, our model then requires only to classify the ADU type of

[1] The source code for reproducing all experiments from Sections 3 to 5 can be found here: http://www.arguana.com/software

[2] Stab and Gurevych (2014a) use other names for the ADU types than we do, such as *Major claim* instead of *Thesis*.

[3] The approach proposed by Stab and Gurevych (2014b) also does not deal with the segmentation of an essay into ADUs, but merely because it classifies ADUs simply based on the ground-truth segmentation.

ADU Type	Training	Test	Total	AAE Total
Thesis	72	18	90	90
Conclusion	325	93	418	429
Premise	652	181	833	1033
None	185	53	238	327
All types	1234	345	1579	1879

Table 1: Distribution of ADU type annotations in the modified dataset. Notice that the difference to the distribution in the original Argument Annotated Essays (AAE) corpus is moderate only.

#	Feature Type	Accuracy	F_1-score
1	Prompt similarity	44.9	41.8
2	Token n-grams	47.8	48.0
3	POS n-grams	41.2	43.5
4	General Inquirer classes	42.3	44.5
5	1st token n-grams	33.6	35.0
6	Sentence position	64.9	66.9
1–6	**Complete feature set**	74.5	**74.5**
	Majority baseline	52.5	36.1
	Stab and Gurevych (2014b)	**77.3**	72.6

Table 2: Effectiveness of our features in classifying ADU types compared to (Stab and Gurevych, 2014b).

each sentence. As Stab and Gurevych (2014b), we tackle this 4-class classification task with supervised machine learning. We employ six feature types that capture the content, style, and position of a sentence:[4]

Prompt Similarity The cosine, Euclidean, Manhattan, and Jaccard similarity of the sentence to the prompt of the given essay, once for all words and once for all non-function words.

Token n-Grams The frequency of each token 1- to 3-gram occurring in $\geq 1\%$ of the training sentences.

POS n-Grams The frequency of each part-of-speech 1- to 3-gram occurring in $\geq 5\%$ of these sentences.

General Inquirer Classes The frequency of each word class specified by the General Inquirer.[5]

1st Token n-Grams Indicators whether the first token 1-, 2-, and 3-gram of the sentence match those 1-, 2-, and 3-grams that are first in $\geq 0.5\%$ of all training ADUs.

Sentence Position Indicators whether a sentence is the first, second, or last within a paragraph and what its relative position is. The same for the sentence and the covering paragraph within the complete essay.

3.3 Experimental Set-up

We evaluated our approach to classify all ADU types in a persuasive essay based on the following set-up:

Data As indicated, we processed the Argument Annotated Essays (AAE) corpus of Stab and Gurevych (2014a), containing 90 persuasive student essays (72 for training, 18 for testing). In each essay, all theses, conclusions, and premises are annotated as ADUs of the respective types. Since we do not tackle ADU segmentation, we enlarged the annotations to span the whole covering sentence. If a sentence contained more than one ADU, we favored rarer classes to benefit training, i.e., we preferred *Thesis* over *Conclusion* over *Premise*. All unannotated sentences from an essay's body were assigned the type *None*. Unlike Stab and Gurevych (2014b), we ignored the titles of the 90 essays as *None* instances; classifying a title based on its position is trivial, but it causes errors on essays without titles. Table 1 compares the numbers of annotations in our modified dataset to those of the original AAE corpus. Besides the ignored titles, the two resources differ considerably only in the number of premises.

Experiments For supervised learning, we used the default configuration of the SMO classifier in Weka 3.7 (Hall et al., 2009). We turned off its feature normalization, though, because we generally normalize all our feature values to the range $[0, 1]$. On the training set of the derived dataset, we trained one classifier for each single feature type and for the complete feature set. We did not optimize any hyperparameters but simply measured the accuracy and weighted average F_1-score of the default SMO on the test set.

Comparison As a rough estimate, we compare the results of our approach to those of Stab and Gurevych (2014b) on the AAE corpus. While the comparability is only limited due to the slightly modified corpus, we do not primarily aim to outperform existing mining approaches but rather to imitate them. In order to ease the global interpretation of our results, we also report on the *majority baseline*.

3.4 Results

Table 2 presents the classification effectiveness of each evaluated feature type. The sentence position features dominate all other types with an accuracy of 64.9 and an F_1-score of 66.9. Still, the others add

[4]The strongest type in (Stab and Gurevych, 2014b) uses the length of an ADU as well as the tokens in its covering sentence. As we classify complete sentences, these features help less here.

[5]For more information on the General Inquirer classes, see http://www.wjh.harvard.edu/∼inquirer/.

Paragraph	Premise: *Secondly, most violent crimes are related to the abuse of guns, especially in some countries where guns are available for people.* Conclusion: *Eventually, guns will create a violent society if the trend continues.* Premise: *Take an example, in American, young adults and even juveniles can get access to guns, which leads to the tragedies of school gun shooting.* Premise: *What is worse, some terrorists are able to possess more advanced weapons than the police, which makes citizens always live in danger.*
ADU flow	(1x Premise, 1x Conclusion, 2x Premise)
ADU change flow	(Premise, Conclusion, Premise)

Figure 3: The ADU flow and the ADU change flow for one paragraph of the AAE corpus (see Section 3).

to the effectiveness of the complete feature set. The complete feature set performs a little worse than Stab and Gurevych (2014b) in terms of accuracy (74.5 vs. 77.3) but better in terms of F_1-score (74.5 vs. 72.6). Thus, we conclude that our mining approach is at eye level with (Stab and Gurevych, 2014b). Moreover, our results appear reasonable within a 4-class classification task. We will see whether they suffice to recognize discriminative argumentative structures and to leverage them for quality assessment.

4 Analyzing Argumentative Structure

This section analyzes the output of our mining approach to find statistically reliable patterns in the argumentative structure of persuasive essays. From these, novel features for machine learning are derived.

4.1 Statistically Reliable Patterns of Argumentative Structure

A persuasive essay is meant to compose a set of arguments in favor of or against a thesis, each combining a set of premises with a conclusion (Stab and Gurevych, 2014a). Such a tree-like structure allows for much variance, rendering a reliable pattern recognition hard. Above, we have hypothesized that essays largely argue sequentially. Given the model from Section 3, we hence restrict our view to the sequences of types of argumentative discourse units (ADUs) in essays. In accordance with our work on sentiment flows from (Wachsmuth et al., 2014b), we look at two kinds of patterns, both exemplified in Figure 3:

ADU Flow The sequence of all ADU types within one paragraph on an essay.

ADU Change Flow The sequence of all different ADU types within one paragraph on an essay.

4.2 Experimental Set-up

To get reliable insights into the structure of persuasive essays, we performed a straightforward analysis:

Data We took the International Corpus of Learner English (ICLE, version 2), containing 6085 English essays from students of 16 mother tongues (Granger et al., 2009). On average, an ICLE essay spans 7.6 paragraphs (standard deviation $\pm$ 5.2) and 33.8 sentences ($\pm$ 16.5) according to our preprocessing.

Experiments We applied the mining approach from Section 3 to all ICLE essays. Then, we computed the relative frequencies of all ADU flows and ADU change flows. In addition, we tested how much these frequencies differ within an essay's first and last paragraph.

4.3 Results

The top part of Table 3 lists the ten most frequent of the 2593 ADU flows found in the ICLE corpus. They cover about half of all paragraphs. The first two ADU flows consist of conclusions only, whereas the others show "real" argumentative structure. After a conclusion, two premises follow most often (5.4%). Still, the number of premises varies, bringing up the question whether a particular number benefits argumentation quality. Patterns such as *(1x Conclusion, 2x Premise, 1x Conclusion)* may refer to restated conclusions but also to paragraphs that combine two arguments.

Overall, we see that all top ten ADU flows begin with a conclusion, i.e., our analysis reveals that students tend to (or are taught to) first state a claim and then argue for it. This is also supported by the top ten ADU change flows in Table 4: Every fourth paragraph matches the pattern *(Conclusion, Premise)*, while only 2.9% order all premises first. Similarly, *None* serves for beginning a paragraph, while theses rather appear at the end. In total, the abstraction of ADU change flows seems to capture much diversity of arguments in persuasive essays: Together, the top ten represent 87.4% of all ICLE paragraphs, and all ADU types occur in at least one combination. Still, we found 319 different ADU change flows.

Both Table 3 and 4 highlight the special roles of the first and last paragraph of an essay, which clearly deviate from the average: The first is mostly made up of *None* and *Thesis*, underlining its introductory nature. In contrast, the last often ends with a conclusion—making the argumentation's final point.

¶'s	#	ADU Flow	Frequency
all	1	(1x Conclusion)	14.5%
	2	(2x Conclusion)	7.1%
	3	(1x Conclusion, 2x Premise)	5.4%
	4	(1x Conclusion, 1x Premise)	4.9%
	5	(1x Conclusion, 3x Premise)	4.2%
	6	(1x Conclusion, 1x Premise, 1x Conclusion)	4.2%
	7	(1x Conclusion, 2x Premise, 1x Conclusion)	3.4%
	8	(1x Conclusion, 4x Premise)	3.0%
	9	(1x Conclusion, 3x Premise, 1x Conclusion)	2.3%
	10	(1x Conclusion, 5x Premise)	2.0%
1st	1	(2x None)	9.7%
	2	(3x None)	8.6%
	3	(2x None, 1x Thesis)	6.2%
	4	(4x None)	6.2%
	5	(3x None, 1x Thesis)	5.7%
last	1	(1x Conclusion)	16.9%
	2	(2x Conclusion)	12.6%
	3	(1x Conclusion, 1x Premise, 1x Conclusion)	8.2%
	4	(1x Conclusion, 2x Premise, 1x Conclusion)	5.7%
	5	(1x Conclusion, 3x Premise, 1x Conclusion)	3.4%

Table 3: The most frequent ADU flows in *all* ICLE paragraphs as well as in the *1st* and *last* paragraphs.

¶'s	#	ADU Change Flow	Frequency
all	1	(Conclusion, Premise)	25.1%
	2	(Conclusion)	22.4%
	3	(Conclusion, Premise, Conclusion)	17.0%
	4	(None)	5.8%
	5	(Premise)	4.3%
	6	(None, Thesis)	3.4%
	7	(Premise, Conclusion)	2.9%
	8	(None, Premise)	2.7%
	9	(Conclusion, Premise, Conclusion, Premise)	2.0%
	10	(None, Premise, Conclusion)	1.8%
1st	1	(None)	42.7%
	2	(None, Thesis)	25.9%
	3	(Thesis)	5.7%
	4	(None, Premise, None)	4.4%
	5	(None, Conclusion)	4.3%
last	1	(Conclusion)	31.6%
	2	(Conclusion, Premise, Conclusion)	27.2%
	3	(Conclusion, Premise)	13.1%
	4	(None, Premise, Conclusion)	4.4%
	5	(Premise, Conclusion)	2.7%

Table 4: The most frequent ADU change flows in the ICLE paragraphs (ignoring type repititions).

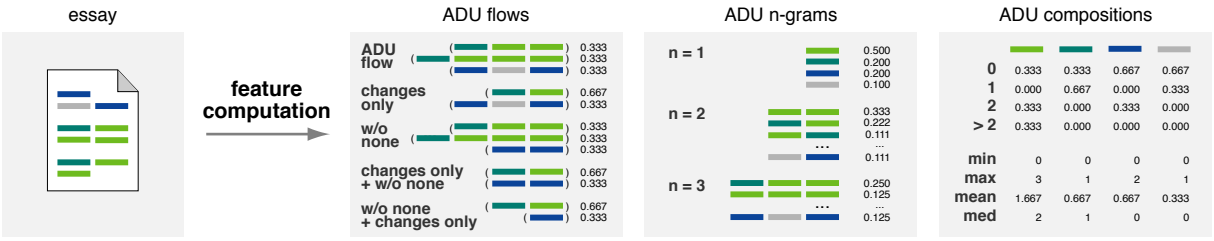

Figure 4: Sketch of the three feature types that we propose based on the output of argument mining.

4.4 Shallow Features for Statistical Significance

The found patterns suggest that persuasive student essays differ in the combination, ordering, and number of ADU types. For the assessment of argumentation quality, we capture these structural variations in the following three novel feature types. The types are kept shallow in order to benefit statistical significance:

ADU Flows The frequencies of all ADU flows in an essay. The hypothesis is that certain flows are favorable. We also examine two flow abstractions: (1) considering changes only, as above, and (2) ignoring the non-argumentative type *None*. Arranging 0 to 2 of these abstractions allows for five flow variations.

ADU n-Grams The frequencies of all ADU type n-grams in an essay for some $n \geq 1$. The hypothesis is that certain combinations of ADU types are favorable.

ADU Compositions The proportions of paragraphs in an essay with a particular number of occurrences of a particular ADU type as well as summary statistics about each type (such as the minimum or mean). The hypothesis is that certain numbers of certain ADU types are favorable.

Figure 4 illustrates the computation of feature values of each type for a sample essay with three paragraphs. The exact feature type configuration that we used in our experiments is specified in Section 5.

5 Assessing Argumentation Quality

Finally, we analyze the benefit of mining argumentative structure for assessing argumentation quality. In particular, we evaluate the three presented feature types in argumentation-related essay scoring.

5.1 Essay Scoring Tasks

We consider four essay scoring tasks that were introduced in successive papers, each of which capturing a particular dimension of argumentation quality. These tasks can be summarized as follows:

Organization Score the quality of an essay's organization. A high score is assigned to essays, which introduce their topic, take and argue for a position on the topic, and conclude (Persing et al., 2010).

Thesis Clarity Score the clarity of the explanation of the thesis that an essay argues for. A high score is assigned to essays, which make their thesis easy to understand (Persing and Ng, 2013).

Prompt Adherence Score the adherence of an essay's content to the essay's prompt. A high score is assigned to essays that consistently remain on the topic of the prompt (Persing and Ng, 2014).

Argument Strength Score the strength of the argument that an essay makes for its thesis. A high score is assigned to essays, which would convince most readers of their thesis (Persing and Ng, 2015).

Our proposed feature types solely focus on the argumentative structure of an essay—as opposed to the essay's content or linguistic style. Accordingly, we hypothesize that the feature types are particularly successful in the organization task. To a minor extent, we expect that they also help for argument strength, because argument strength should emerge from all aspects of an essay. In contrast, the scoring of thesis clarity and prompt adherence rather seems to require an analysis of content and style respectively.

5.2 Approach

Analogue to the authors of the four mentioned papers, we tackle essay scoring with supervised regression. For this purpose, we consider our proposed feature types as well as several baseline features:

ADU Features (a) In terms of the feature types from Section 4, we rely on the following configurations:

- a_1 *ADU flows*. The frequency of each ADU flow that occurs in $\geq 1\%$ of all training essays. All five flow variations described in Section 4 are taken into account.
- a_2 *ADU n-grams*. The frequency of each ADU 1-, 2-, and 3-gram that occurs in $\geq 5\%$ of all training essays. + Indicators that capture the first and the last ADU 1-, 2-, and 3-gram.
- a_3 *ADU compositions*. The percentages of paragraphs with $\{0 \mid 1 \mid 2 \mid >2\}$ occurrences of the type $\{$*Thesis* | *Conclusion* | *Premise* | *None*$\}$. + The {minimum | maximum | mean | median} of each of these ADU types per paragraph. + The percentage of each type in the first and in the last paragraph.

Flow Features (b) Persing et al. (2010) aligned sequences of four paragraph discourse functions: *Body* (own argument), *Rebuttal*, *Introduction*, and *Conclusion*. Since we cannot access their original approach, we approximate it—and also add further strong structure-oriented baseline approaches: In (Wachsmuth et al., 2014a) and (Wachsmuth et al., 2015), we captured the overall structure of a review by comparing the review's sentiment flow to a set of common flow patterns and flow abstractions. Both the patterns and the abstractions were found in a training set before. To model the paragraph-level argumentative structure of persuasive essays, we adapt these patterns and abstractions in the following features:

- b_1 *Function flows*. All flow features defined in (Wachsmuth et al., 2014a) and (Wachsmuth et al., 2015) based on paragraph discourse functions. Functions are found with the heuristic algorithm of Persing et al. (2010). *Body* is mapped to 1.0, *Rebuttal* to 0.0, and the remaining two functions to 0.5, in order to allow for numerical comparison between the flows.
- b_2 *Sentiment flows*. All flow features based on paragraph-level sentiment. A paragraph is assigned the numerical sentiment value 1.0 (0.0), if it contains a positive (negative) but no negative (positive) sentence, otherwise 0.5. We find sentence sentiment with the algorithm of Socher et al. (2013).
- b_3 *Relation flows*. All flow features based on sentence-level discourse relations. Ten relation types from (Mann and Thompson, 1988) are found with our rule-based algorithm (Wachsmuth et al., 2014a). For lack of an adequate mapping, we compare relation flows based on nominal differences only.

Standard Features (c) In order to be able to assess the impact of argumentative structure, we compare all structure-oriented features to two standard types of content and style features:

- c_1 *Content*. The frequency of each token 1-, 2-, and 3-gram that occurs in $\geq 10\%$ of all training essays. + The minimum, maximum, and average prompt similarity (see Section 3.2) over all sentences.
- c_2 *POS n-grams*. The frequency of each part-of-speech 1-, 2-, and 3-gram that occurs in $\geq 10\%$, $\geq 20\%$, and $\geq 40\%$ of all training essays respectively.

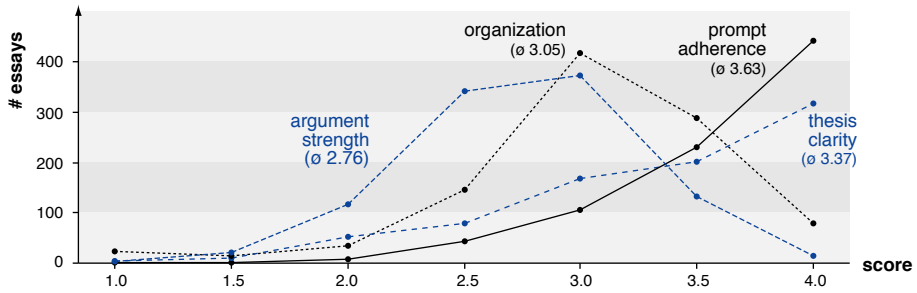

Figure 5: Distribution of essays over the possible scores from [1.0, 4.0] in the datasets of the four tasks.

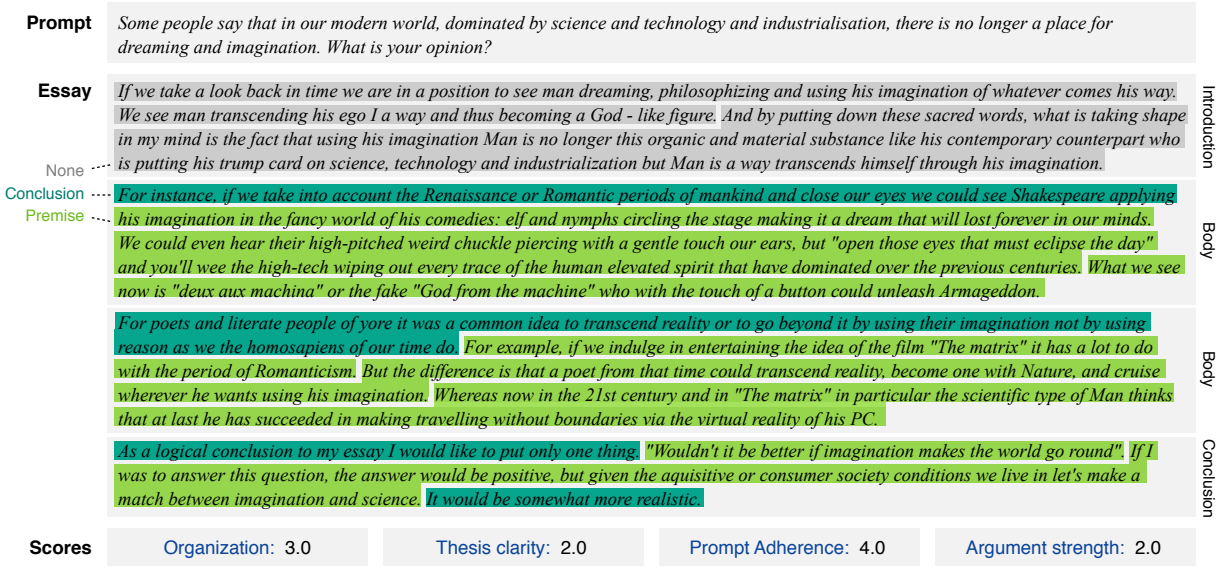

Figure 6: One essay from the four datasets together with its manually assigned scores as well as the ADU types (colored background) and discourse functions (vertical) automatically annotated by our algorithms.

5.3 Experimental Set-up

For direct comparison, we replicated the original experimental set-up of the authors of the aforementioned papers on the datasets they provide for the four essay scoring tasks:

Data For each task, one distinct subset of the ICLE corpus (see Section 4) is manually annotated with half-point scores between 1.0 (worst) and 4.0 (best). These datasets cover 1003 (organization), 830 (thesis clarity, prompt adherence), and 1000 essays (argument strength) respectively. For a rough overview, Figure 5 plots the numbers of scores in each dataset, indicating that only the organization and argument strength scores are Gaussian-like distributed. Exact numbers are found in the original papers. Figure 6 shows one essay included in all datasets with its scores and the annotations created by our algorithms.

Experiments We used linear ε-SVR support vector machine regression from LibSVM in Weka 3.7 (Hall et al., 2009; Chang and Lin, 2011).[6] Each dataset has five predefined folds. As in the original set-up, we performed cross-validation on these folds, training one LibSVM for each feature type and for different type combinations. Accordingly, we then also measured the mean absolute error (MAE) and the mean squared error (MSE) of regression.[7] Different from the original set-up, we omitted a real optimization of the LibSVM cost hyperparameter, but we simply set it permanently to 0.1 after a few initial tests.

Comparison We compare the proposed feature types to the described baseline features and to two general baselines: (**d**) The *average baseline*, which assigns the mean score of the training essays to all test essays. Although trivial, **d** is quite strong under given the score distributions in Figure 5. (**e**) The lowest MAE and MSE values reported by the authors of the four tasks, called *Persing et al. best* below. To our knowledge, these results have not been beaten so far and, thus, define the state of the art until now.

[6] Persing and Ng (2014; 2015) relied on LibSVM, too. In the other two papers, SVM^{light} was used (Joachims, 1999).

[7] From the practical viewpoint of applying automatic essay scoring in MOOCs or similar, the most important requirement is to avoid outliers (in terms of utterly wrong scores) as far as possible. In this regard, the MSE is the more meaningful measure.

Table 5: The mean average error (MAE) and the mean squared error (MSE) ± their standard deviations for each evaluated feature type and type combination in the four essay scoring tasks. All values marked in bold outperform the former state of the art (called *Persing et al. best* here). The most significant results for organization and argument strength each are marked with * and ** respectively.

5.4 Results

Table 5 lists the two mean regression errors and their standard deviations for each single feature type in isolation and for a selection of feature type combinations, averaged over the respective five folds for each of the four evaluated essay scoring tasks.[8]

With respect to the single feature types in the upper part, we see that the ADU compositions (a_3) consistently perform best among all structure-oriented features (a_1–a_3, b_1–b_3) in all four tasks. The ADU flows (a_1) and ADU n-grams (a_2) behave comparable to the function flows (b_1) and sentiment flows (b_2). The relation flows (b_3) compete with most others only in scoring prompt adherence, possibly suggesting that the impact of discourse structure on argumentation quality is limited.[9]

Matching our hypothesis from Section 5.1, the structure-oriented features clearly outperform the standard features (**c**) in scoring *organization*, as shown in the left part of Table 5. In fact, c_1 and c_2 hardly improve over the average baseline (**d**). In isolation, the complete ADU feature set (**a**) produces the lowest errors; an MAE of 0.336 and an MSE of 0.184. Since the quality of the organization of an essay naturally depends on the essay's argumentative structure, this result underpins the adequacy of our features. Moreover, **a** outperforms the best values we measured without using ADU features (those of **b** + **c**). Combined with function flows (**a** + b_1) or with sentiment flows (**a** + b_2), the ADU features already beat Persing et

[8] We did not perform explicit feature ablation tests, because they would provide limited insights only: As we did not optimize the LibSVM cost hyperparameter, leaving out one feature type does not necessarily lead to an increase of the regression errors.

[9] One reason for the low impact of b_3 lies in the varying number of sentences of essays (see Section 4), which impairs flow pattern recognition. A detailed analysis of the use of discourse relations for quality assessment is out of the scope of this paper.

al. best (**e**). The smallest MSE is achieved by the ADU features with sentiment flows and POS n-grams ($\mathbf{a} + b_2 + c_2$). According to a one-sided student t-test, the value 0.164 is significant at $p < 0.1$.

As expected, all structure-oriented features fail in case of *thesis clarity*, being only slightly better than the average baseline (**d**) if at all. The lowest errors (MAE 0.501, MAE 0.425) are observed for the content features (c_1). Still, c_1 cannot compete with **e**—the respective approach of Persing and Ng (2013) employs keyword features that were manually derived from the prompts of all essays.

For *prompt adherence*, at least the errors produced by the ADU compositions (a_3) are close to those of c_1 and c_2, which is why we additionally tested a_3 in combination with the standard feature types. As shown in the bottom part of Table 5, $a_3 + \mathbf{c}$ performs best with an MAE of 0.352 and an MSE of 0.216. These values are not significantly worse than the state of the art (**e**).

$a_3 + \mathbf{c}$ also minimizes the errors in scoring *argument strength*. Both the MAE of 0.378 and the MSE of 0.226 are significantly better than Persing et al. best (**e**) at $p < 0.1$. Again, this observation supports our hypothesis: The strength of an essay's argumentation will hardly ever be independent from the essay's content, but it still benefits from a good argumentative structure. Interestingly, even a_3 alone improves over **e** with an MAE of 0.390 (vs. 0.392) and an MSE of 0.239 (vs. 0.244).

We conclude that our approach denotes the new state of the art for two essay scoring tasks. Under the assumption that the manual score annotations in the processed datasets are adequate, our hypothesis that the benefit of argument mining is high for scoring an essay's organization turns out true. Compared to the findings of Persing et al. (2010), the obtained results thereby reveal that organization is not only about the ordering of discourse functions, but also about argumentative structure. In particular, the novel features that we proposed capture only such structural aspects. Accordingly, their impact is low for thesis clarity and also only fair for prompt adherence, underlining that these tasks are rather related to the content and style of an argumentation. In contrast, argument strength brings together structure and content, and this is indeed reflected by the moderate but significant benefit of our structure-oriented features there.

6 Conclusion

Although argument mining has become a hot topic, the question of what practical benefits it provides for applications has hardly been examined yet. In the paper at hand, we have approached this question for a specific but important task, namely, we have used argument mining to assess argumentation quality. Our results for persuasive student essays underpin the benefit of argument mining, revealing that the mined argumentative structure is particularly helpful for structure-related quality dimensions: Without putting emphasis on the content of arguments, we have improved the state of the art in scoring an essay's organization and even in scoring its argument strength. Our best-performing features capture the composition of types of units in arguments (such as premises and conclusions).

Similar to existing approaches, the mining algorithm we trained and applied in this paper misclassifies about one out of four units. So far, we could not analyze the impact of mining errors on the effectiveness of our essay scoring approaches, since ground-truth data is needed before that brings together argumentative structure and argumentation quality. A question that remains open in this regard is what model of argumentative structure proves most suitable. As adequate training data is still limited, we have modeled shallow unit types only, but we expect that considering attack and support relations, evidence types, or argumentation schemes will prove useful for quality assessment.

Naturally, other quality dimensions of argumentation will depend more on content, so our analysis of argumentative structure does not solve the assessment of argumentation quality in general. Also, essay structure is quite conventionalized, i.e., a transfer of our findings to other argumentative text genres requires further investigation. We plan to continue our research in this regard based on our new corpus for the analysis of argumentation strategies in news editorials (Al-Khatib et al., 2016).

In practice, our approach in its given form most notably contributes to educational applications that analyze argumentative texts, such as automatic grading and writing support systems. These systems need not only mine argumentative structure, but also evaluate the mined structure.[10] To support argumentation quality, another step is then to synthesize suggestions for improvements. We leave this to future work.

[10] A demo application based on our presented approaches is found at: http://webis16.medien.uni-weimar.de/essay-scoring

Abstract

Language students are most engaged while reading texts at an appropriate difficulty level. However, existing methods of evaluating text difficulty focus mainly on vocabulary and do not prioritize grammatical features, hence they do not work well for language learners with limited knowledge of grammar. In this paper, we introduce *grammatical templates*, the expert-identified units of grammar that students learn from class, as an important feature of text difficulty evaluation. Experimental classification results show that grammatical template features significantly improve text difficulty prediction accuracy over baseline readability features by 7.4%. Moreover, we build a simple and human-understandable text difficulty evaluation approach with 87.7% accuracy, using only 5 grammatical template features.

Keywords text difficulty evaluation, education, grammatical templates, language learners.

1 Introduction

Evaluating *text difficulty*, or *text readability*, is an important topic in natural language processing and applied linguistics (Zamanian and Heydari, 2012; Pitler and Nenkova, 2008; Fulcher, 1997). A key challenge of text difficulty evaluation is that linguistic difficulty arises from both vocabulary and grammar (Richards and Schmidt, 2013). However, most existing tools either do not sufficiently take the impact of grammatical difficulty into account (Smith III et al., 2014; Sheehan et al., 2014), or use traditional syntactic features, which differ from what language students actually learn, to estimate grammatical complexity (Schwarm and Ostendorf, 2005; Heilman et al., 2008; François and Fairon, 2012). In fact, language courses introduce grammar constructs together with vocabulary, and grammar constructs vary in frequency and difficulty just like vocabulary (Blyth, 1997; Manzanares and López, 2008; Waara, 2004). Ideally, we would like to have better ways of estimating the grammatical complexity of a sentence.

To make progress in this direction, we introduce *grammatical templates* as an important feature in text difficulty evaluation. These templates are what language teachers and linguists have identified as the most important units of grammatical understanding at different levels, and what students actually learn in language lessons. We also demonstrate that grammatical templates can be automatically extracted from the dependency-based parse tree of a sentence.

To evaluate, we compare the difficulty prediction accuracy of grammatical templates with existing readability features in Japanese language placement tests and textbooks. Our results show that grammatical template features slightly outperform existing readability features. Moreover, adding grammatical template features into existing readability features significantly improves the accuracy by 7.4%. We also propose a multilevel linear classification algorithm using only 5 grammatical features. We demonstrate that this simple and human-understandable algorithm effectively predicts the difficulty level of Japanese texts with 87.7% accuracy.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1692–1702, Osaka, Japan, December 11-17 2016.

2 Related Work

Text difficulty evaluation has been widely studied over the past few decades (Nelson et al., 2012; Sinha et al., 2012; Hancke et al., 2012; Jameel et al., 2012; Gonzalez-Dios et al., 2014; Sinha et al., 2014). Researchers have developed over 200 metrics of text difficulty (Collins-Thompson and Callan, 2004). For example, *Lexile* measures text complexity and readability with word frequency and sentence length (Smith III et al., 2014). *ATOS*[1] includes two formulas for texts and books, both of which take into account three variables to predict text difficulty: word length, word grade level and sentence length. *TextEvaluator* is a comprehensive text analysis system designed to help teachers and test developers evaluate the complexity characteristics of reading materials (Sheehan et al., 2014). It incorporates more vocabulary features, such as meaning and word type, as well as some sentence and paragraph-level features.

Nevertheless, most of these methods provide limited consideration of grammatical difficulty, which is a major challenge for foreign language learners (Callan and Eskenazi, 2007). In fact, text readability not only depends on sentence lengths or word counts, but on 'the grammatical complexity of the language used' as well (Richards and Schmidt, 2013). Based on this fact, recent readability evaluation systems improved performance by incorporating syntactic features like parse tree depth (Schwarm and Ostendorf, 2005) and subtree patterns (Heilman et al., 2008) to measure grammatical complexity. Moreover, researchers have developed an unified framework of text readability evaluation, which combines lexical, syntactic and discourse features, and predicts readability with outstanding accuracy (Pitler and Nenkova, 2008). The relationship between text readability and reading devices was also studied in the past two years (Kim et al., 2014). However, most of these approaches are intended for native speakers and use texts from daily news, economic journals or scientific publications, which are too hard to read for beginning and intermediate language learners. Ideally, we would have specific features and approaches for text difficulty evaluation for language learners.

Recently, language educational researchers conducted a bunch of studies on text readability evaluation for language learners in different languages, such as English, German, Portuguese and French (Blyth, 1997; Waara, 2004; Manzanares and López, 2008; Vajjala and Meurers, 2012; François and Fairon, 2012; Xia et al., 2016). However, they use traditional syntactic features such as sentence length, part of speech ratios, number of clauses and average parse tree height, which differ from the grammatical knowledge that students actually learn in language lessons. For example, Curto et al. measured text difficulty using traditional vocabulary and syntactic features, to predict text difficulty levels for Portuguese language learners (Curto et al., 2015). Unfortunately, 75% accuracy in 5-level classification with 52 features is not satisfactory. Instead, we extract grammatical features from *grammatical templates*, the knowledge units that language students actually learn in classes and that expert language instructors have identified and highlighted in textbooks. We also propose a novel technique that has a simpler and human-interpretable structure, uses only 5 grammatical template features, and predicts text difficulty with 87.7% accuracy in 5-level classification.

3 Grammatical Template Analysis

A key challenge in modeling text difficulty is to specify all prerequisite knowledge required for understanding a certain sentence. Traditional methods measure text difficulty mostly by evaluating the complexity of vocabulary (word count, word frequency, word type, etc.). This is effective for native speakers, who typically understand the grammar of their language but vary in mastery of vocabulary. However, these vocabulary-based methods underperform for language learners who have limited knowledge of grammar (Callan and Eskenazi, 2007; Curto et al., 2015).

To resolve this, we focus our research on grammatical difficulty. We introduce the idea of *grammatical templates*, units of grammar that expert language instructors and linguists have identified as the most important grammatical knowledge, and are typically emphasized as key points in every textbook lesson (Banno et al., 2011; People's Education Press, 2013). Since these grammatical templates are

[1] http://www.renaissance.com/Products/Accelerated-Reader/ATOS/ATOS-Analyzer-for-Text

taught explicitly in language lessons and learned directly by language students, we believe they reflect the conceptual units of grammar more closely than parse trees.

Grammatical templates play an important role in language understanding because:

- Many grammatical templates suggest sentence structure. For example, "hardly ... when ..." in English, "nicht nur ..., sondern auch ..." (not only ... but also ...) in German, and "必ずしも ... とはいえない" (it is not necessarily the case that ...) in Japanese;
- For languages like Chinese and Japanese, lacking knowledge of some grammatical templates will cause difficulties in segmentation. For example, consider the Japanese template "...つ...つ" (two opposite behaviors occuring alternately) in the phrase "行きつ戻りつ" (to walk back and forth), and the Chinese template "越...越好" (the more ... the better) in "越早越好"(the earlier the better);
- Some grammatical templates may refer to special meanings that cannot be understood as the combination of individual words. For example, "in terms of", "such that" in English, "mit etwas zu tun haben" (have something to do with ...) in German, and "... ことはない" (no need to ...) in Japanese.

We show some simple examples of grammatical templates for Japanese in Table 1[2]. Line 2 shows the pronunciation of the templates, line 3 shows the translations, and the uppercase letters in line 4 are provided for notation. We also provide examples of how the grammar of a sentence can be described as combinations of these grammatical templates in Table 2.

3.1 Difficulty Evaluation Standard

To evaluate the difficulty of texts and grammatical templates, we follow the standard of the Japanese-Language Proficiency Test (JLPT). The JLPT is the most widely used test for measuring proficiency of non-native speakers, with approximately 610,000 examinees in 62 countries and areas worldwide in 2011[3]. It has five different levels, ranging from from N5 (beginner) to N1 (advanced). A summary of the levels can be found at JLPT website [4].

3.2 Grammatical Template Library

Due to their significance in Japanese education, grammatical templates are well-studied by Japanese teachers and researches. Grammatical templates are summarized and collected for both Japanese learners (common templates) and native speakers (templates used in very formal Japanese or old Japanese). We referenced 3 books about grammatical templates for Japanese learners (Sasaki and Kiko, 2010; Xu and Reika, 2015; Liu and Ebihara, 2012), all of which divide their templates into N1-N5 levels, for generating our template library at each corresponding level.

Although not common, books may have different opinions on the difficulty of the same template. For example, an N1 template in book A may be recognized as an N2 template in book B. In order to conduct our experiments on a reliable template library, we only pick the templates recognized as the same level by at least two of the three books. For example, if both book A and C recognized template t as an N3 template, we can incorporate template t into our N3 template library. Ultimately, we collected 147 N1 templates, 122 N2 templates, 74 N3 templates, 95 N4 templates and 128 N5 templates in our library. All selected grammatical templates are stored in the format of regular expressions for easy matching in parse trees.

3.3 Grammatical Template Extraction

The framework of grammatical template extraction is shown in Algorithm 1. The program requires the dependency-based parse tree of a sentence as input, runs from bottom to top and returns a set of

[2]A long list of Japanese grammatical templates with English translations can be accessed at the JGram website: http://www.jgram.org/pages/viewList.php. There is also a nice and comprehensive book of Japanese grammatical templates, written by Japanese linguists, with English, Korean and Chinese translations: (Tomomatsu Etsuko and Masako, 2010).

Notation	A	B	C	D	E	F

Table 1: Grammatical Templates in Japanese, with hyphens denoting words to be filled in. Note that some grammatical templates may impose requirements of some properties (e.g. part of speech or form) on the missing words.

Sentence	彼	**は**	すぐ	東京	**に**	到着する	
Pronunciation	kare	**wa**	sugu	*toukyou*	**ni**	touchakusuru	
Translation	he	**(topic)**	soon	*Tokyo*	**to (location)**	arrive	
Templates		A			E		
	“ he will soon arrive in Tokyo ”						
Sentence	僕	**の**	彼女	**を**	見	**に**	行く
Pronunciation	boku	**no**	kanojo	**o**	*mi*	**ni**	iku
Translation	I	**(genitive)**	girlfriend	**(object)**	*see*	**for (purpose)**	go
Templates		B		C		F	
	“ I go to see my girlfriend ”						
Sentence	これ	**は**	君	**の**	本	**では**	**ない**
Pronunciation	kore	**wa**	kimi	**no**	hon	**dewa**	**nai**
Translation	this	**(topic)**	you	**(genitive)**	book	**is**	**not**
Templates		A		B		D	
	“ this is not your book ”						

Table 2: Identified grammatical templates of Japanese sentences. In sentences, pronunciations and translations, grammatical templates are in bold. The word *toukyou* in the first sentence is a noun (Tokyo,東京), as characterized by template E. The word *mi* (to see, 見) in the second sentence is the i-form (動詞連用形) of a verb, as required by template F.

	N1 Texts	N2 Texts	N3 Texts	N4 Texts	N5 Texts
N1 Templates	0.902%	0.602%	0.077%	0.074%	0.056%
N2 Templates	2.077%	1.571%	1.072%	0.298%	0.056%
N3 Templates	4.070%	3.679%	1.531%	0.894%	0.222%
N4 Templates	16.635%	15.449%	13.323%	12.071%	1.832%
N5 Templates	76.316%	78.699%	83.997%	86.662%	97.834%

Table 3: Distribution of grammatical templates of level N1(hard)-N5(easy)

	N1 Texts	N2 Texts	N3 Texts	N4 Texts	N5 Texts
N1 Templates	3.536	2.342	0.295	0.230	0.146
N2 Templates	8.141	6.110	4.130	0.922	0.146
N3 Templates	15.954	14.308	5.900	2.765	0.582
N4 Templates	65.214	60.081	51.327	37.327	4.803
N5 Templates	299.178	306.059	323.599	267.972	256.477

Table 4: Number of templates of level N1(hard)-N5(easy) per 100 sentences

all identified grammatical templates $\mathbf{T}(node_0)$. Line 7 extracts the templates in the children of $node_0$ (and ignores the descendants of the children), by matching the phrase associated with the child nodes $[node_1, node_2, \cdots]$ to all templates stored in terms of regular expressions in our library. The matching is based on both the structure of the phrases and the properties of the words. Line 8 shows $\mathbf{T}(node_0)$ covers all templates identified in subtrees rooted at $node_0$'s children and the templates extracted in the phrase associated with the child nodes $[node_1, node_2, \cdots]$.

Algorithm 1 Grammatical Progression Extraction

Require: A dependency-based parse tree of the sentence

Ensure: $\mathbf{T}(node_0)$ = set of identified grammatical templates in (sub)parse tree rooted at $note_0$.

1: **if** $node_0$ is leaf node **then**
2: return $\mathbf{T}(node_0) = \{\}$
3: **end if**
4: $node_1, node_2, \cdots \leftarrow$ children of $node_0$
5: Calculate: $\mathbf{T}(node_1), \mathbf{T}(node_1), \cdots$ // templates identified in subtrees rooted at $node_0$'s children
6: $\mathbf{T_1}(node_0) \leftarrow \mathbf{T}(node_1) \cup \mathbf{T}(node_2) \cup \cdots$
7: $\mathbf{T_2}(node_0) \leftarrow$ identified templates in phrase $[node_1, node_2, \cdots]$
8: return $\mathbf{T}(node_0) = \mathbf{T_1}(node_0) \cup \mathbf{T_2}(node_0)$

We use Cabocha (Kudo and Matsumoto, 2002) for parsing Japanese sentences. This tool generates the hierarchical structure of the sentence as well as some properties (e.g. base form, pronunciation, part of speech, etc.) of each word. We execute Algorithm 1 on the parse tree to extract all identified templates of a Japanese sentence.

4 Statistics of Grammatical Templates

4.1 Corpus

We build our corpus from two sources: past JLPT exams and textbooks. The reading texts from JLPT exams are ideal for difficulty evaluation experiments since all of them are tagged authoritatively with difficulty levels, and JLPT problem sets before 2010 are publicly released[5]. We also collected reading texts from two popular series of Japanese textbooks: *Standard Japanese* (People's Education Press, 2013) and *Genki* (Banno et al., 2011). *Standard Japanese I* and *Genki I* are designed for the N5 level (the first semester) and *Standard Japanese II* and *Genki II* are designed for the N4 level (the second semester). Ultimately, our corpus consists of 220 texts (150 from past JLPT exams and 70 from textbooks), totaling 167,292 words after segmentation.

4.2 Results

For texts with different difficulties, we calculate the distribution of N1-N5 grammatical templates, which are shown in Table 3. We can see that N1 texts have higher portion of N1 and N2 templates than N2 texts, implying that the difficulty boosts from N2 to N1 are derived from increasing usage of advanced grammar. It is also clear that even in the texts of advanced levels, the majority of the sentences are organized by elementary grammatical templates, and the advanced ones are only used occasionally for formality or preciseness.

We also calculate the per-100-sentence number of templates at each level, which are shown in Table 4. When comparing any two adjacent levels (e.g. N2 and N3), the templates at those levels or above seem to be the most significant. For instance, N1/N2 texts differ in numbers of N1 and N2 templates while they have similar numbers of N3-N5 templates, and the numbers of N1, N2 and N3 templates differentiate

[5]For example, the second exam in 2009 is published in (Japan Educational Exchanges et al., 2010).

the N2/N3 texts while the numbers of N4 and N5 templates seem relatively similar. This phenomenon inspires us to build a simple and effective approach to differentiate the texts of two adjacent levels.

5 Difficulty Level Prediction

5.1 Multilevel Linear Classification

We differentiate two adjacent levels by looking at the knowledge 'on the boundary' and 'outside the boundary'. Concretely, when judging whether a text is harder than level N_i, we consider a grammatical template as:

- *within the boundary*, if the template is easier than N_i (N_{i+1} to N_5);
- *on the boundary*, if the template is exactly at N_i level;
- *outside the boundary*, if the template is harder than N_i (N_1 to N_{i-1}).

We found that texts of adjacent levels are nearly linear-separable with two features: templates 'on the boundary' and templates 'outside the boundary'. For example, Figure 1 shows how N1 and N2 texts are linearly separated based on the numbers of N1 and N2 templates: we can easily obtain a two-dimensional linear classifier separating N1 and N2 texts with 83.4% accuracy. This phenomenon is even more obvious at lower levels. Figure 2 shows N4 and N5 texts are almost perfectly linearly separated with two features: 'number of N5 templates per 100 sentences' (on the boundary) and 'number of N1-N4 templates per 100 sentences' (outside the boundary).

Taking advantage of this phenomenon, we build 4 linear classifiers for 4 pairs of adjacent levels. For example, the N4 classifier judges whether a text is harder than N4 (N1-N3). Our *Multilevel Linear Classification (MLC)* algorithm combines all 4 linear classifiers: A text is judged by the N5 classifier first. If it is no harder than N5, it will be labeled as an N5 text; otherwise, it will be passed to the N4 classifier in order to decide if it is harder than N4. The process continues similarly, until if it is judged to be harder than N2, it will be labeled as an N1 text. Figure 3 shows how the algorithm works.

5.2 Features

We conduct our experiments on the following 4 feature sets:

First, our *grammatical template feature set* has only 5 features:

- Average number of N1-N5 grammatical templates per sentence

We compare our work with recent readability evaluation studies (Kim et al., 2014; Pitler and Nenkova, 2008). In our experiments, the *baseline readability feature set* consists of the following 12 features:

- Number of words in a text
- Number of sentences in a text
- Average number of words per sentence
- Average parse tree depths per sentence
- Average number of noun phrases per sentence
- Average number of verb phrases per sentence
- Average number of pronouns per sentence
- Average number of clauses per sentence
- Average cosine similarity between adjacent sentences
- Average word overlap between adjacent sentences
- Average word overlap over noun and pronoun only
- Article likelihood estimated by language model

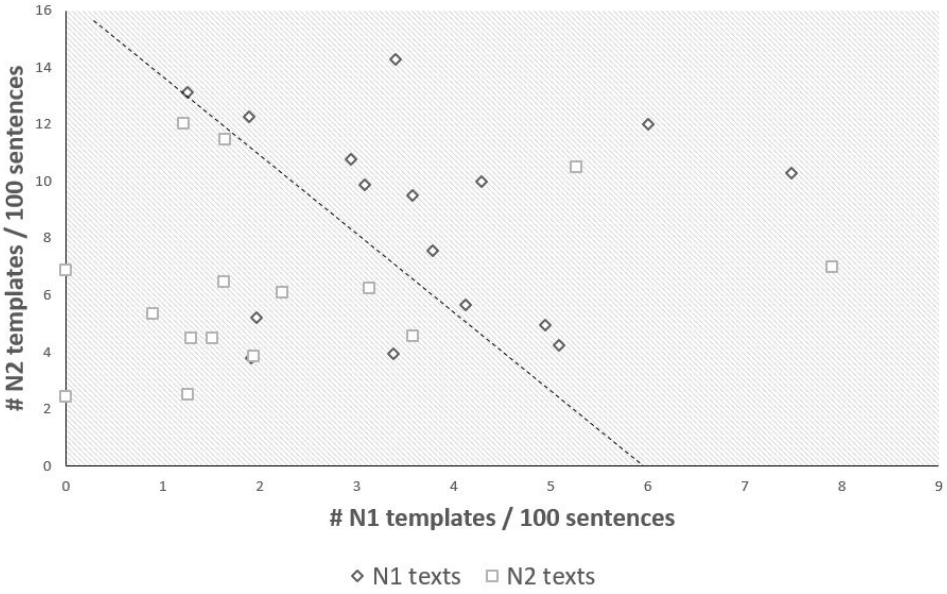

Figure 1: Grammatical difficulty in the N1/N2 texts

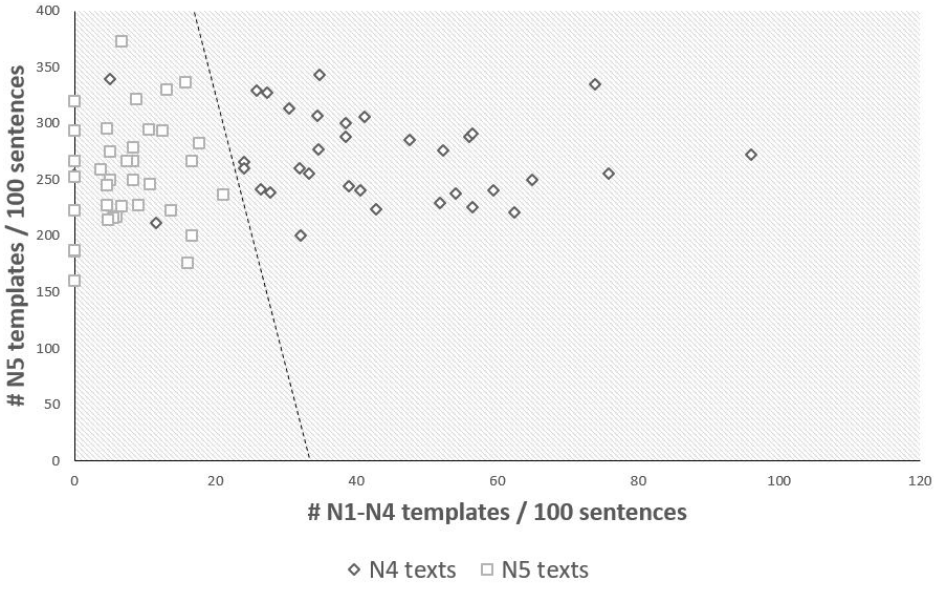

Figure 2: Grammatical difficulty in the N4/N5 texts

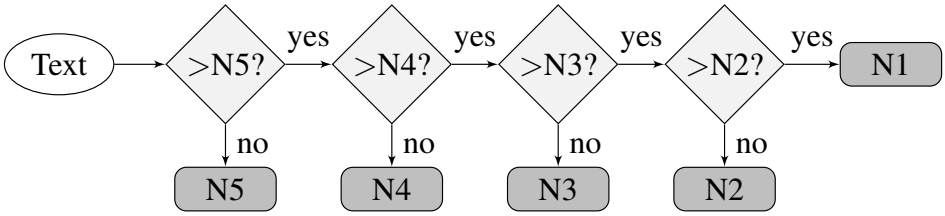

Figure 3: Multilevel Linear Classification (MLC). '>N5?' represents the linear classifier judging whether a text is harder than N5. The classifiers are similar for the other levels.

Feature Set (number of features)	Algorithm	Accuracy
TF-IDF Features (5100)	kNN	69.1%
	SVM	80.5%
Baseline Readability Features (12)	kNN	72.3%
	SVM	80.9%
Grammatical Template Features (**5**)	kNN	78.0%
	SVM	81.1%
	MLC	**87.7%**
Hybrid Features (17)	kNN	85.7%
	SVM	**88.5%**

Table 5: Accuracies of classifying N1-N5 texts

Moreover, we combine these 12 traditional readability features with our 5 grammatical template features, forming a *'hybrid' feature set*, since we would like to see if grammatical template features are really able to improve text difficulty evaluation.

Since the text difficulty level prediction can be regarded as a special text classification problem, we also extract *TF-IDF features* (Sparck Jones, 1972) (Nelson et al., 2012) as an extra baseline, in order to see how general text classification techniques work on text difficulty evaluation.

5.3 Result

We test k-Nearest Neighbor and Support Vector Machines for each feature set. The implementations of these two popular classification algorithms are provided by the WEKA toolkit (Hall et al., 2009) and LibSVM (Chang and Lin, 2011). The SVMs use RBF kernels (Chang et al., 2010). We also test our Multilevel Linear Classification (MLC) algorithm on the grammatical template feature set. We use 5-fold cross validation to avoid overfitting. Table 5 shows the results.

Comparing the results of kNN and SVM across the four different feature sets in Table 5, it is clear that TF-IDF features have the largest feature set yet lowest accuracy, indicating the general word-based text classification techniques do not work well on text difficulty level prediction. Compared with baseline readability features, our grammatical template features have smaller number of features but higher accuracy (slightly higher with SVM but significantly higher with kNN). Moreover, the hybrid features, which combine baseline readability features with grammatical template features, decisively outperform baseline readability features, confirming our expectation that adding grammatical template features to existing readability techniques improves text difficulty evaluation for language learners.

Additionally, our Multilevel Linear Classification algorithm achieves excellent accuracy with only 5 grammatical template features. An accuracy of 87.7% , although slightly lower than hybrid features + SVM (more features, more complexity), still significantly outperforms baseline readability techniques. In conclusion, the Multilevel Linear Classification algorithm has high accuracy, a small number of features, and a simple, human-understandable structure.

6 Conclusions and Future Work

We proposed a new approach for evaluating text difficulty that focuses on grammar and utilizes expert-identified grammatical templates, the grammar knowledge that students actually learn in language lessons. This approach significantly improved the accuracy of text difficulty evaluation for Japanese language learning. We also introduced a simple, human-understandable, and effective text difficulty evaluation approach using only five grammatical template features.

In future work, we are interested in extending our work to other languages like English, and adapting grammatical templates for various languages. To achieve this, we need to itemize the grammar knowledge that students learn from language lessons. We can also develop a machine learning system that can automatically discover discriminative grammatical templates from texts. Moreover, we would like

to study if the topic of a text has considerable impact on text difficulty for language learners, just like vocabulary and grammar.

We also hope to use our approach to recommend reading texts to individual learners at appropriate difficulty levels. For instance, Japanese news articles could be good learning materials for advanced Japanese language learners. We want to build an online tool to collect reading texts from current news reports in specific target languages, and select appropriate ones for language learners, especially intermediate and advanced learners.

Finally, we plan to leverage some novel ideas from Human-Computer Interaction and educational technology (Andersen et al., 2013) to build an *adaptive* Computer-Assisted Language Learning (CALL) system. Using our new approach introduced in this paper, we can decompose the difficulty of a text into several basic skills (grammatical templates), and model the internal hierarchical structure of a sequence of texts with a partial ordering graph. Using this structure, we can comprehensively assess a student's knowledge and tailor optimal learning progressions for individual students.

Abstract

We analyze the performance of encoder-decoder neural models and compare them with well-known established methods. The latter represent different classes of traditional approaches that are applied to the monotone sequence-to-sequence tasks OCR post-correction, spelling correction, grapheme-to-phoneme conversion, and lemmatization. Such tasks are of practical relevance for various higher-level research fields including *digital humanities*, automatic text correction, and speech recognition. We investigate how well generic deep-learning approaches adapt to these tasks, and how they perform in comparison with established and more specialized methods, including our own adaptation of pruned CRFs.

1 Introduction

Encoder-decoder neural models (Sutskever et al., 2014) are a generic deep-learning approach to sequence-to-sequence translation (Seq2Seq) tasks. They encode an input sequence into a vector representation from which the decoder generates an output. These models have shown to achieve state-of-the-art or at least highly competitive results for various NLP tasks including machine translation (Cho et al., 2014), conversation modeling (Vinyals and Le, 2015), question answering (Yin et al., 2016), and, more generally, language correction (Schmaltz et al., 2016; Xie et al., 2016).

We have noticed that, given the enormous interest currently surrounding neural architectures, recent research appears to somewhat over-enthusiastically praise the performance of encoder-decoder approaches for Seq2Seq tasks. For example, while the encoder-decoder G2P model by Rao et al. (2015) achieves an extremely low error rate on the CMUdict dataset (Kominek and Black, 2004), the neural architecture itself has a mediocre performance and only outperforms traditional models *in combination* with a weighted finite state transducer. Similarly, Faruqui et al. (2016) report on "par or better" performance of their inflection generation neural architecture. However, a closer inspection of their results suggests that their system is sometimes worse and sometimes better than traditional approaches.

Here, we aim for a more balanced comparison on three exemplary monotone[1] Seq2Seq tasks, namely *spelling correction*, *G2P conversion*, and *lemmatization*. Monotone Seq2Seq tasks such as morphological analysis/lemmatization, grapheme-to-phoneme conversion (G2P) (Yao and Zweig, 2015; Rao et al., 2015), transliteration (Sherif and Kondrak, 2007), and spelling correction (Brill and Moore, 2000) have been fundamental problem classes in natural language processing (NLP) ever since the origins of the field. Their simplicity vis-à-vis non-monotonic problems such as machine translation renders them as particularly tractable testbeds of technological progress. Unlike previous work, which has typically focussed on only one specific subproblem of monotone Seq2Seq tasks at a time, we consider model performances on *three* such tasks simultaneously. This leads to a more balanced view on the relative performance of different models.

We compare three variants of encoder-decoder models — including attention-based models (Bahdanau et al., 2014; Luong et al., 2015) and the model proposed by Faruqui et al. (2016) — to three very

[1]We call our tasks, described below, monotone because relationships between input and output sequence characters typically obey monotonicity. That is, unlike in machine translation, there are no 'crossing edges' in corresponding alignments.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1703–1714, Osaka, Japan, December 11-17 2016.

well-established baselines for monotone Seq2Seq, namely Sequitur (Bisani and Ney, 2008), DirecTL+ (Jiampojamarn et al., 2010), and Phonetisaurus (Novak et al., 2012). We also offer our own contribution[2], which may be considered a variation of the principles underlying DirecTL+. For that purpose, we have adapted higher-order pruned conditional random fields (PCRFs) (Müller et al., 2013; Lafferty et al., 2001) to handle generic monotone Seq2Seq tasks.

We find that traditional models appear to still be on par with or better than encoder-decoder models in most cases, depending on factors such as training data size and the complexity of the task at hand. We show that neural models unfold their strengths as soon as more complex phenomena need to be learned. This becomes clearly visible in the comparison between lemmatization and the other tasks we have investigated. Lemmatization is the only task at hand in which neural models outperform all established systems — as it is the only one which systematically exhibits long-range dependencies, particularly through Finnish *vowel harmony* (see Section 5). We are thus able to contrast the different challenges imposed by different tasks and show how these differences have significant impact on the performance of encoder-decoder models in comparison to established Seq2Seq models.

To our best knowledge, no systematic comparison with regard to the suitability of these encoder-decoder neural models for a wider and more generic selection of tasks has been conducted.

2 Task Description

Throughout, we denote individual tokens in a sequence by ordinary letters x, and a sequence of symbols by $\vec{x}$. Hence a string of length s is denoted as $\vec{x} = x_1 \dots x_s$. Real-valued vectors are denoted by bold-faced letters, $\mathbf{x}$.

Spelling correction is the problem of converting an 'erroneous' input sequence $\vec{x}$ into a corrected version $\vec{y}$. In terms of errors committed by humans (typos), spelling correction often deals with errors that are due to keyboard adjacency of characters and grapho-phonemic mismatch (e.g. $emergancy \rightarrow emergency$, $wuld \rightarrow would$).

OCR post-correction can be seen as a special case of spelling correction. OCR (optical character recognition) is the process of digitizing printed texts automatically, often applied to make text data from the pre-electronic age digitally available (Springmann et al., 2014). Depending on various factors including paper and scan quality, typeface, and OCR engine, OCR error rate can be extraordinarily high (Reynaert, 2014). OCR post-correction is of particular practical importance in the field of *digital humanities*. Here, paper quality, which is often bleached and tainted, and "unusual" typefaces typically cause major problems. Unlike in human spelling correction, OCR errors often arise due to *visual* similarity of character sub-sequences such as $rn \rightarrow m$ or $li \rightarrow h$.

Previous works in OCR post-correction apply noisy-channel models (Brill and Moore, 2000) and various extensions (Toutanova and Moore, 2002; Cucerzan and Brill, 2004; Gubanov et al., 2014), generic string-to-string substitution models (Xu et al., 2014), discriminative models (Okazaki et al., 2008; Farra et al., 2014), and user-interactive approaches (Reffle and Ringlstetter, 2013). Neural network designs including auto-encoders (Raaijmakers, 2013) and recurrent neural networks (Chrupała, 2014) were also investigated in previous works.

G2P conversion is the problem of converting orthographic representations into sound representations. It is the prime example of a monotone Seq2Seq task, which — as a fundamental building block for speech recognition, speech synthesis, and related tasks — has been researched for decades. It differs from the previous two tasks in that input and output strings are defined over different alphabets.

Lemmatization is the task of deriving the lemma from an inflected word form such as *atmest→atmen*. The problem is relatively simple for morphologically poor languages like English, but much harder for languages like Finnish. The task can be seen as the inverse to inflection generation (Durrett and DeNero, 2013; Ahlberg et al., 2014; Nicolai et al., 2015; Faruqui et al., 2016), where an inflected form is generated from a lemma plus an inflection tag.

[2]Our implementation of PCRF-Seq2Seq is available at:
`https://github.com/UKPLab/coling2016-pcrf-seq2seq`

3 Data

Here we detail the data sets used in our experiments; examples are provided in Table 1. These datasets reflect the different Seq2Seq tasks we aim to investigate.

The **Text+Berg** corpus (Bubenhofer et al., 2015) contains historic proceedings of the *Schweizer Alpenclub* ("Swiss Alpine Club") from the years 1864–1899 in Swiss German and French. The data has been digitized and OCR errors have been corrected manually. The corpus contains 19,024 pages, 17,186 of which are in Swiss German, and 1,838 are in French. We have extracted 88,302 unique misrecognized words along with their manually corrected counterparts.

For our experiments, we have used randomly selected 72K entries for training and test our models on another 9K entries. Furthermore, we report results for each model trained on a reduced training set (10K entries).

Twitter Typo Corpus[3]: We use a corpus of 39,172 spelling mistakes extracted from English Tweets with their respective corrections. The manually corrected mistakes come with a context word on both sides. Again, we have split the data randomly, using a training set of 31K entries and 4K for testing. We also report results on the same test set when using a reduced training set with 10K entries.

The **Combilex** data set (Richmond et al., 2009) provides mappings from English graphemes to phonetic representations (Table 1). We use different subsets for training, with 2K, 5K, 10K, and 20K entries respectively. Furthermore, we employ a test set with 26,609 entries.

P'reunde	→	**F**reunde	(misrecognition)	to_**y**ork_from	→	to_**w**ork_from
Thal wand	→	Thalwand	(segmentation)	before_**tt**_was	→	before_**i**t_was
S**lutl**erfi**m**	→	S**tud**erfi**rn**	(multiple errors)	with_my_daug**th**er	→	with_my_daug**ht**er
kinaatte	→	kinata		Waterloo	→	wOtBr5u
kinaavat	→	kinata		barnacles	→	bArn@k@5z

Table 1: Training data examples from the four corpora used: OCR detection errors for Text+Berg (top left), Twitter Typo Corpus (top right), Wiktionary Morphology Dataset (Finnish) (bottom left), and Combilex G2P mappings (bottom right).

For lemmatization, we use the **Wiktionary Morphology Dataset** (Durrett and DeNero, 2013). The data set contains inflected forms for different languages and parts of speech, corresponding lemmas, and detailed inflection information, including mood, case, and tense. We conduct experiments on the German and Finnish verb datasets and further reduce the size of the latter by considering present tense indicative verb forms in active voice only. Note that our results are not comparable to the ones presented by Durrett and DeNero (2013), Ahlberg et al. (2014), Nicolai et al. (2015), and Faruqui et al. (2016) because we focus on lemmatization, not inflection generation, as mentioned. We do so because this produces less overhead — e.g., Faruqui et al. (2016) train 27 different systems for German verbs, one for each inflection type — and there is a priori not much difference in whether we transform an inflected form to a lemma or vice versa. Hence, the relative ordering of the systems we survey should not be affected by this change of direction in the morphological analysis. In total, we have used training sets of size 43,929 entries for German verbs and 41,094 entries for Finnish verbs, and dev set and test set sizes of 5,400 (German) and 1,200 (Finnish) entries each.

4 Model Description

In this section, we briefly describe encoder-decoder neural models, pruned CRFs, and our three baselines.

4.1 Encoder-Decoder Neural Models

We compare three variants of encoder-decoder models: the 'classic' variant and two modifications:

- `enc-dec`: Encoder-decoder models using recurrent neural networks (RNNs) for Seq2Seq tasks were introduced by Cho et al. (2014) and Sutskever et al. (2014). The encoder reads an input $\vec{x}$ and

[3]Twitter typo corpus: `http://luululu.com/tweet/`

generates a vector representation $\mathbf{e}$ from it. The decoder predicts the output $\vec{y}$ one time step t at a time, based on $\mathbf{e}$. The probability for each output symbol y_t hence depends on $\mathbf{e}$ and all previously generated output symbols: $p(\vec{y}|\mathbf{e}) = \prod_{t=1}^{T'} p(y_t|\mathbf{e}, y_1 \cdots y_{t-1})$ where T' is the length of the output sequence. In NLP, most implementations of encoder-decoder models employ LSTM (long short-term memory) layers as hidden units, which extend generic RNN hidden layers with a memory cell that is able to "memorize" and "forget" features. This addresses the 'vanishing gradients' problem and allows to catch long-range dependencies.

- `attn-enc-dec`: We explore the attention-based encoder-decoder model proposed by Bahdanau et al. (2014) (Figure 1). It extends the encoder-decoder model by learning to align and translate jointly. The essential idea is that the current output unit y_t does not depend on all input units in the same way, as captured by a 'global' vector $\mathbf{e}$ encoding the input. Instead, y_t may be conditioned upon local context in the input (to which it pays *attention*).

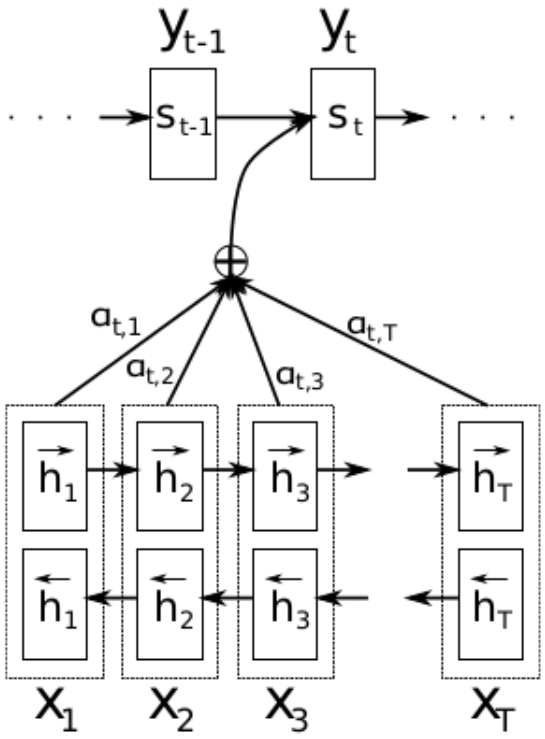

Figure 1: In the encoder-decoder model, the encoder (bottom) generates a representation of the input sequence $\vec{x}$ from which the decoder (top) generates the output sequence $\vec{y}$. The attention-based mechanism (shown here) enables the decoder to "peek" into the input at every decoding step through multiple input representations a_t. Illustration from Bahdanau et al. (2014).

- `morph-trans`: Faruqui et al. (2016) present a new encoder-decoder model designed for morphological inflection, proposing to feed the input sequence directly into the decoder. This approach is motivated by the observation that input and output are usually very similar in problems such as morphological inflection. Similar ideas have been proposed in Gu et al. (2016) in their so-called "CopyNet" encoder-decoder model (which they apply to text summarization) that allows for portions of the input sequence to be simply copied to the output sequence, without modifications. A priori, this observation seems to apply to our tasks too: at least in spelling correction, the output usually differs only marginally from the input.

For the tested neural models, we follow the same overall approach as Faruqui et al. (2016): we perform decoding and evaluation of the test data using an **ensemble** of $k = 5$ independently trained models in order to deal with the non-convex nature of the optimization problem of neural networks and the risk of

running into a local optimum (Collobert et al., 2011). The total probability p_{ens} for generating an output token y_t is estimated from the individual model output probabilities: $p_{\text{ens}}(y_t|\cdot) = \frac{1}{Z}\prod_{i=1}^{k} p_i(y_t|\cdot)^{\frac{1}{k}}$ with a normalization factor Z.

4.2 Pruned Conditional Random Fields

Conditional random fields (CRFs) were introduced by Lafferty et al. (2001) and have been a major workhorse for many sequence labeling tasks such as part-of-speech tagging and named entity recognition during the 2000s. Unfortunately, training and decoding time depend polynomially on the tag set size and exponentially on the *order* of the CRF. Here, order refers to the dependencies on the label side. This makes higher-order CRFs impractical for large training data sizes, which is the reason why virtually only first-order (linear chain) CRFs were used until recently.

Müller et al. (2013) introduced pruned CRFs (PCRFs) that approximate the CRF objective function using coarse-to-fine decoding (Charniak and Johnson, 2005). PCRFs require much shorter runtime and are thus able to make use of higher orders. Higher orders, in turn, have been shown to be highly beneficial for coarse and fine-grained part-of-speech tagging, outperforming first-order models.

For our tasks, we have adapted the implementation from Müller et al. (2013) — originally designed for sequence labeling — to general monotone Seq2Seq tasks. Sequence labeling assumes that an input sequence of length N is mapped to an output sequence of identical length N, while in Seq2Seq tasks, input string lengths may be shorter, longer, or equal to output string lengths.

We address this by first *aligning* input and output sequences as exemplified in

S	l	u	t	l	e	r	f	i	m
S	t	u	d	∅	e	r	f	i	rn

This alignment matches up character subsequences from both strings. It may include 1-to-zero matches (e.g. $l \rightarrow \emptyset$) and 1-to-many matches (e.g. $m \rightarrow rn$). We disallow many-to-1 or many-to-many matches, as they cause a problem during decoding: at test time, it is unclear how to segment a new input string into parts with size ≥ 1. A naïve 'pipeline' approach (first segment, then translate the segmented string) leads to error propagation. More sophisticated 'joint' approaches (Jiampojamarn et al., 2010) are considerably more computationally expensive.

Once the data is aligned as above, input and (modified) output sequences are of equal lengths and we can directly apply higher-order PCRFs. Below, we show that orders up to 5 (and possibly beyond) are beneficial for the Seq2Seq tasks we consider.[4] We refer to this model as **PCRF-Seq2Seq** in the remainder.

Features Conditional random fields are feature-based, so we need to decide which features we use. In view of the end-to-end nature of neural techniques, requiring little linguistic knowledge, we also minimize feature-engineering effort for the traditional approaches and thus only include very simple features. For each position p to tag, we include all consecutive character m-grams (m ranges from 1 to a maximum order of N) within a *window* of size w around p; i.e., in total our window covers $2w + 1$ positions. In our experiments below, we report results for windows of size $w = 4$ and $w = 6$. For simplicity, we set $N = w$ in each case.

4.3 Further Baseline Systems

Considering the similarity of G2P conversion, spelling correction, and lemmatization with regard to their innate monotonicity (Eger et al., 2016; Nicolai et al., 2015; Eger, 2015), we explore for all our datasets three further approaches that were originally designed for G2P conversion.

Sequitur (Bisani and Ney, 2008) is a 'joint' model for Seq2Seq in the sense of the classic distinction between joint and discriminative models. Its core architecture is a model over 'joint n-grams', also termed 'graphones' in the original publication (that is, pairs of substrings of the $\vec{x}$ and $\vec{y}$ sequence).

DirecTL+ (Jiampojamarn et al., 2010) is a discriminative model for monotone Seq2Seq that integrates joint n-gram features. It jointly learns input segmentation, output prediction, and sequence modeling.

[4] In our experiments, higher order CRFs (> 3) substantially outperformed first-order models. Typical performance differences were from about 4 to 7% between first-order and fifth-order models. For brevity, we omit results for orders ≤ 3.

	Text+Berg (72K)	**Text+Berg (10K)**	**Twitter (31K)**	**Twitter (10K)**

Sequitur	68.04%	57.30%	70.74%	58.90%

Table 2: Word accuracies (WACs) for all encoder-decoder models, PCRF-Seq2Seq, and baselines for the **OCR post-correction** task and for the **spelling correction** task. Best configurations for each model are underlined, overall best results are bold-faced.

Since it is based on ordinary CRFs, it is virtually impossible to use this system with higher orders for all practically relevant datasets due to very long training times. Moreover, the system is generally very slow because it jointly learns to segment and translate, as mentioned. For this reason, we have only tested it on the Combilex dataset (Table 3), run with comparable parametrizations (context size, etc.) as PCRF-Seq2Seq.

Phonetisaurus (Novak et al., 2012) implements a weighted finite state transducer (WFST) to align input and output tokens. The EM-driven algorithm is capable of learning multiple-to-multiple alignments where we restrict both sides to a maximum of 2. The alignments learned from the training data are subsequently used to train a character-based n-gram language model. For brevity, we only report results for models with $n = 8$, which outperformed lower-order models in our experiments.

5 Results and Analysis

5.1 Model Performances

We report the results of all our experiments in terms of *word accuracy* (WAC), i.e., the fraction of completely correctly predicted output sequences. Table 2 lists WACs for all our systems on the OCR post-correction task (*Text+Berg*, full and reduced training set) and on the spelling correction task (Twitter, full and reduced training set). Table 3 reports WAC of all tested models on the Combilex dataset with models trained on training sets of different sizes. Table 4 reports WAC for the lemmatization task on the morphology dataset.

For the encoder-decoder models, we report the results with one and two layers of sizes 100 and 200 each. We have additionally conducted sample experiments with larger networks which have shown that neither increasing the number of layers nor the size of the layers leads to further improvements. For the PCRF-Seq2Seq models, we report results for windows of sizes $w = 4$ and $w = 6$. We note that, a priori, more training data tends to favor larger context size w, whereas a large w may lead to overfitting when training data is small. The same holds for model order.

	Combilex (20K)	**Combilex (10K)**	**Combilex (5K)**	**Combilex (2K)**

DirecTL+	72.23%	**65.09%**	55.75%	42.95%
Phonetisaurus ($n = 8$)	**72.29%**	64.14%	55.28%	42.21%
Sequitur	70.57%	62.57%	54.03%	41.94%

Table 3: WACs for all encoder-decoder models, PCRF-Seq2Seq, and baselines for the **G2P** task. Best configurations for each model are underlined, overall best results are bold-faced.

While more training data obviously increases WAC for every model, the specific impact varies. In general, (attention-based) encoder-decoder models deal relatively well with limited test data in our experiments, achieving WACs comparable to PCRF-Seq2Seq. In contrast, they appear to benefit less from increasing data sizes than CRFs do. On the Twitter dataset, for instance, the best-performing encoder-decoder model increases WAC by 7.7 percentage points when tripling the training data size. At the same time, the 5th-order PCRF-Seq2Seq WAC increases by 13.8. When a large amount of training data is available, CRFs therefore consistently outperform neural models, and so do the specialized baseline systems on the G2P conversion tasks (Table 3).

Summarizing, we find that PCRF-Seq2Seq performs best among the tested systems for the two spelling correction tasks when large training data is available. The best performance of PCRF-Seq2Seq is roughly 6-7 percentage points better than the best performance of an encoder-decoder model for both Twitter 31K and Text+Berg 72K. For small training set sizes, PCRF-Seq2Seq and the encoder-decoder models are on a similar level. For the G2P task, an analogous pattern emerges. Moreover, here, all classical systems appear to perform similarly, with DirecTL+ and PCRF-Seq2Seq marginally outperforming the others. For lemmatization, the overall picture looks different. For Finnish verbs, we observe the only case in which attention-based encoder-decoder systems clearly outperform all other approaches. For German, neural models also achieve the best results, albeit only marginally above PCRF-Seq2Seq.

Previous works that employed encoder-decoder models successfully focused on tasks like machine translation and grammar correction in which more challenging linguistic phenomena such as long-range dependencies and 'crossing edges' (re-ordering) occur frequently. In our experiments, too, neural models only outperform traditional ones when long-range dependencies become relevant, namely in lemmatization. In all other tasks at hand, in contrast, neural models perform worse or equal.

The afore-mentioned, more complex linguistic phenomena intuitively require a more global view on long input sequences which is hard to impossible to model for approaches that cannot look beyond a statically defined context. Spelling mistakes, OCR errors, and G2P, however, largely depend on a very local context. For instance, OCR systems typically do not consider more than a small context when

	German Verbs (44K)	Finnish Verbs (41K)
attn-enc-dec (1 layer, size 100)	93.67%	**98.00%**
attn-enc-dec (1 layer, size 200)	93.17%	96.92%

Phonetisaurus ($n = 8$)	86.62%	93.42%
Sequitur	85.63%	92.92%

Table 4: WACs for all encoder-decoder models, PCRF-Seq2Seq, and baselines for the **lemmatization task**. Best configurations for each model are underlined, overall best results are bold-faced.

estimating the probability of a character. Regarding the G2P task, phonetics is generally independent of characters that occur more than two or three positions before of after, at least in most cases and in English. The same is presumably true for human typos, where a mistaken key stroke may be the result of a previous key's position, but does not correlate to any key that was hit several time steps before. Hence, neural networks are unable to benefit from their often advantageous capability of modeling long-range dependencies here.

Especially the Finnish lemmatization experiments confirm that the capability of dealing with long-range dependencies plays an important role. Finnish *vowel harmony* makes a vowel control other vowels in the word, potentially across multiple syllables; see Faruqui et al. (2016) for more detailed explanation.

As a side note, our results are in line with the common notion that the specific impact of a neural network's size (number and sizes of layers) is almost unpredictable. Our results can only confirm the general rule-of-thumb that larger networks are better for larger training sets, while models with fewer parameters outperform larger ones when training data is smaller.

5.2 Training Time

Another potentially limiting factor for the applicability of a model in real-world scenarios, especially for large datasets, is training time. Under all circumstances, weighted finite state transducers (Phonetisaurus) are trained by magnitudes faster than all other approaches. Training times range between as little as 6 seconds for the smallest training set and 247 seconds for the full *Text+Berg* training set (72K entries).

In comparison, training times for the encoder-decoder models range from 2 to 80 hours (without using GPUs) for 30 epochs, depending on the sizes of the networks and the training data. Furthermore, there is no noticeable difference between either of the three encoder-decoder variations. Training time increases approximately linearly with the number of layers, the size of the layers, and the training data size. All these factors add up, meaning that doubling both the number of layers and the size of the layers approximately quadruples training time.

Contrasting DirecTL+ with PCRF-Seq2Seq, both of which rest on similar principles and also perform similarly in our experiments on the G2P task, we find that training PCRF-Seq2Seq was a factor of 30 or 50 times faster than DirecTL+ on Combilex (2K) and Combilex (5K), respectively. In general, training

for PCRF-Seq2Seq across our datasets was in the order of minutes to (few) hours.

5.3 Error Analysis

We divided three of our test sets (*Text+Berg*, Twitter, and Combilex) by input string lengths and evaluated PCRF-Seq2Seq and encoder-decoder neural models on these subsets of the test data. As illustrated in Figures 2 and 3, we observe a consistent tendency: PCRF-Seq2Seq performs relatively robustly over input strings of different lengths, while the performance of the encoder-decoder models plummets more drastically with sequences becoming longer, in particular those without attention-mechanism.

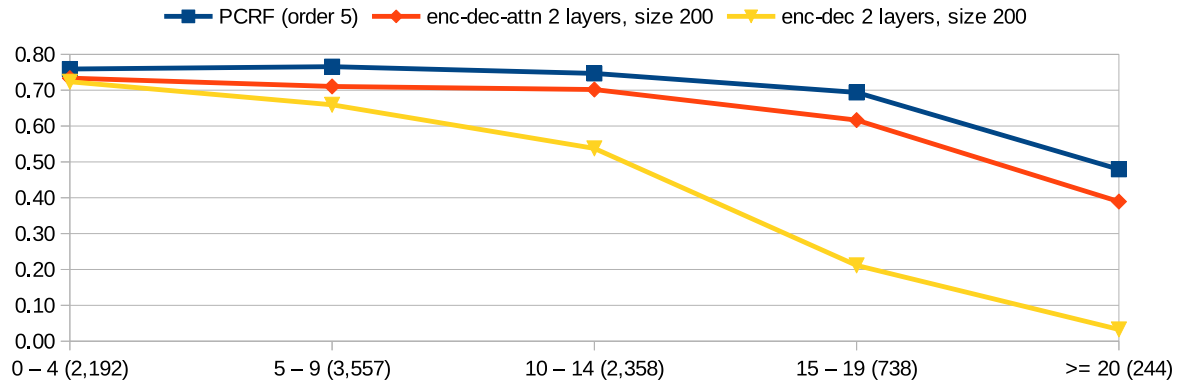

Figure 2: WAC of PCRF-Seq2Seq and encoder-decoder neural models with and without attention-based mechanisms as a function of input string length (number of training samples) on *Text+Berg* **OCR post-correction**.

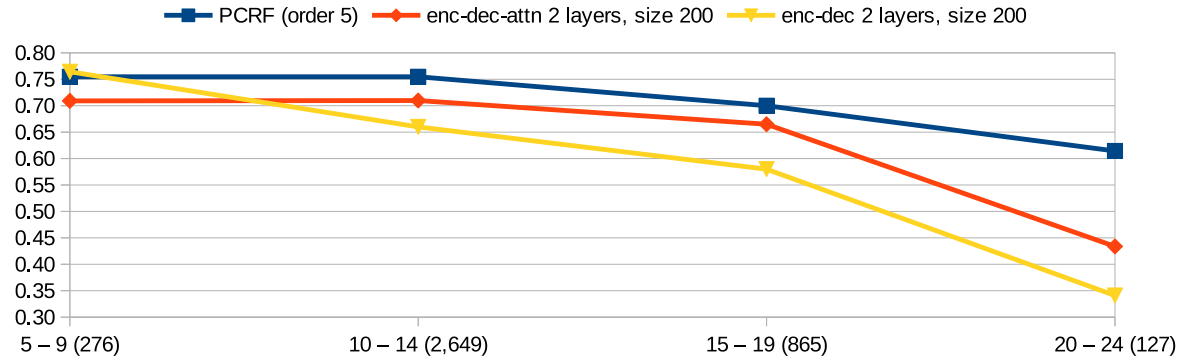

Figure 3: WAC of PCRF-Seq2Seq and encoder-decoder neural models with and without attention-based mechanisms as a function of input string length (number of training samples) on the Twitter **spelling correction** task.

For shorter sequences, we observe that standard encoder-decoder models even slightly outperform their attention-based counterparts as well as PCRF-Seq2Seq on both the Twitter spelling correction task (Figure 3) and on G2P conversion, in contrast to their rather low performance on the full datasets. On the *Text+Berg* data, all systems achieve approximately equal WAC for short sequences (Figure 2).

For longer sequences, the performance of the encoder-decoder models drops dramatically on all data sets. This effect is also visible, albeit less strong, for the attention-based variant. This can be seen particularly well on the OCR post-correction task (Figure 2), where the test set contains numerous long sequences: the accuracy rate for the standard encoder-decoder model drops from 73.32% on very short sequences to below 10% for very long ones ($\geq$ 20), whereas the attention-based model drops less drastically to 38.93% (from 76.92%). At the same time, PCRF-Seq2Seq behaves more stably, particularly on the Twitter data (Figure 3). For the Combilex data, the picture looks very similar — we omit these results for brevity.

6 Conclusions

The generality of neural networks makes them appealing for a wide range of possible tasks. In the scope of this work, we have applied encoder-decoder neural models to monotone Seq2Seq tasks. We have shown that they can perform comparably to more specialized models in some cases, but cannot (yet) consistently outperform established approaches, and are sometimes still substantially below them. Furthermore, the advantage of having rendered feature engineering and hyper-parameter optimization in the traditional sense unnecessary is notoriously substituted by the search for optimal neural network topologies.

At first sight, our analyses based on string lengths are in line with those reported by Bahdanau et al. (2014). They state that — for the field of machine translation — the attention mechanism leads to improvements over the standard encoder-decoder model on longer sentences. We also observe this positive impact for our tasks, where the attention-based mechanism alleviates the drastic performance drop of the standard encoder-decoder models on long sequences to some extent. At the same time, we see that very performance drop persisting — CRFs still outperform encoder-decoder models on long sequences, even when employing attention-mechanisms. As described in Section 5.3, neural models are only able to successfully compete when more complex phenomena occur, on which traditional models fail. Nevertheless, previous works such as Vukotic et al. (2015) also indicate that even in more complex sequence labeling tasks such as spoken language understanding, neural networks are not guaranteed to outperform CRFs.

The task-specific extensions to the encoder-decoder proposed by Faruqui et al. (2016) have been shown to produce mostly bad results in our settings. This is particularly surprising for the OCR data, for which input and output sequences are usually very similar, so that we had expected that re-feeding the input to the decoder should be equally beneficial in that domain. As discussed, one explanation might be that OCR, or spelling correction generally, putatively exhibits few long-range dependencies. This might explain why the `morph-trans` approach works quite well and competitive in morphological analysis tasks, as re-confirmed in our experiments. Thus, long-range dependencies might actually be a more crucial aspect for the performance of the model presented by Faruqui et al. (2016) than the similarity between input and output sequence.

We conclude that neural networks are far from completely replacing established methods at this point, as the latter can be both faster and more accurate, depending on the properties of the task at hand. A systematic analysis of the complexities and challenges a particular task imposes, remains unavoidable. At the same time, one can argue that encoder-decoder neural models are a relatively recent development and might continue to improve much over the next years. Being very generic and largely task-agnostic, they are already able to outperform traditional and specialized approaches under certain circumstances.

Abstract

Knowledge graph (KG) completion adds new facts to a KG by making inferences from existing facts. Most existing methods ignore the time information and only learn from time-unknown fact triples. In dynamic environments that evolve over time, it is important and challenging for knowledge graph completion models to take into account the temporal aspects of facts. In this paper, we present a novel *time-aware* knowledge graph completion model that is able to predict links in a KG using both *the existing facts* and *the temporal information of the facts*. To incorporate the happening time of facts, we propose a time-aware KG embedding model using temporal order information among facts. To incorporate the valid time of facts, we propose a joint time-aware inference model based on Integer Linear Programming (ILP) using temporal consistency information as constraints. We further integrate two models to make full use of global temporal information. We empirically evaluate our models on time-aware KG completion task. Experimental results show that our time-aware models achieve the state-of-the-art on temporal facts consistently.

1 Introduction

Knowledge graphs (KGs) such as Freebase (Bollacker et al., 2008) and YAGO (Fabian et al., 2007) are extremely useful resources for many NLP related applications such as relation extraction and question answering, etc. Although KGs are large in size, they are far from complete (West et al., 2014). Knowledge graph completion, i.e., automatically inferring missing facts between entities in a knowledge graph, has thus become an increasingly important task. Recently a promising approach called KG embedding aims to embed the components (entities and relations) of a KG into a continuous vector space while preserving the inherent structure of a knowledge graph (Nickel et al., 2011; Bordes et al., 2011). This kind of approach has shown good effectiveness and scalability for KG completion.

However, most existing KG embedding models ignore the temporal information of facts. In the real world, many facts are not static but highly ephemeral. For example, (*Steve_Jobs,* `diedIn`*, California*) happened on 2011-10-05; (*Ronaldo,* `playsFor`*, A.C.Milan*) is true only during 2007-2008. Intuitively, temporal aspects of facts should play an important role when we perform KG completion. In this paper, we focus on time-aware KG completion. Specially, we incorporate two kinds of temporal information for KG completion: (a) *temporal order information* and (b) *temporal consistency information*. By *temporal order information*, we mean that many facts have temporal dependencies on others according to the time that they happened. For example, the facts involving a person *P* may follow the following timeline: (*P,* `wasBornIn`*,* _) → (*P,* `graduateFrom`*,* _) → (*P,* `workAt`*,* _) → (*P,* `diedIn`*,* _). Given the time after *P* died , it's not proper to predict relations like `workAt`. By *temporal consistency information*, we mean that many facts are only valid during a short time period. For example, a person's marriage may be valid for a short period. Besides, the periods of a person's different marriages should not overlap. Without considering the temporal aspects of facts, the existing KG embedding methods may make mistakes. It is also non-trivial for existing KG embedding methods to incorporate such temporal information.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1715–1724, Osaka, Japan, December 11-17 2016.

To deal with the issues of the existing KG embedding methods, we propose two *time-aware KG completion* models to incorporate the above two kinds of temporal information, respectively. The extensive experimental results show the effectiveness of the two proposed models. We further propose a joint model that achieves better results. Our contributions include the following:

- To the best of our knowledge, this is the first work for time-aware KG completion. To incorporate the temporal order information, we propose a novel time-aware embedding (TAE) model that encodes the temporal order information as a regularizer on the geometric structure of the embedding space. To incorporate more temporal consistency information, we propose using Integer Linear Programming (ILP) to encode the temporal consistency information as constraints.
- We further propose a joint framework to unify the two complementary time-aware models seamlessly. ILP model considers more temporal constraints than TAE model, while TAE model generates more accurate embeddings for the objective function of ILP model. Our framework can be generalized to many KG embedding models such as TransE (Bordes et al., 2013) model and its extensions.
- We create real-world temporal data sets based on YAGO2 and Freebase for time-aware KG completion. The evaluation results show that our models outperform the start-of-the-art approaches and it confirms the effectiveness of incorporating temporal information.

The rest of the paper is organized as follows. Section 2 and Section 3 describe two time-aware KG completion models, respectively. Experiments, related work and conclusion are shown in Section 4-6.

2 Time-Aware KG Embedding Model

Time-aware KG embedding aims to automatically learn entity and relation embeddings by exploiting both observed triple facts and temporal order information among facts.

2.1 Time-Aware KG Completion Task

We represent facts with temporal annotations by quadruples, *quads* for short. We use (e_i, r, e_j, t) to denote the fact that e_i and e_j has relation r during the time interval $t = [t_b, t_e]$ with $t_b < t_e$. Although our reasoning framework supports arbitrary continuous intervals over real number, for simplicity, we assume time intervals range over **years**. For example, the interval [1980, 1999] starts in 1980 and ends in 1999. For some facts that happened at a certain time and did not last, we have $t_b = t_e$. For some facts that does not end yet, we represent t as $t = [t_b, +\infty]$.

KG completion is the task of predicting whether a given edge (e_i, r, e_j) exists in the graph or not. However, most facts are time-dependent and hold only for a given time period. For example, the fact of George W. Bush's presidency is only meaningful from 2001 to 2009. To incorporate temporal information for a more accurate representation, we extend this task to include the time dimension of the facts and call it *time-aware KG completion*, i.e., to complete the quad (e_i, r, e_j, t) when e_i, r or e_j is missing given a specific time interval t. For example, we can answer the question *"Who is the president of USA in 2010?"* by predicting head entity in *(?,* `presidentOf` *, USA*, [2010,2010]).

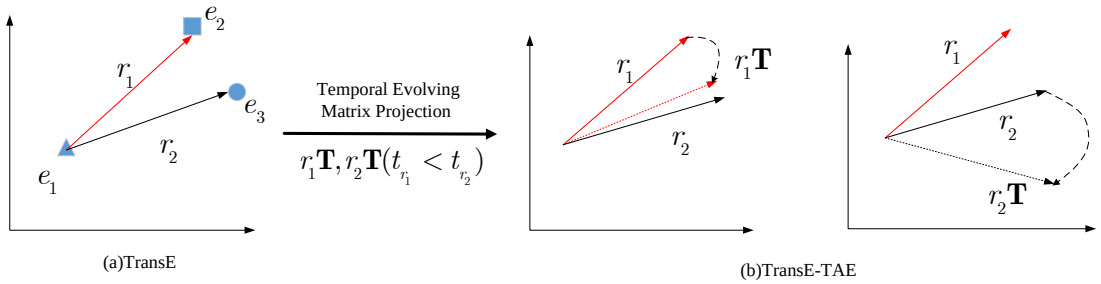
2.2 Traditional KG Embedding Methods

Traditional KG embedding methods use only the observed time-unknown facts (triples) to learn entity and relation representations. TransE (Bordes et al., 2013) is an efficient and simple model among them. The basic idea behind TransE is that the relation between two entities $\mathbf{e}_i, \mathbf{e}_j \in \mathbb{R}^n$ corresponds to a translation vector $\mathbf{r} \in \mathbb{R}^n$ between them, i.e., $\mathbf{e}_i + \mathbf{r} \approx \mathbf{e}_j$ when (e_i, r, e_j) holds. The scoring function is defined as measuring its plausibility in the vector space:

$$f(e_i, r, e_j) = \|\mathbf{e}_i + \mathbf{r} - \mathbf{e}_j\|_{\ell_1/\ell_2}, \tag{1}$$

where $\|\cdot\|_{\ell_1/\ell_2}$ denotes the ℓ_1-norm or ℓ_2-norm. A margin-based ranking loss is optimized to derive the entity and relation representations:

$$\min \sum_{x^+ \in \Delta} \sum_{x^- \in \Delta'} [\gamma + f(x^+) - f(x^-)]_+. \tag{2}$$



(a)TransE (b)TransE-TAE

Figure 1: Simple illustration of Temporal Evolving Matrix $\mathbf{T}$ in the time-aware embedding (TAE) space. For example, r_1=$wasBornIn$ happened before r_2=$diedIn$. After projection by $\mathbf{T}$, we get prior relation's projection $\mathbf{r}_1\mathbf{T}$ near subsequent relation $\mathbf{r}_2$ in the space, i.e.,$\mathbf{r}_1\mathbf{T} \approx \mathbf{r}_2$, but $\mathbf{r}_2\mathbf{T} \neq \mathbf{r}_1$.

Here, $x^+ \in \Delta$ is the observed (i.e., positive) triple, and $x^- \in \Delta'$ is the negative triple constructed by replacing entities in x^+. γ is the margin separating positive and negative triples and $[z]_+ = \max(0, z)$. Please refer to (Wang et al., 2014a; Lin et al., 2015b) for TransH, TransR and other models.

After we obtain the embeddings, the plausibility of a missing triple can be predicted by using the scoring function. In general, triples with higher plausibility are more likely to be true.

2.3 Time-Aware KG Embedding Model

TransE assumes that each relation is time independent and entity/relation representation is only affected by structural patterns in KGs. To better model knowledge evolution, we assume temporal ordered relations are related to each other and evolve in a time dimension. For example, for the same person, there exists a temporal order among relations `wasBornIn`→ `graduatedFrom` → `diedIn`. In time dimension, `wasBornIn` can evolve into `graduateFrom` and `diedIn`, but `diedIn` cannot evolve into `wasBornIn`.

To compare temporal orders, we define a pair of temporal ordering relations sharing the same head entity [1] as **temporal ordering relation pair**, e.g., ⟨`wasBornIn`, `diedIn`⟩. We define the relation happening earlier, e.g., `wasBornIn`, as **prior relation** and the other as **subsequent relation**. We define ⟨prior relation, subsequent relation⟩ as positive temporal ordering pairs and ⟨subsequent relation, prior relation⟩ as negative ones.

To capture the temporal order of relations, we further define a *temporal evolving matrix* $\mathbf{T} \in \mathbb{R}^{n \times n}$ to model relation evolution, where n is the dimension of relation embedding. $\mathbf{T}$ is a parameter to be learned by the model from the data. We assume that prior relation can evolve into subsequent relation through the temporal evolving matrix. The more frequent they have temporal orders, the more they can evolve. Specially, as in Figure 1, prior relation $\mathbf{r}_1$ projected by $\mathbf{T}$ should be near subsequent relation $\mathbf{r}_2$, i.e., $\mathbf{r}_1\mathbf{T} \approx \mathbf{r}_2$, while $\mathbf{r}_2\mathbf{T}$ should be far from $\mathbf{r}_1$. In this way, we are able to separate prior relation and subsequent relation automatically during training.

We formulate time-aware KG completion as an optimization problem based on a regularization term. Given any positive training quad $(e_i, r_k, e_j, t_{r_k}) \in \Delta_t$, we can find a temporally related quad $(e_i, r_l, e_m, t_{r_l}) \in \Delta_t$ sharing the same *head entity* and a temporal ordering relation pair $\langle r_k, r_l \rangle$. If $t_{r_k} < t_{r_l}$, we have a positive temporal ordering relation pair $y^+ = \langle r_k, r_l \rangle$ and the corresponding negative relation pair $y^- = \langle r_k, r_l \rangle^{-1} = \langle r_l, r_k \rangle$ by inverse. Our optimization requires that positive temporal ordering relation pairs should have lower scores (energies) than negative pairs. Therefore, we define a **temporal** scoring function as

$$g(\langle r_k, r_l \rangle) = \|\mathbf{r}_k\mathbf{T} - \mathbf{r}_l\|_{\ell_1/\ell_2}, \tag{3}$$

which is expected to give a low score when the temporal ordering relation pair is in chronological order, and a high score otherwise. Note that $\mathbf{T}$ is asymmetric and the loss function is also asymmetric so as to capture temporal order information.

[1] We only consider relations sharing the same head entity because most temporal facts and temporal relations are partially ordered around a common *protagonist* (usually the head entity), e.g., "wasBornIn", "workAt", and "diedIn" are temporally ordered with a common person. Temporal relations that are ordered with a common tail entity could be transformed by replacing the relation with its inverse relation and exchanging the head and tail entity.

To make the embedding space compatible with the observed triples, we make use of the fact triples set Δ and follow the same strategy adopted in previous methods. Specially, we apply the same **fact** scoring function $f(e_i, r_k, e_j)$ in Equation (1) to each candidate triple. The optimization is to minimize the **joint** scoring function,

$$L = \sum_{x^+ \in \Delta} \Big[\sum_{x^- \in \Delta'} [\gamma_1 + f(x^+) - f(x^-)]_+ + \lambda \sum_{y^+ \in \Omega_{e_i,t_{r_k}}, y^- \in \Omega'_{e_i,t_{r_k}}} [\gamma_2 + g(y^+) - g(y^-)]_+ \Big], \tag{4}$$

where $x^+ = (e_i, r_k, e_j) \in \Delta$ is a positive triple, $x^- = (e'_i, r_k, e'_j) \in \Delta'$ is the corresponding negative triple by replacing entities. The positive temporal ordering relation pair set with respect to (e_i, r_k, e_j, t_{r_k}) is defined as

$$\begin{aligned} \Omega_{e_i,t_{r_k}} = \{\langle r_k, r_l \rangle | (e_i, r_k, e_j, t_{r_k}) \in \Delta_t, (e_i, r_l, e_m, t_{r_l}) \in \Delta_t, t_{r_k} < t_{r_l}\} \\ \cup \{\langle r_l, r_k \rangle | (e_i, r_k, e_j, t_{r_k}) \in \Delta_t, (e_i, r_l, e_m, t_{r_l}) \in \Delta_t, t_{r_k} > t_{r_l}\} \end{aligned} \tag{5}$$

where r_k and r_l share the same head entity e_i. $\Omega'_{e_i,t_{r_k}}$ are the corresponding negative relation pairs by inverse the relation pairs. In experiments, our constrains are $\|\mathbf{e}_i\|_2 \leq 1$, $\|\mathbf{r}_k\|_2 \leq 1$, $\|\mathbf{r}_l\|_2 \leq 1$, $\|\mathbf{e}_j\|_2 \leq 1$, $\|\mathbf{r}_k\mathbf{T}\|_2 \leq 1$, and $\|\mathbf{r}_l\mathbf{T}\|_2 \leq 1$ to avoid overfitting similarly to previous work.

The first term in Equation (1) enforces the generated embedding space compatible with all the observed triples, and the second term further requires the space to be temporally consistent and more accurate. Hyperparameter λ strikes a trade-off between the two cases. Stochastic gradient descent (in mini-batch mode) is adopted to solve the minimization problem.

3 Joint Inference for Time-Aware KG Completion

In this section, we incorporate temporal information as temporal consistency constraints for KG completion. We take advantage of temporal logic transitivity and use ILP to derive more accurate predictions.

3.1 Temporal Consistency Constraints

The candidate predictions we obtained in the traditional KG embedding inevitably include many incorrect predictions. By applying temporal consistency constraints, we can identify and then discard such errors to produce more accurate results.

As the complexity of resolving conflicts strictly depends on the constraints to apply, we need to choose them with great care. In the following, we consider three kinds of temporal constraints.

Temporal Disjointness. The time intervals of any two facts with a common functional relation and a common head entity are non-overlapping. For example, a person can only be spouse of one person at a time: $(e_1, \texttt{wasSpouseOf}, e_2, [1990, 2010)) \wedge (e_1, \texttt{wasSpouseOf}, e_3, [2005, 2013)) \wedge e_2 \neq e_3 \rightarrow$ false.

Temporal Ordering. For some temporal ordering relations, one fact always happens before another fact. For example, a person must be born before he graduated: $(e_1, \texttt{wasBornIn}, e_2, t_1) \wedge (e_1, \texttt{graduateFrom}, e_3, t_2) \wedge t_1 > t_2 \rightarrow$ false.

Temporal Spans. Some facts are true only during a specific time span. In general, the fact is invalid for other time periods outside the range of its time span in KGs. For example, given time interval t' outside the range t in $(e_1, \texttt{presidentOf}, e_2, t) \in$ KG, the fact $(e_1, \texttt{presidentOf}, e_2, t')$ is invalid.

3.2 Integer Linear Program Formulation

We formulate the time-aware inference as an ILP problem with temporal constraints. Traditional KG embedding methods can capture the intrinsic properties of data, which can be treated as a probability to predict unseen facts. For each candidate fact (e_i, r_k, e_j), we use $w_{ij}^{(k)} = f(e_i, r_k, e_j)$ to represent the plausibility predicted by an embedding model, and introduce a Boolean decision variable $x_{ij}^{(k)}$ to indicate whether the fact (e_i, r_k, e_j, t) is true or not for time t. Our aim is to find the best assignment to the decision variables, maximizing the overall plausibility while complying with all the temporal constraints. The objective function can be written as:

$$\max \sum_{x_{ij}^{(k)}} w_{ij}^{(k)} x_{ij}^{(k)}. \tag{6}$$

We add the constraints described in Section 3.1 for the above objective function.

The temporal disjointness constraints avoid the disagreement between the predictions of two facts sharing the same head entity and relation. These constraints can be represented as:

$$x_{ij}^{(k)} + x_{il}^{(k)} \leq 1, \forall k \in \mathcal{C}^d, t_{x_{ij}^{(k)}} \cap t_{x_{il}^{(k)}} \neq \emptyset \tag{7}$$

where $\mathcal{C}^d$ are functional relations described such as `wasSpouseOf` and $t_{x_{ij}^{(k)}}, t_{x_{il}^{(k)}}$ are time intervals for two facts, respectively.

The Temporal Ordering constraints ensure the occurring order for some relation pairs. These constraints can be represented as:

$$x_{ij}^{(k)} + x_{il}^{(k')} \leq 1, \forall (k, k') \in \mathcal{C}^o, t_{x_{ij}^{(k)}} \geq t_{x_{il}^{(k)}} \tag{8}$$

where $\mathcal{C}^o = \{\langle r_k, r'_k \rangle\}$ are relation pairs that have precedent orders such as $\langle$`wasBornIn`,`diedIn`$\rangle$. These relation pairs are discovered automatically in the training set by statistics and finally manually calibrated.

The temporal span constraints ensure the specific time span when the corresponding fact is true. These constraints can be represented as:

$$x_{ij}^{(k)} = 0, \forall k \in \mathcal{C}^s, t_{x_{ij}^{(k)}} \cap t_\Delta = \emptyset \tag{9}$$

where $\mathcal{C}^s$ are those relations valid for only a specific time span such as `presidentOf` and t_Δ is the valid time span in KG.

Using ILP, we can combine the ability of capturing the intrinsic properties of KG data and the temporal constraints that are embedded into global consistencies of the relations together. As shown in Eq.(10), any unseen fact's plausibility is encoded in scores w_{ij}^k which captures the intrinsic properties of KG data. Temporal consistency constraints are formulated as Eq.(7)-(9) and apply to the objective function naturally. By solving Eq.(10), we will obtain a list of selected candidate entities or relations for a missing fact as our final output.

3.3 Integrating Two Time-Aware Models

As mentioned above, the two time-aware models are complementary for each other: ILP model considers more temporal constraints than TAE model while TAE model generates more accurate embeddings for the ILP objective function.

For each unseen quad (e_i, r_k, e_j, t), we use a Boolean decision variable $x_{ij}^{(k,t)}$ to indicate whether it's true or not. We can use the embeddings of TAE model in Section 2.3 to calculate the plausibility $v_{ij}^{(k,t)}$ for the ILP objective function. The objective function is

$$\max \sum_{x_{ij}^{(k,t)}} v_{ij}^{(k,t)} x_{ij}^{(k,t)}. \tag{10}$$

Eq.(7)-(9) remain the same.

4 Experiments

We use similar evaluation metrics as traditional KG completion methods (Bordes et al., 2013) for time-aware KG completion.

4.1 Data Sets

To create temporal KG data sets, we need to decide whether a fact has temporal information. We categorize relations into time-sensitive relations and time-unsensitive relations according to YAGO2 (Hoffart et al., 2013). For example, `diedIn` is time-sensitive, but `hasNeighbor` is not. We extract temporal annotations for time-sensitive facts from YAGO2 and Freebase[2].

In YAGO2, temporal facts are in the form (*factID,occurSince,*t_b), (*factID,occurUntil,*t_e*)* indicating the fact is true during $[t_b, t_e]$. Here *factID* denotes a specific fact (e_i, r, e_j). We directly represent these temporal facts as quads $(e_i, r, e_j, [t_b, t_e])$. We selected 10 frequent time-sensitive relations to make a pure temporal data set. Then we selected the subset of entities which have at least two mentions in temporal

Table 2: Evaluation results on entity prediction.

facts. This resulted in 15,914 triples (quadruples) which were randomly split with the ratio shown in Table 1. This data set is denoted *YG15k*. Although YAGO2 has many temporal annotations for facts, a lot of temporal annotations are still missing for time-sensitive facts. We consider the data set *YG36k* consisting of half facts with temporal annotations and the other half missing temporal annotations to evaluate whether partial temporal information of data improves the performance or not. The relationship set is the same in YG15k and YG36k.

We extracted temporal facts mainly from FB15k (Bordes et al., 2013), a subset of Freebase consisting of 1345 relations. Among them, 707 relations are long relations in the form "$r_1.r_2$" concatenating short relations r_1 and r_2. Long relations do not exist in the original schema of Freebase. Many associated facts in Freebase are organized as a CVT structure (similar to an event), e.g., (Einstein,`hasWonPrize`, Nobel) is stored as (Einstein, */award/award_winner/awards_won*, x), (x,*/award/award_honor/award,Nobel*) in Freebase, where x is called *mediator* and not a real entity. FB15k facts are created by concatenating two relations: (*Einstein,/award/award_winner/awards_won. /award/award_honor/award,Nobel*). We extracted temporal annotations from the original Freebase CVT structure for these facts with long relations. For short relations such as */film/director/film*, we used creation/destruction dates of head or tail entity as their time, e.g., the released date of the film. This resulted in 42 time-sensitive relations and 28,610 temporal facts. We denoted the data set as *FB42*. We further added triples without time annotations and created *FB87*. In FB15k, there are about 50% temporal facts in our setting. The data set will be publicly available. All experiments are repeated five times by drawing new training/validation/test splits, and results averaged over the five rounds are reported.

4.2 Time-aware KG Completion

Time-aware KG completion (link prediction) is to complete the triple (e_i, r, e_j, t) when e_i, r or e_j is missing given a specific time interval t. We divided the stage into two sub-tasks, i.e., entity prediction and relation prediction.

4.2.1 Entity Prediction

Evaluation protocol. For each test triple with missing head or tail entity, various methods are used to compute the scores for all candidate entities and rank them in descending order. We use two metrics for our evaluation as in (Bordes et al., 2013): the mean of correct entity ranks (Mean Rank) and the proportion of valid entities ranked in top-10 (Hits@10). As mentioned in (Bordes et al., 2013), the metrics are desirable but flawed when a corrupted triple exists in the KG. As a countermeasure, we may filter out all these corrupted triples which have appeared in KG before ranking. We name the first evaluation set as *Raw* and the second as *Filter*.

For each test quad (triple), we replace the head/tail entity e_i by those entities with *compatible types* as removing triples with incompatible types during test time leads to better results (Chang et al., 2014;

Wang et al., 2015). Entity type information is easy to obtain for YAGO and Freebase. Then we rank the generated corrupted triples in descending order, according to the plausibility (for baselines and TAE model) or the decision variables (for time-aware ILP model). Then we check whether the original correct triple ranks in top-10. To calculate Hit@10 for ILP model, for each test quad, we add additional constraints that at most 10 corrupted are true: $\sum_{i,j} x_{e_i e_j}^{(r_1)} \leq 10$. Mean Rank is missing for ILP method as we could not rank the binary decision variables.

Baseline methods. For comparison, we select TransE (Bordes et al., 2013), its extensions TransH (Wang et al., 2014b) and TransR (Lin et al., 2015b) as our baselines. We then compare time-aware embedding and time-aware ILP inference with each baseline. For example, TransE with TAE and time-aware ILP is denoted as "TransE-TAE" and "TransE-ILP", respectively. The combined model of the two time-aware models are denoted as "TransE-TAE+ILP".

Implementation details. For all embedding methods, we create 100 mini-batches on each data set. The dimension of the embedding n is set in the range of {20,50,100}, the margin γ_1 and γ_2 are set in the range {1,2,4,10}. The learning rate is set in the range {0.1, 0.01, 0.001}. The regularization hyperparameter λ is tuned in $\{10^{-1},10^{-2},10^{-3},10^{-4}\}$. The best configuration is determined according to the mean rank in validation set. For YAGO data set, the optimal configurations are $n = 100$,$\gamma_1 = \gamma_2 = 4$,$\lambda = 10^{-2}$, learning rate is 0.001 and taking ℓ_1-norm; For Freebase data set, the optimal configurations are $n = 100$,$\gamma_1 = \gamma_2 = 1$,$\lambda = 10^{-1}$, learning rate is 0.001 and taking ℓ_1-norm.

We then incorporate temporal constraints into the six models with optimal parameter settings using ILP. To generate the objective function of ILP, plausibility predicted by embedding models is normalized by $w'_{ij} = (w_{ij} - \text{MIN})/(\text{MAX} - \text{MIN})$, where MAX and MIN are max/min scores for each corrupted test triple. We use the lp_solve package[3] to solve the ILP problem.

Results. Table 2 reports the results for each data set. From the results, we can see that 1) TAE methods outperform all the baselines on all the data sets and with all the metrics. The improvements are quite significant. The Mean Rank drops by about 75%, and Hits@10 rises about 19% to 30%. This demonstrates the superiority and generality of our method. 2) Adding more temporal facts improve the performance for TAE models. YG15k consists of 100% temporal facts while YG36k consists of 50% temporal facts. All the temporal information in YG15k is utilized to model temporal associations and make the embeddings more accurate. Therefor, it obtains larger improvement for TAE than YG36k. 3) Improvement for YAGO is larger than Freebase because YAGO data set contains more temporal ordering relation pairs than Freebase data set.

As we can see from Table2, the time-aware ILP method improves each baseline model by about 10% to 16%. This demonstrates the effectiveness of incorporating temporal consistency constraints. Combining two time-aware models further improves the performance by 2% to 3%. This indicates that 1) although TAE models encode temporal order information, only pair-wise temporal ordering relations are optimized during each training iteration. ILP can take advantage of global temporal transitivity which pair-wise methods can't. 2) Adding time span information in the ILP model can remove more false predictions.

4.2.2 Relation Prediction

Relation prediction aims to predict relations between two entities. Evaluation results are shown in Table 3 on YG15K and FB87 due to space limit, and here we report Hits@1 instead of Hits@10. For ILP models, we report Hits@1 for the same reason in entity prediction. Again, two time-aware models improve baselines greatly.

The ILP models improve the precision by about 10%, showing that incorporating temporal constraints directly is better for this task. The main reason is that our temporal constraints are designed to better handle temporal conflicts in relations. Relation prediction and relation extraction from text have common multi-label problems that the same entity pair may have multiple relation labels. For example, *(Obama,US)* could have two valid relations: *wasPresidentOf, wasBornIn*. Through temporal constraints, we are aware that the two relations have different valid time, and therefore we could remove the false one to

improve Hit@1 accuracy.

Qualitative analysis. Examples of relation prediction for TransE, TransE-TAE and TransE-ILP are compared in Table 4. From the results we have the following two conclusions. 1) Temporal order information is useful to distinguish similar relations. For example, when testing *(Stanford_Moore, ? , Chicago, [1982, 1982])*, it's easy for TransE to mix relations `wasBornIn` and `diedIn` as they behave similarly for a person and a place. But knowing that he `graduated` in 1935 from the training set, and TransE-TAE have learnt temporal order that *wasBornIn→graduated→diedIn*, the regularization term $|\mathbf{r}_{graduate}\mathbf{T} - \mathbf{r}_{died}|$ and $|\mathbf{r}_{graduate}\mathbf{T} - \mathbf{r}_{born}|$ helps rank `diedIn` higher than `wasBornIn`. TransE-ILP also benefits from such temporal order constraints and obtains more accurate predictions. 2) Time span information is useful to make accurate predictions. For example, TransE and TransE-TAE both predict (*Carmen Electra,?,Owen Wilson*,[2004,2005]) has `wasMarriedTo` relation. Temporal order constraints don't work for this example. But the time span constraints help TransE-ILP to remove `wasMarriedTo` because *Carmen Electra* was married to *Dave Navarro* during [2003,2008] and a person cannot marry two people at the same time.

5 Related Work

There are two lines of research related to our work.

Knowledge Graph Completion. Nickel et al. (2016) provide a broad overview of machine learning models for KG completion. These models predict new facts in a given knowledge graph using information from existing entities and relations. The most related work from this line of work is KG embedding models (Nickel et al., 2011; Bordes et al., 2013; Socher et al., 2013). Aside from fact triples, external information is employed to improve KG embedding such as combining text (Riedel et al., 2013; Wang et al., 2014a; Zhao et al., 2015), entity type and relationship domain (Guo et al., 2015; Chang et al., 2014), relation path (Lin et al., 2015a; Gu et al., 2015), and logical rules (Wang et al., 2015; Rocktäschel et al., 2015). However, these methods have not utilized temporal information among facts.

Temporal Information Extraction. This line of work mainly falls into two categories: methods that extract temporal facts from web (Ling and Weld, 2010; Wang et al., 2011; Artiles et al., 2011; Garrido et al., 2012) and methods that infer temporal scopes from aggregate statistics in large Web corpora (Talukdar et al., 2012b; Talukdar et al., 2012a). The TempEval task (Pustejovsky and Verhagen, 2009) and systems (Chambers et al., 2007; Bethard and Martin, 2007; Chambers and Jurafsky, 2008; Cassidy et al., 2014) have been successful in extracting temporally related events. Temporal reasoning is also explored to solve temporal conflicts in KG (Dylla et al., 2011; Wang et al., 2010). This paper differs from this line of work as we directly use temporal information from KG to perform KG completion.

6 Conclusion and Future Work

In this paper, we propose two novel time-aware KG completion models. Time-aware embedding (TAE) model imposes temporal order constraints on the geometric structure of the embedding space and enforces it to be temporally consistent and accurate. Time-aware joint inference with ILP framework considers global temporal constraints as well as KG embeddings. It naturally preserves the benefits of embedding models and is more accurate with respect to various temporal constraints. We further integrate two models to make full use of temporal information.

As future work: 1) Many temporal facts are not stored by current KGs (about 30% facts in YAGO and 50% in Freebase lack temporal annotations), we will extract more temporal information from texts. 2) We will consider using our time-aware KG completion model to predict temporal scopes of new facts.

Abstract

Ordinal regression which is known with learning to rank has long been used in information retrieval (IR). Learning to rank algorithms, have been tailored in document ranking, information filtering, and building large aligned corpora successfully. In this paper, we propose to use this algorithm for query modeling in cross-language environments. To this end, first we build a query-generated training data using pseudo-relevant documents to the query and all translation candidates. The pseudo-relevant documents are obtained by top-ranked documents in response to a translation of the original query. The class of each candidate in the training data is determined based on presence/absence of the candidate in the pseudo-relevant documents. We learn an ordinal regression model to score the candidates based on their relevance to the context of the query, and after that, we construct a query-dependent translation model using a softmax function. Finally, we re-weight the query based on the obtained model. Experimental results on French, German, Spanish, and Italian CLEF collections demonstrate that the proposed method achieves better results compared to state-of-the-art cross-language information retrieval methods, particularly in long queries with large training data.

1 Introduction

The multilingual environment of the Web has long required the researchers in information retrieval (IR) to introduce powerful algorithms for bridging the gaps between the languages (Nie, 2010; Ganguly et al., 2012; Dadashkarimi et al., 2016). Generally, these algorithms can be categorized as follows: *(1)* translating the query of the user to the language of the documents (Ganguly et al., 2012), *(2)* translating all of the documents into the language of the user (Oard, 1998), *(3)* translating the query and the documents into a third language (Kishida and Kando, 2005), *(4)* bringing the query and the documents into a shared low-dimensional space (Vulic and Moens, 2015; Dadashkarimi et al., 2016), and *(5)* using semantic/concept networks (Franco-Salvador et al., 2014). Usually the query translation approach has been opted as the most efficient and effective approach in the literature (Vulic and Moens, 2015; Nie, 2010). Ma et al. (2012), have shown that cross-language information retrieval (CLIR) takes more advantage of weighting all translations than selecting the most probable ones. But, building this translation model demands a statistical analysis of translation candidates over an aligned corpus or a single target collection (Talvensaari et al., 2007; Liu et al., 2005; Ganguly et al., 2012).

Aligned corpora have been exploited in CLIR successfully (Rahimi et al., 2016; Talvensaari et al., 2007). But, these resources are either scarce in some languages or specific to a few number of domains. Therefore, recently query-dependent collections have been shown to be more effective and are available to many languages (Dadashkarimi et al., 2016; Ganguly et al., 2012). Pseudo-relevant documents are useful resources to this end. In this paper we propose to use pseudo-relevant documents to build a query-dependent translation model. To this aim, first we take top-ranked documents retrieved in response to a simple translation of the query as a pseudo-relevant collection; we expect relevant translations to appear in the collection by accepting a limited amount of noise. Thus we build a training data based

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1725–1733, Osaka, Japan, December 11-17 2016.

on presence/absence of the translations in the collection and a number of embedded features. At the next step we aim to learn an ordinal regression model over the translation candidates and then build a translation model for the query using a softmax function. The final model is used in the second retrieval run.

Since this model requires rather large training data, it is expected to be more useful for long queries, where there is enough information about the user intention. Experimental results on French, Spanish, German, and Italian CLEF collections demonstrate that the proposed method performs better than state-of-the-art dictionary-based CLIR methods particularly in long queries.

In Section 2 we provide an overview on related works and then we propose the method and all the formulations in Section 3. Experimental results and related discussions are provided in Section 4. We conclude the paper and provide future works in Section 5.

2 Previous Works

2.1 Query Translation in CLIR

Query translation is opted as an efficient way for bridging the gap between the source language of the query q^s and the language of a target collection $\mathcal{C} = \{d_1, d_2, .., d_{|\mathcal{C}|}\}$ in CLIR (Nie, 2010). In statistical language modeling, a query translation is defined as building a translation model $p(w_t|q_i^s; q^s)$ where w_t is a translation candidate and q_i^s is a query term. Monz and Dorr (2005) introduced an expectation maximization algorithm for estimating this probability: $p(w_t|q_i^s)^n = p(w_t|q_i^s)^{n-1} + \sum_{w_{t'}} a_{w_t,w_{t'}}.p(w_{t'}|q_i^s)$ where $a_{w_t,w_{t'}}$ is a mutual information of a couple of translations. This probability is computed iteratively and then is used for building query model $p(w_t|q^s)$. Dadashkarimi et al. (2014) and Cao et al. (2008), employed similar methods with bigram probabilities $p(w_t|w_{t'})$. On the other hand, Pirkola et al. (2001) introduced structured queries for CLIR in which each translation of a query term can be considered as a member of a synonym set. Structured queries use a number of operators for building this set. For example $\#sum(\#syn(w_1, .., w_k)\#syn(w'_1, .., w'_{k'}))$ treats occurrences of w_t in a document as occurrences of its set and then sums over all the sets for estimating score of a document. There are also selection-based methods that consider only a limited subset of translations in their retrieval task. Nie (2010), demonstrated that these approaches suffer from lower coverage compared to the weighting approaches.

2.2 Pseudo-relevance Feedback for Query Modeling

Top-ranked documents $F = \{d_1, d_2, .., d_{|F|}\}$ in response to the query of a user have long been considered as informative resources for query modeling (Lavrenko and Croft, 2001; Zhai and Lafferty, 2001; Lv and Zhai, 2014). Relevance models are proposed by (Lavrenko et al., 2002; Lavrenko and Croft, 2001) in both monolingual and cross-lingual environments for language modeling. To this end, Zhai and Lafferty (2001) proposed the mixture model for monolingual environments based on an expectation maximization algorithm. Lv and Zhai (2014) proposed a divergence minimization algorithm that outperforms most of the competitive baselines. There are also a further number of powerful algorithms based on machine learning methods in this area (Liu, 2009). Dadashkarimi et al. (2016), employed a divergence minimization framework for pseudo-relevance feedback using embedded features of words from a positive and a negative sample set of feedback documents. Liu et al. (2005), introduced maximum coherence model for query translation whose aim is to estimate overall coherence of translations based on their mutual information. Dadashkarimi et al. (2016), recently published another work for query translation using low-dimensional vectors of feedback terms from a couple of pseudo-relevant collections. The cross-lingual word embedding translation model (CLWETM) first learns the vectors of feedback terms separately and then aims at finding a query dependant transformation matrix $\mathbf{W}$ for projecting the source vectors to their equivalents in the target language. The projected vectors $\mathbf{W}^T\mathbf{v}_w$ are then used to build a translation model for the query. The authors have shown that CLWETM outperforms the state-of-the-art dictionary-based cross-lingual relevance models.

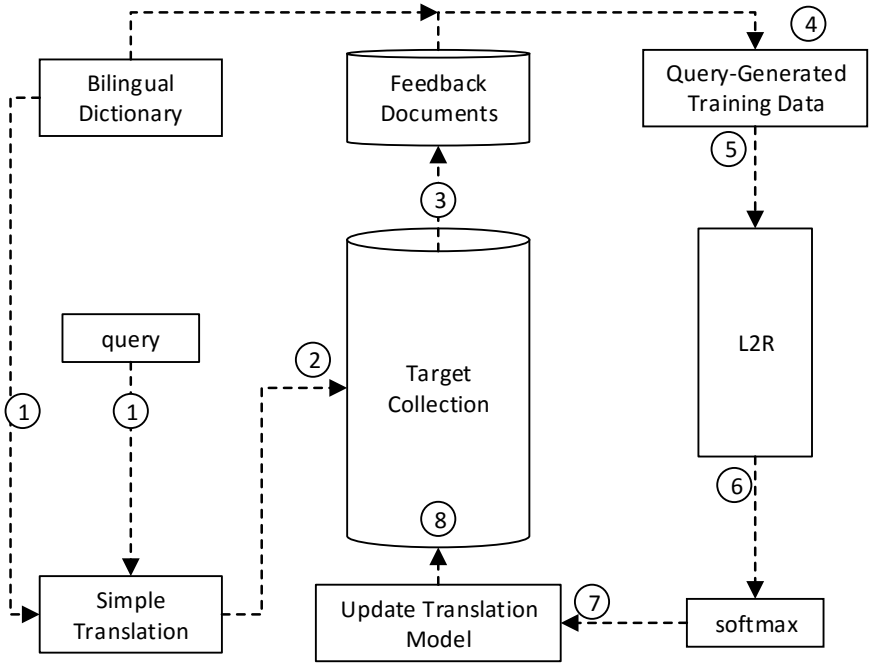

Figure 1: The whole process of building translation model using ordinal linear regression and query-generated training data.

3 Learning to Weight Translations using Query-generated Training Data and Embedded Features

In this section we propose a learning approach for weighting translations of query terms. To this end we first elaborate on building a query-generated training data in Section 3.1. In Section 3.2, we introduce the formulations of the proposed method and finally in Section 3.3 we introduce a number of embedded features used in the learning process.

3.1 Query-generated Training Data for Ordinal Regression

Let $q = \{q_1, .., q_m\}$ be the query and let $q^t = \{w_1, ..w_n\}$ be all the translation candidates of q. We expect correct translations to appear in pseudo-relevant collection F by accepting a limited amount of noise (see Section 2.2). As an example, let the query be $q = \{world, cup, 2018\}$ and assume that $q^t = \{[monde, univers], [coupe, tasse], [2018]\}$ is the set of translation candidates in French. By using a uniform distribution of weights over translation words, $q^t = \{[(1/2, monde), (1/2, univers)], [(1/2, coupe), (1/2, tasse)], [(1, 2018)]\}$ could be a simple query model in the target language. Since $\{monde, coupe, 2018\}$ are conceptually better translations, we expect them to appear in F. Thus, the presence/absence of the translations in F can be indicators of their relevance to the query. We use this information for building a query-generated training data to learn an ordinal regression model for scoring the translations. Let $y_i \in \{-1, +1\}$ indicates the presence/absence of w_i represented by feature vector $\mathbf{x}_i \in \mathbb{R}^n$, and then assume that $D = \{(\mathbf{x}_i, y_i) \in \mathbb{R}^{|\mathbf{x}_i|} \times \{-1, +1\}\}$ is the training data. D is then be used as the training data for our regression model.

3.2 Learning to Rank for Ordinal Translation Regression

We aim to find $f(\mathbf{x}) = \mathbf{w}^T\mathbf{x} + b$, where $\mathbf{w} \in \mathbb{R}^{|\mathbf{x}|}$ is the weight vector and b is a bias both specific to a query, satisfying the following constraint:

$$f(\mathbf{x}_i) > f(\mathbf{x}_j) \Longleftrightarrow y_i > y_j \quad \forall(\mathbf{x}_i, y_i), (\mathbf{x}_j, y_j) \in D \tag{1}$$

Table 1: Descriptions of the features in **x**.

Feature	Description
$[\mathbf{u}_{w_j}]_k$	the $k-$th dimension of w_j in its low dimensional vector $\mathbf{u}_{w_j} \in \mathbb{R}^{c\times 1}$
$p(w_j\|C)$	the maximum likelihood probability of w_j in the collection
$p(w_j\|\theta_F)$	the maximum likelihood probability of w_j in the feedback documents
$p(w_j\|q^t)$	the maximum likelihood probability of w_j in the simple translation of the query
$\sum_{w_{j'}\notin q_{w_j}} p(w_j, w_{j'})$	sum of the bi-gram probability of w_j with all translations of $q_{w_{j'}} \neq q_{w_j}$

where $f(\mathbf{x})$ should give higher rank to a pseudo relevant translation w_i compared to a non-relevant translation w_j. If we define the set of all translation words' pairs with $P = \{(i,j) : y_i > y_j\}$, finding $f(\mathbf{x})$ requires minimizing the following loss function:

$$\mathcal{L}(\theta) = \frac{1}{2}\mathbf{w}^T\mathbf{w} \qquad s.t. \;\; \forall (i,j) \in P : (\mathbf{w}^T\mathbf{x}_i) \geq (\mathbf{w}^T\mathbf{x}_j) \tag{2}$$

Generally speaking, Equation 2 shows loss-function of an ordinal regression with parameter **w** (Herbrich et al., 1999; Joachims, 2006). Here, the goal is to score $w \in q^t$ based on the embedded feature vectors $\mathbf{x}_{1:n}$ and build a translation model as follows:

$$p(w_j|q) = \frac{1}{m}\frac{\delta_{w_j} e^{\mathbf{w}^T \mathrm{x}_j + b}}{\sum\limits_{w_{j'}} \delta_{w_{j'}} e^{\mathbf{w}^T \mathrm{x}_{j'} + b}} \tag{3}$$

where δ_{w_j} is a weight function specific to each word and m is the number of query terms. We choose $\delta_{w_j} = c(w_j, F)^{\frac{1}{2}}$ equal to the count of w_j in F to the power of $\frac{1}{2}$. This power is for rewarding rare words and penalizing the common ones (Goldberg and Levy, 2014). Figure 1 shows the whole process of building training data and weighting the translations.

3.3 Embedded Features

In Section 3.1 we proposed a query-dependant training data. In this section, we shed light on **x**, the feature vectors in D. As shown in Table 1, we exploited two categories of features: query-dependent features and query-independent features. $p(w_j|C)$ and $[\mathbf{u}_{w_j}]_k$ are independent of the query and capture the frequency of w_j in the collection and the semantic information of w_j in the target language respectively. On the other hand, the other features are specific to the q. $p(w_j|\theta_F)$ captures frequency of w_j in the pseudo-relevant documents. For example in $q = \{world, cup, 2018\}$, although the frequency of $[tasse]$ in collection is more than $[coupe]$, but in F, $[coupe]$ is a more frequent translation compared to $[tasse]$. $p(w_j|q^t)$ is a useful feature for long queries where there are multiple instances of a topical term in the query. According to (Dadashkarimi et al., 2014; Gao et al., 2005), $\sum_{w_{j'}\notin q_{w_j}} p(w_j, w_{j'})$ captures coherence of w_j with the context of the query.

4 Experiments

4.1 Experimental Settings

Details of the used collections are provided in Table 2. As shown in the table we provided experiments on four European languages. For each collection we experiment on both short queries, derived from title of the topics, and long queries, derived from title and description of the topics. We used Lemur toolkit in all experiments[1]. All the queries and documents are stemmed using the Porter stemmer (Porter, 1997). The collections are also normalized and purified from stopwords[2]. We used Dirichlet smoothing method with prior $\mu = 1000$ in a statistical language modeling framework with KL-divergence similarity measure.

The embedding features $[\mathbf{u}_{w_j}]_k$ are computed with word2vec introduced in (Mikolov et al., 2013) on each collection; size of the window, number of negative samples and size of the vectors are set to typical values of 10, 45, and 100 respectively. We also used the svm-rank toolkit for learning $\mathbf{w}$ (Joachims, 2006)[3].

As shown in Table 3 and Table 4 we have the following experimental runs: *(1)* Monolingual retrieval run (MONO). It is the primary comparison baseline for CLIR in the literature (Pirkola et al., 2001; Levow et al., 2005); *(2)* translating by top-ranked translation of a bilingual dictionary (TOP-1) (Ma et al., 2012; Esfahani et al., 2016; Dadashkarimi et al., 2014); *(3)* uniform weighting of translations in the query language modeling (UNIF); *(4)* structured query using $\#syn$ operator as described in Section 2.1 (STRUCT); *(5)* binary coherence translation model (BiCTM) introduced in (Dadashkarimi et al., 2014); cross-lingual word embedding translation model (CLWETM) recently introduced by (Dadashkarimi et al., 2016); and *(6)* the proposed learning to rank (L2R) algorithm. We used the simple STRUCT method for our initial retrieval run to build the query-generated training data as described in Equation 3.1.

4.2 Performance Comparison and Discussion

All the experimental results are provided in Table 3 and Table 4. As shown in Table 3, although L2R outperforms most of the baselines with short queries, the improvements with respect to CLWETM, the most competitive baseline, are marginal. The first reason for these outcomes could be the lower number of training data as shown in Table 6. L2R reaches 70.39%, 81.46%, 78.14%, and 55.54% of performances of the monolingual run in FR, DE, ES, and IT collections respectively.

On the other hand, the proposed L2R outperforms all the baselines with long queries in almost all the metrics. According to Table 4, L2R reaches 77.77%, 70.11%, 77.84%, 61.79% of performance of the monolingual run in FR, DE, ES, and IT collections respectively. Although CLWETM, the state-of-the-art dictionary-based translation model, takes advantage of a couple of collections in the source and target language, L2R successfully outperforms CLWETM with only one collection in the target. Nevertheless, the authors did not exploit comparable corpora for their evaluations and used a pool of multiple news agencies in the source language instead.

Table 5 shows three translation models for the topic 'Brain-Drain Impact' based on UNIF, BiCTM, CLWETM, and L2R. As shown in the table BiCTM and CLWETM are more likely to be trapped in a local optimum. BiCTM originally estimates the query model based on co-occurrences of translations through a collection and thus does not use the pseudo-relevant data. Therefore, it is possible that some translations are co-occurred with each other in the collection but not in a query-dependent collection. On the other hand, CLWETM considers semantic information of the query using low-dimensional vectors of the candidates in top-ranked documents and then combines the obtained translation model with a collection dependent model. CLWETM expects this combination to prevent the final model to be biased to each of the query-dependent/independent collection. This expectation works well in very short queries in which there is a limited information about the intention of the user (e.g., bi-gram queries). But when the original query has an informative knowledge about the intention of the user (i.e., long queries), it is better to consider statistics of the original query as a number of feature alongside the other query-dependent/independent features. For example in Table 5 [*tete*] absorbed all translation weight of 'brain' and then prevented the model to have more coverage/recall. On the other hand, appearing [*cerveau*] as a relevant observation in D, lead L2R to distribute translation probability more justly between [*tete*] and [*cerveau*]. Therefore, we believe that L2R defines a reliable hyperplane discriminating between the context words and the noisy ones more effectively.

4.3 Parameter Sensitivity

$|D|$ is the only parameter in the proposed L2R method. For each collection, we opted $|D|$ that gives the optimum MAP on L2R over a small subset of queries and then tested on remaining topics (Gao et al.,

Table 6: Expected number of query terms ($|q|$) and size of the query-generated training data ($|D|$).

FR				DE				ES				IT			
short		long		short		long		short		long		short		long	
$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$	$\|q\|$	$\|D\|$
2.76	10.62	11.58	53.44	2.8	15.62	11.54	82.7	2.8	11.6	11.56	59.9	2.82	11.14	11.73	60.76

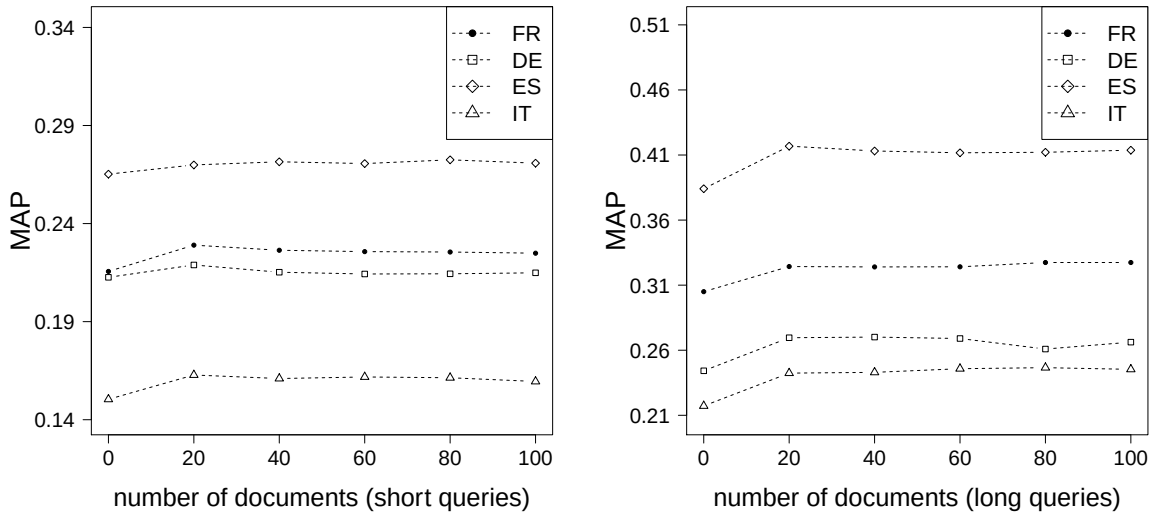

Figure 2: MAP sensitivity of L2R to the number of feedback documents in short and long queries respectively.

2005; Dadashkarimi et al., 2016). As shown in Figure 2, the proposed method works stably in all the collections. In long queries, amount of the improvements are clearly larger than the short ones (see the amounts of jumps from $|D| = 0$ to $|D| = 20$).

5 Conclusion and Future Works

In this paper we proposed a learning to rank method based on ordinal regression on a query-generated training data. We built the query-generated training data of translation words by using their presence/absence in pseudo-relevant documents as labels. This training data consists of embedded features representing each translation word. The result of the regression model was used in the scoring function to weight the translation words.

The method was tested on four different collections in four European languages. The experiments showed that the proposed method outperforms the state-of-the-art dictionary-based CLIR methods, especially in long queries, and it reached up to 81.46% of the performance in the monolingual task. As a future work, the authors would like to test the model on multi-lingual information filtering.

Abstract

In real-world data, e.g., from Web forums, text is often contaminated with redundant or irrelevant content, which leads to introducing noise in machine learning algorithms. In this paper, we apply Long Short-Term Memory networks with an attention mechanism, which can select important parts of text for the task of similar question retrieval from community Question Answering (cQA) forums. In particular, we use the attention weights for both selecting entire sentences and their subparts, i.e., word/chunk, from shallow syntactic trees. More interestingly, we apply tree kernels to the filtered text representations, thus exploiting the implicit features of the subtree space for learning question reranking. Our results show that the attention-based pruning allows for achieving the top position in the cQA challenge of SemEval 2016, with a relatively large gap from the other participants while greatly decreasing running time.

1 Introduction

Previous work on modeling high-level semantic tasks, e.g., paraphrasing, recognizing textual entailment, and question answering (QA), has shown that syntactic and semantic structures are essential for boosting the accuracy of the applied machine learning algorithm. However, when dealing with real-world data, automatic parsers typically decrease their accuracy. Additionally, there is often a considerable amount of meaningless text for the task, contributing to generating noisy structures. This kind of phenomena can be clearly observed in new Web applications, such as community Question Answering (cQA), where the presence of informal, redundant, and often unrelated text constitutes a major challenge for learning the automatic detection of related topics. For example, given the original question:

Which all places are there for tourists to Qatar? My nephew 18 years on visit.

a cQA system has to infer whether the following question is related:

What are the tourist places in Qatar? I'm likely to travel in the month of june. Just wanna know some good places to visit.

This implies that the system has to (i) recognize the sentences, *My nephew 18 years on visit* and *I'm likely to travel in the month of june*, as irrelevant for the classification task; and (ii) deal with non-standard writing (e.g., *wanna*). If the above steps are carried out with *good* accuracy, complex semantic models can be applied to the selected text to achieve better performance. In particular, such models have to encode structural relations between the constituents of the two questions, e.g., *places are there for tourists* and *some good places to visit*, in the learning algorithm. This is a challenging task as we do not know which relations might be useful, whereas explicitly including all of them is an intractable problem.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1734–1745, Osaka, Japan, December 11-17 2016.

One solution for handling this problem for the answer selection task of standard QA was proposed in (Severyn and Moschitti, 2012). They applied tree kernels (TK) to relational syntactic structures, i.e., a graph representing both question and answer structures. TKs allow for using all the substructures of the relational structures as features in the learning algorithm. However, in Web forums the TK performance is downgraded by the presence of noise and insignificant information, which also makes TKs too slow for processing large datasets. This suggests that text selection (TS) models, applied before TKs in both learning and classification phases have great potential to positively impact the final performance.

In this paper, we study several methods for TS: (i) unsupervised methods based on scalar products with and without TF×IDF weights and (ii) supervised approaches based on attention weights learned by a Long Short-Term Memory (LSTM) network. Additionally, we apply the techniques above with two different strategies reflecting two different granularity levels for: (i) selecting the set of sentences constituting the question trees, and (ii) filtering out tree constituents, where the latter represent pairs of input questions to TKs. We measure the benefit of our TS models against a strong baseline based on TKs and domain specific features for the task of question reranking for cQA, which was recently proposed in SemEval 2016 (Nakov et al., 2016).

Our extensive experiments on the official SemEval dataset produced the following results. First, our basic model, which is based on a combination of (*i*) features using traditional text similarity measures, e.g., bag-of-word models, (*ii*) the initial rank provided by the search engine (providing the initial question rank), and (*iii*) TKs applied to the syntactic structure of the sentences of original and retrieved questions, is state of the art as it ranked 2nd at the official SemEval 2016 challenge (Nakov et al., 2016). Second, TS significantly impacts the performance of TKs by feeding them with better representations. In particular, when using supervised methods, i.e., attention model weights, in sentence selection and tree pruning strategies both provide better representations, and higher results than the models using all sentences or those selected by TF×IDF approaches. Finally, our TS-based system outperforms the top system of the SemEval cQA challenge.

The rest of the paper is organized as follows. Section 2 overviews related work. Section 3 describes our learning-to-rank approach. Section 4 describes the application of LSTMs in TK-based ranking models. Section 5 describes our text selection strategies. Section 6 discusses our experiments and the obtained results. Finally, Section 7 concludes the paper.

2 Related Work

Question ranking in cQA has been central in the research community practically since the begining of cQA system design. Beside "standard" similarity measures, different characterizations and models have been explored. For instance, Cao et al. (2008) proposed a question recommendation system based on the questions' topic and Duan et al. (2008) added the question's focus into the formula. A different approach using topic modeling for question retrieval was introduced by Ji et al. (2012) and Zhang et al. (2014). Here, the authors use LDA topic modeling to learn the latent semantic topics that generate question/answer pairs and use the learned topic distribution to retrieve similar historical questions.

Various methods rely on machine-translation models. For instance, Jeon et al. (2005) and Zhou et al. (2011) used monolingual phrase-based translation models to compare the questions. Jeon et al. (2005) built their translator from a collection of previously identified similar questions whereas Zhou et al. (2011) used question–answer pairs.

Other approaches are based on syntactic representations. This is the case of Wang et al. (2009), who consider the number of common substructures of parse trees to estimate the similarity between two questions. Both Barrón-Cedeño et al. (2016) and Filice et al. (2016) use parse trees as well. The difference is that they use them directly within a tree kernel, with the use of the KeLP platform (Filice et al., 2015a). The latter two models were applied on the SemEval 2016 Task 3 challenge on cQA (Nakov et al., 2016), which proposed a task on question ranking (together with one on answer ranking). The best-performing system in this task was the one from Franco-Salvador et al. (2016), which used SVM^{rank} (Joachims, 2006) on a manifold of features, including distributed representations and semantic resources. To our knowledge, the only work exploring text selection for improving cQA or QA systems is (Barrón-Cedeño

Original Question			
$\mathbf{q}_o$: What are the tourist places in Qatar? I'm likely to travel in the month of June. Just wanna know some good places to visit.			
G	*GS*	*R*	**Retrieved Questions**
1	-1	8	The Qatar banana island will be transfered by the end of 2013 to 5 stars resort called Anantara. Has anyone seen this island? Where is it? Is it near to Corniche?
2	+1	2	Is there a good place here where I can spend some quality time with my friends?
3	-1	7	Where is the best beach in Qatar? Maybe a silent and romantic bay? Where to go for it?
4	-1	9	Any suggestions on what are the happenings in Qatar on Holidays? Something new and exciting suggestions please?
5	-1	3	Where in Qatar is the best place for Snorkeling? I'm planning to go out next friday but don't know where to go.
6	-1	6	Can you give me some nice places to go or fun things to do in Doha for children 17-18 years old? Where can we do some watersports (just for once, not as a member), or some quad driving? Let me know please. Thanks.
7	+1	1	Which all places are there for tourists to Qatar? My nephew 18 years on visit.
8	-1	10	Could you suggest the best holiday destination in the world?
9	-1	5	I really would like to know where the best place to catch fish here in Qatar is. But of course from the beach. I go every week to Umsaeed but rerly i catch somthing! So experianced people your reply will be appreciated.

Table 1: A re-ranking example: we report the Google rank (G), the gold standard relevance (GS) and our rank (R) for each question.

et al., 2016), which exploits tree kernel function itself to auto-filter the non relevant subtrees. The main difference with the approach we present in the current paper is the use of neural networks for learning attention weights and thus modeling sentence or word pruning.

Neural Approaches Recent work has shown the effectiveness of neural models for answer selection (Severyn and Moschitti, 2015; Tan et al., 2015; Feng et al., 2015) and question similarity (dos Santos et al., 2015) in community question answering. For instance, dos Santos et al. (2015) used CNN and bag-of-words (BOW) representations of original and related questions in order to compute cosine similarity scores. Recently, Bahdanau et al. (2014) presented a neural attention model for machine translation and showed that the attention mechanism is helpful for addressing long sentences. We use an LSTM model (Hochreiter and Schmidhuber, 1997) with an attention mechanism for capturing long dependencies in questions for the question similarity task. The major difference with previous work is that we exploit the weights learned by the attention model for selecting important text segments (words, chunks and sentences) for improving syntactic tree-kernel models.

3 Learning to Rank Questions in cQA

This section describes the question reranking problem that we study in this paper and provides state-of-the-art models for its solution. As shown by some methods presented in SemEval, TKs are important for achieving top results.

Class	train	dev	test	overall
Relevant	1,083	214	233	1,530
Irrelevant	1,586	286	467	2,339
Total	2,669	500	700	3,869

Table 2: Class distribution in the training, development, and test partitions.

3.1 Problem Description

The task we focus on is defined as follows: given an original question, q_o, and l candidate questions, q_s, retrieved with a search engine, rerank them with respect to their relevance to q_o.

We use the SemEval 2016 cQA dataset (Nakov et al., 2016), which is composed of 386 user questions, each of which includes 10 potentially related questions. At construction time, the Google search engine, which represents also the strong baseline for the task[1], was used to select potentially relevant forum questions. Table 1 shows an example of the data: an original question on top, followed by several questions retrieved by Google. Nakov et al. crowdsourced the manual annotation of the relevance of the questions. Table 2 shows the amount of relevant and irrelevant instances in the different partitions of the corpus, whereas Table 3 illustrates the distribution of relevant/irrelevant forum questions per ranking position.

[1]The task assumes that the Google Rank is not optimal.

Table 3: Average fraction (and standard deviation) of Relevant questions at different ranking positions.

Although relevant questions tend to concentrate towards the top of the Google-generated ranking, they are fairly spread on the entire ranking scale.

3.2 The Reranking Approach

Reranking can be modeled by a scoring function $r : \mathcal{Q} \times \mathcal{Q} \rightarrow \mathbb{R}$, where $\mathcal{Q}$ is the set of questions. In turn, r can be modeled as a linear function $r(q_o, q_s) = \vec{w} \cdot \phi(q_o, q_s)$, where $\vec{w}$ is the model and $\phi()$ provides a feature vector representation of the pair.

Binary classifiers, such as SVMs (Joachims, 1999), can be applied for implementing r, where the ranked list is derived from the prediction scores.[2] We model $\phi(q_o, q_s)$ with different advanced feature sets: (*i*) TKs applied to the syntactic structures of question pairs, (*ii*) similarity features computed between q_o and q_s, and (*iii*) a rank feature, i.e., the rank assigned to the question by the search engine.

3.3 Tree Kernels for Question-to-Question Similarity

Kernelized SVMs can express $\vec{w}$ as $\sum_{i=1}^{n} \alpha_i y_i \phi(q_o^i, q_s^i)$, where n are the number of training examples, α_i are weights, y_i are the example labels, $\phi(q_o^i, q_s^i)$ is the representation of pairs of the original and candidate questions. This leads to the following scoring function:

$$r(q_o, q_s) = \sum_{i=1}^{n} \alpha_i y_i \phi(q_o, q_s) \cdot \phi(q_o^i, q_s^i) = \sum_{i=1}^{n} \alpha_i y_i K\big(\langle q_o, q_s \rangle, \langle q_o^i, q_s^i \rangle\big),$$

where the kernel, $K(\cdot, \cdot)$, intends to capture the similarity between pairs of objects constituted by the original and retrieved questions.

The definition of effective Ks for QA and other relational learning tasks, e.g., textual entailment and paraphrasing, has been studied in a large body of work, e.g., (Zanzotto and Moschitti, 2006; Filice et al., 2015b). Given the high similarity between question ranking in cQA and passage ranking in QA, we opted for the state-of-the-art model proposed by Severyn and Moschitti (2012). It should be noted that we apply TK models to pairs of questions rather than questions with their passages.

Figure 1 displays an example of the structure we used for representing the original question, q_o and the seventh candidate question, q_s, in Table 1. The graph is composed by two macro-trees, one for each question, which in turn are constituted by the syntactic trees of the sentences composing the two questions[3]. Additionally, we link the two macro-trees by connecting phrases, e.g., NP, VP, PP, when there is at least lexical match between the phrases of q_o and q_s. Such links are marked with the presence of a REL tag. Finally, we apply the following kernel:

$$K\big(\langle q_o, q_s \rangle, \langle q_o^i, q_s^i \rangle\big) = TK(t(q_o, q_s), t(q_o^i, q_s^i)) + TK(t(q_s, q_o), t(q_s^i, q_o^i)) \ ,$$

where TK is a tree kernel function, e.g., the partial tree kernel by Moschitti (2006) and $t(x, y)$ returns the syntactic tree from the text x, enriching it with the REL tags computed with respect to the syntactic tree of y.

[2] In a set of preliminary experiments, we compared, a true re-ranker, SVM^{rank} (Joachims, 2002), with a standard SVM, the results were comparable.

[3] We have used the OpenNLP tool to build the trees: `https://opennlp.apache.org`.

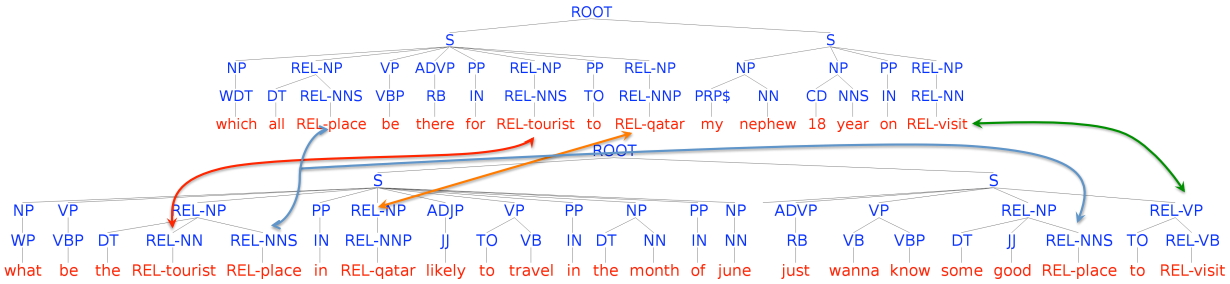

Figure 1: Representation of two questions as syntactic trees. Related nodes are enriched with REL links.

3.4 Feature Vectors

We combine the kernel above with an RBF kernel applied to feature vectors composed of similarity features. These are computed between the original and the related question and the Google rank. Such **text similarity features** (***sim***) are 20 similarities $sim(q_o, q_s)$ using word n-grams ($n = [1, \ldots, 4]$), after stopword removal, using greedy string tiling (Wise, 1996), longest common subsequences (Allison and Dix, 1986), Jaccard coefficient (Jaccard, 1901), word containment (Lyon et al., 2001), and cosine similarity. We also add a structural similarity obtained by comparing the syntactic trees of the questions of an example pair using the partial tree kernel, i.e., $TK(t(q_o, q_s), t(q_s, q_o))$. Note that the operands of the kernel function are members of the same pair. The **ranking-based feature** (***rank***) is computed using the ranking generated by the baseline Google search engine system. Each candidate question is located in one position in the range $[1, \ldots, 10]$. We exploit this information as the inverse of the position.

4 Long Short-Term Memory Networks for TK-based Reranking

As shown in Section 2, several neural approaches have been successfully applied to QA tasks. Unfortunately, question retrieval in cQA is heavily affected by a large amount of noise and a rather different domain, which make it difficult to effectively use out-of-domain embeddings to pre-train neural networks. This probably prevented the participants to SemEval tasks from achieving satisfactory results with such models (Nakov et al., 2016). In this work, we also tried to exploit neural models using their top-level representations for the (q_o, q_s) pair and fed them into the TK classifier as proposed by Tymoshenko et al. (2016), but this simple combination proved to be ineffective as well. In contrast, neural embeddings and weights can be useful for selecting better representations for TK models. In the reminder of this section, we present LSTM networks for question retrieval and our approach for incorporating them into TK-based rerankers.

We approach question ranking as a classification task: given a pair (q_o, q_s), we need to classify q_s as relevant or irrelevant. In order to evaluate the neural classifiers on our ranking task, we can rank candidates, q_s, according to their posterior probability. Among the different models, we were interested in having feedback on the most important pieces of text, thus we opted for LSTM (Hochreiter and Schmidhuber, 1997), which can easily incorporate attention models. LSTMs have proven to be useful in a number of language understanding tasks. Recently, Rocktäschel et al. (2016) adapted an attentional LSTM model (Bahdanau et al., 2014) to textual entailment, and a similar model has been applied to cQA (Hsu et al., 2016). We follow the same setup of the latter: given a pair (q_o, q_s), we learn two serial LSTM models. First, LSTM$_o$ reads the words' vectors of q_o, one by one, and records the corresponding memory cells and hidden states. Second, the final memory cell is used to initialize LSTM$_s$, which reads the words' vectors of q_s. The final hidden state of LSTM$_s$, $\vec{h}_{s,N}$, is used as a feature vector to feed a multi-layer perceptron with one hidden layer, followed by a softmax classifier. The objective function is the cross-entropy objective over binary relevant/irrelevant target labels. We refer to (Hsu et al., 2016) for more details on the architecture and only define the attention model here, as it will be used for TS.

Given the hidden states produced by LSTM$_o$, we compute a weighted representation of q_o:

$$\vec{h}_o = \sum_{i=1}^{L} \beta_i \vec{h}_{o,i} \ ,$$

where $\vec{h}_{o,i}$ are the hidden states corresponding to the words of the original question, and the attention weights are computed as:

$$\beta_i = \frac{exp(a(\vec{h}_{o,i}, \vec{h}_{s,N}))}{\sum_{j=1}^{L} exp(a(\vec{h}_{o,j}, \vec{h}_{s,N}))} \ .$$

Here $a()$ is parameterized as multi-layered perceptron (MLP) with one hidden layer and a *tanh* non-linearity (Rocktäschel et al., 2016). The input to the MLP is then a concatenation of $\vec{h}_o$ and $\vec{h}_{s,N}$. We also concatenate a one-hot vector encoding of the search engine rank (this worked better than scaling the rank into a real-valued feature as $\frac{1}{\text{rank}}$).

Intuitively, β_i assigns a higher weight to words in q_o, if they are useful for determining the relation to q_s. As we will see, these attention weights turn out to be useful for selecting important parts of the questions for the TK models. Note also that the attention here is one-sided, only on q_o. In practice, we train another model, with attention on q_s, and use its weights.

5 Text Selection

Our goal is to select important sentences and/or their constituents to improve the representation of the TK-based system proposed in Section 3. We consider two strategies: selecting a subset of sentences among those composing each question or pruning tree nodes in a bottom-up fashion. For each strategy, we consider both supervised methods by LSTM attention weights and unsupervised methods for TS.

5.1 Sentence selection

Given an original question q_o, with its sentences $\{s^o_1, ..., s^o_n\}$, and a related question q_s, with its sentences $\{s^s_1, ...s^s_m\}$, we aim at selecting those sentences that are most relevant for determining the similarity between q_o and q_s. For this purpose, we create two ranked sentence lists, Σ_o and Σ_s, such that the top-k (from each set) will constitute the sets to be parsed and used to build the macro-trees described in Section 3.3. We experiment with different values for the k parameter. Our sorting algorithm is rather simple: we (i) find the most similar pair of sentences, $(\sigma_o, \sigma_s) \in q_o \times q_s$, using a scoring function, $sim(\sigma_o, \sigma_s)$; (ii) store them individually in Σ_o and Σ_s, respectively, by also preserving the insertion order; and (iii) remove such sentences from q_o and q_s. We continue executing these steps until $q_o \times q_s$ is empty. The scoring (similarity) function can be modeled with both supervised and unsupervised methods.

Unsupervised methods We generate the vector representation of each sentence in q_o and q_s by averaging 300-dimensional word2vec (Mikolov et al., 2013a; Mikolov et al., 2013b) vector representations after stopword removal (we use the Google News default model). Then, we compute sim as the standard cosine similarity. We call this model **sim(nw)**. As a second approach, we apply the same algorithm above by weighing the word2vec vectors with TF×IDF (**sim(tf-idf)**), where IDF is derived from the entire dataset. Note that averaging has the consequence of ignoring the word order in the sentence. We leave the exploration of more sophisticated sentence representation models (e.g., Skip-Thought (Kiros et al., 2015)) for future work.

Supervised Methods We conjectured that using the information encoded by question labels to guide TS may improve our ability to measure question similarity. For this purpose, we exploit the attention weights learned by our LSTM model (Section 4). In more detail, the sentence scores for σ_o and σ_s are computed with the average attention weights β_i over sentence words. Since the attention model is one-sided, it generates weights for either the original or the related question. We thus train two separate models, for q_o and q_s, and rank each sentence list independently, on the basis of the attention weights[4].

[4]In practice, we found it useful to consider only the top-m weights in the average weights computation. In our experiments, we set $m = 3$, which worked well in preliminary experiments.

Model	**MAP**	AvgRec	MRR

sim + rank	74.58	89.09	83.57
sim + rank + TK	76.15	90.79	84.76
LSTM	67.96	85.03	76.63

(b) Performance on the test set

Table 4: Different feature combination methods and learning models on the development and test sets.

We call this model ***attention***. Additionally, similarly to the unsupervised approaches, we compute a cosine similarity score for sentence pairs, where each sentence is represented as a bag-of-lemmas vector whose entries are the corresponding attention weights. Note that the attention model may assign different weights to identical words that appear more than once in the sentence. In this case, we use the average attention weight over identical lemmas. We name this model ***sim(att)***.

5.2 Tree pruning

Our second approach to TS works on the syntactic tree nodes and it is illustrated by Algorithm 1. Its main idea is to filter out the leaf nodes of the parse tree corresponding to words associated with weights lower than a user-defined threshold, where the word weights are provided by either β_i or TF×IDF. The most important step of Algorithm 1 is the recursive function *pruneNode*, which is initially invoked for the root node of the tree. Function *pruneNode* checks whether the node n is a leaf (Line 4) and then applies the appropriate strategy: (i) for non-leaf nodes, *pruneNode* is invoked for the children of n, then n is removed if all of its children are removed; and (ii) a leaf node is removed if its weight is lower than the user-defined threshold, h. Additionally, since the REL tagging has proved to be effective for paraphrasing and textual entailment tasks (Filice et al., 2015b), we experiment with the simple rule no REL-tagged node (see Section 3.3) is removed, independently of its weight and number of children.

```
1  Function PruneTree (T, h);
   Input  : a tree T;
            a pruning threshold h;
   Output: a pruned version of T
2  pruneNode(root(T), h);
3  Function pruneNode (n, h);
4  if |children(n)| > 0 then
5      for c ∈ children(n) do
6          pruneNode(c, h);
7      end
8      if |children(n)| = 0 && !REL_Node(n)) then
9          remove (n, T);
10     end
11 else
12     if n.weight < h && !REL_Node(n)) then
13         remove (n, T);
14     end
15 end
```

Algorithm 1: Function *PruneTree* for pruning a tree according to tf-idf or attention weights.

Finally, it should be noted that different thresholds determine different percentages of pruned nodes.

6 Experiments

In these experiments, we first evaluate our state-of-the-art reranker to establish a strong baseline. Then, we measure the impact of our different TS models with respect to accuracy and speed.

6.1 Testing the Baseline Models

We use binary SVMs to generate our rankings, where TKs are enabled by the KeLP toolkit[5]. KeLP allows for combining our three types of features within different kernels, namely RBF for the similarity features, TKs for the parse trees, and RBF kernels for the ranking-based feature[6]. We set the C parameter of SVMs to 1 in all experiments whereas we used the default values for TK and RBF kernel parameters. MAP is computed over all questions and then averaged.

[5] https://github.com/SAG-KeLP

[6] RBF proved superior than linear kernels for both similarity and ranking features in our internal experiments.

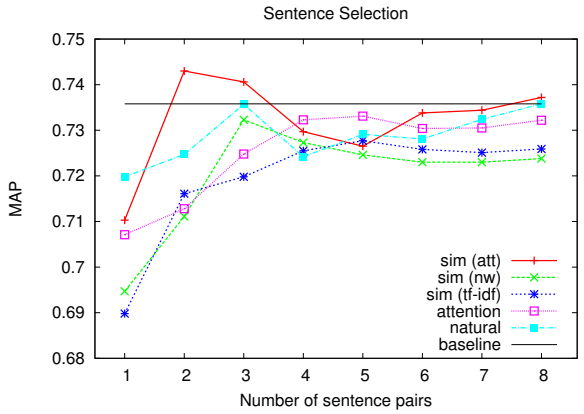

Figure 2: MAP evaluated on the dev. set according to the number of selected sentences. The different text selection methods are the natural order, the average attention weight, and cosine similarity computed with three weighting models: attention (att), no weight (nw), and tf-idf. The *baseline* uses all the sentences.

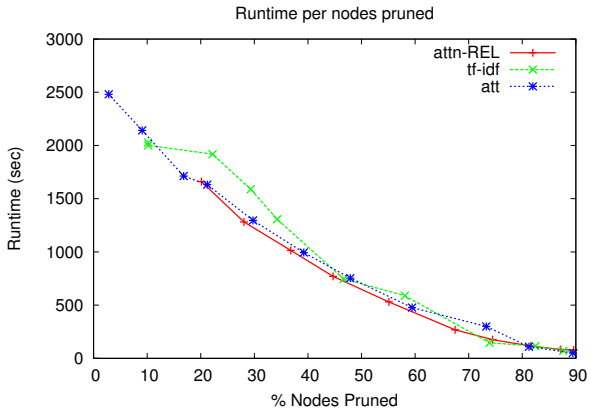

Figure 3: Reranker training time with respect to the percentage of pruned nodes using: attention weights (attn), attention weights without pruning REL nodes (attn-REL), and TF×IDF weights without pruning REL nodes (tf-idf).

Tree Kernels and Feature Combinations We first experimented with the features defined in Section 3.4: similarities (*sim*) and the *rank* feature. Additionally, we combine these features with the TKs described in Section 3.3. Tables 4a and 4b report the obtained performance on the development and test datasets. We note that (i) the Google rank baseline is rather strong; (ii) the MAP of *sim* alone is below the baseline; (iii) combining *rank* and *sim* produces an increase but the result is still below the baseline; and (iv) only the full combination, *sim+rank+TK*, improves on Google. Table 5b reports the three top systems of the SemEval cQA competition, where ConvKN (Da San Martino et al., 2016; Barrón-Cedeño et al., 2016) is the model we described in Sec. 3 whereas KeLP (Filice et al., 2016) shares a number of features with ConvKN along with the TK-based approach.

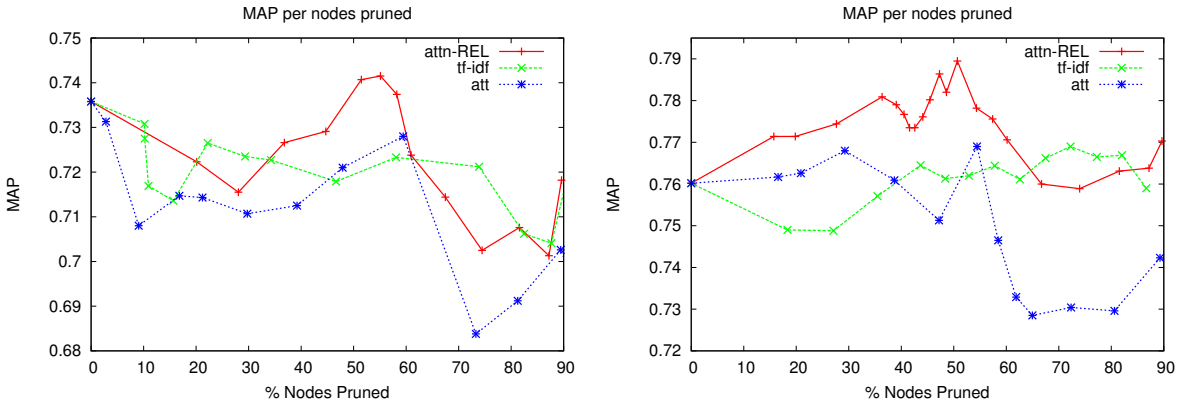
Neural Networks Tables 4a and 4b also show the results obtained with the LSTM, which does not improve upon the strong Google baseline, even though its rank is incorporated as an additional feature. This is in line with (Hsu et al., 2016), where a combination method was necessary to obtain a better performance. The low MAP can be attributed to the small dataset size (only 2,669 training examples). Nevertheless, the attention weights learned by the neural model are still useful for TS (see next section).

6.2 Measuring the Impact of the Text Selection Methods

In these experiments, we focus on reducing the text used for generating the trees (the other features are computed on the standard text). We use sentence selection and tree pruning, as described in Section 5.

Sentence selection results We test different algorithms for sorting sentences for both original and related questions, i.e., to obtain the sorted lists, Σ_o and Σ_s (see Sec. 5.1), and then use the top k sentences to build the TK representations. Figure 2 shows the results on the dev. set of our reranker using different sorting algorithms: *natural* is the natural order (it can be considered as a competitive baseline), *attention* uses the average attention weight to sort sentences, and *sim(att)*, *sim(nw)* and *sim(tf-idf)* apply cosine similarity, where the sentence vector weights are constituted by attention weights, no weight (nw), and TF×IDF weights, respectively. The system *baseline* uses all the sentences, i.e., it is the best model tested in the previous section.

We note that (i) all the models using only one sentence perform lower than the *baseline*, i.e., using all sentences. (ii) The first sentence is intuitively very important as *natural* with one sentence is the best model. (iii) As soon as the number of sentences increases, the supervised models, i.e., *sim(att)* and *attention*, perform better than the unsupervised approaches, i.e., *sim(nw)* and *sim(tf-idf)*. In particular,



(a) On the development set.

(b) On the test set.

Figure 4: MAP scores after pruning the input texts using: attention weights (attn), attention weights without pruning REL-tagged nodes (attn-REL), and TF×IDF weights without pruning REL-tagged nodes (tf-idf).

sim(att) outperforms the *baseline*, e.g., 74.30 vs. 73.58 (although only when using 2 or 3 sentences). In any case, almost all the results are interesting since, when the number of sentences decreases, the computational complexity of TK applied to the reduced trees becomes much lower. We measured a decrease of 5 times of the training time required by the reranker. However, sentence selection may be considered too coarse-grained to be effective.

Tree pruning results Given word-level weights, either by TF×IDF or the attention model, we prune the parse trees according to the strategies described in Section 5.2: pruning using the weights of the (i) attention model (*attn*); (ii) attention model but retaining all REL-tagged nodes (*attn-REL*); (iii) TF×IDF model preserving all REL nodes (*tf-idf*). The experiments with TF×IDF without REL-tagging are not reported due to poor performance.

Figure 4 compares several pruning thresholds in terms of MAP on both the development and the test sets. The x-axis values indicate the percentage of nodes that were removed after pruning the question parse trees. Pruning results rather beneficial: after an initial performance decrease, MAP improves the *baseline* model (state of the art). For example, according to the results on the dev. set, *attn-REL*, which uses attention weights and also preserves the REL nodes, allows us to reduce the size of the trees by 55%, obtaining a MAP value of 74.15 (+0.57 with respect to using the full trees). This improvement is also statistically significant at 95% with respect to the $baseline$. The increase in performance is much more evident on the test set, where the best MAP of *attn-REL* is 78.95, obtained by pruning 50% of the nodes. Note that the best pruning threshold on the development set, i.e., corresponding to 55% of filtering, when used for the test set, achieves a MAP of 77.82, which, even if lower than the top result, 78.95, still outperforms the 76.70 MAP of the winner system of Semeval 2016 (Nakov et al., 2015); compare tables 5a and 5b. The other two models, based on TF×IDF and attention weights without preserving REL nodes, do not improve MAP, although they can produce a great speedup with a small loss in MAP. Figure 3 reports the running times of the three pruning models above with respect to the percentage of pruned nodes. All pruning strategies can reduce the size of the trees significantly, and consequently reduce the running time, for all weight sources. For example, the most accurate model on the dev. set (see Figure 4) filters 55% of the nodes, speeding up training by 5 times, i.e., 530 versus 2,580 seconds.

7 Conclusions

In this paper, we showed that TK-based models achieve the state of the art in cQA. Nevertheless, such models are affected by noise in the syntactic structure and redundant information, typically added by Web users when formulating or answering forum questions. We proposed to alleviate this problem selecting more significant text segments from the question text. For this purpose, we used unsupervised meth-

ods and supervised methods based on LSTM with attention weights. The results show that supervised text selection can improve unsupervised models, thus enhancing the performance of a tree-kernel-based reranker. Additionally, using less text produces a boost in the speed of tree kernels —up to five times the speed of the model using all the sentences— while also improving MAP. Finally, our model achieves a top result with respect to the top performing systems submitted to the SemEval 2016 task on cQA. In the future, we would like to experiment with more advanced techniques that have been shown successful for traditional text summarization, e.g., using discourse structure.

Abstract

This work focuses on answering single-relation factoid questions over Freebase. Each question can acquire the answer from a single fact of form (subject, predicate, object) in Freebase. This task, simple question answering (SimpleQA), can be addressed via a two-step pipeline: entity linking and fact selection. In fact selection, we match the *subject entity in a fact candidate* with the entity mention in the question by a *character-level* convolutional neural network (char-CNN), and match the *predicate in that fact* with the question by a *word-level* CNN (word-CNN). This work makes two main contributions. (i) A simple and effective entity linker over Freebase is proposed. Our entity linker outperforms the state-of-the-art entity linker over SimpleQA task. [1] (ii) A novel attentive maxpooling is stacked over word-CNN, so that the predicate representation can be matched with the predicate-focused question representation more effectively. Experiments show that our system sets new state-of-the-art in this task.

1 Introduction

Factoid question answering (QA) over knowledge bases such as Freebase (Bollacker et al., 2008) has been intensively studied recently (e.g., Bordes et al. (2014), Yao et al. (2014), Bast and Haussmann (2015), Yih et al. (2015), Xu et al. (2016)). Answering a question can require reference to multiple related facts in Freebase or reference to a single fact. This work studies simple question answering (SimpleQA) based on the *SimpleQuestions* benchmark (Bordes et al., 2015) in which answering a question does not require reasoning over multiple facts. Single-relation factual questions are the most common type of question observed in various community QA sites (Fader et al., 2013) and in search query logs. Even though this task is called "simple", it is in reality not simple at all and far from solved.

In SimpleQA, a question, such as "what's the hometown of Obama?", asks a single and direct topic of an entity. In this example, the entity is "Obama" and the topic is hometown. So our task is reduced to finding one fact (subject, predicate, object) in Freebase that answers the question, which roughly means the *subject* and *predicate* are the best matches for the topical entity "Obama" and for the topic description "what's the hometown of", respectively. Thus, we aim to design a method that picks a fact from Freebase, so that this fact matches the question best. This procedure resembles answer selection (Yu et al., 2014) in which a system, given a question, is asked to choose the best answer from a list of candidates. In this work, we formulate the SimpleQA task as a fact selection problem and the key issue lies in the system design for how to match a fact candidate to the question.

The first obstacle is that Freebase has an overwhelming number of facts. A common and effective way is to first conduct entity linking of a question over Freebase, so that only a small subset of facts remain as candidates. Prior work achieves entity linking by searching word n-grams of a question among all entity names (Bordes et al., 2015; Golub and He, 2016). Then, facts whose subject entities match those n-grams are kept. Our first contribution in this work is to present a simple while effective entity linker

*This work was conducted during the first author's internship at IBM Watson Group.

[1] *We release our entity linking results at*: https://github.com/Gorov/SimpleQuestions-EntityLinking

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1746–1756, Osaka, Japan, December 11-17 2016.

to this task. Our entity linker first uses each word of a question (or of an entity mention in the question) to search in the entity vocabulary, all entities are kept if their names *contain one of the query words*. Then, we design three simple factors to give a raw ranking score for each entity candidate: (i) the ratio of words in the entity name that are covered by the question; (ii) the ratio of words in the question that are covered by the entity name; (iii) the position of the entity mention in the question. We choose top-N ranked entities as candidates. Our entity linker does not consider the semantics or topic of an entity; it considers only the string surface. Nevertheless, experiments show that these three factors are the basis for a top-performing entity linker for SimpleQA.

Based on entity linking results, we consider each fact as a fact candidate that has one of the entity candidates as subject. Then our system solves the task of *fact selection*, i.e., matching the question with each fact candidate and picking the best one. Our system is built based on two observations. (i) Surface-form match between a subject entity and its mention in the question provides more straight-forward and effective clue than their semantic match. For example, "Barack Obama" matches with "Obama" in surface-form, which acts as a fundamental indicator that the corresponding fact and the question are possibly about the same "Obama". (ii) Predicate in a fact is a paraphrase of the question's pattern where we define the *pattern* to be the topic asked by the question about the entity, and represent it as the question in which the entity mention has been replaced by a special symbol. Often the predicate corresponds to a keyword or a rephrased token of the pattern, this means we need to create a flexible model to handle this relationship.

These observations motivate us to include two kinds of convolutional neural networks (CNN, LeCun et al. (1998)) in our deep learning system. (i) A character-level CNN (*char-CNN*) that models the match between an Freebase entity and its mention in the question on surface-form. We consider CNN over character-level rather than the commonly-used word-level, so that the generated representation is more robust even in the presence of typos, spaces and other character violations. (ii) A word-level CNN (*word-CNN*) with attentive maxpooling that learns the match of the Freebase predicate with the question's pattern. A Freebase predicate is a predefined relation, mostly consisting of a few words: "place of birth", "nationality", "author editor" etc. In contrast, a pattern is highly variable in length and word choice, i.e., the subsequence of the question that represents the predicate in a question can take many different forms. Convolution-maxpooling slides a window over the input and identifies the best matching subsequence for a task, using a number of filters that support flexible matching. Thus, convolution-maxpooling is an appropriate method for finding the pattern subsequence that best matches the predicate description. *We add attention to this basic operation of convolution-maxpooling.* Attentions are guided by the predicate over all n-gram phrases in the pattern, finally system pools phrase features by considering the feature values as well as the attentions towards those features. *Phrases more similar to the predicate, i.e., with higher attention values, will be selected with higher probability than other phrases to represent the pattern.*[2]

Our overall approach is for the entity linker to identify top-N entity candidates for a question. All facts that contain one of these entities as subject are then the fact search space for this question. Char-CNN and word-CNN decompose each question-fact match into an entity-mention surface-form match and a predicate-pattern semantic match. Our approach has a simple architecture, but it outperforms the state-of-the-art, a system that has a much more complicated structure.

2 Related Work

As mentioned in Section 1, factoid QA against Freebase can be categorized into single-relation QA and multi-relation QA. Much work has been done on multi-relation QA in the past decade, especially after the release of benchmark WebQuestions (Berant et al., 2013). Most state-of-the-art approaches (Berant et al., 2013; Yahya et al., 2013; Yao and Van Durme, 2014; Yih et al., 2015) are based on semantic parsing, where a question is mapped to its formal meaning representation (e.g., logical form) and then translated to a knowledge base (KB) query. The answers to the question can then be retrieved simply

[2]Surface-form entity linking has limitations in candidate collection as some entities have the same names. We tried another word-CNN to match the pattern to the entity description provided by Freebase, but no improvement is observed.

by executing the query. Other approaches retrieve a set of candidate answers from KB using relation extraction (Yao and Van Durme, 2014; Yih et al., 2014; Yao, 2015; Bast and Haussmann, 2015) or distributed representations (Bordes et al., 2014; Dong et al., 2015; Xu et al., 2016). Our method in this work explores CNN to learn distributed representations for Freebase facts and questions.

SimpleQA was first investigated in (Fader et al., 2013) through PARALEX dataset against knowledge base Reverb (Fader et al., 2011). Yih et al. (2014) also investigate PARALEX by a system with some similarity to ours – they employ CNNs to match entity-mention and predicate-pattern. Our model differs in two-fold. (i) They use the same CNN architecture based on a word-hashing technique (Huang et al., 2013) for both entity-mention and predicate-pattern matches. Each word is first preprocessed into a count vector of character-*trigram* vocabulary, then forwarded into the CNN as input. We treat entities and mentions as character sequences. Our char-CNN for entity-mention match is more end-to-end without data preprocessing. (ii) We introduce attentive maxpooling for better predicate-pattern match.

The latest benchmark SimpleQuestions in SimpleQA is introduced by Bordes et al. (2015). Bordes et al. (2015) tackle this problem by an embedding-based QA system developed under the framework of Memory Networks (Weston et al., 2015; Sukhbaatar et al., 2015). The setting of the SimpleQA corresponds to the elementary operation of performing a single lookup in the memory. They investigate the performance of training on the combination of SimpleQuestions, WebQuestions and Reverb training sets. Golub and He (2016) propose a character-level attention-based encoder-decoder framework to encode the question and subsequently decode into (subject, predicate) tuple. Our model in this work is much simpler than these prior systems. Dai et al. (2016) combine a unified conditional probabilistic framework with deep recurrent neural networks and neural embeddings to get state-of-the-art performance.

Treating SimpleQA as fact selection is inspired by work on answer selection (e.g., Yu et al. (2014), Yin et al. (2016b), Santos et al. (2016)) that looks for the correct answer(s) from some candidates for a given question. The answer candidates in those tasks are raw text, not structured information as facts in Freebase are. We are also inspired by work that generates natural language questions given knowledge graph facts (Seyler et al., 2015; Serban et al., 2016). It hints that there exists a kind of match between natural language questions and FB facts.

3 Task Definition and Data Introduction

We first describe the Freebase (Bollacker et al., 2008) and SimpleQuestions task (Berant et al., 2013).

Freebase is a structured knowledge base in which entities are connected by predefined predicates or "relations". All predicates are directional, connecting from the subject to the object. A triple (subject, predicate, object), denoted as (h, p, t), describes a fact; e.g., (U.S. Route 2, major_cities, Kalispell) refers to the fact that U.S. Route 2 runs through the city of Kalispell.

SimpleQuestions benchmark, a typical SimpleQA task, provides a set of single-relation questions; each question is accompanied by a ground truth fact. The object entity in the fact is the answer by default. The dataset is split into train (75,910), dev (10,845) and test (21,687) sets. This benchmark also provides two subsets of Freebase: FB2M (2,150,604 entities, 6,701 predicates, 14,180,937 atomic facts), FB5M (4,904,397 entities, 7,523 predicates, 22,441,880 atomic facts). While single-relation questions are easier to handle than questions with more complex and multiple relations, single-relation question answering is still far from being solved. Even in this restricted domain there are a large number of paraphrases of the same question. Thus, the problem of mapping from a question to a particular predicate and entity in Freebase is hard.

The task assumes that single-relation questions can be answered by querying a knowledge base such as Freebase with a single subject and predicate argument. Hence, only the tuple (h, p) is used to match the question. The evaluation metric is accuracy. Only a fact that matches the ground truth in both subject and predicate is counted as correct.

4 Entity Linking

Given a question, the entity linker provides a set of top-N entity candidates. The input of our deep learning model are (subject, predicate) and (mention, pattern) pairs. Thus, given a question, two problems

we have to solve are (i) identifying candidate entities in Freebase that the question refers to and (ii) identifying the span (i.e., mention) in the question that refers to the entity. Each problem can be handled before the other, which results in two entity linkers. (i) **Passive Entity Linker**: First search for entity candidates *by all question words*, then use returned entities to guide the mention detection; (ii) **Active Entity Linker**: First identify the entity mention in the question, then *use the mention span* to search for entity candidates. We now introduce them in detail.

Passive Entity Linker. We perform entity linking by deriving the *longest consecutive common subsequence* (LCCS) between a question and entity candidates and refer to it as σ. Given a question q and all entity names from Freebase, we perform the following three steps.

(i) Lowercase/tokenize entity names and question

(ii) Use each component word of q to retrieve entities whose names contain this word. We refer to the set of all these entities as C_e.

(iii) For each entity candidate e in C_e, compute its LCCS σ with the question q. Let p be the position of the last token of σ in q. Compute $a = |\sigma|/|q|$, $b = |\sigma|/|e|$ and $c = p/|q|$ where $|\cdot|$ is length in words. Finally, entity candidate e is scored by the weighted sum $s_e = \alpha a + \beta b + (1 - \alpha - \beta)c$. Parameters α and β are tuned on dev. Top-N ranked entities are kept for each question.

Discussion. Factor $a = |\sigma|/|q|$ means we prefer candidates that cover *more consecutive words* of the question. Factor $b = |\sigma|/|e|$ means that we prefer the candidates that cover *more consecutive words of the entity*. Factor $c = p/|q|$ means that we prefer candidates that appear *close to the end of the question*; this is based on the observation that most entity mentions are far from the beginning of the question. Despite the simplicity of this passive entity linker, it outperforms other state-of-the-art entity linkers of this SimpleQuestions task by a big margin. Besides, this entity linker is unsupervised and runs fast. We will show its promise and investigate the individual contributions of the three factors in experiments.

Each question q is provided top-N entity candidates from Freebase by entity linker. Then for *mention detection*, we first compute the LCCS σ *on word level* between q and entity e. If the entity is longer than σ and has l (resp. r) words on the left (resp. right) of σ, then we extend σ in the question by l left (resp. r right) words and select this subsequence as the candidate mention. For example, entity "U.S. Route 2" and question "what major cities does us route 2 run through" have LCCS σ "route 2". The FB entity "U.S. Route 2" has one extra word "u.s." on the left of σ, so we extend σ by one left word and the candidate mention is "us route 2". We do this so that the mention has the same word size as the entity string.[3]

In rare cases that the LCCS on the word level has length 0, we treat both entity string and question as character sequence, then compute LCCS σ on character level. Finally, mention is formed by expanding σ on both sides up to a space or the text boundary.

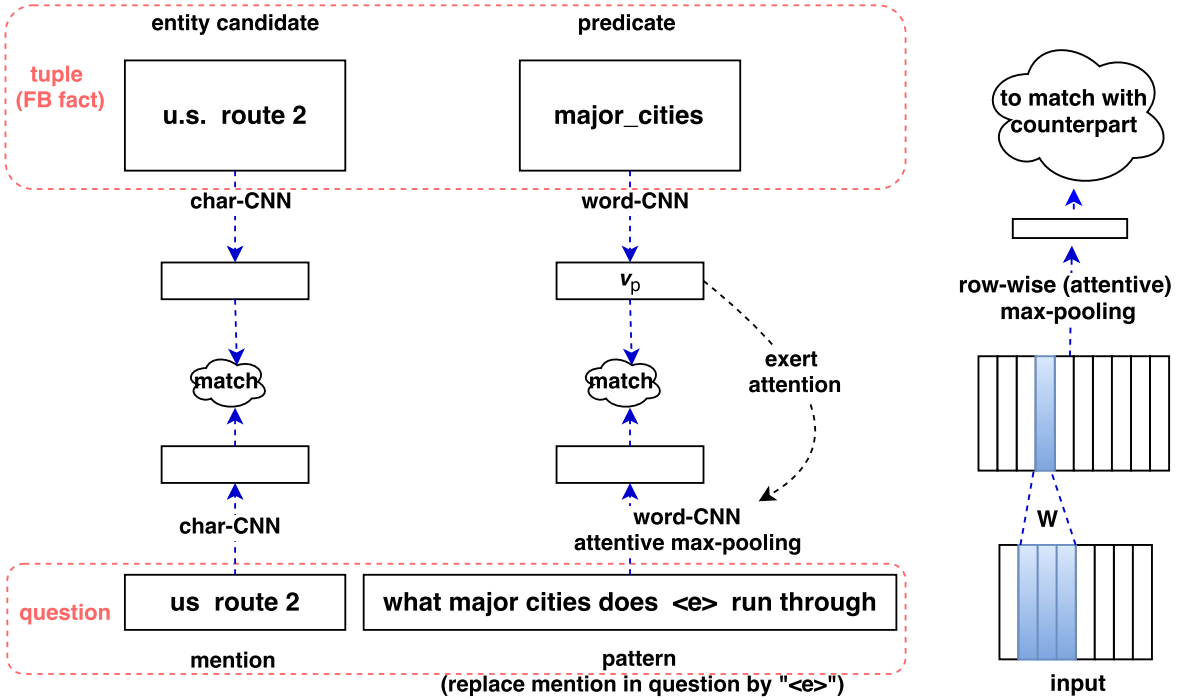
For each question, this approach to mention detection usually produces *more than one (mention, pattern) pair*.

Active Entity Linker. In the training set of SimpleQuestions, the topic entity of each question is labeled. Active entity linker is then achieved by detecting mention in a question by sequential labeling. The key idea is to train a model to predict the text span of the topic entity which can match the gold entity. This is inspired by some prior work. For example, Dai et al. (2016) map the gold entity back to the text to label the text span for each question and then train a BiGRU-CRF model to do the mention detection. Golub and He (2016) propose a generative model which generates the topic entity based on character-level text spans with soft attention scores. Similar to the work (Dai et al., 2016), we trained a BiLSTM-CRF model to detect the entity mentions.

This approach to mention detection produces *only one (mention, pattern) pair* for each question. Then, based on this detected mention, *we use each word of it* to search for the entity candidates via the three steps in "Passive Entity Linker".

We presented two styles of mention detection in questions – passive or active. In passive mention detection, the mention of a question depends on the entity candidates returned by an entity linker. Due

[3]Only using LCCS as mention performed worse.



(a) The whole system. Question: what major cities does us route 2 run through; Tuple: ("u.s. route 2", "major_cities")

(b) Convolution for representation learning

Figure 1: CNN System for SimpleQA

to the different furface-forms of entity candidates, a question can be detected in different spans as mentions. Instead, active mention detection is conducted in a similar way with Name Entity Recognition. Hence, the mention does not depend on the returned entity candidates, a single-relation question has only one mention. Our experiments will show that active entity linker bring better coverage of ground truth entities, nevertheless this method requires the availability of entity-labeled questions as training data.

After mention detection, we then convert the question into the tuple (mention, pattern) where pattern is created by replacing the mention in the question with <e>.

5 Fact Selection

Entity linker provides top-N entity candidates for each question. All facts having those entities as subject form a fact pool, then we build the system to seek the best.

Our whole system is depicted in Figure 1(a). It consists of match from two aspects: (i) a CNN on character level (char-CNN) to detect the similarity of entity string and the mention string in surface-form (the left column); (ii) a CNN with attentive maxpooling (AMP) in word level (word-AMPCNN) to detect if the predicate is a paraphrase of the pattern.

Word-AMPCNN is motivated by the observation that the FB predicate name is short and fixed whereas the corresponding pattern in the question is highly variable in length and word choice. Our hypothesis is that the predicate-pattern match is best done based on keywords in the pattern (and perhaps humans also do something similar) and that the CNN therefore should identify helpful keywords. Traditional maxpooling treats *all n-grams equally*. In this work, we propose *attentive maxpooling* (AMP). AMP gives *higher weights to n-grams that better match the predicate*. As a result, the predicate-pattern match computed by the CNN is more likely to be correct.

Next, we introduce the CNN combined with maxpooling for both char-CNN and word-CNN, then present AMPCNN. Figure 1(b) shows the common framework of char-CNN and word-CNN; only input granularity and maxpooling are different.

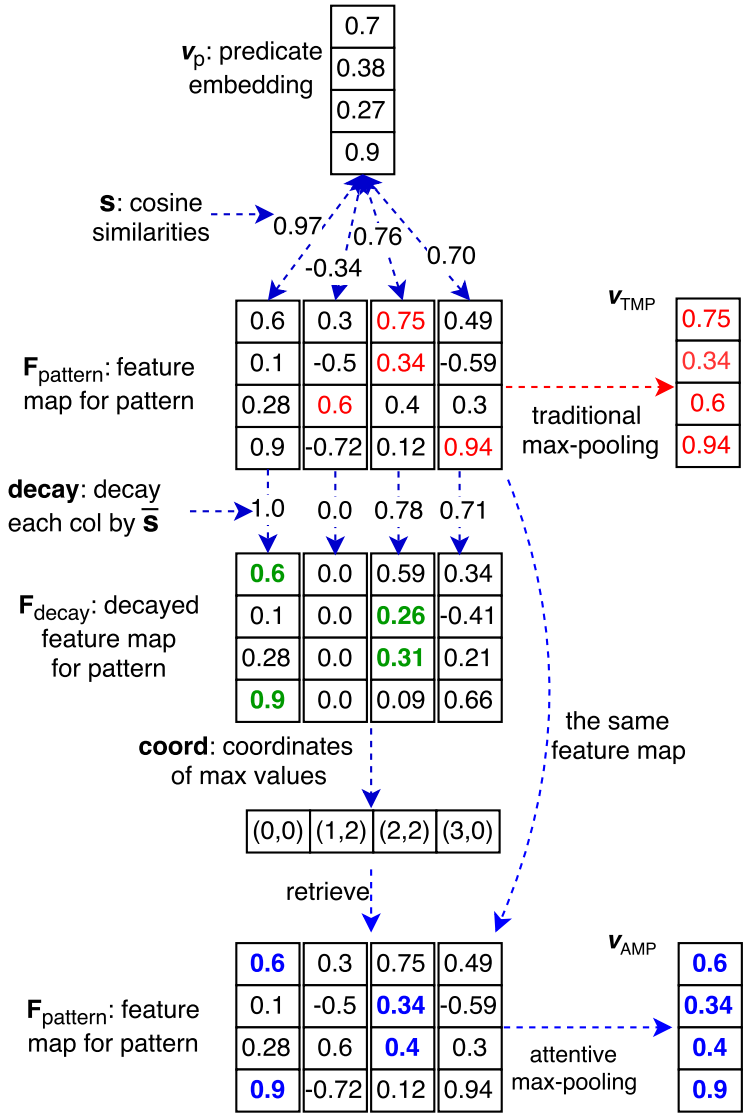


Figure 2: Traditional maxpooling vs. Attentive maxpooling

5.1 Framework of CNN-Maxpooling

Both char-CNN and word-CNN have two weight-sharing CNNs, as they model two pieces of text. In what follows, we use "entry" as a general term for both character and word.

The **input layer** is a sequence of entries of length s where each entry is represented by a d-dimensional randomly initialized embedding; thus the sequence is represented as a feature map of dimensionality $d \times s$. Figure 1(b) shows the input layer as the lower rectangle with multiple columns.

Convolution Layer is used for representation learning from sliding n-grams. For an input sequence with s entries: $v_1, v_2, \ldots, v_s$, let vector $\mathbf{c}_i \in \mathbb{R}^{nd}$ be the concatenated embeddings of n entries $v_{i-n+1}, \ldots, v_i$ where n is the filter width and $0 < i < s + n$. Embeddings for v_i, $i < 1$ or $i > s$, are zero padded. We then generate the representation $\mathbf{p}_i \in \mathbb{R}^d$ for the n-gram $v_{i-n+1}, \ldots, v_i$ using the convolution weights $\mathbf{W} \in \mathbb{R}^{d \times nd}$:

$$\mathbf{p}_i = \tanh(\mathbf{W} \cdot \mathbf{c}_i + \mathbf{b}) \tag{1}$$

where bias $\mathbf{b} \in \mathbb{R}^d$.

Maxpooling. All n-gram representations $\mathbf{p}_i$ $(i = 1 \cdots s+n-1)$ are used to generate the representation of input sequence $\mathbf{s}$ by maxpooling: $\mathbf{s}_j = \max(\mathbf{p}_{j1}, \mathbf{p}_{j2}, \cdots)$ $(j = 1, \cdots, d)$.

5.2 AMPCNN: CNN-Attentive-Maxpooling

Figure 2 shows TMP (Traditional MaxPooling) and AMP (Attentive MaxPooling) as we apply them to SimpleQA. Recall that we use standard CNNs to produce (i) the predicate representation $\mathbf{v}_p$ (see Figure 1(a)) and (ii) a feature map of the pattern, i.e., a matrix with columns denoting n-gram representations (shown in Figure 1(b), the matrix below "row-wise (attentive) maxpooling"). In Figure 2, we refer to the feature map as $\mathbf{F}_{\text{pattern}}$ and to the predicate representation as $\mathbf{v}_p$.

TMPCNN, i.e., traditional maxpooling, outputs the vector shown as $\mathbf{v}_{\text{TMP}}$; the same $\mathbf{v}_{\text{TMP}}$ is produced for different $\mathbf{v}_p$. The basic idea of AMPCNN is to let the predicate $\mathbf{v}_p$ *bias the selection and weighting of subsequences of the question to compute the representation of the pattern*. The first step in doing that is to compute similarity scores $\mathbf{s}$ between the predicate representation $\mathbf{v}_p$ and each column vector of $\mathbf{F}_{\text{pattern}}$:

$$\mathbf{s}_i = \mathbf{cos}(\mathbf{v}_p, \mathbf{F}_{\text{pattern}}[:, i]) \tag{2}$$

These cosines are then transformed into *decay* values by setting negative values to 0 (negatively correlated column vectors are likely to be unrelated to the predicate) and normalizing the positive values by dividing them by the largest cosine (.97 in this case), so that the largest decay value is 1.0. This is shown as "decay" and $\bar{\mathbf{s}}$ in the figure. Finally, we compute the reweighted feature map $\mathbf{F}_{\text{decay}}$ as follows:

$$\mathbf{F}_{\text{decay}}[:, i] = \mathbf{F}_{\text{pattern}}[:, i] * \bar{\mathbf{s}}_i \tag{3}$$

In $\mathbf{F}_{\text{decay}}$, the matrix with four green values, we can locate the maximal values in each dimension. Notice that they are not the true features by CNN any more, instead, *they convey the original feature values as well as their importance to be considered*. In $\mathbf{F}_{\text{decay}}$, we can see that the maximal values in each dimension mostly come from the first column and the third column which have relatively higher similarity scores 0.97 and 0.76 respectively to the predicate. *We use the coordinates of those maximal values to retrieve features from* $\mathbf{F}_{pattern}$ as a final pattern representation $\mathbf{v}_{\text{AMP}}$, the blue column vector[4].

In summary, TMP has no notion of context. The novelty of AMP is that it is guided by attentions from the context, in this case attentions from the predicate. In contrast to TMP, we expect AMP to mainly extract features that come from n-grams that are related to the predicate.

6 Experiments

6.1 Training Setup

Our fact pool consists of all facts whose subject entity is in the top-N entity candidates. For train, we sample 99 negative facts for each ground truth fact; for dev and test, all fact candidates are kept.

Figure 1(a) shows two-way match between a tuple t and a question q: entity-mention match by char-CNN (score m_e), predicate-pattern match by word-AMPCNN (score m_r). The overall ranking score of the pair is $s_t(q, t) = m_e + m_r + s_e$ where s_e is the entity ranking score in entity linking phase.

Our objective is to minimize ranking loss:

$$l(q, t^+, t^-) = \max(0, \lambda + s_t(q, t^-) - s_t(q, t^+)) \tag{4}$$

where λ is a constant.

We build word and character vocabularies on train. OOV words and characters from dev and test are mapped to an OOV index. Then, words (resp. characters) are randomly initialized into d_{word}-dimensional (resp. d_{char}-dimensional) embeddings. The output dimensionality in convolution, i.e., Equation 1, is the same as input dimensionality. We employ Adagrad (Duchi et al., 2011), L_2 regularization and diversity regularization (Xie et al., 2015). Hyperparameters (Table 1) are tuned on dev. For active mention detection, we trained a two-layer BiLSTM followed by a CRF, the hidden layer sizes of both BiLSTM are 200.

[4]We tried max-pooling over $\mathbf{F}_{\text{decay}}$ as $\mathbf{v}_{\text{AMP}}$ directly, but much worse performance was observed.

Table 2: Experimental results for entity linking

6.2 Entity Linking

In Table 2, we compare our (passive and active) entity linkers with the state-of-the-art entity linker (Golub and He, 2016) in this SimpleQA task. Golub and He (2016) report the coverage of ground truth by top-N cases ($N \in \{1, 10, 20, 50, 100\}$). In addition, they explore a reranking algorithm to refine the entity ranking list.

Table 2 first shows the *overall* performance of our passive entity linker and its performance without factor a, b or c (-a, -b, -c). Our passive entity linker outperforms the baseline's *raw* results by big margins and is 2–3 percent above their *reranked* scores. This shows the outstanding performance of our passive entity linker despite its simplicity. The table also shows that all three factors (a, b, c) matter. Observations: (i) Each factor matters more when N is smaller. This makes sense because when N reaches the entity vocabulary size, all methods will have coverage 100%. (ii) The position-related factor c has less influence. From top1 to top100, its contribution decreases from 4.3 to .9. Our linker still outperforms the reranked baseline for $N \geq 20$. (iii) Factor a is dominant for small N, presumably because it chooses the longer one when two candidates exist, which is critical for small N. (iv) Factor b plays a more consistent role across different N.

The last column of Table 2 shows the overall results of our active entity linker, which are significantly better than the results of baseline linker and our passive linker. *We release our entity linking results for follow-up work to make better comparison.*

6.3 SimpleQuestions

Table 3 compares AMPCNN with two baselines. (i) **MemNN** (Bordes et al., 2015), an implementation of memory network for SimpleQuestions task. (ii) **Encoder-Decoder** (Golub and He, 2016), a character-level, attention-based encoder-decoder LSTM (Hochreiter and Schmidhuber, 1997) model. (iii) **CFO** (Dai et al., 2016), the state-of-the-art system in this task with CNN or BiGRU subsystem.

We report results for both passive entity linker and active entity linker. Furthermore, we compare AMPCNN to TMPCNN, i.e., we remove attention and representations for the predicate-pattern match are computed without attention. We choose top-20 (i.e., $N = 20$) entities returned by entity linker. Table 3 shows that AMPCNN with active entity linker has optimal performance for FB2M and FB5M. Performance on FB5M is slightly lower than on FB2M, which should be mainly due to the lower coverage for entity linking on FB5M – about 2% below that on FB2M. In addition, our CNN can still get competitive performance even if the attention mechanism is removed (TMPCNN result). This hints that CNN is promising for SimpleQA.

Settings		Methods	FB2M	FB5M
passive entity linker	baseline	random guess	4.9	4.9

Table 4: Comparing different attention schemes of CNN in terms of RC, *extra* parameters brought (Para).

6.4 Effect of Attentive Maxpooling (AMP)

We compare AMP (one main contribution of this work) with three CNN attention mechanisms that are representative of related work in modeling two pieces of text: (i) **HABCNN**: Hierarchical attention-based CNN (Yin et al., 2016a); (ii) **ABCNN**: Attention-based CNN (Yin et al., 2016b); (iii) **APCNN**: CNN with attentive pooling (Santos et al., 2016).

Since attentive matching of predicate-pattern is only one part of our jointly trained system, it is hard to judge whether or not an attentive CNN performs better than alternatives. We therefore create a relation classification (RC) subtask to compare AMP with baseline schemes directly. RC task is created based on SimpleQuestions: label each question (converted into a pattern first) with the ground truth predicate; all other predicates of the gold subject entity are labeled as negative. The resulting datasets have sizes 72,239 (train), 10,310 (dev) and 20,610 (test). It is worth mentioning that this relation classification task is not unspecific to the SimpleQA task, as RC is actually the predict-pattern match part. Hence, this RC subtask can be viewed to check how well the predict-pattern subsystem performs within the whole architecture, and the effectiveness of various attention mechanisms is more clear.

In the three baselines, two pieces of text apply attention to each other. We adapt them into *one-way attention* (OWA) as AMP does in this work: fix predicate representation, and use it to guide the learning of pattern representation. To be specific, ABCNN first gets predicate representation by mean pooling, then uses this representation to derive similarity scores of each n-gram in pattern as attention scores, finally averages all n-gram embeddings weighted by attentions as pattern representation. HABCNN first gets predicate representation by max pooling, then computes attention scores the same way as ABCNN, finally does maxpooling over representations of top-k similar n-grams. APCNN is similar to ABCNN except that the similarity scores are computed by a nonlinear bilinear form.

Table 4 shows that AMPCNN performs well on relation classification, outperforming the best baseline APCNN by 0.8%. AMPCNN also has fewer parameters and runs faster than APCNN.

7 Conclusion

This work explored CNNs for the SimpleQA task. We made two main contributions. (i) A simple and effective entity linker that brings higher coverage of ground truth entities. (ii) An attentive maxpooling stacked above convolution layer that models the relationship between predicate and question pattern more effectively. Our model shows outstanding performance on both simpleQA and relation classification.

Abstract

This paper presents a novel approach to recurrent neural network (RNN) regularization. Differently from the widely adopted dropout method, which is applied to *forward* connections of feed-forward architectures or RNNs, we propose to drop neurons directly in *recurrent* connections in a way that does not cause loss of long-term memory. Our approach is as easy to implement and apply as the regular feed-forward dropout and we demonstrate its effectiveness for Long Short-Term Memory network, the most popular type of RNN cells . Our experiments on three NLP benchmarks show consistent improvements even when combined with conventional feed-forward dropout.

1 Introduction

Recurrent Neural Networks, LSTMs in particular, have recently become a popular tool among NLP researchers for their superior ability to model and learn from sequential data. These models have shown state-of-the-art results on various public benchmarks ranging from sentence classification (Wang et al., 2015; Irsoy and Cardie, 2014; Liu et al., 2015) and various tagging problems (Dyer et al., 2015) to language modelling (Kim et al., 2015; Zhang et al., 2015), text generation (Zhang and Lapata, 2014) and sequence-to-sequence prediction tasks (Sutskever et al., 2014).

Having shown excellent ability to capture and learn complex linguistic phenomena, RNN architectures are prone to overfitting. Among the most widely used techniques to avoid overfitting in neural networks is the dropout regularization (Hinton et al., 2012). Since its introduction it has become, together with the L2 weight decay, the standard method for neural network regularization. While showing significant improvements when used in feed-forward architectures, e.g., Convolutional Neural Networks (Krizhevsky et al., 2012), the application of dropout in RNNs has been somewhat limited. Indeed, so far dropout in RNNs has been applied in the same fashion as in feed-forward architectures: it is typically injected in input-to-hidden and hidden-to-output connections, i.e., along the input axis, but not between the recurrent connections (time axis). Given that RNNs are mainly used to model sequential data with the goal of capturing short- and long-term interactions, it seems natural to also regularize the recurrent weights. This observation has led us and other researchers (Moon et al., 2015; Gal, 2015) to the idea of applying dropout to the recurrent connections in RNNs.

In this paper we propose a novel *recurrent dropout* technique and demonstrate how our method is superiour to other recurrent dropout methods recently proposed in (Moon et al., 2015; Gal, 2015). Additionally, we answer the following questions which helps to understand how to best apply recurrent dropout: (i) how to apply the dropout in recurrent connections of the LSTM architecture in a way that prevents possible corruption of the long-term memory; (ii) what is the relationship between our *recurrent dropout* and the widely adopted dropout in input-to-hidden and hidden-to-output connections; (iii) how the dropout mask in RNNs should be sampled: once per step or once per sequence. The latter question of sampling the mask appears to be crucial in some cases to make the recurrent dropout work and, to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1757–1766, Osaka, Japan, December 11-17 2016.

the best of our knowledge, has received very little attention in the literature. Our work is the first one to provide empirical evaluation of the differences between these two sampling approaches.

Regarding empirical evaluation, we first highlight the problem of information loss in memory cells of LSTMs when applying *recurrent dropout*. We demonstrate that previous approaches of dropping *hidden state* vectors cause loss of memory while our proposed method to use dropout mask in *hidden state update* vectors does not suffer from this problem. We experiment on three widely adopted NLP tasks: word- and character-level Language Modeling and Named Entity Recognition. The results demonstrate that our *recurrent dropout* helps to achieve better regularization and yields improvements across all the tasks, even when combined with the conventional feed-forward dropout. Furthermore, we compare our dropout scheme with the recently proposed alternative recurrent dropout methods and show that our technique is superior in almost all cases.

2 Related Work

Neural Network models often suffer from overfitting, especially when the number of network parameters is large and the amount of training data is small. This has led to a lot of research directed towards improving their generalization ability. Below we primarily discuss some of the methods aimed at improving regularization of RNNs.

Pham et al. (2013) and Zaremba et al. (2014) have shown that LSTMs can be effectively regularized by using dropout in forward connections. While this already allows for effective regularization of recurrent networks, it is intuitive that introducing dropout also in the hidden state may force it to create more robust representations. Indeed, Moon et al. (2015) have extended the idea of dropping neurons in forward direction and proposed to drop cell states as well showing good results on a Speech Recognition task. Bluche et al. (2015) carry out a study to find where dropout is most effective, e.g. input-to-hidden or hidden-to-output connections. The authors conclude that it is more beneficial to use it once in the correct spot, rather than to put it everywhere. Bengio et al. (2015) have proposed an algorithm called scheduled sampling to improve performance of recurrent networks on sequence-to-sequence labeling tasks. A disadvantage of this work is that the scheduled sampling is specifically tailored to this kind of tasks, what makes it impossible to use in, for example, sequence-to-label tasks. Gal (2015) uses insights from variational Bayesian inference to propose a variant of LSTM with dropout that achieves consistent improvements over a baseline architecture without dropout.

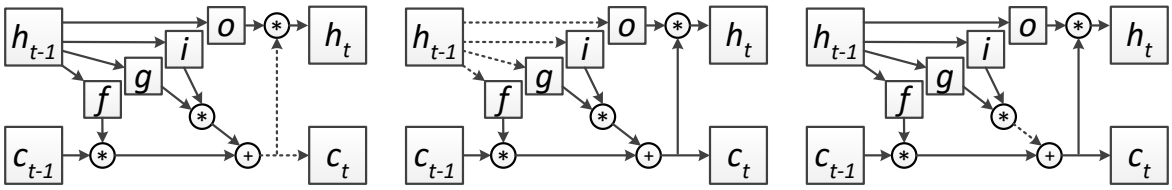
The main contribution of this paper is a new *recurrent dropout* technique, which is most useful in gated recurrent architectures such as LSTMs and GRUs. We demonstrate that applying dropout to arbitrary vectors in LSTM cells may lead to loss of memory thus hindering the ability of the network to encode long-term information. In other words, our technique allows for adding a strong regularizer on the model weights responsible for learning short and long-term dependencies without affecting the ability to capture long-term relationships, which are especially important to model when dealing with natural language. Finally, we compare our method with alternative *recurrent dropout* methods recently introduced in (Moon et al., 2015; Gal, 2015) and demonstrate that our method allows to achieve better results.

3 Recurrent Dropout

In this section we first show how the idea of feed-forward dropout (Hinton et al., 2012) can be applied to recurrent connections in vanilla RNNs. We then introduce our *recurrent dropout* method specifically tailored for gated architectures such as LSTMs and GRUs. We draw parallels and contrast our approach with alternative recurrent dropout techniques recently proposed in (Moon et al., 2015; Gal, 2015) showing that our method is favourable when considering potential memory loss issues in long short-term architectures.

3.1 Dropout in vanilla RNNs

Vanilla RNNs process the input sequences as follows:



(a) Moon et al., 2015 (b) Gal, 2015 (c) Ours

Figure 1: Illustration of the three types of dropout in recurrent connections of LSTM networks. Dashed arrows refer to dropped connections. Input connections are omitted for clarity.

$$\mathbf{h_t} = f(\mathbf{W_h}[\mathbf{x_t}, \mathbf{h_{t-1}}] + \mathbf{b_h}), \tag{1}$$

where $\mathbf{x_t}$ is the input at time step t; $\mathbf{h_t}$ and $\mathbf{h_{t-1}}$ are hidden vectors that encode the current and previous states of the network; $\mathbf{W_h}$ is parameter matrix that models input-to-hidden and hidden-to-hidden (recurrent) connections; $\mathbf{b}$ is a vector of bias terms, and f is the activation function.

As RNNs model sequential data by a fully-connected layer, dropout can be applied by simply dropping the previous hidden state of a network. Specifically, we modify Equation 1 in the following way:

$$\mathbf{h_t} = f(\mathbf{W_h}[\mathbf{x_t}, d(\mathbf{h_{t-1}})] + \mathbf{b_h}), \tag{2}$$

where d is the dropout function defined as follows:

$$d(\mathbf{x}) = \begin{cases} mask * \mathbf{x}, & \text{if train phase} \\ (1-p)\mathbf{x} & \text{otherwise,} \end{cases} \tag{3}$$

where p is the dropout rate and $mask$ is a vector, sampled from the Bernoulli distribution with success probability $1 - p$.

3.2 Dropout in LSTM networks

Long Short-Term Memory networks (Hochreiter and Schmidhuber, 1997) have introduced the concept of gated inputs in RNNs, which effectively allow the network to preserve its memory over a larger number of time steps during both forward and backward passes, thus alleviating the problem of vanishing gradients (Bengio et al., 1994). Formally, it is expressed with the following equations:

$$\begin{pmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \mathbf{g}_t \end{pmatrix} = \begin{pmatrix} \sigma(\mathbf{W}_i \left[\mathbf{x}_t, \mathbf{h}_{t-1}\right] + \mathbf{b}_i) \\ \sigma(\mathbf{W}_f \left[\mathbf{x}_t, \mathbf{h}_{t-1}\right] + \mathbf{b}_f) \\ \sigma(\mathbf{W}_o \left[\mathbf{x}_t, \mathbf{h}_{t-1}\right] + \mathbf{b}_o) \\ f(\mathbf{W}_g \left[\mathbf{x}_t, \mathbf{h}_{t-1}\right] + \mathbf{b}_g) \end{pmatrix} \tag{4}$$

$$\mathbf{c}_t = \mathbf{f}_t * \mathbf{c}_{t-1} + \mathbf{i}_t * \mathbf{g}_t \tag{5}$$

$$\mathbf{h}_t = \mathbf{o}_t * f(\mathbf{c}_t), \tag{6}$$

where $\mathbf{i}_t, \mathbf{f}_t, \mathbf{o}_t$ are input, output and forget gates at step t; $\mathbf{g}_t$ is the vector of cell updates and $\mathbf{c}_t$ is the updated cell vector used to update the hidden state $\mathbf{h}_t$; σ is the sigmoid function and $*$ is the element-wise multiplication.

Gal (2015) proposes to drop the previous *hidden state* vectors when computing values of gates and updates of the current step, where he samples the dropout mask once for every sequence:

$$\begin{pmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \mathbf{g}_t \end{pmatrix} = \begin{pmatrix} \sigma(\mathbf{W}_i \left[\mathbf{x}_t, d(\mathbf{h}_{t-1})\right] + \mathbf{b}_i) \\ \sigma(\mathbf{W}_f \left[\mathbf{x}_t, d(\mathbf{h}_{t-1})\right] + \mathbf{b}_f) \\ \sigma(\mathbf{W}_o \left[\mathbf{x}_t, d(\mathbf{h}_{t-1})\right] + \mathbf{b}_o) \\ f(\mathbf{W}_g \left[\mathbf{x}_t, d(\mathbf{h}_{t-1})\right] + \mathbf{b}_g) \end{pmatrix} \tag{7}$$

Moon et al. (2015) propose to apply dropout directly to the cell values and use per-sequence sampling as well:

$$\mathbf{c}_t = d(\mathbf{f}_t * \mathbf{c}_{t-1} + \mathbf{i}_t * \mathbf{g}_t) \tag{8}$$

In contrast to dropout techniques proposed by Gal (2015) and Moon et al. (2015), we propose to apply dropout to the *cell update* vector $\mathbf{g}_t$ as follows:

$$\mathbf{c}_t = \mathbf{f}_t * \mathbf{c}_{t-1} + \mathbf{i}_t * d(\mathbf{g}_t) \tag{9}$$

Different from methods of (Moon et al., 2015; Gal, 2015), our approach does not require sampling of the dropout masks once for every training sequence. On the contrary, as we will show in Section 4, networks trained with a dropout mask sampled per-step achieve results that are at least as good and often better than per-sequence sampling. Figure 1 shows differences between approaches to dropout.

The approach of (Gal, 2015) differs from ours in the overall strategy – they consider network's hidden state as input to subnetworks that compute gate values and cell updates and the purpose of dropout is to regularize these subnetworks. Our approach considers the architecture as a whole with the hidden state as its key part and regularize the whole network. The approach of (Moon et al., 2015) on the other hand is seemingly similar to ours. In Section 3.3 we argue that our method is a more principled way to drop recurrent connections in gated architectures.

It should be noted that while being different, the three discussed dropout schemes are not mutually exclusive. It is in general possible to combine our approach and the other two. We expect the merge of our scheme and that of (Gal, 2015) to hold the biggest potential. The relations between recurrent dropout schemes are however out of scope of this paper and we rather focus on studying the relationships of different dropout approaches with the conventional forward dropout.

Lastly, we note that our dropout is also applicable to the recently introduced Gated Recurrent Unit (GRU) networks (Cho et al., 2014). GRU networks are built on the same design principles as LSTM networks and our dropout technique applies in a similar fashion.

3.3 Dropout and memory

We found that an intuitive idea to drop previous hidden states directly, as proposed in Moon et al. (2015), produces mixed results. We have observed that it helps the network to generalize better when not coupled with the forward dropout, but is usually no longer beneficial when used together with a regular forward dropout.

The problem is caused by the scaling of neuron activations during inference. Consider the hidden state update rule in the test phase of an LSTM network. For clarity, we assume every gate to be equal to 1:

$$\mathbf{h}_t = (\mathbf{h}_{t-1} + \mathbf{g}_t)p, \tag{10}$$

where $\mathbf{g}_t$ are update vectors computed by Eq. 4 and p is the probability to not drop a neuron. As h_{t-1} was, in turn, computed using the same rule, we can rewrite this equation as:

$$\mathbf{h}_t = ((\mathbf{h}_{t-2} + \mathbf{g}_{t-1})p + \mathbf{g}_t)p \tag{11}$$

Recursively expanding $\mathbf{h}$ for every timestep results in the following equation:

$$\mathbf{h}_t = ((((\mathbf{h}_0 + \mathbf{g}_0)p + \mathbf{g}_1)p + ...)p + \mathbf{g}_t)p \tag{12}$$

Pushing p inside parenthesis, Eq. 12 can be written as:

$$\mathbf{h}_t = p^{t+1}\mathbf{h}_0 + \sum_{i=0}^{t} p^{t-i+1}\mathbf{g}_i \tag{13}$$

Since p is a value between zero and one, sum components that are far away in the past are multiplied by a very low value and are effectively removed from the summation. Thus, even though the network is

able to learn long-term dependencies, it is not capable of exploiting them during test phase. Note that our assumption of all gates being equal to 1 helps the network to preserve hidden state, since in a real network gate values lie within (0, 1) interval. In practice trained networks tend to saturate gate values (Karpathy et al., 2015) what makes gates to behave as binary switches. The fact that Moon et al. (2015) have achieved an improvement can be explained by the experimentation domain. Le et al. (2015) have proposed a simple yet effective way to initialize vanilla RNNs and reported that they have achieved a good result in the Speech Recognition domain while having an effect similar to the one caused by Eq. 13. One can reduce the influence of this effect by selecting a low dropout rate. This solution however is partial, since it only increases the number of steps required to completely forget past history and does not remove the problem completely.

One important note is that the dropout function from Eq. 3 can be implemented as:

$$d(\mathbf{x}) = \begin{cases} mask * \mathbf{x}/p, & \text{if train phase} \\ \mathbf{x} & \text{otherwise} \end{cases} \tag{14}$$

In this case the above argument holds as well, but instead of observing exponentially decreasing hidden states during testing, we will observe exponentially increasing values of hidden states during training.

Our approach addresses the problem discussed previously by dropping the update vectors $\mathbf{g}$. Since we drop only candidates, we do not scale the hidden state directly. This allows for solving the scaling issue, as Eq. 13 becomes:

$$\mathbf{h}_t = p\mathbf{h}_0 + \sum_{i=0}^{t} p\ \mathbf{g}_i = p\mathbf{h}_0 + p\sum_{i=0}^{t} \mathbf{g}_i \tag{15}$$

Moreover, since we only drop differences that are added to the network's hidden state at each time-step, this dropout scheme allows us to use per-step mask sampling while still being able to learn long-term dependencies. Thus, our approach allows to freely apply dropout in the recurrent connections of a gated network without hindering its ability to process long-term relationships.

We note that the discussed problem does not affect vanilla RNNs because they overwrite their hidden state at every timestep. Lastly, the approach of Gal (2015) is not affected by the issue as well.

4 Experiments

First, we empirically demonstrate the issues linked to memory loss when using various dropout techniques in recurrent nets (see Sec. 3.3). For this purpose we experiment with training LSTM networks on one of the synthetic tasks from (Hochreiter and Schmidhuber, 1997), specifically the Temporal Order task. We then validate the effectiveness of our *recurrent dropout* on three public benchmarks: word and character-level Language Modeling and Named Entity Recognition comparing directly to alternative *recurrent dropout* methods from (Moon et al., 2015; Gal, 2015).

4.1 Synthetic Task

Data. In this task the input sequences are generated as follows: all but two elements in a sequence are drawn randomly from {C, D} and the remaining two symbols from {A, B}. Symbols from {A, B} can appear at any position in the sequence. The task is to classify a sequence into one of four classes ({AA, AB, BA, BB}) based on the order of the symbols. We generate data so that every sequence is split into three parts with the same size and emit one meaningful symbol in first and second parts of a sequence. The prediction is taken after the full sequence has been processed. We use two modes in our experiments: `Short` with sequences of length 15 and `Medium` with sequences of length 30.

Setup. We use LSTM with one layer that contains 256 hidden units and *recurrent dropout* with 0.5 strength. Network is trained by SGD with a learning rate of 0.1 for 5k epochs. The networks are trained on 200 mini-batches with 32 sequences and tested on 10k sequences.

Results. Table 1 reports the results on the Temporal Order task when *recurrent dropout* is applied using our method and methods from (Moon et al., 2015) and (Gal, 2015). Using dropout from (Moon et al., 2015) with per-sequence sampling, networks are able to discover the long-term dependency, but fail to

Sampling	Moon et al. (2015)				Gal (2015); Ours

0.5	per-sequence	125.4	117.4	98.4	92.5	107.8	101.8

Table 2: Perplexity scores of the LSTM network on word level Language Modeling task (lower is better). Upper and lower parts of the table report results without and with forward dropout respectively. Networks with forward dropout use 0.2 and 0.5 dropout rates in input and output connections respectively. Values in bold show best results for each of the recurrent dropout schemes with and without forward dropout.

use it on the test set due to the scaling issue. Interestingly, in `Medium` case results on the test set are worse than random. Networks trained with per-step sampling exhibit different behaviour: in `Short` case they are capable of capturing the temporal dependency and generalizing to the test set, but require 10-20 times more iterations to do so. In `Medium` case these networks do not fit into the allocated number of iterations. This suggests that applying dropout to hidden states as suggested in (Moon et al., 2015) corrupts memory cells hindering the long-term memory capacity of LSTMs.

In contrast, using our *recurrent dropout* methods, networks are able to solve the problem in all cases. We have also ran the same experiments for longer sequences, but found that the results are equivalent to the `Medium` case. We also note that the approach of (Gal, 2015) does not seem to exhibit the memory loss problem.

4.2 Word Level Language Modeling

Data. Following Mikolov et al. (2011) we use the Penn Treebank Corpus to train our Language Modeling (LM) models. The dataset contains approximately 1 million words and comes with pre-defined training, validation and test splits, and a vocabulary of 10k words.

Setup. In our LM experiments we use recurrent networks with a single layer with 256 cells. Network parameters were initialized uniformly in [-0.05, 0.05]. For training, we use plain SGD with batch size 32 with the maximum norm gradient clipping (Pascanu et al., 2013). Learning rate, clipping threshold and number of Backpropagation Through Time (BPTT) steps were set to 1, 10 and 35 respectively. For the learning rate decay we use the following strategy: if the validation error does not decrease after each epoch, we divide the learning rate by 1.5. The aforementioned choices were largely guided by the work of Mikolov et al. (2014). To ease reproducibility of our results on the LM and synthetic tasks, we have

Table 3: Bit-per-character scores of the LSTM network on character level Language Modelling task (lower is better). Upper and lower parts of the table report results without and with forward dropout respectively. Networks with forward dropout use 0.2 and 0.5 dropout rates in input and output connections respectively. Values in bold show best results for each of the recurrent dropout schemes with and without forward dropout.

released the source code of our experiments[1].

Results. Table 2 reports the results for LSTM networks. We also present results when the dropout is applied directly to hidden states as in (Moon et al., 2015) and results of networks trained with the dropout scheme of (Gal, 2015). In addition, we report results of networks trained with no regularization and with dropout in only forward connetions in first rows of upper and lower parts of the table respectivelly. We make the following observations: (i) our approach shows better results than the alternatives; (ii) per-step mask sampling is better when dropping hidden state directly; (iii) on this task our method using per-step sampling seems to yield results similar to per-sequence sampling; (iv) in this case forward dropout yields better results than any of the three recurrent dropouts; and finally (v) both our approach and that of (Gal, 2015) are effective when combined with the forward dropout, though ours is more effective.

4.3 Character Level Language Modeling

Data. We train our networks on the dataset described in the previous section. It contains approximately 6 million characters, and a vocabulary of 50 characters. We use the provided partitions train, validation and test partitions.

Setup. We use networks with 1024 units to solve the character level LM task. The characters are embedded into 256 dimensional space before being processed by the LSTM. All parameters of the networks are initialized uniformly in [-0.01, 0.01]. We train our networks on non-overlapping sequences of 100 characters. The networks are trained with the Adam (Kingma and Ba, 2014) algorithm with initial learning rate of 0.001 for 50 epochs. We decrease the learning rate by 0.97 after every epoch starting from epoch 10. To avoid exploding gradients, we use MaxNorm gradient clipping with threshold set to 10.

Results. Results of our experiments are given in Table 3. Note that on this task regularizing only the recurrent connections is more beneficial than only the forward ones. In particular, LSTM networks trained with our approach and the approach of (Gal, 2015) yield a lower bit-per-character (bpc) score than those trained with forward dropout onlyWe attribute it to pronounced long term dependencies. In addition, our approach is the only one that improves over baseline LSTM with forward dropout. The overall best result is achieved by a network trained with our dropout with 0.25 dropout rate and per-step sampling, closely followed by network with Gal (2015) dropout.

Table 4: F1 scores (higher is better) of the LSTM network on NER task (average scores over 3 runs). Upper and lower parts of the table report results without and with forward dropout respectively. Values in bold show best results for each of the recurrent dropout schemes with and without forward dropout.

4.4 Named Entity Recognition

Data. To assess our recurrent Named Entity Recognition (NER) taggers when using *recurrent dropout* we use a public benchmark from CONLL 2003 (Tjong Kim Sang and De Meulder, 2003). The dataset contains approximately 300k words split into train, validation and test partitions. Each word is labeled with either a named entity class it belongs to, such as `Location` or `Person`, or as being not named. The majority of words are labeled as not named entities. The vocabulary size is about 22k words.

Setup. Previous state-of-the-art NER systems have shown the importance of using word context features around entities. Hence, we slightly modify the architecture of our recurrent networks to consume the context around the target word by preprocessing the inputs by a convolutional layer. The size of the convolutional kernel is fixed to 5 words (the word to be labeled, two words before and two words after) and the number of filters is fixed to 256. The recurrent layer size is 1024 units. The network inputs include word embeddings (initialized with pretrained word2vec embeddings (Mikolov et al., 2013) and kept static) and capitalization features. For training we use the Adam algorithm (Kingma and Ba, 2014) with initial learning rate of 0.001. We train for 50 epochs and multiply the learning rate by 0.95 after every epoch starting at epoch 10. We also combine our *recurrent dropout* with the conventional forward dropout with the rate 0.2 in input and 0.5 in output connections. Lastly, we found that using $relu(x) = max(x, 0)$ nonlinearity resulted in higher performance than $tanh(x)$. We train our network on randomly extracted samples up to 15 words long and use full sentences for testing.

Results. Table 4 reports the results of networks trained with and without forward dropout and compares our algorithm to approaches of (Moon et al., 2015) and (Gal, 2015). We make the following observations: (i) forward dropout provides a much bigger improvement than recurrent one, what can be explained by the fact that long term dependencies are much less important in the NER task, in contrast to the Language Modeling; (ii) the results of our approach and dropout of (Gal, 2015) are comparable and both better than those of (Moon et al., 2015); and (iii) all three approaches consistently outperform baseline networks without dropout in recurrent connections.

5 Conclusions

This paper presents a novel *recurrent dropout* method specifically tailored to the gated recurrent neural networks. Our approach is easy to implement and is even more effective when combined with conventional forward dropout. We have shown that applying dropout to arbitrary cell vectors results in suboptimal performance. We discuss in detail the cause of this effect and propose a simple solution to overcome it. The effectiveness of our approach is verified on three public NLP benchmarks.

Our findings along with our empirical results help us to answer the questions posed in Section 1: (i) while is straight-forward to use dropout in vanilla RNNs due to their strong similarity with the feed-forward architectures, its application to LSTM networks is not so straightforward. We demonstrate that *recurrent dropout* is most effective when applied to *hidden state update* vectors in LSTMs rather than to *hidden states*; (ii) we observe an improvement in the network's performance when our *recurrent dropout* is coupled with the standard forward dropout, though the extent of this improvement depends on the values of dropout rates; (iii) per-step mask sampling is at least as good as per-sequence mask sampling when using our *recurrent dropout* method, with the most pronounced difference in the character level LM experiments, while the results of (Moon et al., 2015) and (Gal, 2015) are mixed.

Abstract

The exchangeability assumption in topic models like Latent Dirichlet Allocation (LDA) often results in inferring inconsistent topics for the words of text spans like noun-phrases, which are usually expected to be topically coherent. We propose copulaLDA, that extends LDA by integrating part of the text structure to the model and relaxes the conditional independence assumption between the word-specific latent topics given the per-document topic distributions. To this end, we assume that the words of text spans like noun-phrases are topically bound and we model this dependence with copulas. We demonstrate empirically the effectiveness of copulaLDA on both intrinsic and extrinsic evaluation tasks on several publicly available corpora.

1 Introduction

Probabilistic topic models, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), are generative models that describe the content of documents by discovering the latent topics underlying them.

A limitation inherent from the bag-of-words representation in such state-of-the-art models concerns the independence assumption: given their topics, words are assumed to occur independently. While this exchangeability assumption greatly impacts the involved computations and, in particular, the calculations of the conditional probabilities, it is rather naive and unrealistic (Heinrich, 2005). As another limitation caused by the exchangeability assumption, the grouping of words in topically coherent spans, that is contiguous text spans like sentences, is lost.

On the other hand, text structure generally contains useful information that could be leveraged in inference process. Sentences or phrases, for instance, are by definition text spans complete in themselves that convey a concise statement. To better illustrate how text structure could help in topic identification, consider the example of Figure 1. It illustrates the topics inferred by LDA for the words (excluding stop-words) of a sentence drawn from a Wikipedia page. At the sentence level, one could argue that the sentence is generated by the "Cinema" topic since it discusses a film and its authors. LDA, however, fails and assigns several topics to the words of the sentence. Importantly, several of those topics like "Elections" and "Inventions" are unrelated. In finer text granularity, LDA also fails to assign consistent topics in noun-phrases like "film noir classic" and entities like "Brian Donlevy". A binding mechanism among the topics of the words of a sentence, or a phrase, could have prevented those limitations and taking simple text structure into account would be beneficial.

Motivated by the previous example, we propose to incorporate text structure in the form of sentence or phrase boundaries as an intermediate structure in LDA. We plan to model this binding mechanism with copulas. Copulas have been found to be a flexible tool to model dependencies in the fields of

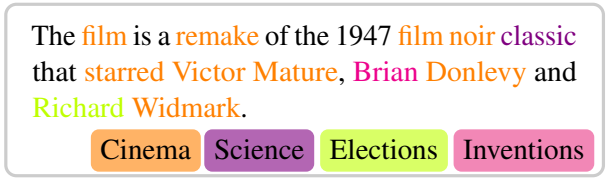

Figure 1: Applying LDA on Wikipedia documents.

risk management and finance (Embrechts et al., 2002). They are a family of distribution functions that offer a flexible way to model the joint probability of random variables using only their marginals. This results in decoupling the marginal distributions by the underlying dependency. These properties make them appealing and some preliminary studies have started investigating their integration into different learning tasks (Wilson and Ghahramani, 2010; Tran et al., 2015; Amoualian et al., 2016).

The remainder of the paper is organized as follows: Section 2 presents the related work. The main contribution of this article is presented in Section 3, in which we propose to bind the latent topics that generate the words of a segment using copulas. We show that sampling word topics from copulas offers an elegant way to impose different levels and types of correlation between them. Section 4 then illustrates the behavior of *copulaLDA*, the copula-based version of LDA introduced in Section 3, while Section 5 concludes the paper.

2 Related Work

Despite the success that vector-space models (Salton et al., 1975) have enjoyed, they come with a number of limitations. We mention, for instance, their inability to model synonymy and polysemy and the sparse, high-dimensional induced representations. Many research studies have researched these problems, and Probabilistic Latent Semantic Analysis (Hofmann, 1999) was among the first attempts to model textual corpora using latent topics. In our work, we build on LDA (Blei et al., 2003), which is often used as a building block for topic models. In its context, the corpus is associated with a set of latent topics, and each document is associated with a random mixture of those topics. The words are assumed exchangeable, that is their joint probability is invariant to their permutation. Previous work proposed a variety of extensions to LDA in order to incorporate additional information such as class labels (Blei and McAuliffe, 2008) and temporal dependencies between stream documents (Wang et al., 2012). Here, our goal is to extend LDA by incorporating simple text structure in its generative and inference processes using copulas.

One may identify two lines of research to address the limitations due to the exchangeability assumption in LDA: extensions to account for the boundaries of text spans like sentences and extensions to account for the word order. With respect to the first line, (Wang et al., 2009) combine a unigram language model with topic models over sentences so that the latent topics are represented by sentences instead of terms. In (Griffiths et al., 2004), the authors investigate a combination of a topic model with a Hidden Markov Model (HMM). They assume that the HMM generates the words that handle the long-range dependencies (semantic dependencies) and the topic model the words that handle the short range dependencies (syntactic dependencies). Also, (Boyd-Graber and Blei, 2009) proposed the Syntactic Topic Model whose goal is to integrate the text semantics and the syntax in a non-parametric topic model. In another effort, (Zhu et al., 2006) propose *TagLDA*, where they replace the unigram word distributions by a factored representation that is conditioned on the topic and the part-of-speech tag of a term. Recently, (Balikas et al., 2016) introduced *senLDA*, that assumes that the terms occurring within a sentence are generated by the same topic. In our work here, we integrate part of the text structure in LDA by relying only on the boundaries of contiguous text spans like sentences, which can be obtained without deep linguistic analysis like the one required in the Syntactic Topic Model. Also, differently from *senLDA*, we do not restrict the words of the spans to be generated by the same topic. Instead, using copulas we pose correlations between those topics, which is more flexible.

The second line of research investigates how topic models can be extended to incorporate word order. In (Shafiei and Milios, 2006), the authors propose a four-level hierarchical structure where the latent topics of paragraphs are decided after performing a nested word-based LDA operation. In a similar context, (Wang et al., 2007) study how the word order in the form of n-grams can be leveraged to better capture a document's topical content. Their topical n-gram model extends LDA by determining unigram words and phrases based on context and assigning mixture of topics to both individual words and n-gram phrases.

Another interesting line of research studied the task of discovering and partitioning text in topically coherent spans. In (Du et al., 2010; Du et al., 2013) the authors rely on hierarchical Bayesian models to accomplish it. In this work, contrary to identifying such spans, we assume them to be topically coherent *a priori*, and we investigate how to leverage and incorporate this information to LDA.

Lately, there is an increasing interest over the integration of copulas in machine learning applications (Elidan, 2013) such as classification (Elidan, 2012) or structure learning (Liu et al., 2009). Interestingly, (Wilson and Ghahramani, 2010) have shown how to incorporate copulas in Gaussian processes in order to model the dependency between random variables with arbitrary marginals with a practical application on predicting the standard deviation of variables in the financial sector (volatility estimation). In another generic framework, (Tran et al., 2015) have shown the benefits of using copulas to model complex dependencies between latent variables in the general variational inference setting. The idea of using copulas with topic models was recently investigated in (Amoualian et al., 2016). In the context of document streams they proposed a topic model where the dependencies between the topic distributions of two consecutive documents are captured by copulas.

3 Integrating text structure to LDA using copulas

In this section we develop *copulaLDA* (hereafter *copLDA*), that extends LDA by integrating simple text structure in the model using copulas. We assume that the topics that generate the terms of coherent text spans are bound. A strong binding signifies high probability for the terms to have been generated by the same topic. Therefore, as we show, the conditional independence of topics given the per-document topic distributions does not hold. Before presenting the generative and inference processes of *copLDA*, we shortly discuss the idea of *coherent text spans*.

Each sentence is a coherent, meaningful segment of text and we consider them as coherent text spans in this study. However, each sentence can be further decomposed into smaller segments through syntactic analysis. Figure 2 illustrates the output of a shallow parsing step of the example sentence of Figure 1, generated using the Stanford Parser.[1] Among these different segments, noun phrases play a particular role as they are, for instance, at the basis of terminology extraction that aims at capturing concepts from a document. Noun phrases usually constitute a semantic unit, pertaining to a given concept related to few, related topics. For this reason, we also consider noun phrases as coherent text spans in this study. Another advantage of the two types of coherent text spans we consider (whole sentences and noun phrases) is that they can be easily extracted using shallow parsing techniques, and one needs not resort to complex syntactic analysis in practice.

The film is a remake of *the 1947 film noir classic* that starred *Victor Mature*, *Brian Donlevy* and *Richard Widmark*.

Figure 2: Shallow parsing using the Stanford Parser. Contiguous words in italics denote a noun-phrase.

3.1 Copulas and random variables

Copulas are interesting because they separate the dependency structure of random variables from their marginals. Formally (Nelsen, 2007; Trivedi and Zimmer, 2007), a p-dimensional copula C is a p-variate distribution function with $C : \mathbb{I}^p = [0,1]^p \rightarrow [0,1]$ whose univariate marginals are uniformly distributed on $\mathbb{I}$ and $C(u_1, \ldots, u_p) = P(U_1 \leq u_1, \ldots, U_p \leq u_p)$. Copulas allow one to explicitly relate joint and marginal distributions, through Sklar's theorem (Sklar, 1959):

Theorem 3.1 *Let F be a p-dimensional distribution function with univariate margins $F_1, \ldots, F_p$. Let A_j denote the range of F_j. Then there exists a copula C such that for all $(x_1, \ldots, x_p) \in \mathbb{R}^p$*

$$F(x_1, \ldots, x_p) = C(F_1(x_1), \ldots, F_d(x_p)) \tag{1}$$

Furthermore, when $F_1, \ldots, F_p$ are all continuous, then C is unique.

As a result any multivariate distribution F can be decomposed into its marginals $F_i, i \in \{1, \ldots, p\}$ and a copula, allowing to study the multivariate distribution independently of the marginals. Sklar's theorem also provides a way of sampling multivariate distributions with a large number of random variables using copulas: $F(x_1, \ldots, x_p) = F\left(F_1^{-1}(u_1), \ldots, F_p^{-1}(u_p)\right) = P[U_1 \leq u_1, \ldots, U_p \leq u_p] = C(u_1, \ldots, u_p)$. Hence, to sample F it suffices to sample the dependence structure modeled by copulas and then transform

[1] http://nlp.stanford.edu/software/lex-parser.shtml

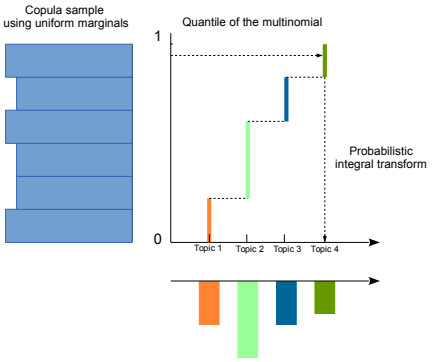

Figure 3: The transformation of a random variate to multinomial (or arbitrary) marginals. The arrows illustrate the generalized inverse; the histograms in y (resp. x) axis depict the distributions of the initial (resp. transformed) samples.

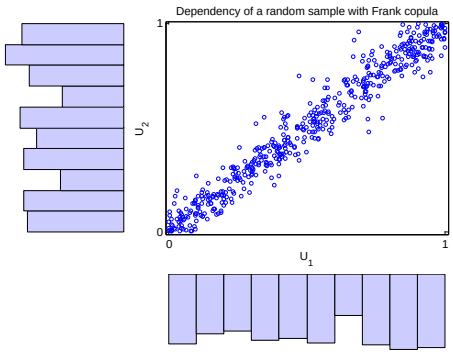

Figure 4: The positive correlation imposed to two random variates when sampling from a Frank copula with $\lambda = 25$. The histograms in x (resp. y) axis show the distributions of each of the variates that generate the scatterplot.

the obtained sample in the marginals of interest using the probabilistic integral transform. We illustrate this transformation for one variable in Figure 3. Sampling the copula returns, for each variate, a sample as the one indicated in the histogram of the y axis. One can then transform the sample using the quantile (F^{-1}) of an arbitrary marginal.

Before proceeding further, we visit some extreme conditions of dependence illustrating the respective copulas that model them: (1) *Independence*, which is a frequently assumed simplification in topic models and is obtained with $\prod_{i=1}^{p} u_i$, and (2) *Co-monotonicity*, which is the complete, positive correlation between the random variables u_p, obtained with $\min(u_1, \ldots, u_p)$.

In the rest of our development we will be using a particular family of copulas, the Archimedean copulas. Archimedean copulas are widely used copulas and are defined with respect to a generator function ψ. They take the form: $C(u_1, \cdots, u_d) = \psi^{-1}(\psi(u_1) + \cdots + \psi(u_d))$. A special case of Archimedean copulas corresponds to Frank copulas, which are obtained by setting: $\psi_\lambda(u) = \frac{-1}{\lambda}\log(1-(1-e^{-\lambda})e^{-u})$. When $\lambda \to 0$, the Frank copula approaches the independency copula; when $\lambda \to \infty$ it approaches the co-monotonicity copula. Hence, the Frank copula allows one to model all dependencies between complete independence to perfect dependence while varying λ from 0 to ∞. Therefore, λ can be seen as an additional hyper-parameter to be tuned or learned from the data. Figure 4 illustrates the positive dependence between two random variables sampled from a Frank copula with $\lambda = 25$. To sample from the Archimedean copulas, we rely on the algorithm proposed by (Marshall and Olkin, 1988), which was further improved in (McNeil, 2008; Hofert, 2011) and implemented in the R language (Hofert et al., 2011).

3.2 Extending LDA with copulas

As mentioned above, copulas provide a nice way to bind random variables. We are making use of them here to bind word-specific topics (the z variables in LDA) within coherent text spans, the rationale being that coherent text spans can not be generated by many different, uncorrelated topics. This leads us to the following generative model:

- For each topic $k \in [1, K]$, choose a per-word distribution: $\phi_k \sim Dir(\beta)$, with $\phi_k, \beta \in \mathbb{R}^{|V|}$
- For each document d_i, $i \in \{1, \ldots, D\}$:
  - Choose a per-document topic distribution: $\theta_i \sim Dir(\alpha)$, with $\theta_i, \alpha \in \mathbb{R}^{|K|}$
  - Sample number of segments in d_i: $S_i \sim Poisson(\xi)$;
  - For each segment $s_{i,j}, j \in \{1, \ldots, S_i\}$:

* Sample number of words: $N_{i,j} \sim Poisson(\xi_d)$;
* Sample topics $\mathcal{Z}_{i,j} = (z_{i,j,1}, \ldots, z_{i,j,N_{i,j}})$ from a distribution admitting $Mult(1, \theta_i)$ as margins and C as copula;
* Sample words $W_{i,j} = (w_{i,j,1}, \ldots, w_{i,j,N_{i,j}})$: $w_{i,j,n} \sim Mult(1, \phi_{z_{i,j,n}})$, $1 \leq n \leq N_{i,j}$.

There are two main differences between *copLDA* and LDA. Firstly, the former assumes a hierarchical structure in the documents: the topics that generate the words in the coherent segments exhibit topical correlation, hence the conditional independence assumption between the terms of a segment given the document per-topic distribution (θ_i) no longer holds. Secondly, this topical correlation is modeled using copulas. Figure 5 provides the graphical model for *copLDA*. For clarity, we draw each word in a coherent segment S $(w1, \ldots, w_N)$ to make the dependencies explicit. Notice how the topics of those words depend on both the copula parameter λ and the per-document topic distribution θ.

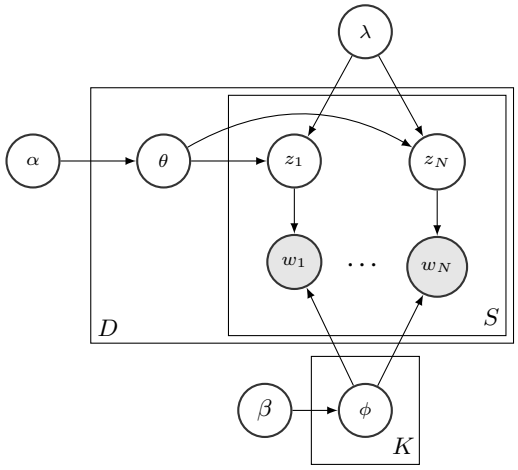

Figure 5: The *copLDA* generative model. We model the dependency between the topics underlying a segment with copulas.

The hyper-parameters α and β correspond to priors of the model. Following (Blei et al., 2003), we assume them here to be symmetric and we fix them to $\frac{1}{K}$, with K the number of topics retained. The hyper-parameter λ is chosen after exploration of a grid of possible values, and is the same for the whole corpus. We choose the value that minimizes perplexity.

3.3 Inference with Gibbs sampling

The parameters of the above model, that are ϕ, θ and the topics of each segment $\mathcal{Z}_{i,j} = (z_{i,j,1}, \cdots, z_{i,j,N_{i,j}})$, can be directly estimated through Gibbs sampling. Denoting Ω and Ψ the count matrices such that $\Omega = (\Omega_{i,k})$ (resp. $\Psi = (\Psi_{k,v})$) represents the count of word belonging to topic k assigned to document d_i (resp. the count of word v being assigned to topic k), the Gibbs updates for θ and ϕ are the same as the ones for the standard LDA model (Blei et al., 2003):

$$\theta_i \sim Dir(\alpha + \Omega_i) \quad \text{and} \quad \phi_k \sim Dir(\beta + \Psi_k) \tag{2}$$

The update for the variables z is obtained as follows:

$$p(\mathcal{Z}_{i,j}|\mathcal{Z}_{-i,j}, W, \Theta, \Phi, \alpha, \beta, \lambda) = \frac{p(\mathcal{Z}_{i,j}, \mathcal{Z}_{-i,j}, W|\Theta, \Phi, \alpha, \beta, \lambda)}{p(\mathcal{Z}_{-i,j}, W|\Theta, \phi, \alpha, \beta, \lambda)} =$$
$$\frac{p(\mathcal{Z}_{i,j}, W_{i,j}|\Theta, \Phi, \lambda)p(\mathcal{Z}_{-i,j}, W_{-i,j}|\Theta, \Phi, \lambda)}{p(W_{i,j}|\Theta, \phi)p(\mathcal{Z}_{-i,j}, W_{-i,j}|\Theta, \Phi, \lambda)} = \frac{p(\mathcal{Z}_{i,j}, W_{i,j}|\Theta, \Phi, \lambda)}{\sum_{\mathcal{Z}_{i,j}} p(\mathcal{Z}_{i,j}, W_{i,j}|\Theta, \Phi, \lambda)} =$$
$$\frac{p(W_{i,j}|\mathcal{Z}_{i,j}, \Phi)p(\mathcal{Z}_{i,j}|\Theta, \lambda)}{\sum_{\mathcal{Z}_{i,j}} p(W_{i,j}|\mathcal{Z}_{i,j}, \Phi)p(\mathcal{Z}_{i,j}|\Theta, \lambda)} \sim p(W_{i,j}|\mathcal{Z}_{i,j}, \Phi)p(\mathcal{Z}_{i,j}|\Theta, \lambda) = p(\mathcal{Z}_{i,j}|\Theta, \lambda) \prod_{n=1}^{N_{i,j}} \phi_{w_{i,j,n}, z_{i,j,n}} \tag{3}$$

where W, Θ and Φ stand for the whole parameter set of w, θ and ϕ and the probability outside the product in the last step admits a copula C_λ and $Mult(1, \theta_i)$ as margins. As is standard in topic models, the notation $-i, j$ means excluding the information for i, j. Note that in case where $\lambda \to 0$, the words of a segment become conditionally independent given the per-document distribution and one recovers the non collapsed Gibbs sampling updates of LDA.

From the expression of Eq. (3), a simple acceptance/rejection algorithm can be formulated: (1) Sample a random variable of pdf $p(\mathcal{Z}_{i,j}|\Theta, \lambda)$ using copula, and, (2) Accept the sample with probability $p(W_{i,j}|\mathcal{Z}_{i,j}, \Phi) = \prod_{n=1}^{N_{i,j}} \phi_{w_{i,j,n}, z_{i,j,n}}$. Algorithm 1 summarizes the inference process.

3.4 Computational Considerations

As the values of $\phi_{w_{i,j,1},z_{i,j,1}} \times \cdots \times \phi_{w_{i,j,n},z_{i,j,n}}$ tend to be very low, the acceptance/rejection sampling step described above is very slow in practice (see below). We propose here to speed it up by considering, for each word $w_{i,j,n}$ in a given segment, not the exact probability of $z_{i,j,n}$, but its mean (noted M) over all the other words in the segment:

$$M(z_{i,j,n}|\mathcal{Z}_{-i,j}, W, \Theta, \Phi, \alpha, \beta, \lambda) = \sum_{w_{ij,l}, l \neq n} \sum_{z_{ij,l}, l \neq n} P(\mathcal{Z}_{i,j}|\mathcal{Z}_{-i,j}, W, \Theta, \Phi, \alpha, \beta, \lambda) \propto \phi_{w_{i,j,n}} \theta_{d,z_{i,j,n}}$$

as $\sum_{w_{ij,l}} \phi_{w_{i,j,l}} = 1$. Note that the above form is a marginalization of $P(\mathcal{Z}_{i,j}|\mathcal{Z}_{-i,j}, W, \Theta, \Phi, \alpha, \beta, \lambda)$ and thus defines a valid probability and a valid Gibbs sampler, even though on a joint distribution that slightly differs from the original one.

Figure 6 compares the perplexity scores achieved in 200 documents from the Wikipedia dataset "Wiki46" of Table 1 by the copLDA model, when considering noun-phrases as coherent spans, with and without rejection sampling. We repeat the experiment 10 times and also plot the standard deviation. We first note that approximating Algorithm 1 by ignoring the rejection sampling step results in slightly worse performance. On the other hand, without the rejection sampling, copLDA converges faster in terms of iterations. Furthermore, the cost in terms of running time of a single iteration is significantly smaller: for instance, for 30 iterations with rejection sampling, the algorithm needs almost 6 hours, that is 100 times more than the 3.5 minutes needed without the rejection sampling. Hence, in the rest of the study, for scaling purposes, we adopt the above mean approximation.

Algorithm 1: A Gibbs Sampling iteration for *copLDA*

```
Input: documents' words grouped in segments, α, β, K, Copula
family and its parameter λ
//Initialize counters Ψ, Ω
for document d_i, i ∈ [1, D] do

        Draw a random vector U = (U_1, ..., U_{N_{i,j}}) that
        admits a copula C_λ
        do /* If the mean approximation is used, the loop is
           done once, ignoring the acceptance condition */
            for words w_{i,j,k}, k ∈ [1, W_{N_{i,j}}] in s_{i,j} do
                Decrease counter variables Ψ, Ω
                Get z_{i,j,k} by transforming U_k to Mult.
                marginals with the generalized inverse
                Assign topic z_{i,j,k} to w_{i,j,k}
                Increase counters Ψ, Ω
            end
        while Accept the new segment topic assignments with
        probability φ_{w_{i,j,1},z_{i,j,1}} × ··· × φ_{w_{i,j,n},z_{i,j,n}}
    end
end
```

4 Experimental study

Models In our experiments, we compare the following topic models: (1) *copLDA$_{sen}$* that considers sentences as coherent segments, (2) *copLDA$_{np}$* that considers noun-phrases as coherent segments, (3) LDA as proposed in (Blei et al., 2003) using the collapsed Gibbs sampling inference of (Griffiths and Steyvers, 2004), and (4) *senLDA* described in (Balikas et al., 2016) using its public implementation. For *copLDA$_x$* models, we use the Frank copula which was reported to obtain the best performance in similar tasks (Amoualian et al., 2016) and was also found to achieve the best performance in our local validation settings compared to Gumbel and Clayton copulas. We have implemented the models using Python;[2] for sampling the Frank copulas we used the R `copula` package (Hofert et al., 2011) and `rPY`.[3] As mentioned in Section 3.2, λ is set to 2 for *copLDA$_{sen}$* and to 5 for *copLDA$_{np}$* (values which we found to perform well in every dataset we tried). Furthermore, the hyper-parameters α and β where set to $1/K$, where K is the number of topics, which was selected from $\{50, 100, 200, 300, 400\}$ for each dataset. For the shallow parsing step, required for *copLDA$_{np}$*, we used the Stanford Parser (Klein and Manning, 2003). The text pre-processing steps performed are: lower-casing, stemming using the Snowball Stemmer and removal of numeric strings.

[2]The models used in this paper are available for research purposes at `https://github.com/balikasg/topicModelling`.

Table 1: The basic statistics, the perplexity and the classification scores of the datasets used.

Datasets We have used the following publicly available data collections to test the performance of the topic models: (1) 20NG (20 news groups), which is a standard text dataset for such tasks as provided by (Bird et al., 2009), (2) Reuters (Reuters-21578, the "ModApte" version), also discussed in (Bird et al., 2009), (3) TED, that is transcriptions of TED talks released in the framework of the International Workshop on Spoken Language Translation 2013 evaluation campaign[4] (we have merged the train, development and test parts and we selected the transcriptions with at least one associated label among the 15 most common in the data[5]), (4) Wiki$_x$, with $x \in \{15, 37, 46\}$ and PubMed, both excerpts[6] from the Wikipedia dataset of (Partalas et al., 2015) and the PubMed dataset of (Tsatsaronis et al., 2015) used in (Balikas et al., 2016), and (5) "Austen", where we concatenated three books[7] written by Jane Austen, available from the Gutenberg project (each paragraph is considered as a document). Table 1 presents some basic statistics for these datasets.

Manual inspection of the topics We begin by comparing LDA and *copLDA*$_{\text{np}}$. For presentation purposes, we train the two topic models using the Wiki$_{47}$ dataset with 10 topics and we illustrate the top-10 words learned for each topic by the two models in Table 2. As one can note, since the two models have been trained on the same data with the same training parameters, the identified topics are very similar. This said, *copLDA*$_{\text{np}}$ manages to produce arguably better topics. This is for example the case for the topic "Birth"; although both models assign high probability to words like "born" and "american" due to the content of the dataset, copLDA$_{\text{np}}$ manages to identify several words corresponding to months which makes the topic more thematically consistent and easier to interpret compared to its LDA counterpart. In the same line, Table 3 visualizes the inferred topics for parts of the Wiki$_{47}$ dataset. Notice here that given the topic interpretations of Table 2, both models manage to identify intuitive topics. Note however how in most of the cases the text structure information used by *copLDA*$_{\text{np}}$ helps to obtain consistent topics to generate noun-phrases like "crime thriller film" and "raspy voice", a consistency that LDA is lacking.

Intrinsic evaluation: perplexity We present in Table 1 the perplexity scores achieved by the 4 models in

Table 3: The discovered topics underlying the words of example documents for LDA (left) and copLDA (right). The parts of the documents in italics indicate the noun-phrases obtained by the Stanford Parser. The text colours refer to the topics described in Table 2.

each of the datasets we examined. We split each dataset in two parts with 80%/20% of the documents: we use the former for learning the model and the second for calculating the perplexity scores. First note that *copLDA*$_{\text{np}}$ achieves the lowest scores in most of the datasets. LDA is the second best performing model, whereas the third one is *copLDA*$_{\text{sen}}$. We believe that the difference between *copLDA*$_{\text{sen}}$ and *copLDA*$_{\text{np}}$ stems from the fact that perplexity is an evaluation measure that is calculated on the basis of words. Hence, considering sentences as coherent spans whose topics are bound results in less flexibility and this is reflected in higher perplexity scores. However, using copulas results in more flexibility than assigning the same topic in each term of the sentence which is illustrated in the performance difference between *copLDA*$_{\text{sen}}$ and *senLDA*. The former being more flexible, due to the copulas, performs better. In the same line, Figure 7 illustrates the perplexity curves of the hold-out documents for the four models on three of the datasets of Table 1 for 200 Gibbs sampling iterations. Note that *senLDA* is the model with the fastest convergence rate with respect to the number of Gibbs iterations. On the other hand, LDA, *copLDA*$_{\text{sen}}$ and *copLDA*$_{\text{np}}$ require the same number of iterations, which depends on the dataset. *copLDA*$_{\text{np}}$ manages to achieve the lowest perplexity scores: notice its steep curves in the first iterations.

Extrinsic evaluation: text classification To further highlight the merits of *copLDA*, we also present in Table 1 the classification results for the datasets used. The reported scores are the averages of 10-fold cross-validation. We use the per-document topic distributions as classification features fed to Support Vectors Machines (SVMs). We have used the implementation of (Pedregosa et al., 2011) with $C = 1$ for the SVM regularization parameter. For the multi-label datasets (TED and PubMed) we employed one-versus-rest: the SVMs return every category with a positive distance from the separating hyper-planes. As one can note, *copLDA*$_{\text{np}}$ and LDA achieve the highest MiF scores in most of the datasets, without a clear advantage to one vs the other. Binding the topics of sentence words with copulas improves over the

results of *senLDA*: *copLDA*$_{\text{sen}}$ performs only slightly worse than LDA and *copLDA*$_{\text{np}}$ on most datasets and outperforms them, only slightly again, on one dataset.

5 Conclusions

We proposed *copLDA* that extends LDA to incorporate the topical dependencies within sentences and noun-phrases using copulas. We have shown empirically the advantages of considering text structure and incorporating it in LDA with copulas. In our future work we plan to integrate procedures to learn the λ parameter of Frank copulas and to investigate ways to model not only dependencies within text segments like noun-phrases, but also dependencies between such segments with nested copulas.

Abstract

Reading comprehension has embraced a booming in recent NLP research. Several institutes have released the Cloze-style reading comprehension data, and these have greatly accelerated the research of machine comprehension. In this work, we firstly present Chinese reading comprehension datasets, which consist of People Daily news dataset and Children's Fairy Tale (CFT) dataset. Also, we propose a consensus attention-based neural network architecture to tackle the Cloze-style reading comprehension problem, which aims to induce a consensus attention over every words in the query. Experimental results show that the proposed neural network significantly outperforms the state-of-the-art baselines in several public datasets. Furthermore, we setup a baseline for Chinese reading comprehension task, and hopefully this would speed up the process for future research.

1 Introduction

The ultimate goal of machine intelligence is to read and comprehend human languages. Among various machine comprehension tasks, in recent research, the Cloze-style reading comprehension task has attracted lots of researchers. The Cloze-style reading comprehension problem (Taylor, 1953) aims to comprehend the given context or document, and then answer the questions based on the nature of the document, while the answer is a single word in the document. Thus, the Cloze-style reading comprehension can be described as a triple:

$$\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$$

where $\mathcal{D}$ is the document, $\mathcal{Q}$ is the query and $\mathcal{A}$ is the answer to the query.

By adopting attention-based neural network approaches (Bahdanau et al., 2014), the machine is able to learn the relationships between document, query and answer. But, as is known to all, the neural network based approaches need large-scale training data to train a reliable model for predictions. Hermann et al. (2015) published the CNN/Daily Mail news corpus for Cloze-style reading comprehensions, where the content is formed by the news articles and its summarization. Also, Hill et al. (2015) released the Children's Book Test (CBT) corpus for further research, where the training samples are generated through automatic approaches. As we can see that, automatically generating large-scale training data for neural network training is essential for reading comprehension. Furthermore, more difficult problems, such as reasoning or summarization of context, need much more data to learn the higher-level interactions.

Though we have seen many improvements on these public datasets, some researchers suggested that these dataset requires less high-level inference than expected (Chen et al., 2016). Furthermore, the public datasets are all automatically generated, which indicate that the pattern in training and testing phase are nearly the same, and this will be easier for the machine to learn these patterns.

In this paper, we will release Chinese reading comprehension datasets, including People Daily news datasets and Children's Fairy Tale datasets. As a highlight in our datasets, there is a human evaluated

[*]This work was done by the Joint Laboratory of HIT and iFLYTEK (HFL).

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1777–1786, Osaka, Japan, December 11-17 2016.

dataset for testing purpose. And this will be harder for the machine to answer these questions than the automatically generated questions, because the human evaluated dataset is further processed, and may not be accordance with the pattern of automatic questions. More detailed analysis will be given in the following sections. The main contributions of this paper are as follows:

- To our knowledge, this is the first released Chinese reading comprehension datasets and human evaluated test sets, which will benefit the research communities in reading comprehension.
- Also, we propose a refined neural network that aims to utilize full representations of query to deal with the Cloze-style reading comprehension task, and our model outperform various state-of-the-art baseline systems in public datasets.

The rest of the paper will be organized as follows. In Section 2, we will briefly introduce the existing Cloze-style datasets, and describe our Chinese reading comprehension datasets in detail. In Section 3, we will show our refined neural network architecture for Cloze-style reading comprehension. The experimental results on public datasets as well as our Chinese reading comprehension datasets will be given in Section 4. Related work will be described in Section 5, and we make a brief conclusion of our work at the end of this paper.

2 Chinese Reading Comprehension Datasets

We first begin with a brief introduction of the existing Cloze-style reading comprehension datasets, and then introduce our Chinese reading comprehension datasets: People Daily and Children's Fairy Tale.

2.1 Existing Cloze-style Datasets

Typically, there are two main genres of the Cloze-style datasets publicly available, which all stem from the English reading materials.

CNN/Daily Mail.[1] The news articles often come with a short summary of the whole report. In the spirit of this, Hermann et al. (2015) constructed a large dataset with web-crawled CNN and Daily Mail news data. Firstly, they regard the main body of the news article as the *Document*, and the *Query* is formed through the summary of the article, where one entity word is replaced by a placeholder to indicate the missing word. And finally, the replaced entity word will be the *Answer* of the *Query*. Also, they have proposed the *anonymize* the named entity tokens in the data, and re-shuffle the entity tokens for every sample in order to exploit general relationships between anonymized named entities, rather than the common knowledge. But as Chen et al. (2016)'s studies on these datasets showed that the anonymization is less useful than expected.

Children's Book Test. [2] There was also a dataset called the Children's Book Test (CBT) released by Hill et al. (2015), which is built from the children's book story. Different from the previously published CNN/Daily Mail datasets, they formed the *Document* with 20 consecutive sentences in the book, and regard the 21st sentence as the *Query*, where one word is blanked with a placeholder. The missing word are chosen from named entities (NE), common nouns (CN), verbs and prepositions. As the verbs and prepositions are less dependent with the document, most of the studies are focusing on the NE and CN datasets.

2.2 People Daily and Children's Fairy Tale Datasets

In this part, we will introduce our Chinese reading comprehension datasets in detail[3]. Though many solid works on previously described public datasets, there is no studies on Chinese reading comprehension datasets. What makes our datasets different from previous works are listed as below.

- As far as we know, the proposed dataset is the first Chinese Cloze-style reading comprehension datasets, which will add language diversity in the community.

According to report of “New York Times”, the Wall Street stock market continued to rise as the global stock market in the last day of 2013, ending with the highest record or near record of this year. 2 ||| “New York times” reported that the S&P 500 index rose 29.6% this year, which is the largest increase since 1997. 3 ||| Dow Jones industrial average index rose 26.5%, which is the largest increase since 1996. 4 ||| NASDAQ rose 38.3%. 5 ||| In terms of December 31, due to the prospects in employment and possible acceleration of economy next year, there is a rising confidence in consumers. 6 ||| As reported by Business Association report, consumer confidence rose to 78.1 in December, significantly higher than 72 in November. 7 ||| Also as “Wall Street journal” reported that 2013 is the best U.S. stock market since 1995. 8 ||| In this year, to chase the “silly money” is the most wise way to invest in U.S. stock. 9 ||| The so-called “silly money” is that, to buy and hold the common combination of U.S. stock. 10 ||| This strategy is better than other complex investment methods, such as hedge funds and the methods adopted by other professional investors.
Query	所谓 的 “ 傻钱 ” **XXXXX**， 其实 就 是 买 入 并 持有 美国 股票 这样 的 普通 组合 。	The so-called “silly money” **XXXXX** is that, to buy and hold the common combination of U.S. stock.
Answer	策略	strategy

Figure 1: Example training sample in People Daily datasets (the English translation is given in the right box). The "**XXXXX**" represents the missing word. In this example, the document consists of 10 sentences, and the 9th sentence is chosen as the query.

- We provide a large-scale Chinese reading comprehension data in news domain, as well as its validation and test data as the in-domain test.
- Further, we release two out-of-domain test sets, and it deserves to highlight that one of the test sets is made by the humans, which makes it harder to answer than the automatically generated test set.

People Daily. We roughly collected 60K news articles from the People Daily website[4]. Following Liu et al. (2016), we process the news articles into the triple form $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$. The detailed procedures are as follows.

- Given a certain document $\mathcal{D}$, which is composed by a set of sentences $\mathcal{D} = \{s_1, s_2, ..., s_n\}$, we randomly choose an answer word $\mathcal{A}$ in the document. Note that, we restrict the answer word $\mathcal{A}$ to be a noun, as well as the answer word should appear at least twice in the document. The part-of-speech and sentence segmentation is identified using LTP Toolkit (Che et al., 2010). We do not distinguish the named entities and common nouns as Hill et al. (2015) did.
- Second, after the answer word $\mathcal{A}$ is chosen, the sentence that contains $\mathcal{A}$ is defined as the query $\mathcal{Q}$, in which the answer word $\mathcal{A}$ is replaced by a specific placeholder $\langle X \rangle$.
- Third, given the query $\mathcal{Q}$ and document $\mathcal{D}$, the target of the prediction is to recover the answer $\mathcal{A}$.

In this way, we can generate tremendous triples of $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ for training the proposed neural network, without any assumptions on the nature of the original corpus. Note that, unlike the previous work, using the method mentioned above, the document can be re-used for different queries, which makes it more general to generate large-scale training data for neural network training. Figure 1 shows an example of People Daily datasets.

Children's Fairy Tale. Except for the validation and test set of People Daily news data, we also present two out-of-domain test sets as well. The two out-of-domain test sets are made from the Children's Fairy Tale (CFT), which is fairly different from the news genre. The reason why we set out-of-domain test sets is that, the children's fairy tale mainly consists of the stories of animals or virtualized characters, and

Table 1: Statistics of People Daily datasets and Children's Fairy Tale datasets.

this prevents us from utilizing the gender information and world knowledge in the training data, which is important when solving several types of questions, such as coreference resolutions etc.

In CFT dataset, one test set is automatically generated using the algorithms described above, and the other one is made by the human, which suggest that the latter is harder than the former one. Because the automatically generated test sets are aware of the co-occurence or fixed collocation of words, and thus when the pattern around the query blank exactly appeared in the document, it is much easier for the machine to identify the correct answer. While in building human evaluation test set, we have eliminated these types of samples, which makes it harder for the machine to comprehend. Intuitively, the human evaluation test set is harder than any other previously published Cloze-style test sets.

The statistics of People Daily news datasets as well as Children's Fairy Tale datasets are listed in the Table 1.

3 Consensus Attention Sum Reader

In this section, we will introduce our attention-based neural network model for Cloze-style reading comprehension task, namely Consensus Attention Sum Reader (CAS Reader). Our model is primarily motivated by Kadlec et al. (2016), which aims to directly estimate the answer from the document, instead of making a prediction over the full vocabularies. But we have noticed that by just concatenating the final representations of the query RNN states are not enough for representing the whole information of query. So we propose to utilize every time slices of query, and make a *consensus* attention among different steps.

Formally, when given a set of training triple $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$, we will construct our network in the following way. We first convert one-hot representation of the document $\mathcal{D}$ and query $\mathcal{Q}$ into continuous representations with a shared embedding matrix W_e. As the query is typically shorter than the document, by sharing the embedding weights, the query representation can be benefited from the embedding learning in the document side, which is better than separating embedding matrices individually.

Then we use two different bi-directional RNNs to get the contextual representations of document and query, which can capture the contextual information both in history and future. In our implementation, we use the bi-directional Gated Recurrent Unit (GRU) for modeling. (Cho et al., 2014)

$$e(x) = W_e * x, \ where \ \ x \in \mathcal{D}, \mathcal{Q} \tag{1}$$

$$\overrightarrow{h_s} = \overrightarrow{GRU}(e(x)) \tag{2}$$

$$\overleftarrow{h_s} = \overleftarrow{GRU}(e(x)) \tag{3}$$

$$h_s = [\overrightarrow{h_s}; \overleftarrow{h_s}] \tag{4}$$

We take h_{doc} and h_{query} to represent the contextual representations of document and query, both of which are in 3-dimension tensor shape. After that, we directly make a dot product of h_{doc} and $h_{query}(t)$ to get the "importance" of each document word, in respect to the query word at time t. And then,

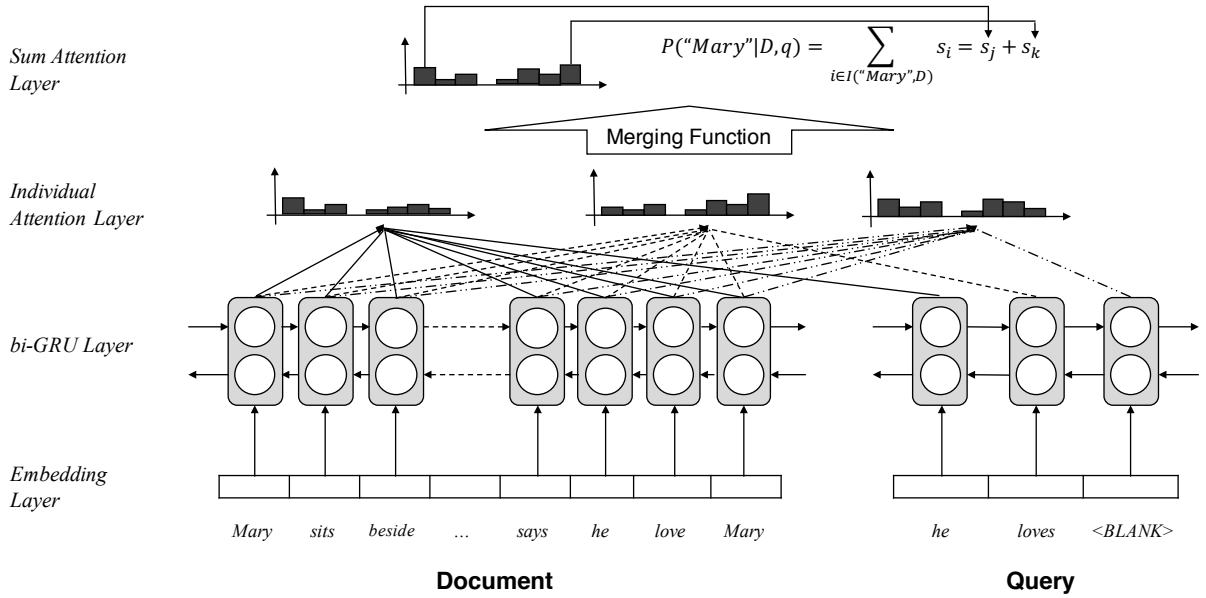

Figure 2: Architecture of the proposed Consensus Attention Sum Reader (CAS Reader).

we use the softmax function to get a probability distribution α over the document h_{doc}, also known as "attention".

$$\alpha(t) = softmax(h_{doc} \odot h_{query}(t)) \tag{5}$$

In this way, for every time step t in the query, we can get a probability distribution over the document, denoted as $\alpha(t)$, where $\alpha(t) = [\alpha(t)_1, \alpha(t)_1, ..., \alpha(t)_n]$, $\alpha(t)_i$ means the attention value of ith word in the document at time t, and n is the length of the document. To get a *consensus attention* over these individual attentions, we explicitly define a merging function f over $\alpha(1)...\alpha(m)$. We denote this as

$$s = f(\alpha(1), ..., \alpha(m)) \tag{6}$$

where s is the final attention over the document, m is the length of the query. In this paper, we define the merging function f as one of three heuristics, shown in equations below.

$$s \propto \begin{cases} softmax(\sum_{t=1}^{m} \alpha(t)), & \text{if } mode = sum; \\ softmax(\frac{1}{m} \sum_{t=1}^{m} \alpha(t)), & \text{if } mode = avg; \\ softmax(\max_{t=1...m} \alpha(t)), & \text{if } mode = max. \end{cases} \tag{7}$$

Finally, we map the attention result s to the vocabulary space V, and sum the attention value which occurs in different place of the document but shares the same word, as Kadlec et al. (2016) do.

$$P(w|\mathcal{D}, \mathcal{Q}) = \sum_{i \in I(w,\mathcal{D})} s_i, \;\; w \in V \tag{8}$$

where $I(w, \mathcal{D})$ indicate the position that word w appear in the document $\mathcal{D}$. Figure 2 shows the proposed neural network architecture.

4 Experiments

4.1 Experimental Setups

Training details of neural network models are illustrated as follows.

	Embed. # units	Hidden # units	Dropout

Vocabulary	118,497			53,063			53,185		

Table 3: Statistics of public Cloze-style reading comprehension datasets: CNN news data and CBTest NE(Named Entites) / CN(Common Nouns).

- Embedding Layer: We use randomly initialized embedding matrix with uniformed distribution in the interval $[-0.1, 0.1]$. Note that, no pre-trained word embeddings are used in our experiments.
- Hidden Layer: We initialized the GRU units with random orthogonal matrices (Saxe et al., 2013). As GRU still suffers from the gradient exploding problem, we set gradient clipping threshold to 10 in our experiments (Pascanu et al., 2013) .
- Vocabulary: For training efficiency and generalization, in People Daily and CFT datasets, we truncate the full vocabulary (about 200K) and set a shortlist of 100K. All unknown words are mapped to 10 different specific symbols using the method proposed by Liu et al. (2016). There is no vocabulary truncation in CNN and CBTest dataset.
- Optimization: We used the ADAM update rule (Kingma and Ba, 2014) with an initial learning rate $lr = 0.0005$, and used negative log-likelihood as the training objective function. The batch size is set to 32.

Other neural network setups, such as dimensions of embedding layer and hidden layer, and dropout (Srivastava et al., 2014) for each task, are listed in Table 2. We trained model for several epochs and choose the best model according to the performance of validation set. All models are trained on Tesla K40 GPU. Our model is implemented with Theano (Theano Development Team, 2016) and Keras (Chollet, 2015).

4.2 Results on Public Datasets

To verify the effectiveness of our proposed model, we first tested our model on public datasets. Our evaluation is carried out on CNN news datasets (Hermann et al., 2015) and CBTest NE/CN datasets (Hill et al., 2015), and the statistics of these datasets are listed in Table 3. No pre-processing is done with these datasets. The experimental results are given in Table 4. We evaluate the model in terms of its accuracy. Due to the time limitations, we did not evaluate our model in ensemble.

CNN News. The performance on CNN news datasets shows that our model is on par with the Attention Sum Reader, with 0.4% decrease in validation and 0.5% improvements in the test set. But we failed to outperform the Stanford AR model. While the Stanford AR utilized GloVe embeddings (Pennington et

Table 5: Results on People Daily datasets and Children's Fairy Tale (CFT) datasets.

al., 2014), and only normalized the probabilities over the named entities in the document, rather than all the words, and this could make a difference in the results. But in our model, we do not optimize for a certain type of dataset, which make it more general.

CBTest NE/CN. In CBTest NE dataset, our model gives slight improvements over AS Reader, where 0.4% improvements in the validation set and 0.6% improvements in the test set. In CBTest CN, though there is a slight drop in the validation set with 0.6% declines, there is a boost in the test set with an absolute improvements 2.3%, which suggest our model is effective, and it is beneficial to consider every slices of the query when answering.

4.3 Results on Chinese Reading Comprehension Datasets

The results on Chinese reading comprehension datasets are listed in Table 5. As we can see that, the proposed CAS Reader significantly outperform the AS Reader in all types of test set, with a maximum improvements 2.1% on the CFT test-auto dataset. The results indicate that making a consensus attention over multiple time steps are better than just relying on single attention (as AS Reader did). This is similar to the use of "model ensemble", which is also a consensus voting result by different models.

We also evaluated different merging functions. From the results, we can see that the avg and sum methods significantly outperform the max heuristics, and the max heuristics failed to outperform the AS Reader. A possible reason can be explained that the max operation is very sensitive to the noise. If a non-answer word is given to a high probability in one time step of the query, the avg and sum could easily diminish this noise by averaging/summing over other time steps. But once there is a higher value given to a non-answer word in max situation, the noise can not be removed, and will preserve till the end of final attentions, which will influence the predictions a lot.

Also, we have noticed that, though we have achieved over 65% in accuracy among People Daily datasets, there is a significant drop in the two CFT test sets. Furthermore, the the human evaluated test set meets a sharp decline over 8% accuracy to the automatically generated test set. The analyses can be

concluded as

- As we regard the CFT datasets as the out-of-domain tests, there is a gap between the training data and CFT test data, which poses declines in these test sets. Such problems can be remedied by introducing the similar genre of training data.

- Regardless of the absolute accuracies in CFT datasets, the human test set is much harder for the machine to read and comprehend as we discussed before. Through these results, we can see that there is a big gap between the automatically generated queries and the human-selected questions.

Note that, in our human-evaluated test set, the query is also formulated from the *original* sentence in the document, which suggest that if we use more general form of queries, there should be another rise in the comprehension difficulties. For example, instead of asking "I went to the **XXXXX** this morning .", we change into a general question form of "Where did I go this morning ?", which makes it harder for the machine to comprehend, because there is a gap between the general question form and the training data.

5 Related Work

Many NN-based reading comprehension models have been proposed, and all of them are attention-based models, which indicate that attention mechanism is essential in machine comprehensions.

Hermann et al. (2015) have proposed a methodology for obtaining a large quantities of $\langle \mathcal{D}, \mathcal{Q}, \mathcal{A} \rangle$ triples. By using this method, a large number of training data can be obtained without much human intervention, and make it possible to train a reliable neural network to study the inner relationships inside of these triples. They used attention-based neural networks for this task. Evaluation on CNN/DailyMail datasets showed that their approach is effective than traditional baselines.

Hill et al. (2015) also proposed a similar approach for large scale training data collections for children's book reading comprehension task. By using window-based memory network and self-supervision heuristics, they have surpass all other methods in predicting named entities(NE) and common nouns(CN) on both the CBT and the CNN QA benchmark.

Our CAS Reader is closely related to the work by Kadlec et al. (2016). They proposed to use a simple model that using the attention result to directly pick the answer from the document, rather than computing the weighted sum representation of document using attention weights like the previous works. The proposed model is typically motivated by Pointer Network (Vinyals et al., 2015). This model aims to solve one particular task, where the answer is only a single word and should appear in the document at least once. Experimental results show that their model outperforms previously proposed models by a large margin in public datasets (both CBTest NE/CN and CNN/DailyMail datasets).

Liu et al. (2016) proposed an effective way to generate and exploit large-scale pseudo training data for zero pronoun resolution task. The main idea behind their approach is to automatically generate large-scale pseudo training data and then using the neural network model to resolve zero pronouns. They also propose a two-step training: a pre-training phase and an adaptation phase, and this can be also applied to other tasks as well. The experimental results on OntoNotes 5.0 corpus is encouraging and the proposed approach significantly outperforms the state-of-the-art methods.

In our work, we proposed an entirely new Chinese reading comprehension dataset, which add the diversity to the existing Cloze-style reading comprehension datasets. Moreover, we propose a refined neural network model, called Consensus Attention-based Sum Reader. Though many impressive progress has been made in these public datasets, we believe that the current machine comprehensions are still in the pre-mature stage. As we have discussed in the previous section, to answer a *pseudo query* to the document is not enough for machine comprehension. The general question form can be seen as a comprehensive processing of our human brains. Though our human-evaluated test set is still somewhat easy for machine to comprehend (but harder than the automatically generated test set), releasing such dataset will let us move a step forward to the real-world questions, and becomes a good bridge between automatic questions and real-world questions.

6 Conclusion

In this paper, we introduce the first Chinese reading comprehension datasets: People Daily and Children's Fairy Tale. Furthermore, we also propose a neural network model to handle the Cloze-style reading comprehension problems. Our model is able to take all question words into accounts, when computing the attentions over the document. Among many public datasets, our model could give significant improvements over various state-of-the-art baselines. And also we set up a baseline for our Chinese reading comprehension datasets, that we hopefully make it as a starter in future studies.

The future work will be carried out in the following aspects. First, we would like to work on another human-evaluated dataset, which will contain the real-world questions and is far more difficult than the existing datasets publicly available. Second, we are going to investigate hybrid reading comprehension models to tackle the problems that rely on comprehensive induction of several sentences.

Abstract

In modern text annotation projects, crowdsourced annotations are often aggregated using item response models or by majority vote. Recently, item response models enhanced with generative data models have been shown to yield substantial benefits over those with conditional or no data models. However, suitable generative data models do not exist for many tasks, such as semantic labeling tasks. When no generative data model exists, we demonstrate that similar benefits may be derived by conditionally modeling documents that have been previously embedded in a semantic space using recent work in vector space models. We use this approach to show state-of-the-art results on a variety of semantic annotation aggregation tasks.

1 Introduction

Text annotation is a crucial part of natural language processing (NLP), enabling content analysis (Krippendorff, 2012) and providing training data for supervised and semi-supervised machine learning algorithms in NLP. Modern text annotation is often crowdsourced, meaning that the work is divided up and assigned to internet workers on micro-task marketplaces such as Amazon's Mechanical Turk[1] or CrowdFlower.[2] Although crowdsourced annotations tend to be error-prone, high quality labels may be obtained by aggregating multiple redundant low-quality annotations (Surowiecki, 2005). For many tasks, aggregated crowdsourced judgments have been shown to be more reliable than expert judgments (Snow et al., 2008; Cao et al., 2010; Jurgens, 2013).

Traditionally annotations were aggregated via majority vote. More sophisticated approaches jointly model annotator reliability and document labels. These models can down-weight the annotations of workers who often disagree with others and up-weight the annotations of workers who often agree with others. However, when annotation error is high or few annotations are available it can be difficult for these models to know which annotators to trust. Jin and Ghahramani (2002), Raykar et al. (2010), Liu et al. (2012), and Yan et al. (2014) show that crowdsourcing annotation models can be enhanced by conditioning the model on the document data (e.g., word content), improving the model by identifying annotators whose judgments tend to agree with word patterns found in the documents being annotated.

Recent work has shown that generative data models allow crowdsourcing models to converge to useful estimates even when few annotations are available, whereas by the time a conditional model has enough information (in the form of annotations) to be useful, the problem is often largely solved by majority vote (Felt et al., 2015b). However, although generative data modeling has been shown to be effective in categorizing text according to its topic, realistic generative data models are not always available. In this paper, we use advances in text representation to demonstrate that data-conditional annotation models can

achieve gains similar to those of data-generative annotation models, including for tasks where generative data models are currently unavailable, such as paired text similarity and compatibility.

In Section 2 we briefly review annotation models with generative and conditional data components and also discuss representing words and documents via embeddings in a semantic vector space. In Section 3 we show that data-conditional annotation models succeed on a variety of text datasets and classification tasks. In Section 4 we conduct error analysis on an anomalous dataset, and in Sections 5 and 6 we list additional related work and summarize our conclusions.

2 Background

Most crowdsourcing models extend the item-response model of Dawid and Skene (1979). The Bayesian version of this model, referred to here as ITEMRESP, is illustrated by Figure 1a and defines the joint distribution $p(y, a, \theta, \gamma)$, where a is the annotation and y is an unobserved document label. In the generative story for this model, a confusion matrix γ_j is drawn for each human annotator j. Each row γ_{jc} of the confusion matrix γ_j is drawn from $Dir(b^{(\gamma)}_{jc})$, and encodes a probability distribution over label classes that annotator j is apt to choose when presented with a document whose true label is c. A general prior over label classes θ is drawn from $Dirichlet(b^{(\theta)})$, then for each document d an unobserved document label y_d is drawn from categorical distribution $Cat(\theta)$. Finally, annotations are generated as annotator j corrupts the true label y_d according to the multinomial distribution $Mult(\gamma_{jy_d})$.

2.1 Data-aware annotation models

Notice that the ITEMRESP model entirely ignores document data x (e.g., words). ITEMRESP extensions model the data x and related feature parameters ϕ either conditionally $p(y, a, \gamma, \phi|x)$ or else generatively $p(y, a, x, \theta, \gamma, \phi)$.

Conditional crowdsourcing models make few assumptions about the data and can use the same general log-linear structure as maximum entropy classifiers, which have enjoyed success in a large number of classification problems. Figure 1b shows a Bayesian formulation of a conditional crowdsourcing model $p(y, a, \gamma, \phi|x)$. For each class k, ϕ_k is drawn from a multivariate Gaussian distribution $Gauss(0, \Sigma)$. Then for each document, y_d is drawn from a log-linear distribution $p(y_d|\phi, x) \propto e^{\phi_{y_d}^T x}$. For this reason we refer to this model as LOGRESP. LOGRESP is representative of a popular class of conditional crowdsourcing models (Jin and Ghahramani, 2002; Raykar et al., 2010; Liu et al., 2012; Yan et al., 2014). In previous work we found that LOGRESP often provides only incremental gains over majority vote (Felt et al., 2015b). This partly because its ϕ estimates, like other conditional models, tend to converge relatively slowly with $O(N)$ labeled examples (Ng and Jordan, 2001). By the time LOGRESP's ϕ estimates become useful, there are often enough annotations available that majority vote is sufficient.

Generative data-aware crowdsourcing models have complementary strengths. Although they make strong assumptions about the data that they model, their parameters can converge quickly with only $O(logn)$ labeled examples (Ng and Jordan, 2001). This means that when data does not violate a generative model's assumptions too badly, the generative model can offer dramatic improvements over majority vote, especially when few annotations are available. Figures 1c and 1d depict two such generative models. In Figure 1c, each document d draws its data x_d from a class-conditional multinomial word distribution $Mult(\phi_{y_d})$. We call this model MOMRESP because it models data as a mixture of multinomials. MOMRESP represents a common class of generative crowdsourcing models (Bragg et al., 2013; Lam and Stork, 2005; Simpson and Roberts, 2015). Figure 1d shows CSLDA, a more sophisticated generative crowdsourcing model based on supervised topic modeling (Felt et al., 2015a).

For inference in the ITEMRESP, LOGRESP and MOMRESP crowdsourcing models, we use existing variational inference (Felt et al., 2015b). Note that variational inference for ITEMRESP is easily derived as a special case of MOMRESP inference where terms involving the data are dropped. Inference for CSLDA is stochastic expectation maximization.

2.2 Word and Document Representations

Documents have historically been represented in NLP algorithms by large, sparse word count vectors $x_d = \sum_{n=1}^{|x_d|} \mathbb{1}(x_{dn})$ where $\mathbb{1}(x_{dn})$ is a one-hot vector having length equal to the size of the vocabulary. However, word-count document representations have a number of drawbacks. They define a space that is often so high-dimensional and sparse that inter-document distances and other vector computations have little meaning. In word-count representations, features that strongly relate to one another (e.g., the words "horse" and "equine") are represented as entirely orthogonal dimensions, exploding the number of parameters needed by downstream learning algorithms.

Recently, methods have been developed to represent words as locations in low-dimensional vector spaces where distance and direction encode semantic and syntactic meaning (Mikolov et al., 2013a; Pennington et al., 2014). These embedding vectors have been shown to improve a variety of language tasks including named entity recognition, phrase chunking (Turian et al., 2010), relation extraction (Nguyen and Grishman, 2014), and part of speech induction (Lin et al., 2015). The hypothesis investigated by the current work is that semantic, vector-based text representations can help conditional annotation aggregation models achieve some of the same early performance advantage seen in their generative counterparts, as well as help them operate on datasets that make semantic distinctions. This hypothesis is plausible *a priori* because using data embeddings is akin to using semi-supervision to enable faster learning. The reason for this is that data embeddings are traditionally induced in an unsupervised manner on extremely large corpora before being applied to a downstream supervised task. In addition, operating on dense, low-dimensional vector data reduces the number of model parameters which can also reduce the number of instances required to learn effectively.

Although it might be possible to extend the CSLDA model to generatively model the embedding as described by Das et al. (2015), but it is unclear how the inference approach used there (Gibbs sampling based on Cholesky decompositions) would be efficiently applied in the context of the CSLDA model, thus we leave this possibility to future work and focus on using embeddings discriminatively. We use the

Dataset	Size	Unique Annotators	Annotations per Instance	Classes	Average Doc size	Gold Labels	Timestamps
Sentiment	1,000	83	5	2	12.8	1,000	No
Weather	1,000	102	20	5	13.6	724	Yes
Compatibility	17,977	411	10	2	2×1	15,157	No
Paraphrase	4,000	119	5	2	2×11.2	838	Yes

Table 1: Dataset statistics. Evaluation metrics are calculated only over the subset of each dataset for which gold labels are available. The timestamps column indicates whether or not it is known exactly when each annotation was generated. When available, timestamps determine the order of annotation in reported learning curves.

word2vec algorithm introduced by Mikolov et al. (2013a) to convert words to vectors for the purposes of this paper, understanding that other text embedding methods may be swapped in for additional improvements as they are developed. Word2vec operates on individual words. When sentences or documents must be vectorized, we do so by averaging the vectors of each word in the sentence or document without any word filtering or selection. While we briefly experimented with gensim's *doc2vec* implementation of Le and Mikolov (2014), we noticed little benefit for the twitter data explored in this paper, possibly because of the short, focused nature of tweets.

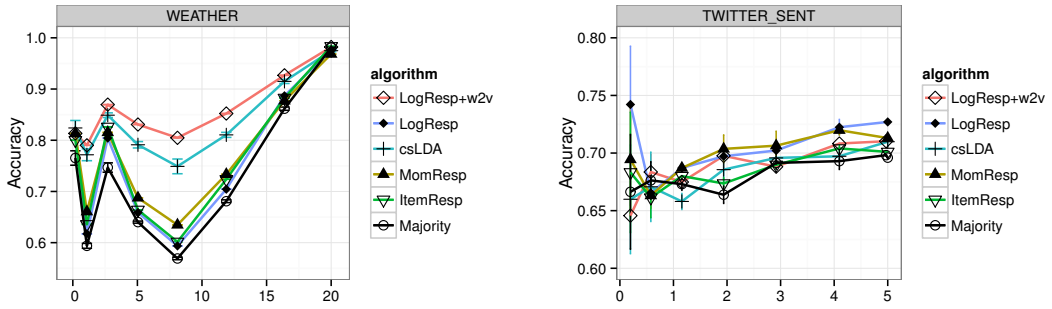
3 Experiments

In order to test the hypothesis that vector space document representations can improve conditional crowdsourcing model performance on semantic classification tasks, we plot and visually compare learning curves charting the accuracy of the labels inferred by various crowdsourcing models. All of the algorithms from Section 2 are trained on sparse one-hot vector representations of text; and an additional variant of LOGRESP is reported which is trained on low dimensional semantic vector representations (LOGRESP+w2v). Learning curves advance as annotations from multiple annotators are incrementally added to the set of annotations available to each model. When annotation timestamps are available, annotations are added in the empirical order in which they were created. When unavailable, annotations are added in randomized breadth-first order so that each document gets one annotation before any document receives a second. Accuracy is computed over the subset of gold labels having at least one annotation. This process illustrates model behavior both when few annotations per document are available (in the early stages of learning curves) and when many annotations per document are available (in the late stages of the learning curves).

For our word embedding model, we use the word2vec algorithm, implemented by the gensim document processing library (Řehůřek and Sojka, 2010) to train word embeddings on a June 2015 snapshot of the English Wikipedia pages and articles dump (approximately 2.1 billion words). The word2vec algorithm requires a number of parameters, which we report here for replicability. We train embeddings using a context window of 10 words, discarding words that occur fewer than 5 times. For training, we use hierarchical sampling with a skip-gram model and no negative sampling. Embeddings of size 300 are learned. All of these settings are rather standard for a large corpus like Wikipedia.

3.1 Datasets

In order to calculate the accuracy of inferred labels, we require datasets that have both crowdsourced annotations as well as gold standard labels for evaluation. We identify four suitable datasets, briefly describing both their annotation task as well as the way their gold standard labels are constructed. For all Twitter data, we use the Twitter text normalization dictionary of Han et al. (2012) to normalize tweets before embedding them. Note that for two of the datasets described below, **Compatibility** and **Weather**, the gold standard does not consist of the hand labels of an expert, but rather is constructed from the consensus vote of a reasonable number of crowd workers. A fundamental tenet of crowdsourcing is that



(a) The **Weather** Dataset (b) The **Sentiment** Dataset

Figure 2: Inferred label accuracy (y axis) learning curves of various crowdsourcing models. The x axis is the number of annotations $\times$ 1,000.

inexpert workers are, in aggregate, trustworthy. The purpose of automatic aggregation models such as those decribed in Section 2 is to arrive at the same judgment with a few annotations that a simpler scheme like majority vote would have arrived at given many annotations. Therefore, a crowd-constructed gold standard is appropriate for evaluation of such models.

Paraphrase. During an exploratory annotation phase, Xu et al. (2014) paid Amazon Mechanical Turk workers to annotate 4,000 tweet pairs with binary judgments indicating whether or not the tweet pair communicates the same information.[3] For example, the tweets "Star Wars Return of the Jedi is on" and "My favorite Star Wars movie is on" communicate mostly the same information and are labeled as paraphrases of one another, while the tweet "and of course because I drink and like Star Wars I know nothing about football" communicates different information, and is labeled as not a paraphrase of the other two tweets. Each tweet pair received 5 binary annotations. Gold standard labels were constructed for a subset of 838 tweet pairs by experts who rated each pair on a scale from 0-5. Following the original authors, expert ratings of 0-2 are labeled *no paraphrase*, and 4-5 are labeled *paraphrase*. Ratings of 3 are ignored for evaluation purposes.

Compatibility. Kruszewski and Baroni (2015) paid CrowdFlower workers to rate word pairs according to their semantic compatibility, meaning that the two words can be used to refer to the same real-world entity.[3] For example, the words "artist" and "teacher" are compatible with one another, whereas "bread" and "rattlesnake" are not. Each word pair was rated by 10 different annotators on a 7-point scale. Following the original authors, the gold standard is constructed by labeling items with a mean rating less than 1.6 as incompatible, and those with a mean rating greater than 3.7 as compatible. Ratings between 1.7 and 3.7 are ignored for evaluation purposes.

Sentiment. Mozafari et al. (2014) paid Mechanical Turk workers to annotate tweets with binary sentiment labels: *Positive* and *Negative*, and manually created gold standard labels using trusted (non-crowdsourced) labelers.[4]

Weather. CrowdFlower has made a number of annotated datasets freely available.[5] In their "Weather sentiment" dataset, 20 annotators were paid to annotate weather-related tweets with sentiment labels: *Negative*, *Neutral*, *Positive*, *Unrelated to weather*, and *I can't tell*. A gold standard was constructed by running a separate evaluation task called "Weather sentiment evaluated" in which 10 additional annotators were paid to annotate the majority vote label from the previous task as correct or incorrect. We form a gold standard from those labels that are judged to be correct by at least 9/10 annotators.

Our focus in this paper is on challenging sentiment classification tasks which tend to have few classes. In preliminary experiments we observed that even on topical classification datasets such as 20 Newsgroups or the LDC-labeled Enron emails, LOGRESP is perceptibly improved by running on vector space features, although CSLDA remains dominant. Note that in the experiments described below, the **Weather** and **Paraphrase** annotations are applied in the order indicated in the dataset, however, the ac-

tual order of **Sentiment** and **Compatibility** annotations is not provided in the data set so they are applied in random order.

3.2 Comparison with generative methods

Two datasets, **Weather** and **Sentiment**, are traditional text classification tasks with instances consisting of one label per text document. We use these datasets to compare the performance of LOGRESP trained on vector space text features (LOGRESP+w2v) to the performance of alternatives using sparse word-count features, including LOGRESP as well as the generative models MOMRESP and CSLDA. The majority vote and ITEMRESP algorithms serve as baselines. In Figure 2a we see that on the **Weather** dataset, LOGRESP with embeddings (LOGRESP+w2v) performs far better than traditional LOGRESP, and even outperforms the previous state-of-the-art for this dataset, CSLDA. Although all algorithms eventually reach a high level of performance on the **Weather** dataset, we prefer algorithms like LOGRESP+w2v that reach high levels of accuracy using as few annotations as possible, potentially reducing annotation cost. The accuracy of all of the models is unstable until a reasonable number of annotations is obtained, 5,000 to 10,000 in this case. Models which make little or no use of the words themselves (especially Majority vote and ITEMRESP) are particularly susceptible to variability in the initial annotations. Data-sensitive models like CSLDA and LOGRESP+w2v are far less susceptible to these swings.

In Figure 2b we see that no algorithm improves much over majority vote on the **Sentiment** dataset. Also, the baseline accuracy levels at the end of the curves are extremely low for a binary classification task with 5 annotations per instance, meaning that annotator accuracy is unusually low. We include this dataset as a reminder that the "no free lunch" theorem applies to crowdsourcing models the same as to any other class of models. In Section 4 we explore in more detail what makes the **Sentiment** dataset particularly difficult for crowdsourcing models.

3.3 When generative methods are unavailable

The datasets **Compatibility** and **Paraphrase** both involve data pairs being compared for semantic content (see Section 3.1 for examples of these tasks). **Compatibility** compares the semantic compatibility of word pairs while **Paraphrase** compares the semantic similarity of tweets pairs. Generative crowdsourcing models such as MOMRESP and CSLDA do not natively accommodate such paired data since the data does not comport with these models' generative stories. To make them do so would require restructuring the models and their inference procedures. On the other hand, it is straightforward to combine the semantic vector representations of two documents v_1 and v_2. We do so by forming a new feature vector

$$\begin{aligned} v_{new} = &\langle cos(v_1, v_2), \\ &L1(v_1 - v_2), L2(v_1 - v_2), \\ &PC_{50}(v_1), PC_{50}(v_2), \\ &PC_{50}(v_1) - PC_{50}(v_2)\rangle \end{aligned}$$

		Alternative Gold Standard			
		Neg	Pos	None	Hard
Gold Standard	Neg	35	**6**	**5**	**1**
	Pos	**9**	29	**11**	**3**

Table 2: Disagreement between the original gold standard (rows) and an alternative gold standard (columns) on 100 arbitrarily selected tweets. The alternative gold standard employs a more flexible label set. Neg=*Negative*, Pos=*Positive*, None=*No sentiment*, Hard=*Can't decide*. Bold values reflect various kinds of disagreement between the labelings.

where $cos(\cdot)$ is cosine distance, $L1(\cdot)$ and $L2(\cdot)$ are the first two p-norms, and $PC_n(v)$ is a vector consisting of the top-n components of v, found via PCA on the set of embedded documents.

Figure 3a shows that LOGRESP with semantic embeddings outperforms majority vote and ITEMRESP baselines on the word **Compatibility** dataset when there are fewer than 3 annotations per instance. Later in the learning curve, when annotations become sufficiently abundant (up to 20 per instance), the data appears to no longer be helpful. Fortunately, incorporating data information using LOGRESP with semantic embeddings appears to never actually hurt compared with using just ITEMRESP.

On the other hand, Figure 3b shows that on the **Paraphrase** dataset, LOGRESP with semantic embeddings dramatically outperforms the baselines along the entire learning curve. This is partly because, unlike the **Compatibility** task, **Paraphrase** accuracy is low enough to permit the improved vector data representation to benefit LOGRESP.

3.4 Summary of experiments

Overall, with the exception of the somewhat anomalous **Sentiment** dataset, which we examine in more detail in Section 4, running LOGRESP on semantically embedded data is always an improvement over LOGRESP running on traditional document representations. The gains in Figures 3a and 3b strongly confirm the hypothesis that semantic embeddings can allow crowdsourcing models to see some of the same efficiency gains for challenging semantic labeling tasks as previously observed using generative data-aware crowdsourcing models on more straight-forward topical labeling tasks. Not only that, but the fact that semantic embeddings lend themselves to sensible vector-space operations allows data-aware crowdsourcing models to be applied to complex tasks like labeling paired text similarity and compatibility, which was not previously possible.

4 Sentiment dataset error analysis

An analysis of the **Sentiment** dataset (results in Figure 2b) helps explain why algorithms behave so differently on it than on the other datasets. Kilgarriff (1998) identifies three sources of annotation noise: inherent data ambiguity, poor task definition, and annotator error. The crowdsourcing models used here account only for annotator error. However, the **Sentiment** dataset task definition dictates that each tweet be labeled with a binary sentiment label, forcing annotators to make arbitrary decisions when tweets encode little or ambiguous sentiment. For example, the tweet "EBTM.com is BACK?!" is genuinely ambiguous, and the tweet "@comeagainjen if you dont, neither do i" contains little explicit sentiment. Kilgarriff (1998) suggests that an important step towards addressing data ambiguity is ensuring that tasks are defined so that annotators have the ability to explicitly identify ambiguous instances.

To assess the impact of inherent data ambiguity and task definition on the **Sentiment** dataset, we arbitrarily chose 100 instances with gold labels and compared them with an alternative gold standard labeled according to a more flexible annotation scheme. The latter labels were generated by a pair of graduate students working in tandem. We added a *No sentiment* label to address problems with task definition and a *Can't decide* label to capture inherent data ambiguity. Table 2 shows the confusion matrix between the two gold standard sets. A large percentage (16%) of tweets were assigned to *No sentiment* in the alternative gold standard. This indicates that task definition affects this dataset strongly.

Although this analysis does not make this dataset any less interesting (indeed, the problems associated with modeling and correcting the effects of task misspecification are highly interesting), it does warn us that it is less representative than the others of annotation projects where effort is made up-front to iteratively refine an annotation specification before paying for large number of annotations.

5 Additional Related Work

A sizable body of research is currently underway to improve vector word representations. Although most commonly word embeddings are trained in an unsupervised manner, they may be tuned to maximize performance on a particular target task (Le and Mikolov, 2014). They may also be supervised by multiple tasks simultaneously (Collobert et al., 2011). Others fit one embedding per word sense rather than per lexical type, improving model fit (Neelakantan et al., 2014). Srikumar and Manning (2014) embed not only word types, but also label types, modeling the fact that some labels are more similar than others.

Another line of work explores ways of embedding larger spans of text. Although words tend to compose surprisingly well simply via linear combination, many phrases are more than the sum of their parts (e.g., collocations like "White House"). These can be dealt with by using heuristics to identify and combine token phrases (Mikolov et al., 2013b). Other approaches incorporate composition functions as first-class constituents of the objective function itself. Mitchell and Lapata (2010) motivate a general composition framework and compare a number of simple instantiations, including additive, multiplicative, and tensor product combination. Socher et al. (2012) assign vectors representing semantic content and matrices representing semantic transformations to every node in a parse tree. Fyshe et al. (2015) focus on learning phrasal representations whose dimensions are easily interpretable by humans, similar to successful models whose topics are easy for humans to recognize and name because they align with a topic distinction known *a priori* to the human.

In this work we focus on using instance data to improve probabilistic crowdsourcing models. Passonneau and Carpenter (2014) argue that probabilistic crowdsourcing models are generally more effective and reliable than traditional chance-adjusted agreement heuristics such as Krippendorff's alpha for assessing corpus quality (Krippendorff, 2012). Other previous work in crowdsourcing ignores the data being annotated, focusing instead on modeling other aspects of the annotation process, such as item difficulty and noise (Whitehill et al., 2009; Welinder et al., 2010). Hovy et al. (2013) model the nonlinear nature of human reliability by adding binary variables to each annotator indicating whether they are a spammer or not. These extensions are orthogonal to the issue explored by this paper and could be incorporated into any of the models used here.

6 Conclusions and Future Work

Previous work indicates that generative crowdsourcing models enjoy significant learning advantages when aggregating topic-based document labels. Unfortunately, some text classification tasks make distinctions for which no good generative text models currently exist, such as labeling the similarity or compatibility of paired words and sentences. We have demonstrated that vector space text embeddings can be used to gain similar advantages using conditional models and for an even broader class of data. Using this approach, we have shown state-of-the-art annotation aggregation for several semantic annotation aggregation tasks. Future work includes experimenting with deep learning methods of jointly learning embeddings and hidden labels, rather than pipelining the two tasks.

Abstract

Interactive-predictive machine translation (IPMT) is a translation mode which combines machine translation technology and human behaviours. In the IPMT system, the utilization of the prefix greatly affects the interaction efficiency. However, state-of-the-art methods filter translation hypotheses mainly according to their matching results with the prefix on character level, and the advantage of the prefix is not fully developed. Focusing on this problem, this paper mines the deep constraints of prefix on syntactic level to improve the performance of IPMT systems. Two syntactic subtree matching rules based on phrase structure grammar are proposed to filter the translation hypotheses more strictly. Experimental results on LDC Chinese-English corpora show that the proposed method outperforms state-of-the-art phrase-based IPMT system while keeping comparable decoding speed.

1 Introduction

In recent years, the machine translation (MT) technology has achieved great progress. However, up till now the MT output still cannot meet the practical requirements on translation quality in many scenarios, and need to be post-edited by human translators before actually put to use. In order to help MT systems collaborate with human translators more effectively, researchers carried out the study on computer-assisted translation (CAT), in which the main goal of MT is supporting professional translators in improving their productivity. Therefore, the ability to interact with human becomes an important research topic in CAT.

The first interactive machine translation systems (Kay and Martins, 1973; Zajac, 1988; Yamron et al., 1993) focus on having human translators disambiguate the source texts through answering questions. However, this question-answering process remains a laborious one for human translators. Under such circumstances, the interactive-predictive machine translation (IPMT) method is proposed (Foster et al., 1997). In the IPMT mode, first the system generates one or more raw suggestions, and then the human translator validates the longest correct prefix in the suggestions and revises the first character in the corresponding suffix, next the new prefix is used to help the system predict the optimal suffix. This process is repeated until the correct translation is acquired. The IPMT technology enables human translators to avoid the burden of explaining the source text, and directly control the final translation generation, so it attracted widespread attention.

It can be seen that the essential difference between IPMT and MT is the introduction of a constraint, namely the target sentence must start with the human validated prefix. To achieve this goal, researchers attempted various MT models (Och et al., 2003; Civera et al., 2004; Tomás and Casacuberta, 2006; Barrachina et al., 2009; González-Rubio et al., 2013). In these methods, prefix is mainly used for performing character-level matching on translation hypotheses to reduce the search space. However, the hypotheses that only match the prefix on character level are perhaps not correct. Figure 1 gives an ex-

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1797–1806, Osaka, Japan, December 11-17 2016.

ample.

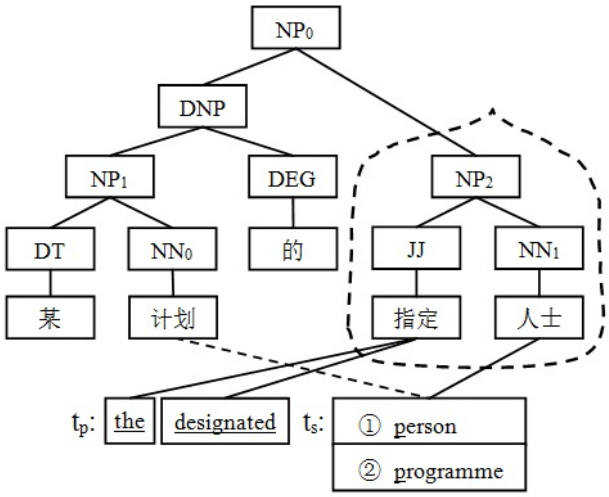

Figure 1: Example of translation hypothesis selection on character level.

In Figure 1, the validated prefix is "the designated p". Two hypotheses that start with "the designated person" and "the designated programme" both meet the requirement. If we use "person" to extend the prefix (see the alignment by solid line), then the hypothesis will form a complete subtree translation (circled by dashed line). But if we use "programme" to extend the prefix, then an error will occur. The circled subtree has only been partly translated before the hypothesis turns to translate another subtree (see the alignment by dashed line). In the future interactions, no matter how to extend the hypothesis, no reasonable syntactic alignment will be generated. Therefore, other than character-level matching results with the prefix, we should also take syntactic-level matching results into account for hypothesis selection. Only when a reasonable syntactic alignment is formed between the hypothesis and the source sentence, can we decide this is a good hypothesis.

In this paper we present a mathematical IPMT framework based on the syntactic alignment between the source sentence and the prefix. On the basis of the framework, we proposed two syntactic subtree constraints based on phrase structure grammar for selecting translation hypotheses. Experimental results on LDC corpora show that our method reduced the human-computer interaction times under comparable decoding speed.

2 Related Work

The task of IPMT (Barrachina et al., 2009) is to find the optimal suffix under the condition of a given source sentence s and a validated prefix t_p:

$$\hat{t}_s = \underset{t_s}{\operatorname{argmax}}\ P(t_s \mid s, t_p) = \underset{t_s}{\operatorname{argmax}}\ P(t_p, t_s \mid s) \quad (1)$$

where $(t_p, t_s)=t$, indicating that the prefix t_p and the predicted suffix t_s concatenate to form a complete translation t.

As previously discussed, when modelling $P(t_p, t_s \mid s)$, current methods mainly make use of the character-level matching results with the prefix. To enhance the guiding effect of the prefix, some work also considered other factors.

Sanchis-Trilles et al. (2008) integrates the user's mouse actions into the IPMT system. The method is based on an assumption that the first character of the predicted suffix must be different from the current suffix when the user clicks the mouse on the translation. In this way, the clues hidden in the prefix are further exploited. However, this method still restricted to character or word level matching.

Some researchers investigated the word alignment between the prefix and the source sentence. Nepveu et al. (2004) proposed a cache-based adaptive prediction model. For the predicted translation w of each active word a, once the user accepts w, a word pair (a, w) will be stored in the cache. Higher language model probability and translation probability will be assigned to w if a new source sentence

contains the word *a*. Ortiz-Martínez et al. (2009) performs word alignment between the prefix and the source sentence. The generation of suffix is limited to the translation of the unaligned parts in the source sentence. These methods deepened the prefix matching level, but still did not reach the syntactic level.

González-Rubio et al. (2013) adopts hierarchical phrase-based model (HPBM) to IPMT. Because HPBMs are on the basis of synchronous grammar, the prefix can guide decoding on a deeper level. However, the synchronous grammar in hierarchical phrases has no linguistic meaning, and cannot evaluate the reasonableness of the hypotheses from the view of syntactic structure.

Compared with the above research, our method made use of the prefix on syntactic level. The hypotheses for which it is impossible to generate reasonable syntactic structure alignment with the source sentence are identified and filtered.

3 IPMT Mathematical Model

In this paper, we examine the syntactic alignment between the source sentence s and t_p when we make use of the prefix. A hidden variable $T(s)$ is introduced to represent the parse tree of s. Consequently, $P(t_p, t_s \mid s)$ is converted to:

$$P(t_p, t_s \mid s) = \sum_{T(s)} P(t_p, t_s, T(s) \mid s) \tag{2}$$

The item on the right side is further deduced with:

$$P(t_p, t_s, T(s) \mid s) = P(T(s) \mid s) \times P(t_p \mid T(s), s) \times P(t_s \mid t_p, T(s), s) \tag{3}$$

The first factor on the right side is the syntactic parsing model of the source language, which is provided by the parser. The second factor corresponds to the transformation from the source sentence to the prefix, which is the machine translation model. So the two models need not be discussed. The third factor is the key model of this paper, which corresponds to the prediction of suffix t_s. We will emphasize on the modelling of this factor.

There are two ways to model $P(t_s \mid t_p, T(s), s)$. One is completely adopting the syntax-based MT framework and performing prefix matching during decoding. The other is adding syntactic information into the PBM-based SMT framework as rules. In comparison, the former way is more straightforward, but it is prone to be influenced by the performance of parsing and translation rule extraction algorithms. Incorrect parse tree of the source sentence and incorrect translation rules can both lead to the consequence that the prediction will never succeed. Although some researchers proposed forest-based translation approaches (Mi and Huang, 2008; Zhang et al., 2009) to avoid relying on 1-best parse tree, the computation costs of these approaches are too high for the IPMT systems which have strict speed requirements. The latter way allows the existence of non-syntactic phrases and has larger search space. To alleviate the negative effect of wrong parsing results, we can filter the hypotheses only when there is more than one candidate. In other words, the syntactic structure can play the role as soft constraints if we adopt relatively tolerant syntactic tree matching rules. Once the prefix of a hypothesis has the possibility of being correctly aligned to the source-language parse tree, the hypothesis will be kept. In this way, the system can be more error-tolerant. Therefore, we built the model in the latter way and adopted the phrase-based model (PBM) as in (Barrachina et al., 2009).

We introduce a hidden variable A to represent the phrase alignment between t_p and $T(s)$. The third factor of Equation 3 can be transformed to:

$$P(t_s \mid t_p, T(s), s) = \sum_{A} P(t_s, A \mid t_p, T(s), s) \tag{4}$$

This paper estimates the factor on the right side as follows:

$$P(t_s, A \mid t_p, T(s), s) = \begin{cases} P(t_s \mid t_p, s) & \text{if } \xi(t_p, A, T(s)) = \text{TRUE} \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

where $\xi(t_p, A, T(s))$ is a function to judge whether the alignment A conforms to the syntactic tree matching rules. The goal is to decide whether there is possibly correct syntactic alignment between the prefix and the source sentence.

4 Hypothesis Selection

Generally, syntactic structure can be represented or labelled by two forms. One is the phrase structure grammar (PSG), and the other is the dependency structure grammar (DSG). In this paper we choose PSG for the extension of prefix. There are two reasons: first, PSG can clearly give the syntactic component borders (subtrees) with complete linguistic meaning; second, the PSG parsers mainly use probabilistic context-free grammar (PCFG), and the produced N-gram translation rules can well model the orders of the syntactic components. Such information can straightforwardly direct the extension of translation hypotheses. But the dependency grammar describes the binary head-modifier structure, so it is inefficient for the PBM model which takes multi-word phrases as the basic processing units.

In order to use the syntactic structure of the source sentence to guide the prefix extension, we analysed the nature of the prefix and propose two subtree matching rules (or constraints) which should be followed while selecting translation hypotheses.

4.1 Complete Subtree Constraint

This constraint requires that the selection of the phrase to extend the prefix needs to consider whether the current subtree[1] has been completely translated. Figure 2 gives an example.

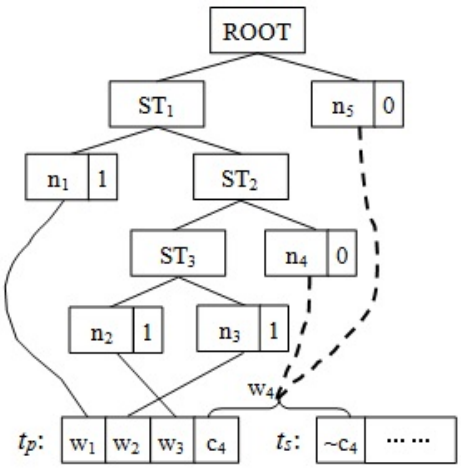

Figure 2: Translation hypothesis extension based on complete subtree constraint.

In Figure 2, the prefix t_p consists of complete words w_1, w_2, w_3 and an incomplete word c_4. The suffix t_s starts with an incomplete word $\sim c_4$. c_4 and $\sim c_4$ together form a complete word w_4. The data structure of node n_i records the information whether the word has already been translated (1 for *yes*, 0 for *no*). In this example, n_1, n_2 and n_3 are translated nodes (the word alignments are indicated by solid lines), n_4 and n_5 are untranslated nodes. If the translations of n_4 and n_5 can both be used to extend w_3 (indicated by dashed lines), then we need to examine the subtree (ST_1) to which n_2 belongs. Since there is still a node n_4 left untranslated in the subtree, n_4 should be chosen to perform extension.

The core of the complete subtree constraint is to judge whether the subtree to which the phrase to be extended belongs has been completely translated. Since a subtree may be nested in another subtree, it is possible that the same phrase is contained in multiple subtrees. In this paper we select the subtree with the minimum span to constrain the hypothesis extension.

After deciding the subtree ST to constrain hypothesis extension, the phrase p_1 which is to be extended and the phrase p_2 which is to extend p_1 are examined. Through checking the positions of the words covered by p_1 in the source sentence, the words not covered by subtree ST can be found. Because there

[1] In this paper, since it is meaningless to examine nodes under the complete tree S, the term "subtree" refers to proper subtree and does not include the complete tree.

are re-orderings in the translation, the positions of these words are perhaps not continuous. Therefore, the translation hypotheses should meet the following requirements: a) the positions of the source words covered by p_2 are fully contained in the span of the subtree; or b) the positions of the source words covered by p_2 are continuous and are located at the tail of the source words covered by the subtree, and the source words covered by p_1 fully cover the remained positions of the subtree.

4.2 Subtree Order Constraint

This constraint requires that the selection of the subtree to be extended (translated) needs to consider the overall structure of the syntactic tree and the re-ordering rules. Figure 3 gives an example.

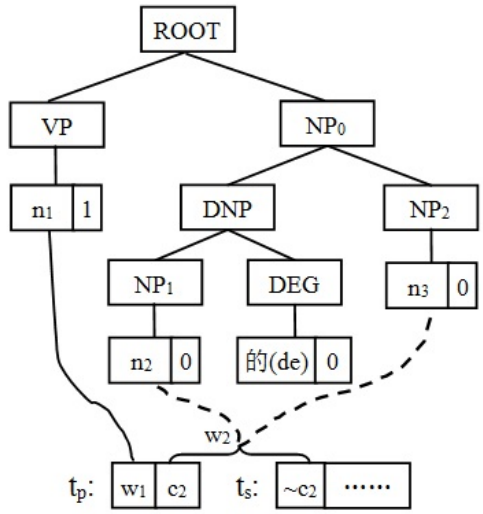

Figure 3: Translation hypothesis extension based on subtree order constraint.

In Figure 3, the prefix consists of a complete word w_1 and an incomplete word c_2. The suffix t_s starts with an incomplete word $\sim c_2$. If the translations of n_2 and n_3 can both be used to extend w_1, then we need to examine the subtrees to which n_2 and n_3 belongs. This example possesses an "NP_1 *de* NP_2" structure. According to the re-ordering rules, it should be translated into "NP_2 *of* NP_1". This means that we should choose the subtree to which n_3 belongs to perform extension.

We use the NiuTrans (Xiao et al., 2012) system to generate tree-to-string translation rules to evaluate whether the order of the subtrees are reasonable. First perform syntactic parsing on the source sentence and get the parse tree T; then identify all the subtrees ST_i in T and record the child nodes LC_i (left child) and RC_i (right child) of the root node of each subtree; next use these subtree structures to filter the candidate translation rule set RT that can be used by the current sentence. During decoding, the hypothesis with highest score that matches the translation rules is selected for extension.

The key of this constraint is judging whether the phrase p_1 to be extended and the phrase p_2 to extend p_1 are closely adjacent in the translation rule. To achieve this goal, we need to identify the minimum common subtree MCT of the source phrases corresponded to p_1 and p_2, and then use the translation rules that match this subtree to perform judging.

Since the translation rule base cannot fully cover all the syntactic structure instances, this paper generalized the subtree to acquire the rules that nearly match. If the needed rule is not in the rule base, then the subtrees in MCT will be generalized to their parent nodes from bottom to up. As long as any translation rule can match a generalized subtree, the new parent node will replace the child nodes for order judgement.

4.3 Balancing Strategies

During decoding, the two constraints go forward one by one. First judge whether the two phrases conform to the complete subtree constraint. If so, continue to judge whether they conform to the subtree order constraint. In any of the above two stages, once there is no hypothesis that matches the constraint, the algorithm will go back and accept the result of the previous stage.

However, there exist many mistakes in the parsing results. Therefore, strictly following the subtree constraints according to the parsing results will lead to the loss of some good hypotheses. To achieve balance between analysis depth and searching precision, we adopt the following strategies:

(1) If the hypotheses to extend the current translation contain the candidates that meet the constraints, then searching is limited within the scope of these candidates, otherwise we still search within all the hypotheses. This strategy can better take advantage of the non-syntactic phrases in the PBM-based SMT models.

(2) To reduce the complexity, we do not distinguish the border word of the prefix, but take phrases as the basic processing unit and examine whether the phrase to be extended and the phrase to extend it conform to the subtree constraints.

(3) We do not require that every hypothesis extension conforms to the two constraints. Considering the characteristics of IPMT task, we propose three strategies. a) only consider the subtree constraints when the hypothesis to be extended has not fully covered the prefix; b) only consider the subtree constraints when the hypothesis to be extended just covers the prefix; c) consider the subtree constraints under both the above two situations.

5 Experimental Results

5.1 Data Setup

This paper uses the Chinese-English Hong Kong Laws Parallel Text (LDC2000T47) as the corpora. 200,000 sentence pairs are taken as the training set. 1000 sentence pairs are randomly extracted from the remaining corpora as the development set, and 1558 sentence pairs as the testing set. Table 1 gives a detailed description of the corpora.

Corpus		Chinese	English
Training Set	Sentences	200K	200K
	Words	5.15M	5.11M
	Vocabulary	30K	31K
Development Set	Sentences	1000	1000
	Words	15K	15.7K
	Vocabulary	73.24	48.65
Testing Set	Sentences	1558	1558
	Words	20.6K	21.6K
	Perplexity	72.67	46.75

Table 1: Statistics of the Evaluation Corpora.

The Chinese portions of these data were pre-processed by ICTCLAS word segmenter[2], and the English portions were tokenized and lowercased. GIZA++ tool was used to perform the bi-directional word alignment of the training data, and the "grow-diag-final" strategy was used to merge the bi-directional results. A 3-gram language model was trained on the English portion of the training corpus with SRILM. For the building of PB SMT models, Moses (Koehn et al., 2007) was used, and the model includes 14 default features. For adjusting feature weights, the MERT (Och, 2003) method was applied, optimizing the BLEU-4 metric obtained on the development corpus. The parse trees were produced by the Berkeley parser, and 1-best tree was used for subtree extraction. During decoding, the size of hypothesis stack is set to 30, and the maximum number of translation options is set to 20 for each source phrase.

We used Key-stroke Ratio (Barrachina et al., 2009) to evaluate the performance of the IPMT systems. The lower the KSR score, the better the system performance. The baseline system is the state-of-the-art PBM-based IPMT approach using multi-stack-decoding algorithm as described in (Barrachina et al., 2009). We follow the user simulation approach for evaluation as previous works in the literature (Barrachina et al., 2009; González-Rubio et al., 2013). Statistical significance test is conducted using the resampling method proposed in (Koehn, 2004; Zhang et al., 2004).

5.2 Results and Analysis

Table 2 gives the comparative experimental results after using the complete subtree constraint (the distortion distance is limited to 10). ST_CM_BCP represents considering the rule when the hypothesis to be extended has not fully covered the prefix, ST_CM_ACP represents considering the rule when the hypothesis to be extended just covers the prefix, and ST_CM represents considering the rule under both the above two situations. We evaluated the systems on different *K*-best lists. The best results are displayed in bold fonts and have a statistically significant difference with respect to the baseline (95% confidence).

Method	1-best	5-best	10-best	20-best
baseline	48.66	47.93	47.76	47.55
ST_CM_BCP	48.05	47.41	47.18	46.97
ST_CM_ACP	48.44	47.75	47.48	47.21
ST_CM	**47.85**	**47.16**	**46.88**	**46.69**

Table 2: KSR scores after using the complete subtree constraint.

From Table 2 we can see that adding source-language syntactic structure constraint can effectively reduce the interaction times. And using the complete subtree constraint in the whole process of prefix generation (ST_CM) achieved more improvement than only using it in a certain stage (ST_CM_BCP and ST_CM_ACP). The reason is that the prefix is a fragment validated by the human, and it can guide the hypothesis extension at any stage. The following experiments in the paper are all based on this setting (consider the rules under both situations). With the increase of the number of translations, the complete subtree constraint also plays a positive role. On the testing corpus, the underling MT engine achieves a BLEU score of 0.2678.

Table 3 gives the KSR scores after adding the subtree order constraint. Experiments are conducted under different distortion distances. ST_CM represents only using the complete subtree constraint, ST_RD represents only using the subtree order constraint, and ST_IMT represents using both constraints.

Method	Distortion distance limitation = 10				Distortion distance limitation = 15			
	1-best	5-best	10-best	20-best	1-best	5-best	10-best	20-best
baseline	48.66	47.93	47.76	47.55	47.61	46.53	46.29	46.09
ST_CM	47.85	47.16	46.88	46.69	47.18	46.11	45.86	45.68
ST_RD	48.21	47.58	47.13	46.94	47.39	46.32	46.05	45.89
ST_IMT	**47.74**	**47.07**	**46.73**	**46.41**	**46.88**	**45.83**	**45.59**	**45.41**

Table 3: KSR scores after using the subtree order constraint.

Table 3 shows that after using the subtree order constraint, the interaction times decrease. But the improvement is not as obvious as the complete subtree constraint. The reason is that the translation rules consider the inner structure of the subtrees and are more fine-grained. So the matching difficulty increases. It also can be seen that using both constraints leads to larger improvement in performance, indicating that they are complementary constraints which guide the hypothesis selection from different aspects. These results verify that the user-validated prefixes are effective on multiple levels. In fact, when a user gives a prefix, he/she is making a comprehensive decision after analysing the overall structure and orders of the translation. And the proposed method exploits the syntactic structure information hidden in the prefix. In addition, although there are parsing mistakes, we can still get positive results; this shows that the method is error-tolerant.

Through comparing the IPMT process on specific sentences, we find that the decoding of many sentences will fail in the baseline system. In other words, there is no hypothesis that can match the prefix in the stack. However, after adding the subtree constraints, some hypotheses that do not have reasonable syntactic structures will be filtered during extension, thus some lower-ranked hypotheses have the opportunities to be pushed into the stack and finally match the prefix. In such cases, the efficiency of human-computer interaction greatly improves. In our experiment, 1.8% sentences which cannot find

the correct translation with the baseline method succeeded in finding the correct translation with the new method.

Table 4 shows the decoding speeds of different systems when using 1-best result for user reference (the distortion distance is limited to 10). The speed is the number of sentences decoded per second on the testing corpus. The hardware setting is 4G memory, 500G hard disk, Core i5 3.2GHz processor.

Method	Speed (sent/sec)
baseline	3.43
ST_CM_BCP	3.07
ST_CM_ACP	3.23
ST_CM	2.86

ST_IMT	2.78

Table 4: Decoding speed using different subtree constraints.

We can see that incorporating syntactic information did not lead to much decrease in the predicting/responding speed. This is because the subtree constraints help filtering some bad hypotheses and reduced the search space. This balanced the time cost in rule matching. We should note that in our experiments the testing corpus is parsed in advance. In practice, if the corpus cannot be acquired in advance, then each source sentence should be input to the IPMT procedure after parsing.

5.3 Comparison with Other Work

Some researchers proposed methods (Quirk et al., 2005; Marton and Resnik, 2008; Shen et al., 2008; Gao et al., 2011) that introduce the syntactic information to the phrase-based MT system on the basis of hierarchical phrase-based models. In these methods, hierarchical phrases rather than flat phrases are employed. However, the decoding is not in a left-to-right manner, and has difficulty in applying to the prefix matching process of IPMT systems.

The work more similar with ours are those in (Collins et al., 2005; Wang et al., 2007; Galley and Manning, 2008; Hunter and Resnik, 2010). Galley and Manning (2008) adopts a left-to-right shift-reduce method to build hierarchical structures for flat phrases. But this method is "formally syntactic-based" rather than "linguistically syntactic-based". Collins et al. (2005) and Wang et al. (2007) perform pre-ordering in the pre-processing stage instead of deciding the phrase orders in the decoding stage. This strategy may remove the translation hypotheses that match the prefix too early. Hunter and Resnik (2010) directly introduce the source-language syntactic constraints into the decoding of phrase-based MT system, which are almost the same as our work. However, this method builds an independent syntactic re-ordering model and scores the hypotheses through features. In fact, in the IPMT systems the user clearly gives the correct prefix, which can act as an explicit constraint that the hypotheses must match. So it is more suitable to use the syntactic constraints in the form of rules.

6 Conclusion

This paper deepened the constraints of prefix in state-of-the-art PBM-based IPMT system. We built the mathematical framework of IPMT model based on the syntactic alignment between the source sentence and the prefix. On the basis of the framework we proposed a method that introduces source-language syntactic information to hypothesis selection in the form of soft constraints, evaluating the hypotheses from the aspects of subtree completion and subtree order. We also proposed the strategies to avoid the matching rules from being too strict, making the system tolerant to the parsing mistakes. Experimental results proved that our method reduced the human-computer interaction times while the decoding speed does not decrease obviously.

Abstract

In recent years, neural machine translation (NMT) has demonstrated state-of-the-art machine translation (MT) performance. It is a new approach to MT, which tries to learn a set of parameters to maximize the conditional probability of target sentences given source sentences. In this paper, we present a novel approach to improve the translation performance in NMT by conveying topic knowledge during translation. The proposed *topic-informed* NMT can increase the likelihood of selecting words from the same topic and domain for translation. Experimentally, we demonstrate that topic-informed NMT can achieve a 1.15 (3.3% relative) and 1.67 (5.4% relative) absolute improvement in BLEU score on the Chinese-to-English language pair using NIST 2004 and 2005 test sets, respectively, compared to NMT without topic information.

1 Introduction

In statistical machine translation (SMT) (Och and Ney, 2000; Marcu and Wong, 2002; Koehn et al., 2007), several models are trained separately and then linearly integrated using the log-linear model (Och, 2003). Neural machine translation (NMT) (Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), being a new approach, employs an individual large neural network to maximize the translation probability directly.

One observation we obtain from machine translation (MT) training data is that some of the words within the same sentence often belong to the same or similar topic. Examine the example presented in Figure 1, where words *Commercial*, *market*, *prices* and *bank* have higher probabilities of being in the *Financial* domain. Intuitively, by allowing the topic information of the source input sentence and previous translated words to be provided to the decoder, we can maintain the same topic in the translations during the decoding phase, and consequently better translations can be produced. Specifically, when a source word has more than one translation option available (e.g. the word *bank* in Figure 1), it is clear that the translation in the *Financial* domain is more likely to be selected because many of the source words are from the same topic.

Topic models have been applied successfully in many SMT works. For example, similar "topic consistent" behaviour is also observed by Su (2015). In his work, a context-aware topic model is integrated into SMT for better lexical selection. Xiao et al. (2012) and Zhang et al. (2014) focus on document translations and propose a topic-similarity model and a topic-sensitivity model for hierarchical phrase-based SMT (Chiang, 2005) on the document level. The topic-similarity model is used to encourage or penalize topic-sensitive rules, and the topic-sensitivity model is applied to balance topic-insensitive rules. However, these approaches cannot be directly used in NMT.

In this work, we propose our novel topic-informed NMT model. In topic models, word-topic distributions can be viewed as a vector. In NMT, words are represented as vector-space representations. Thus, it is very natural to use them together. Word expressions in neural models are derived by its near context words while the topic vectors represent the document-level topic information. For this reason, we see

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1807–1817, Osaka, Japan, December 11-17 2016.

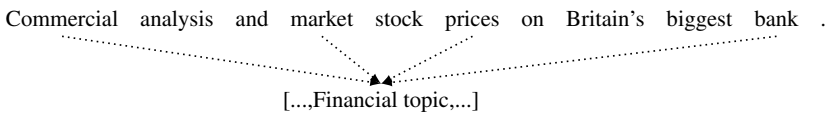

Figure 1: Some words within the same sentence belong to the same topic.

them as complementary to one another. Our intuition is that incorporating topic information will benefit NMT. Thus, we explore incorporating topic information into NMT in either/both the source side and target side.

The remainder of this paper is structured as follows. Section 2 presents related work. Section 3 gives review of the NMT architecture we use. Section 4 introduces our topic-informed NMT system, while Section 5 presents experimental results and some observations. Finally, the conclusions and future directions are provided in Section 6.

2 Related Work

Topic modelling has been applied successfully in many SMT works, especially in the domain adaptation literature. The motivation for introducing topic-model information in MT is that the translation performance decreases when there are dissimilarities between the training and the testing domains. A better approach is to make the use of the topic knowledge learned during training. Such knowledge can yield a better word or phrase choice in translation. Early work shows that the lexical translation table conditioned on the provenance of each domain can significantly improve translation quality (Chiang et al., 2011). Eidelman (2012) extends the provenance idea by including topic-dependent lexical weighting probabilities on the source side. Hasler (2012) successfully combines sparse word-pair and phrase-pair features with topic models. Later, Hasler (2014) also reports that translation performance is improved by using similarity features, which are computed from training phrase-pair and test-context vectors generated from the phrase-pair topic model. However, these ideas cannot be directly applied in NMT given the different training algorithms used in SMT and NMT.

Despite the fact that neural network training has been shown to be advantageous in many natural language processing tasks, little work has been proposed on using additional knowledge in NMT. Gulcehre et al. (2015) leverage monolingual corpora for NMT and propose two approaches to integrate a neural language model into the encoder-decoder architecture. He et al. (2016) integrate SMT features into NMT in order to solve the out-of-vocabulary problem. Furthermore, they use a n-gram language model trained on large monolingual data to enhance the local fluency of translation outputs. Linguistic information can also be used during NMT training (Sennrich and Haddow, 2016; García-Martínez et al., 2016). There are also works that include topic modelling in neural language model training. Mikolov and Zweig (2012) use a contextual real-valued input vector associated with each word in a recurrent neural network (RNN) language model.

3 Neural Machine Translation

3.1 Encoder-Decoder Architecture

In a nutshell, the fundamental job of the encoder-decoder architecture (Cho et al., 2014) in NMT is to probabilistically decode a target sequence given the encoded source sequence, where the two sequences can be of different lengths. Given a sentence pair (S, T), S is the foreign input sentence and T is the translation, where $S = (s_1, s_2, ..., s_{m-1}, s_m)$ and $T = (t_1, t_2, ..., t_{n-1}, t_n)$ are the words in the sentence pair. The encoder-decoder architecture needs to find the translation probabilities for each word in T, as in Equation (1):

$$p(T|S) = \sum_{j=1}^{n} p(t_j|t_{1:j-1}, S) \tag{1}$$

and the conditional probability is given by the decoder, which uses the $softmax$ function outputting the probability distribution on all words in the target, as in Equation (2):

$$p(t_j = t|t_{1:j-1}, S) = softmax(f(h_j)) \tag{2}$$

where f is a function that can transform the target context h_j into a vector, which has the same size with the size of target vocabulary. h_j is defined in Equation (3):

$$h_j = g(t_{j-1}, h_{j-1}, c) \tag{3}$$

where c is the source context vector computed by the encoder, t_{j-1} is the word vector representation of word $j-1$, h_{j-1} is the hidden state for time $j-1$ and g is a non-linear activation function. Thus, we use the source input sentence and previous translated words to predict the next word.

3.2 Attention Model

The encoder-decoder architecture uses a fixed-sized vector to represent the whole source input. Although RNNs are known to be better at capturing long range dependencies, experimental results (Bahdanau et al., 2015) show that translation quality decreases for long input sentences. Bahdanau (2015) use an attention mechanism to learn dynamic *soft-alignment* during the network training, as in Equation (4):

$$e_{ij} = a(h_{j-1}, h_i) \tag{4}$$

where e_{ij} is the alignment model to score the alignment at position i and j in S and T, respectively. h_{j-1} is the target hidden state as seen in Equation (3), and h_i is the source hidden state at time i.

Thus, a distinct context vector c_j can be computed for each word in T, and the source context vector c is rewritten as in (5):

$$c_j = \sum_{i=1}^{m} \alpha_{ij} h_i \tag{5}$$

where α_{ij} is a normalized weight for each hidden state in S, computed as in (6):

$$\alpha_{ij} = \frac{exp(e_{ij})}{\sum_{i=1}^{m} exp(e_{ij})} \tag{6}$$

With the attentional model, source information can be spread across the source context vector, and the decoder can selectively pay attention to different parts of the source context during decoding.

3.3 Bidirectional RNN

During the encoding phase, words can also be fed into the encoder in both directions, in which case we are using a bidirectional RNN. The intuition behind such a model is to include both *positive* and *negative* time stamps of the source input during encoding, which can shorten the distance between the decoding part with the relevant encoded part. Sutskever et al. (2014) claim that it is "extremely valuable" and can "greatly boost the performance" by using a bidirectional RNN in NMT.

In this paper, following Cho et al. (2014) and Bahdanau et al. (2015), we use the encoder-decoder architecture with a single layer bidirectional gated recurrent unit (GRU) (Chung et al., 2014) as the encoder, and a single layer GRU with attention model as the decoder in our NMT system.[1]

4 Topic-Informed Neural Machine Translation

In this section, we provide an explanation of how to include topic knowledge in NMT.

[1]More hidden layers usually result in much better quality. However, the training time increases. Thus, we use only a single layer in the encoder or the decoder.

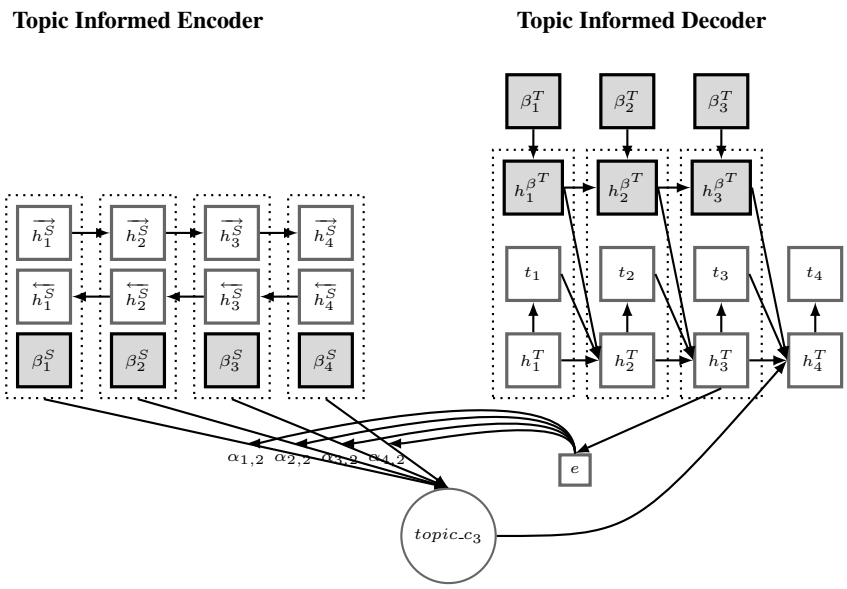

Figure 2: A graphical illustration of the proposed topic-informed NMT model, with 4 input words and 4 output words. The shaded units indicate the topic information used in the encoder and decoder. In order to distinguish the hidden states in the encoder-decoder architecture, we use h^S and h^T to represent the hidden states of the encoder and decoder, respectively, e.g. h_1^S indicates the encoder hidden state at time 1. Furthermore, in order to keep the notation consistent with Section 4.1, e.g. β_i^S denotes the word distributions over topics for the source word at position i, a similar notation is also used for the target words. For example, β_1^T indicates the word distributions over topics for the target word at position 1.

4.1 Topic-Informed Encoder

The encoder in standard NMT uses only word embedding to compute the source context vector. By using topic information on the source side, the decoder can have an overview of the source topics during decoding. Furthermore, the attention model can implicitly pay attention to the topic distributions of each source word. Topic information on the source side can be helpful to generate more accurate translations. Therefore, we first compute the topic distributions (word distributions over topics) for each source word of the input sentence. We then concatenate the topic distributions with each corresponding hidden state of the input source words. Finally, the hidden states with the topic information are used to compute the topic-informed source context vector $topic\_c_j$, as in Equation (7):

$$topic\_c_j = \sum_{i=1}^{m} \alpha_{ij}[h_i, \beta_i^S] \tag{7}$$

to obtain our topic-informed encoder, where β_i^S denotes the word distributions over topics for each source word in S, and $[h_i, \beta_i^S]$ denotes the concatenation operation on the corresponding h_i and β_i^S. Thus, Equation (3) is updated as in (8):

$$h_j = g(t_{j-1}, h_{j-1}, topic\_c_j) \tag{8}$$

in order to obtain the source topic-informed NMT model.

4.2 Topic-Informed Decoder

While the source topic-informed NMT model is useful for generating accurate translations, introducing topic information on the target side can help topic consistency between target words. A natural choice for maintaining this topic consistency is to use the same architecture as the decoder (i.e. GRU), to obtain the topic hidden state for the corresponding target word. We use $h_{j-1}^{\beta^T}$ to represent the hidden state of target topics for time $j-1$. We then can update Equation (3) as in (9):

$$h_j = g(t_{j-1}, h_{j-1}, c, h_{j-1}^{\beta^T}) \tag{9}$$

	Source	Target
Sentence Num.	1,501,652	1,501,652
Token Num.	38,388,118	44,901,788

Table 1: Training data statistics.

to obtain the target topic-informed NMT model. Consequently, the decoder can then use the topic knowledge of previous translated words to increase the likelihood of selecting words from the same topic.

4.3 Topic-Informed NMT

We now can combine the topic-informed encoder and the topic-informed decoder to obtain the overall topic-informed NMT system, as in Equation (10):

$$h_j = g(t_{j-1}, h_{j-1}, topic\_c_j, h_{j-1}^{\beta^T}) \tag{10}$$

Figure 2 provides a the graphical illustration of this novel topic-informed NMT model.

4.4 Topic Modeling

Instead of documents, sentences are often used to represent the mixture of topics in MT. For example, given the source or target training corpus, we can choose a fixed N topics to learn. The effectiveness of such an approach is that the topic representations can be learned directly using off-the-shelf algorithms. We take the same approach in this work, and use the translation training data directly to learn the topic representations. We use the Latent Dirichlet Allocation (LDA) implementation in the topic modeling toolkit (Řehůřek and Sojka, 2010) to train the topic model and compute the topic distributions of words.[2] We train the models with 200 iterations. Training takes approximately 40 hours on average for all the LDA models used in this work. For a detailed explanation of LDA, we refer the reader to Blei et al. (2003). Other options are to use Latent Semantic Analysis (LSA) (Deerwester et al., 1990) or Hidden Topic Markov Models (HTMM) (Gruber et al., 2007), which have not been studied in this work. We leave them as part of our future research.

5 Experiments

5.1 Data and Experiment Models

We report our experimental results on the NIST evaluation data set in the Chinese-to-English translation direction. Our MT training data are extracted from LDC corpora,[3] and NIST 2002 is used as our development set. Table 1 shows the details of the training data used. We use NIST 2004 and 2005 as our test sets. The English training data is tokenized and lowercased using scripts in Moses (Koehn et al., 2007). The Stanford Chinese word segmenter (Tseng et al., 2005) is used to segment the Chinese training data. In NMT, we limit our vocabularies to be the top 16,000 most frequent words, which covers 97.57% and 98.77% of the original words in the source and target training corpora, respectively. Outside the 16,000 threshold, all tokens are mapped to *UNK*.

We compare our approach against two baselines. The SMT baseline is trained using Moses, with a lexicalized reordering model (Koehn et al., 2005; Galley and Manning, 2008) and a 5-gram KenLM (Heafield, 2011) language model trained using the target side of the parallel training data. We use all the default parameters in Moses. Our second baseline is an NMT system. We use the encoder-decoder architecture with a single layer bidirectional GRU as the encoder, and a single layer GRU with attention model as the decoder. Each word in the training corpora is converted into a 512-dimensional vector during training. The hidden layers of the encoder and decoder each contain 1,024 hidden units. The bidirectional RNN described in Section 3.3 is also used. We use beam search during translation, with a beam size of 5. We use a minibatch (with batch size 32) stochastic gradient descent algorithm together with Adadelta (Zeiler, 2012) to train our models. All NMT models are trained up to 320,000 updates

Target Topic-Informed NMT (10)	36.31	35.43‡	32.50‡
Topic-Informed NMT (40,10)	34.86	35.91‡	32.79‡

Table 2: BLEU scores of the trained SMT and NMT models. We use ‡ and † to indicate significant (Koehn, 2004) improvements upon the baseline NMT using bootstrapping method at the level p = 0.01 and p = 0.05 level, respectively (with 1000 iterations).

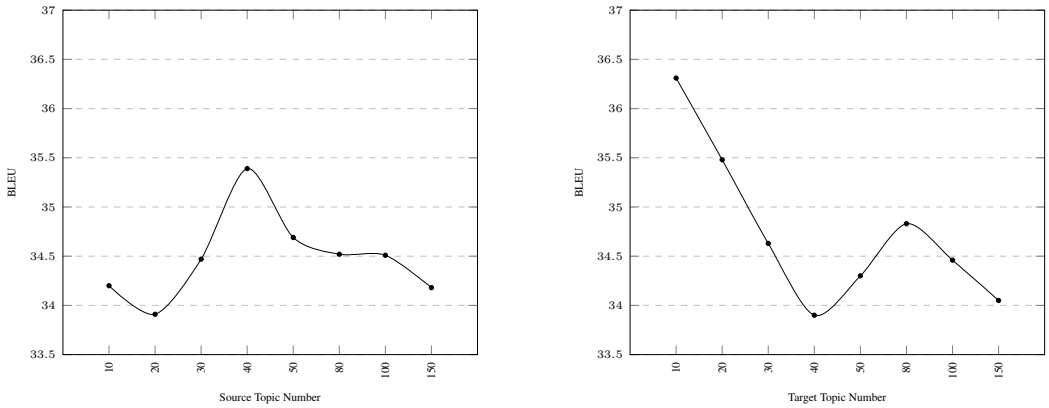

Figure 3: Topic numbers vs. translation BLEU scores on the NIST 2002 development dataset.

and the models are saved at each 1,000 updates. The training takes approximately 3 days on an NVIDIA GeForce GTX TITAN X GM200 GPU machine. We then choose the final model based on the BLEU[4] (Papineni et al., 2002) score on the development data.

5.2 Results

Table 2 presents the experiment results on the development and test data. In Table 2, the number next to each topic-informed NMT system indicates the number of topics used in the system, i.e. we use 40 source topics in the source topic-informed NMT system, and 10 target topics in the target topic-informed NMT model. The source and target topic numbers are experimentally chosen from $\{10, 20, 30, 40, 50, 80, 100, 150\}$ according to the development BLEU scores, as seen in Figure 3. We then leverage topic information on both source (with 40 topics) and target (with 10 topics) sides, which produces the topic-informed system (40,10) in Table 2. We think that the source topic number and the target topic number are not necessarily to be the same as the topic distributions are used differently in the proposed NMT model. The source topic distribution is appended to each word in the encoder, and the target distribution is passed via the RNN in the decoder.

We first compare the system performance on the development data. According to Table 2, using topic information can improve system performance over the two baseline systems. The source topic-informed NMT (40) system can gain absolute improvements of 1.97 (5.8% relative) and 1.06 (3.1% relative) BLEU scores compared to the SMT and NMT baseline systems, respectively. When using the topic information on the target side, we can observe absolute BLEU score improvements of 2.89 (8.6% relative) and 1.98 (5.8% relative) compared to the SMT and NMT baseline systems, respectively, which is the best-performed system on the development data. The topic-informed NMT (40, 10) system can only gain absolute 0.53 (1.5% relative) and 1.44 (4.3% relative) improvements compared to the SMT and NMT baseline systems, respectively.

In Table 2, significant improvements can be observed on the test data. There is a gain of 0.41 (absolute, 1.8% relative) and 0.83 (absolute, 2.7% relative) BLEU scores compared with the NMT baseline systems when the topic information is employed on the source side, on the NIST 2004 and NIST 2005 data sets,

respectively. Furthermore, we find further absolute BLEU score improvements of 0.67 (absolute, 1.9% relative) and 1.38 (absolute, 4.4% relative) on the target topic-informed NMT (10) system, on the NIST 2004 and NIST 2005 data sets, respectively. The best-performing system on the test data is the topic-informed NMT (40,10) system, which achieves 35.91 and 32.79 BLEU scores on the NIST 2004 and NIST 2005 data sets, respectively. These results are 1.15 (absolute, 3.3% relative) and 1.67 (absolute, 5.4% relative) higher compared with the NMT baseline systems. Overall, the topic-informed NMT system significantly improves upon the baseline translation performance.

5.3 Observations

As we described earlier, by allowing topic information into the decoder, topic-consistent behaviour can be maintained, and consequently better translations can be produced. We find that the translations produced by the baseline NMT system is more fluent compared to SMT. However, two types of errors are still commonly made.

The first type of error produced in NMT translations is the lexical selection error. We find that when words can be translated by NMT, some of the translations are not appropriate in the context, i.e. words are not suitable for the domain. For example, in the baseline NMT translation examples in Figure 4, 抢救/"emergency treatment" is translated into *rescue* and 打/attack is translated into *fight*. In topic-informed NMT translations in Figure 4, the source input sentences and previous translations, e.g. *hospital* in the first example, and *British*, *government* and *US* in the second example, can give strong indications to the decoder about the current topics, namely "*Hospital*" and "*Politics*" topics in the two examples, respectively, that better word choices can thus be produced in the translations.

The second type of error that can be observed in the NMT translations is that the lexical coverage is low. Some of the source words are translated as *UNK* even though the correct translations can be found in the target vocabulary list. Comparing the *UNK* numbers produced by the baseline NMT and the topic-informed NMT, we observe that the number of *UNK* tokens has been reduced in the topic-informed NMT translations, as presented in Table 2. Interestingly, we also find that the topic-informed NMT system tends to produce more words in translations, namely 50,913 and 34,695 words in NIST 2004 and NIST 2005, respectively. In contrast, the NMT baseline produces 44,552 and 30,558 words in NIST 2004 and NIST 2005, respectively. In conclusion, topic-informed NMT can reduce the *UNK* number even when more words appear in the translation outputs. We think the reason for this the topic distribution of the *UNK* token favours to one particular topic. If the source inputs do not belong to the

	Baseline NMT	Topic-Informed NMT
NIST 2004	2.3%	1.9%
NIST 2005	2.7%	2.3%

Table 3: The percentage of *UNK* tokens produced in translation outputs by baseline NMT and topic-informed NMT systems.

same topic in which *UNK* appears, the *UNK* token will have less chance to be chosen as the translation output. Therefore, other word choices than *UNK* can be made and the overall *UNK* number is reduced. Inspecting the translation examples in Figure 5, 议长/speaker and 活跃/active fail to be translated by the baseline NMT system. However, topic-informed NMT is able to use the known topic information, either from the source sentences or previous translations, to produce correct translations. For example, the source words 议长/speaker and 活跃/active are translated into *speaker* and *active*, respectively. The source word 卡伊达/Qaida does not appear in the parallel training data, so both systems produce *UNK* in this case.

Figure 6 compares the word alignments produced by the two systems. In this example, we can find that the word alignments of topic-informed NMT can give more weights (α_{ij} in Equation (6)) to the correct aligned words, which consequently indicates to the decoder to pay more attentions on the correct source works to translate.

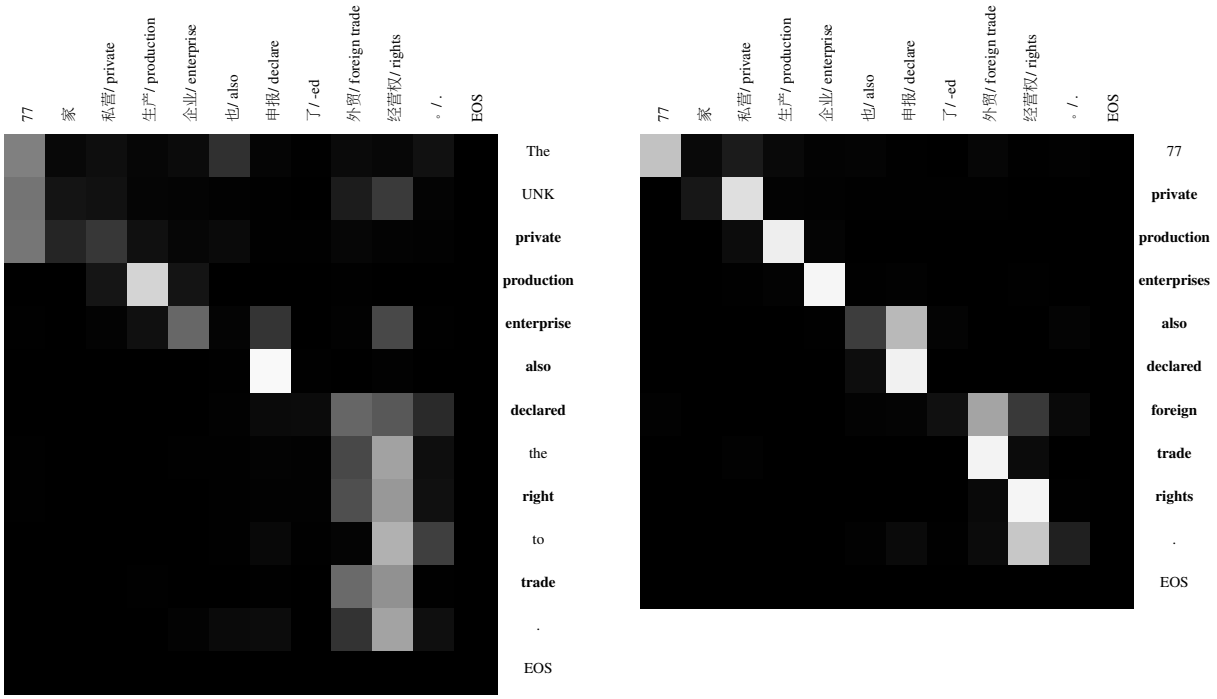

Figure 6: The comparison of alignments generated without (left) and with (right) topic knowledge. The example is chosen from the development data, where the x-axis sentence is the source training sentence (Chinese), and the y-axis sentence is the target training sentence (English). In the heatmap, we use grayscale colour schemes, where black means the word alignment probability is low, and white means the word alignment probability is high.

Our baseline NMT system contains 58,427,521 parameters to learn. Since we concatenate the source topic information and use a GRU network to store the target topic information, the topic-informed NMT system contains 817,984 more parameters to learn. During our experiments, we see that all of the trained NMT models (baseline NMT and topic-informed NMT systems listed in Table 2) produce their best-performing models between 280,000 and 320,000 in terms of update numbers. The baseline NMT and the topic-informed NMT systems require 284,000 and 289,000 updates to learn the best-performing models on the development data, respectively.

6 Conclusion

NMT has a lot of potential as a new approach to MT. In this paper, we present a novel approach of integrating topic knowledge into the existing NMT architecture. Through our experiments, we show that translation quality can be improved. We demonstrate that our topic-informed NMT can achieve 1.15 and 1.67 absolute improvements in BLEU score on two different test sets. The experimental results not only demonstrate the effectiveness of the proposed model, but also show an approach to enrich the representation of the context vector produced by the encoder and decoder. We show that introducing topic information in NMT can produce translations with better lexical selection, and a lower number of UNKs. We give concrete examples to support our observations. Furthermore, we argue that better word alignments can also be learned which consequently benefits translation quality.

In the future, we want to experiment on other topic learning approaches, e.g. LSA or HTMM, or jointly train neural topic model (Cao et al., 2015) and translation. We are also interested in further exploring the correlation between NMT performance and the quality of the topic modeling itself.

Abstract

We introduce a distribution based model to learn bilingual word embeddings from monolingual data. It is simple, effective and does not require any parallel data or any seed lexicon. We take advantage of the fact that word embeddings are usually in form of dense real-valued low-dimensional vector and therefore the distribution of them can be accurately estimated. A novel cross-lingual learning objective is proposed which directly matches the distributions of word embeddings in one language with that in the other language. During the joint learning process, we dynamically estimate the distributions of word embeddings in two languages respectively and minimize the dissimilarity between them through standard back propagation algorithm. Our learned bilingual word embeddings allow to group each word and its translations together in the shared vector space. We demonstrate the utility of the learned embeddings on the task of finding word-to-word translations from monolingual corpora. Our model achieved encouraging performance on data in both related languages and substantially different languages.

1 Introduction

Learning word vector representations based on neural network is now a ubiquitous technique in natural language processing tasks and applications. Tremendous advances have been brought by distributed representations to the state-of-the-art methods (Bengio et al., 2003; Collobert and Weston, 2008; Mikolov et al., 2013a; Pennington et al., 2014). In these models, words are represented by *dense real-valued low-dimensional vectors* referred to as word embeddings learned from raw text. Distributed representations have the property that similar words are represented by similar vectors and thus can achieve better generalization. Such representations are usually learned from monolingual data and therefore might not be generalized well across different languages.

In order to learn useful syntactic and semantic features that are invariant to languages, several models for learning cross-lingual representations have been proposed and achieved impressive effects by incorporating cross-lingual distributional information (Klementiev et al., 2012; Zou et al., 2013; Chandar et al., 2014; Faruqui and Dyer, 2014; Hermann and Blunsom, 2014; Gouws et al., 2015; Luong et al., 2015; Shi et al., 2015; Vulić and Moens, 2015; Upadhyay et al., 2016). In the cross-lingual settings, similar representations are desired for words denoting similar concepts in different languages (e.g., the embeddings of the English word *computer* and the French word *ordinateur* should be similar). Cross-lingual representations are especially useful for many natural language processing tasks such as machine translation (Zou et al., 2013; Zhang et al., 2014), computing cross-lingual word similarity (Zhang et al., 2016) and transferring knowledge from high-resource languages to low-resource languages (Guo et al., 2015), etc.

However, all these cross-lingual models require some form of cross-lingual supervision such as seed lexicon,word-level alignments, sentence-level alignments and document-level alignments. Reliance on supervision might limit the development and application of cross-lingual representations. In this paper, we proposed a distribution based model to learn bilingual word embeddings from monolingual data. The

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1818–1827, Osaka, Japan, December 11-17 2016.

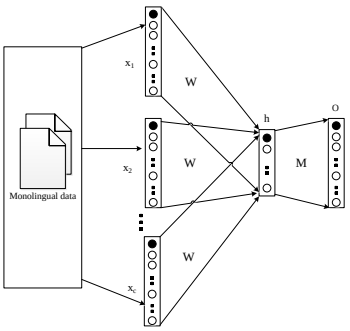

Figure 1: The CBOW architecture predicts the current word based on the context. It is a monolingual representations learning model.

proposed approach is complementary to the existing methods that rely on supervision. Our contributions are the following:

- We introduce a novel cross-lingual objective which is employed to match the distributions of monolingual embeddings as they are being trained in an online setting. Our model only requires monolingual data and therefore could be applied to any languages or domains that we are interested in.
- Our model can capture the common regularity shared by natural languages. The resulting bilingual embeddings allow to group a word and its translations together in vector space. We demonstrate the utility of our model on the task of finding word-to-word translations solely from monolingual corpora. Our model achieved encouraging performance on both related languages and substantially different languages.

2 Monolingual Word Embeddings Learning

Our framework is general enough to be built based on any monolingual embedding learning model. We adopt the popular continuous bag-of-Words (CBOW) model (Mikolov et al., 2013a) to demonstrate our approach. The CBOW model uses continuous distributed representation of the context where each word is mapped to a learned vector. The architecture is shown in the Figure 1. The training data D is a set of pairs in the form of (x, y), in which y is a word and $x = (x_1, x_2, ..., x_C)$ is a set containing C context words in which y appears. We have $y, x_i \in (1, 2, ..., V)$, where V is the vocabulary size. The training criterion is to seeking parameters minimizing the loss function which is the negative log probability of y given x:

$$\hat{W}, \hat{M} = \underset{W,M}{\operatorname{argmin}} \sum_{(x,y)\in D} L(W, M, x, y) = \underset{W,M}{\operatorname{argmin}} \sum_{(x,y)\in D} -log(P(y|x, W, M)) \tag{1}$$

We use the one-hot V-dimension column vector $\vec{x}_i$ to refer the context word x_i in which only the x_i^{th} unit is 1, and all other units are 0. W is a $K \times V$ matrix representing the weights between the input layer and the K-dimensional hidden layer. Each column of W is the K-dimensional vector representation of the associated word of the input layer. W transforms each context word x_i into a K-dimension real value vector. Each context word x_i is mapped into a real value K-dimensional vector by W. The CBOW model takes the average of these vectors as the value of hidden layer.

$$\vec{h} = \frac{1}{C} \sum_{i=1}^{C} W\vec{x}_i \tag{2}$$

where the matrix W is shared by all context words.

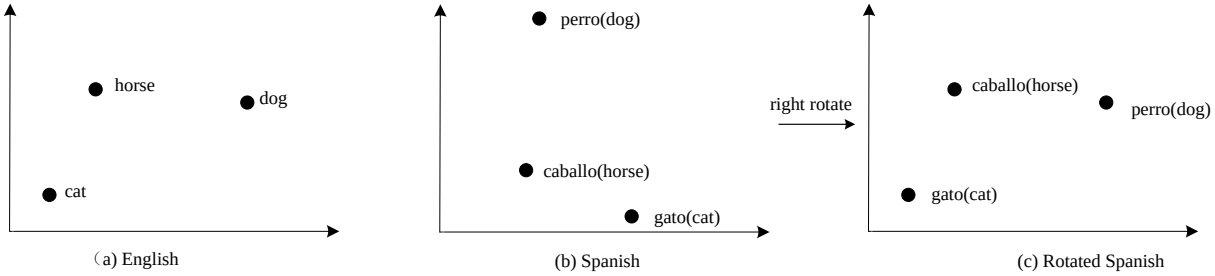

Figure 2: Monolingual embeddings have been shown to have similar geometric shape (a & b). It is desired to have more explicit similarity (a & c). (Mikolov et al., 2013b) achieved this by leaning a linear projection with a bilingual dictionary.

From the hidden layer to the output layer, there is a $V \times K$ weight matrix M by which the hidden vector is mapped into a V-dimensional output vector:

$$\vec{O} = M\vec{h} \tag{3}$$

which will be normalized by the soft-max function as a distribution over V candidate words. Finally, the probability of the word y given its context x is:

$$P(y|x, W, M) = \frac{exp(O_y)}{\sum_{i=1}^{V} exp(O_i)} \tag{4}$$

where O_i is the i^{th} unit of vector $\vec{O}$.

The parameters of W and M are tuned by the standard stochastic gradient descent (SGD) algorithm. There are very interesting properties in the learned word vectors. For example, similar words are nearby vectors in a vector space. And more importantly, if vectors learned for languages are manually rotated, Mikolov et al. (2013b) observed that languages share similar geometric arrangements in vector spaces (shown in Figure 2). The reason is that all common languages share universal structure of human lexical semantics(Youn et al., 2016). To capture the similarities, they use a bilingual dictionary to learn a linear projection between vectors learned independently from each language.

Our work is also motivated by the observation in (Mikolov et al., 2013b). Rather than relying on geometric transformation, we focus on word embeddings learning itself and explore an joint bilingual learning framework.

3 Learning Bilingual Word Embeddings by Distribution Matching

In the cross-lingual setup, we desire word embeddings to be generalized well across different languages. For example, given embedding of English context words {*the, cats, on, the, mat*}, cross-lingual models should not only be able to predict that the current word can be *sits* in English, but also be able to predict it can be *assis* in French. Similarly, given embeddings of French context words {*le, chat, est, sur, ma*}, cross-lingual models should be able to predict both *sits* and *assis*. Such desire bears a strong resemblance to the problem of domain adaptation which is well-studied in the field of natural language processing (Blitzer et al., 2006; Daume III, 2007). We apply the theory on domain adaptation which can learn cross-domain features to the task of learning cross-lingual features(word embeddings). Before we detail the proposed framework for unsupervised cross-lingual representation learning, we briefly introduce methods in domain adaptation.

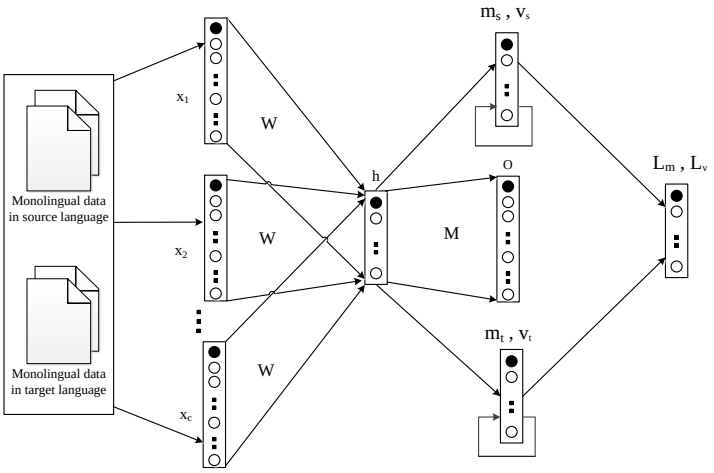

Figure 3: Bi-lingual representation learning is achieved by matching the distribution of the source and target languages. The dynamic statistic of hidden states of the source and target languages are calculated on line, and the dissimilarities between them are minimized through standard back propagation algorithm.

3.1 Domain Adaptation

This work is inspired by theory on domain adaptation (Ben-David et al., 2006; Ben-David et al., 2010) which suggest that, for effective domain transfer, predictions must be made based on data representations that cannot discriminate the source and target domains. Based on this theory, very simple and efficient domain adaptation approaches have been developed (Ajakan et al., 2014; Ganin and Lempitsky, 2015) for representation learning in neural networks. The main idea is matching feature space distributions of source and target domain. To this end, Ganin and Lempitsky (2015) added a domain classifier connected to the feature extractor. Feature distributions over the two domains are made similar (as indistinguishable as possible for the domain classifier), thus resulting in the domain-invariant features.

A straightforward way to learn cross-lingual representations is extending the ideas of Ganin and Lempitsky (2015) by replaceing their domain classifer with a language classifier. Alternatively, in this paper we explore a much more direct approach.

3.2 Model Architecture

We observed that, unlike features in image processing which are *high-dimensional*, language representations are usually in form of *dense real-valued low-dimensional* vector and therefore the distribution of them can be accurately estimated, given the freely available large scale raw text data. Based on this observation, we propose a novel learning objective which directly matches the distributions of word embeddings in one language with that in the other language. An overview of the architecture of bilingual word embeddings learning is given in Figure 3.

Same to that in the CBOW model, W and M are still $K \times V$ and $V \times K$ matrixes. But, now we have $V = V_s + V_t$ where V_s and V_t is the vocabulary size of source and target data respectively. All what we add to the CBOW model are the statistics of hidden states. We assume that the distribution of hidden states of each language is subject to a multi-dimensional normal distribution. So we have two statistics for each language, namely the mean $\vec{m}_s$ and the variance $\vec{v}_s$ on the source side, the mean $\vec{m}_t$ and the variance $\vec{v}_t$ on the target side. Like the hidden states, each statistic is also a K-dimensional vector. We use D_s and D_t to denote the nonparallel monolingual training data set from source language and target language respectively. Mathematically, on the source data, the mean is defined as:

$$\vec{m}_s = \frac{1}{|D_s|} \sum_{(x,y) \in D_s} \vec{h}(x) \tag{5}$$

where the hidden state h is defined in equation 2. And the variance is:

$$\vec{v}_s = \frac{1}{|D_s|} \sum_{(x,y) \in D_s} (\vec{h}(x) - \vec{m}_s)^2 \tag{6}$$

where the square operation is performed on each element of the K-dimensional vector respectively. On the target data, $\vec{m}_t$ and $\vec{v}_t$ are defined in the same way.

In order to encourage the source and the target data to have similar distributions in the shared space, one can directly minimize the dissimilarity between statistics of the source and the target data. More formally, the bilingual training criterion is to seeking parameters minimizing the standard monolingual objective of all data and the distribution dissimilarity:

$$\hat{W}, \hat{M} = \underset{W,M}{\operatorname{argmin}} (\sum_{(x,y) \in D_s \cup D_t} L(W, M, x, y) + \lambda_m L_m(\vec{m}_s, \vec{m}_t) + \lambda_v L_v(\vec{v}_s, \vec{v}_t)) \tag{7}$$

where L is defined in equation 1. L_m and L_v are cross-lingual objectives which are defined as the dissimilarities between statistics:

$$L_m(\vec{m}_s, \vec{m}_t) = \frac{1}{2} \sum_{i=1}^{K} ((\vec{m}_s)_i - (\vec{m}_t)_i)^2 \tag{8}$$

$$L_v(\vec{v}_s, \vec{v}_t) = \frac{1}{2} \sum_{i=1}^{K} ((\vec{v}_s)_i - (\vec{v}_t)_i)^2 \tag{9}$$

where i is index of each element in the vectors.

3.3 Dynamic Estimation

However, it is nontrivial to optimize the monolingual and cross-lingual objectives simultaneously in equation 7. The statistics defined in equation 5 and 6 can only be calculated when all word embeddings are given and fixed, while word embeddings have to be learned online by stochastic gradient descent algorithm. So it is impractical to use these statistics to guide the online learning of word embeddings. To deal with this chicken-egg problem, we propose to dynamically estimate the statistics. Initially, we have:

$$\vec{m}_s = 0 \tag{10}$$

$$\vec{v}_s = 0 \tag{11}$$

which will be iteratively updated by each incoming training instance (x_i,y_i):

$$\vec{m}_s = \frac{1}{scount + 1} (\vec{m}_s * scount + \vec{h}(x_i)) \tag{12}$$

$$\vec{v}_s \approx \frac{1}{scount + 1} (\vec{v}_s * scount + (\vec{h}(x_i) - \vec{m}_s)^2) \tag{13}$$

where $scount$ is the number of source training instances that have been used by the learning algorithm so far. The value of $scount$ is increased by one when a new training instance comes. To capture the latest trends and decay the effect the outdate data during training, we do not increase $scount$ anymore when it reaches 100 thousands.

On the target data, $\vec{m}_t$ and $\vec{v}_t$ are approximated in the same way.

3.4 Online Bilingual Training

Now we are ready to introduce the joint training procedure. In practice, we use multiple threads to train our model with source data and target data in parallel. On the source data, when a training instance (x_i, y_i) is accessed by the learning algorithm, we dynamically update the $\vec{m}_s$ and $\vec{v}_s$ with equation 12 and 13 as the output of the network. Then the golden references are the real time values of $\vec{m}_t$ and $\vec{v}_t$ which are being estimated in parallel on the target data. Based on loss function defined in equation 8 and 9, the gradient of distribution dissimilarities with respect to the hidden state is:

$$\frac{\partial(L_m + L_v)}{\partial \vec{h}(x_i)} = \frac{\lambda_m}{scount + 1}(\vec{m}_t - \vec{m}_s) + \frac{\lambda_v}{scount + 1}(\vec{v}_t - \vec{v}_s) \tag{14}$$

which will be added to the standard gradient of monolingual objective of the CBOW model:

$$\frac{\partial(L_m + L_v)}{\partial \vec{h}(x_i)} + \frac{\partial L(W, M, x, y)}{\partial \vec{h}(x_i)} \tag{15}$$

This gradient sum is utilized by the standard back propagation algorithm to make source data distribution similar to that of target data on one hand, and optimize the monolingual objective on the other hand.

In parallel, on the target data, the similar training procedure is being performed. Thus, the jointly learned source language word embeddings and target word embeddings will share similar distributions.

3.5 Bilingual Negative Sampling

The exact computation for probability shown in equation 4 for all words for every training instance is very expensive. Following the CBOW model, we adopted the negative sampling algorithm for high computational efficiency. As usual, for each source word y_s and its context x_s, we randomly sample a few words other than y_s from the *source* vocabulary. For example, given source word *sits* and its context {*the, cats, on, the, mat*}, we will sample a few words other than *sits*. Each selected word y_s^n is treated as a negative sample and the probability of predicting y_s^n given x_s is minimized.

Different from the CBOW model, we also randomly sample a few words from the *target* vocabulary and minimize the probability of predicting each selected target word y_t^n given x_s. Such bilingual negative sampling(BNS) procedure may introduce noises if the sampled target word y_t^n just happens to be the translation of the source word y_s. But, statistically such chance is quite small given the big vocabulary size of large scale text.

To further reduce such chance, we apply word frequency based diagonal beam (Nuhn et al., 2012) to constrain the BNS. Intuitively, the translation of a high frequency word should also be a frequent word, and vice-versa. Nuhn et al. (2012) use diagonal beam to select translation candidates, in this paper we apply it to filter out possible translations. We sort both source and target words by their frequency. Let $r(y_s)$ and $r(y_t)$ be the frequency rank of a source/target word. To avoid selecting y_t^n which is the translation of y_s, we require that the frequency rank of the sampled target word y_t^n should satisfy:

$$\left| r(y_t^n) - r(y_s)\frac{V_t}{V_s} \right| > BS \tag{16}$$

where BS is the beam size.

Similarly, we also apply the above BNS procedure when learning word embeddings for the target data in parallel.

4 Experiments

In this section we present experiments which evaluate the utility of the induced bilingual word embeddings. We implemented our model in C by building on the word2vec. The implementation launches a monolingual CBOW model by separate threads for each language. All threads access the shared embedding parameters and distribution means/variances. We evaluated the induced bilingual embeddings on the task of finding word-to-word translations from nonparallel corpora. This task is referred as decipherment which has drawn significant amounts of interest in the past few years (Nuhn et al., 2012;

Ravi, 2013; Dou et al., 2015). Decipherment views a foreign language as a cipher for English and finds a translation table that converts foreign texts into sensible English. It is a very challenging task since there is not any supervision.

4.1 Settings

We use MonoGiza[1] which implemented the state-of-the-art decipherment algorithms described in Dou and Knight (2012) and Dou et al. (2015) as baseline. In the preprocessing step, MonoGiza converts all words in data into integers and does not make any use of morphology similarity. For a fair comparison and to be general, we neither utilize that at all. All experiments are performed on plain raw text, we leave the use of syntactic relations for future work. The word embeddings used by MonoGiza are trained with word2vec. For all word embeddings in both word2vec and our model, the dimensionality is 50.

4.2 French to English Decipherment

Data The datasets in our English to French experiments are publicly-available Europarl data[2]. From the English-French Europarl parallel data, we select the first half of English sentences and the second half French sentences respectively as non-parallel corpora for decipherment experiments. To evaluate the decipherment, we use Giza++ (Och and Ney, 2003) to align the Europarl parallel data to build a dictionary. All texts are tokenized by scripts from www.statmt.org. Table 1 lists the sizes of monolingual and parallel data used in this experiment.

Decipherment In order to make all results comparable, results for all methods reported here were obtained using the same nonparallel corpora. λ_m and λ_v were set to 0.2 and 0.1 respectively. The number of negative samples from both source and target side for each word are 5. The beam size of BNS was set to 1000. We use default values for all other hyper parameters in word2vec and MonoGiza. Table 2 shows the experimental results. Bilingual word embeddings are induced by optimizing the objectives in equation 7. For each French word, we select its top-5 nearest neighbor words in English as translations based on the cosine similarity defined in the shared 50-dimensional space. We use the evaluation script included in the package of MonoGiza. Though the absolute accuracy is not very high, we believe it is encouraging given that there is not any supervised information. Only optimizing the monolingual training objective L can capture some similarities between languages, but the accuracy is pretty low. Simultaneously minimizing L and distribution mean dissimilarity L_m is effective. We achieved the best performance when three objectives L, L_m and L_v are optimized together. In such case, the distributions of source and target data share more similarities.

Table 3 shows a number of example translations from French to English. Though they are far from perfect, some translations are meaningful and are semantically related to the correct translation.

4.3 Chinese to English Decipherment

We have demonstrated the effect of our model with experiments on French and English which are related languages. To further evaluate the ability our model, we experiment on data in Chinese and English which are substantially different.

Data We use large scale Chinese and English data released by LDC. The monolingual Chinese data is the Xinhua part of Chinese Gigaword. The monolingual English data is the LDC English Gigaword. Bilingual word embeddings are induced based the above non-parallel data. A golden dictionary is built by Giza++ based on parallel corpus LDC2002E18, LDC2003E07, LDC2003E14, Hansards portion of LDC2004T07, LDC2004T08 and LDC2005T06. All Chinese sentences are segmented by the Stanford Word Segmenter[3]. Table 4 lists the sizes of monolingual and parallel data used in this experiment. The settings are the same as the French-English case.

Decipherment For the calculation of accuracy, we discarded Chinese words if they are not covered by the gold dictionary. Table 5 shows the experimental results of Chinese to English decipherment. Though the two languages are substantially different, the results indicate that our model is still able to learn translation equivalences from the monolingual data by using only the learned bilingual word embeddings.

5 Conclusions and Future Work

We have proposed a novel model to learn bilingual word embeddings directly from monolingual raw text, without requiring any parallel data or dictionaries. A novel cross-lingual learning objective is proposed which directly matches the distributions of word embeddings in one language with that in the other language. We have demonstrated the utility of the learned word embeddings in the task of decipherment. Our model achieved encouraging performance on data from both related languages and substantially

[3]http://nlp.stanford.edu/software/segmenter.shtml

different languages. In the future, we would apply our method to more real applications such as cross-lingual dependency parsing, cross-lingual document classification and machine translation. Our model is complementary to the existing methods that rely on supervision, so we are also interested in combining it with supervised models to achieve much better cross-lingual word representations.

Pre-Translation for Neural Machine Translation

firstname.surname@kit.edu

Abstract

Recently, the development of neural machine translation (NMT) has significantly improved the translation quality of automatic machine translation. While most sentences are more accurate and fluent than translations by statistical machine translation (SMT)-based systems, in some cases, the NMT system produces translations that have a completely different meaning. This is especially the case when rare words occur.

When using statistical machine translation, it has already been shown that significant gains can be achieved by simplifying the input in a preprocessing step. A commonly used example is the pre-reordering approach.

In this work, we used phrase-based machine translation to pre-translate the input into the target language. Then a neural machine translation system generates the final hypothesis using the pre-translation. Thereby, we use either only the output of the phrase-based machine translation (PBMT) system or a combination of the PBMT output and the source sentence.

We evaluate the technique on the English to German translation task. Using this approach we are able to outperform the PBMT system as well as the baseline neural MT system by up to 2 BLEU points. We analyzed the influence of the quality of the initial system on the final result.

1 Introduction

In the last years, statistical machine translation (SMT) system generated state-of-the-art performance for most language pairs. Recently, systems using neural machine translation (NMT) were able to outperform SMT systems in several evaluations. These models are able to generate more fluent and accurate translation for most of sentences.

Neural machine translation systems provide the output with high fluency. A weakness of NMT systems, however, is that they sometimes lose the original meaning of the source words during translation. One example from the first conference on machine translation (WMT16) test set is the segment in Table 1.

The English word *goalie* is not translated to the correct German word *Torwart*, but to the German word *Gott*, which means *god*. One problem could be that we need to limit the vocabulary size in order to train the model efficiently. We used Byte Pair Encoding (BPE) (Sennrich et al., 2016) to represent the text using a fixed size vocabulary. In our case the word *goali* is splitted into three parts *go*, *al* and *ie*. Then it is more difficult to transport the meaning to the translation.

In contrast to this, in phrase-based machine translation (PBMT), we do not need to limit the vocabulary and are often able to translate words even if we have seen them only very rarely in the training. In the example mentioned before, for instance, the PBMT system had no problems translating the expression correctly.

On the other hand, official evaluation campaigns (Bojar et al., 2016) have shown that NMT system often create grammatically correct sentence and are able to model the morphologically agreement much better in German.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1828–1836, Osaka, Japan, December 11-17 2016.

Table 1: Example translation of NMT

NMT:	der Gott
NMT(gloss):	the god

The goal of this work is to combine the advantages of neural and phrase-based machine translation systems. Handling of rare words is an essential aspect to consider when it comes to real-world applications. The pre-translation framework provides a straightforward way to support such applications. In our approach, we will first translate the input using a PBMT system, which can handle the rare words well. In a second step, we will generate the final translation using an NMT system. This NMT system is able to generate a more fluent and grammatically correct translation. Since the rare words are already handled by the PBMT system, there should be less problems to generate the translation of these words. Using this approach naturally introduces a necessity to handle the potential errors by the PBMT systems.

The remaining of the paper is structured as follows: In the next section we will review the related work. In Section 3, we will briefly review the phrase-based and neural approach to machine translation. Section 4 will introduce the approach presented in this paper to pre-translate the input using a PBMT system. In the following section, we will evaluate the approach and analyze the errors. Finally, we will finish with a conclusion.

2 Related Work

The idea of linear combining of machine translation systems using different paradigms has already been used successfully for SMT and rule-based machine translation (RBMT) (Dugast et al., 2007; Simard et al., 2007). They build an SMT system that is post-editing the output of an RBMT system. Using the combination of SMT and RBMT, they could outperform both single systems.

Those experiments promote the area of automatic post-editing (Bojar et al., 2015). Recently, it was shown that models based on neural MT are very successful in this task (Junczys-Dowmunt and Grundkiewicz, 2016).

For PBMT, there has been several attempts to apply preprocessing in order to improve the performance of the translation system. A commonly used preprocessing step is morphological splitting, like compound splitting in German (Koehn and Knight, 2003). Another example would be to use pre-reordering in order to achieve more monotone translation (Rottmann and Vogel, 2007).

In addition, the usefulness of using the translations of the training data of a PBMT system has been shown. The translations have been used to re-train the translation model (Wuebker et al., 2010) or to train additional discriminative translation models (Niehues and Waibel, 2013).

In order to improve the translation of rare words in NMT, authors try to translate words that are not in the vocabulary in a post-processing step (Luong et al., 2015). In (Sennrich et al., 2016), a method to split words into sub-word units was presented to limit the vocabulary size. Also the integration of lexical probabilities into NMT was successfully investigated (Arthur et al., 2016).

3 Phrase-based and Neural Machine Translation

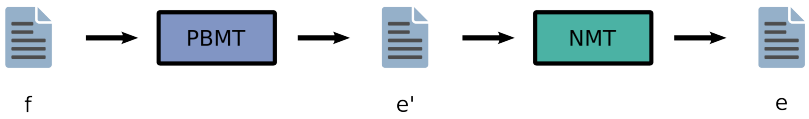
Starting with the initial work on word-based translation system (Brown et al., 1993), phrase-based machine translation (Koehn et al., 2003; Och and Ney, 2004) segments the sentence into continuous phrases that are used as basic translation units. This allows for many-to-many alignments.

Based on this segmentation, the probability of the translation is calculated using a log-linear combination of different features:

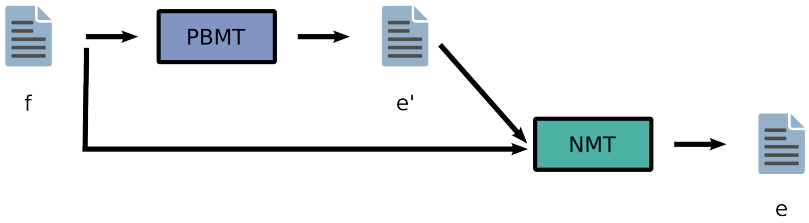
$$P(e^I, f^I) = \frac{exp(\sum_{n=1}^{N} \lambda_n h_n(e^I, f^I))}{\sum_{e'^I} exp(\sum_{n=1}^{N} \lambda_n h_n(e'^I, f^I))} \quad (1)$$

In the initial model, the features are based on language and translation model probabilities as well as a few count based features. In advanced PBMT systems, several additional features to better model the

Figure 1: Pre-translation methods



(a) Pipeline combination



(b) Mixed Input

translation process have been developed. Especially models using neural networks were able to increase the translation performance.

Recently, state-of-the art performance in machine translation was significantly improved by using neural machine translation. In this approach to machine translation, a recurrent neural network (RNN)-based encoder-decoder architecture is used to transform the source sentence into the target sentence.

In the encoder, an RNN is used to encode the source sentence into a fixed size continuous space representation by inserting the source sentence word-by-word into the network. In a second step, the decoder is initialized by the representation of the source sentence and is then generating the target sequence one word after the other using the last generated word as input for the RNN (Sutskever et al., 2014).

One main drawback of this approach is that the whole source sentence has to be stored in a fixed-size context vector. To overcome this problem, (Bahdanau et al., 2014) introduced the soft attention mechanism. Instead of only considering the last state of the encoder RNN, they use a weighted sum of all hidden states. Using these weights, the model is able to put attention on different parts of the source sentence depending on the current status of the decoder RNN. In addition, they extended the encoder RNN to a bi-directional one to be able to get information from the whole sentence at every position of the encoder RNN. A detailed description of the NMT framework can be found in (Bahdanau et al., 2014).

4 PBMT Pre-translation for NMT (PreMT)

In this work, we want to combine the advantages of PBMT and NMT. Using the combined system we should be able to generate a translation for all words that occur at least once in the training data, while maintaining high quality translations for most sentences from NMT. Motivated by several approaches to simplify the translation process for PBMT using preprocessing, we will translate the source as a preprocessing step using the phrase-base machine translation system.

The main translation task is done by the neural machine translation model, which can choose between using the output of the PBMT system or the original input when generate the translation.

4.1 Pipeline

In our first attempt, we combined the phrase-based MT and the neural MT in one pipeline as shown in Figure 1a. The input is first processed by the phrase-based machine translation system from the input language f to the target language e'. Since the machine translation system is not perfect, the output of the system may not be correct translation containing errors possibly. Therefore, we will call the output language of the PBMT system e'.

In a second step, we will train a neural monolingual translation system, that translates from the output of the PBMT system e' to a better target sentence e.

4.2 Mixed Input

One drawback of the pipelined approach is that the PBMT system might introduce some errors in the translation that the NMT can not recover from. For example, it is possible that some information from the source sentence gets lost, since the word is entirely deleted during the translation of the PBMT system.

We try to overcome this problem by building an NMT system that does not only take the output of the PBMT system, but also the original source sentence. One advantage of NMT system is that we can easily encode different input information. The architecture of our system is shown in Figure 1b.

The implementation of the mixed input for the NMT system is straight forward. Given the source input $f = f_1, \dots f_I$ and the output of the PBMT system $e' = e'_1, \dots e'_{J'}$, we generated the input for the NMT system. First, we ensured a non-overlapping vocabulary of f and e' by marking each token in f by a character and e' by different ones. Then both input sequences are concatenated to the input e^* of the NMT system.

Using this representation, the NMT can learn to focus on source word f_j and words $e'_{i'}$ when generating a word e'_j.

4.3 Training

In both cases, we can no longer train the NMT system on the source language and target language data, but on the output of the PBMT system and the target language data. Therefore, we need to generate translations of the whole parallel training data using the PBMT system.

Due to its ability to use very long phrases, a PBMT system normally performs significantly better on the training data than on unseen test data. This of course will harm the performance of our approach, because the NMT system will underestimate the number of improvements it has to perform on the test data.

In order to limit this effect, we did not use the whole phrase tables when translating the training data. If a phrase pair only occurs once, we cannot learn it from a different sentence pair. Following (Niehues and Waibel, 2013), we removed all phrase pairs that occur only once for the translation of the corpus.

5 Experiments

We analyze the approach on the English to German news translation task of the Conference on Statistical Machine Translation (WMT). First, we will describe the system and analyze the translation quality measured in BLEU. Afterwards, we will analyze the performance depending on the frequency of the words and finally show some example translations.

5.1 System description

For the pre-translation, we used a PBMT system. In order to analyze the influence of the quality of the PBMT system, we use two different systems, a baseline system and a system with advanced models. The systems were trained on all parallel data available for the WMT 2016[1]. The news commentary corpus, the European parliament proceedings and the common crawl corpus sum up to 3.7M sentences and around 90M words.

In the baseline system, we use three language models, a word-based, a bilingual (Niehues et al., 2011) and a cluster based language model, using 100 automatically generated clusters using MKCLS (Och, 1999).

The advanced system use pre-reodering (Herrmann et al., 2013) and lexicalized reordering. In addition, it uses a discriminative word lexicon (Niehues and Waibel, 2013) and a language model trained on the large monolingual data.

Both systems were optimized on the tst2014 using Minimum error rate training (Och, 2003). A detailed description of the systems can be found in (Ha et al., 2016).

The neural machine translation was trained using Nematus[2]. For the NMT system as well as for the PreMT system, we used the default configuration. In order to limit the vocabulary size, we use BPE as

[1] http://www.statmt.org/wmt16/translation-task.html

[2] https://github.com/rsennrich/nematus

described in (Sennrich et al., 2016) with 40K operations. We run the NMT system for 420K iterations and stored a model every 30K iterations. We selected the model that performed best on the development data. For the ensemble system we took the last four models. We did not perform an additional fine-tuning.

The PreMT system was trained on translations of the PBMT system of the corpus and the target side of the corpus. For this translation, we only used the baseline PBMT system.

5.2 English - German Machine Translation

The results of all systems are summarized in Table 2. It has to be noted, that the first set, tst2014, has been used as development data for the PBMT system and as validation set for the NMT-based systems.

System	Dev/Valid	Test

PBMT	19.76	21.80	26.42
Advanced PBMT	21.62	23.34	28.13
Pipeline	20.56	22.04	26.75
Pipeline Advanced	21.76	22.92	27.61
Mix	21.88	24.11	28.04
Mix Advanced	22.53	24.37	29.62
Mix Advanced Ensemble	23.16	25.35	30.67

Table 2: Experiments for English→German

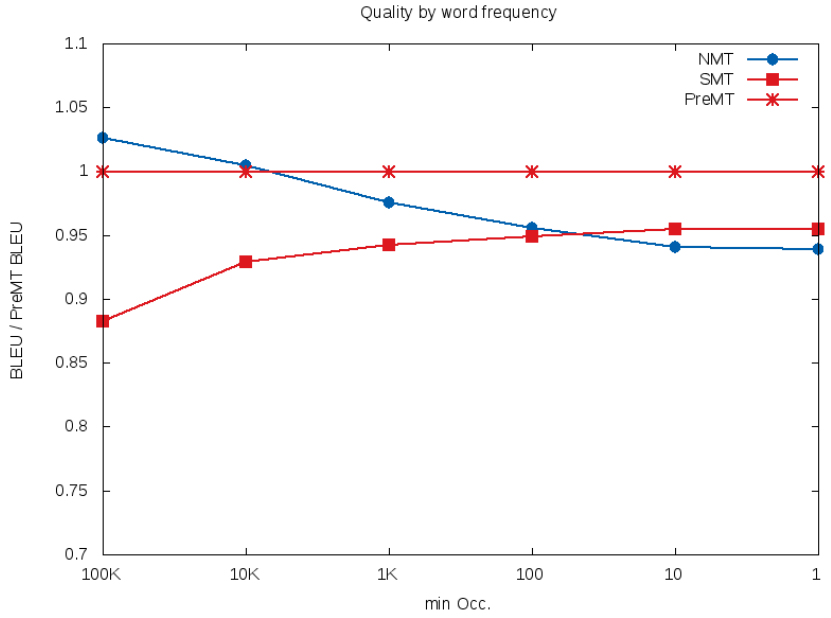
Using the neural MT system, we reach a BLEU score of 23.34 and 27.65 on tst2015 and tst2016. Using an ensemble system, we can improve the performance to 24.03 and 28.89 respectively. The baseline PBMT system performs 1.5 to 1.2 BLEU points worse than the single NMT system. Using the PBMT system with advanced models, we get the same performance on the tst2015 and 0.5 BLEU points better on tst2016 compared to the NMT system.

First, we build a PreMT system using the pipeline method as described in Section 4.1. The system reaches a BLEU score of 22.04 and 26.75 on both test sets. While the PreMT can improve of the baseline PBMT system, the performance is worse than the pure NMT system. So the first approach to combine neural and statistical machine translation is not able the combine the strength of both system. In contrast, the NMT system seems to be not able to recover from the errors done by the SMT-based system.

In a second experiment, we use the advanced PBMT system to generate the translation of the test data. We did not use it to generate a new training corpus, since the translation is computationally very expensive. So the PreMT system stays the same, being trained on the translation of the baseline PBMT. However, it is getting better quality translation in testing. This also leads to an improvement of 0.9 BLEU points on both test sets. Although it is smaller then the difference between the two initial phrase-based translation systems of around 1.5 BLUE points, we are able to improve the translation quality by using a better pre-translation system. It is interesting to see that we can improve the quality of the PreMT system, but improving one component (SMT Pre-Translation), even if we do it only in evaluation and not in training. But the system does not improve over the pure NMT system and even the post editing of the NMT system lowers the performance compared to the initial PBMT system used for pre-translation.

After evaluating the pipelined system, we performed experiments using the mixed input system. This leads to an improvement in translation quality. Using the baseline PBMT system for per-translation, we perform 0.8 BLEU points better than the purely NMT system on tst2015 and 0.4 BLEU point better on tst2016. It also showed better performance than both PBMT systems on tst2015 and comparable performance with the advanced PBMT on tst2016. So by looking at the original input and the pre-translation, the NMT system is able to recover some of the errors done by the PBMT system and also to prevent errors the NMT does if it is directly translating the source sentence.

Figure 2: Compare BLEU score by word frequency



Using the advanced PBMT system for input, we can get additional gains of 0.3 and 1.6 BLEU points The system even outperforms the ensemble system on tst2016. The experiments showed that deploying a pre-translation PBMT system with a better quality improves the NMT quality in the mixed input scheme, even when it is used only in testing, not in training.

By using an ensemble of four model, we improve the model by one BLEU point on both test sets, leading to the best results of 25.35 and 30.67 BLEU points. This is 1.3 and 1.8 BLEU points better than the pure NMT ensemble system.

5.3 System Comparison

After evaluating the approach, we further analyze the different techniques for machine translation. For this, we compared the single NMT system, the advanced PBMT system and the mixed system using the advanced PBMT system as input.

Out initial idea was that PBMT systems are better for translating rare words, while the NMT is generating more fluent translation. To confirm this assumption, we edited the output of all system. For all analyzed systems, we replaced all target words, which occur in the training data less than N times, by the *UNK* token. For large N, we have therefore only the most frequent words in the reference, while for lower N more and more words are used.

The results for $N \in \{1, 10, 100, 1K, 10K, 100K\}$ are shown in Figure 2. Of course, with lower N we will have fewer *UNK* tokens in the output. Therefore, we normalized the BLEU scores by the performance of the PreMT system.

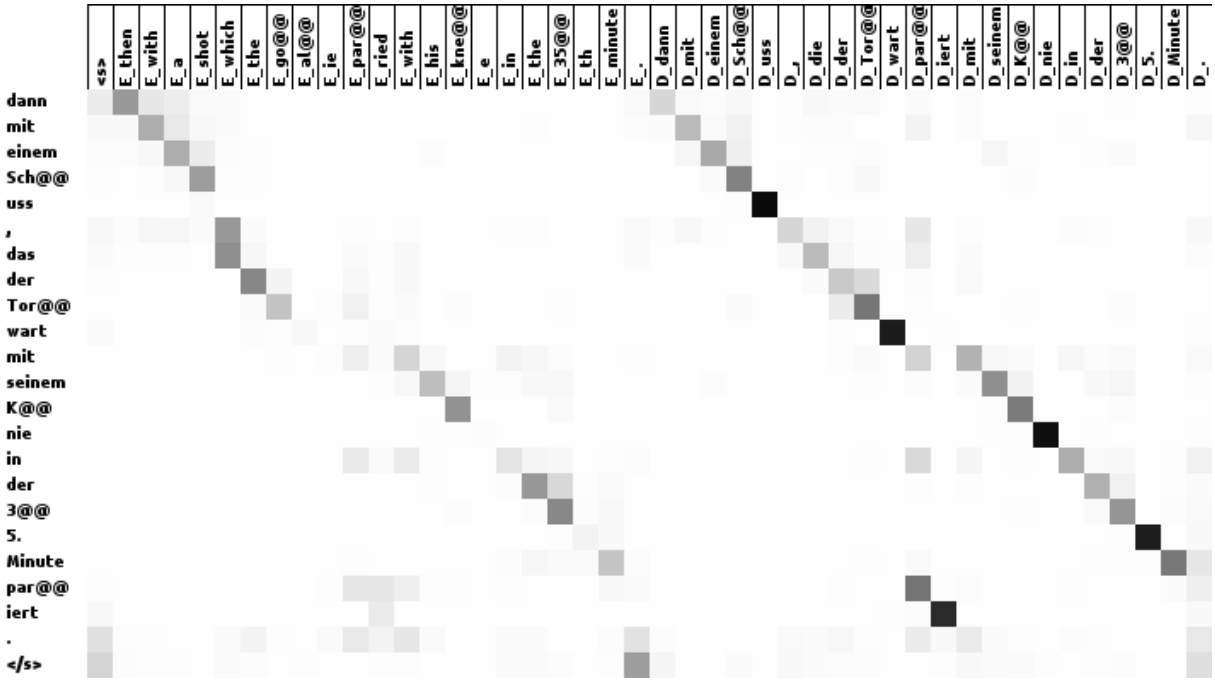
We can see in the figure, that when $N = 100K$, where only the common words are used, we perform best using the NMT system. The PreMT system performs similar and the PBMT system performs clearly worse. If we now decrease N, more and more less frequent words will be considered in the evaluation of the translation quality. Although the absolute BLEU scores raise for all systems, on these less frequent words the PBMT performs better than the NMT system and therefore, finally it even achieves a better performance.

In contrast to this, the PreMT is able to benefit from the pre-translation of the PBMT system and therefore stays better than the PBMT system.

Table 3: Example sentence translated by different techniques

English:	Then with a shot which the **goalie parried** with his knee in the 35th minute.
PBMT:	Dann mit einem Schuss, die der **Torwart pariert** mit seinem Knie in der 35. Minute.
NMT:	Dann mit einem Schuss, den der **Gott** mit seinem Knie in der 35. Minute.
Pre:	Dann mit einem Schuss, das der **Torwart** mit seinem Knie in der 35. Minute **pariert**.
Pre(gloss):	Then with a shoot, that the goali with his knee in the 35th minute parried.

Figure 3: Alignment generated by attention model



5.4 Examples

In Table 3 we show the output of the PBMT, NMT and PreMT system. First, for the PBMT system, we see a typical error when translating from and to German. The verb of the subclause *parried* is located at the second position in English, but in the German sentence it has to be located at the end of the sentence. The PBMT system is often not able to perform this long-range reordering.

For the NMT system, we see two other errors. Both, the words *goalie* and *parried* are quite rarely in the training data and therefore, they are splitted into several parts by the BPE algorithm. In this case, the NMT makes more errors. For the first word, the NMT system generates a complete wrong translation *Gott (engl. god)* instead of *Torwart*. The second word is just dropped and does not appear in the translation.

The example shows that the pre-translation system prevents both errors. It is generating the correct words *Torwart* and *pariert* and putting them at the correct position in the German sentence.

To better understand how the pre-translation system is able to generate this translation, we also generated the alignment matrix of the attention model as shown in Figure 3. The x-axis shows the input, where the words from the pre-translation are marked by $D\_$ and the words from the original source by $E\_$. The y-axis carries the translation. The symbol @@ marks subword units generated by the BPE algorithm. First, as indicated by the two diagonal lines the model is considering as both inputs, the original source and the pre-translation by the two diagonal lines.

Secondly, we see that the attention model is mainly focusing on the pre-translation for words that are not common and therefore got splitted into several parts by the BPE, such as *shoot*, *goalie* and *parried*.

A second example, which shows what happens with rare words occur in the source sentence, is shown in Table 4. In this case, the word *riot* is not translated but just passed to the target language. This

Table 4: Example of rare word translation

English:	... a riot in the stadium.
PBMT:	... einen Aufruhr im Stadion.
NMT:	... einen Riot im Stadion.
Pre:	... einen Aufruhr im Station.
Pre (gloss):	... a riot in_the stadium.

behaviour is helpful for rare words like named entities, but the NMT system is using it also for many words that are not named entities. Other examples for words that were just passed through and not translated are *crossbar* or *vigil*.

6 Conclusion

In this paper, we presented a technique to combine phrase-based and neural machine translation. Motivated by success in statistical machine translation, we used phrase-based machine translation to pre-translate the input and then we generate the final translation using neural machine translation.

While a simple serial combination of both models could not generate better translation than the neural machine translation system, we are able to improve over neural machine translation using a mixed input. By simple concatenation of the phrase-based translation and the original source as input for the neural machine translation, we can increase the machine translation quality measured in BLEU. The single pre-translated system could even outperform the ensemble NMT system. For the ensemble system, the PreMT system could outperform the NMT system by up to 1.8 BLEU points.

Using the combined approach, we can generate more fluent translation typical for the NMT system, but also translate rare words. These are often more easily translated by PBMT. Furthermore, we are able to improve the overall system performance by improving the individual components.

Abstract

With the success of word embedding methods in various Natural Language Processing tasks, all the fields of distributional semantics have experienced a renewed interest. Beside the famous word2vec, recent studies have presented efficient techniques to build distributional thesaurus; in particular, Claveau et al. (2014) have already shown that Information Retrieval (IR) tools and concepts can be successfully used to build a thesaurus. In this paper, we address the problem of the evaluation of such thesauri or embedding models. Several evaluation scenarii are considered: direct evaluation through reference lexicons and specially crafted datasets, and indirect evaluation through a third party tasks, namely lexical subsitution and Information Retrieval. For this latter task, we adopt the query expansion framework proposed by Claveau and Kijak (2016). Through several experiments, we first show that the recent techniques for building distributional thesaurus outperform the word2vec approach, whatever the evaluation scenario. We also highlight the differences between the evaluation scenarii, which may lead to very different conclusions when comparing distributional models. Last, we study the effect of some parameters of the distributional models on these various evaluation scenarii.

1 Introduction

For years, distributional semantic has aimed at building thesauri (or lexicons) automatically from text corpora. For a given input (ie. a given word), these thesauri identify semantically similar words based on the assumption that they share a distribution similar to the input word's one. In practice, this distributional assumption is set such that two words would be considered close if their occurrences share similar contexts. These contexts are typically co-occurring words in a limited window around the considered words, or words syntactically linked. Recently, many studies have explored new techniques to represent the word (or phrase or document) through embeddings: most often, words are thus represented in a vector space, such that two words with close meanings are close in this space. One of the most popular approach is the famous word2vec technique (Mikolov et al., 2013). Of course, such embedding techniques rely on the same assumption than "traditional" distributional semantics (although many studies do not acknowledge it clearly).

Evaluating these thesauri or embeddings remains a crucial point to assess the quality of the construction methods and parameters used. In this article, we propose to examine this evaluation problem with different evaluation protocols. Indeed, a commonly used approach is to compare the generated thesauri to one or several reference lexicons. This evaluation procedure, called 'intrinsic', has the advantage of being straightforward and simple as it aims at estimating the quality and completeness of the generated thesaurus. However, it is based on reference lexicons whose own completeness, quality, or simply their availability for the considered domain/language/genre are not always granted. Here, we propose to examine the impact of these problems by also using other evaluation protocols, based on other types of reference datasets, and by third-party tasks. In particular, following the work of Claveau and Kijak (2016), we rely on information retrieval (IR) as a realistic evaluation use case. The comparison of the results obtained with these different protocols/datasets should help us to judge the relevance of these assessment scenarios.

After a review of related work (next section), the article addresses the aforementioned subjects: the aspects related to the construction of thesauri are presented in Section 3, while those about the evaluation

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1837–1848, Osaka, Japan, December 11-17 2016.

with specially crafted resources or by IR are respectively discussed in Section 4 and Section 5. Finally, we present some conclusions and perspectives about this work in the last section.

2 Related work

2.1 Building distributional thesauri

Distributional thesauri rely on the famous formula of Firth (Firth, 1957): *"You should know a word by the company it keeps"*. In such thesauri, each word is semantically characterized by all the contexts in which it appears. The semantic neighbors of an entry word are then words whose contexts are similar to that of the entry. Since the pioneering work of Grefenstette (1994) and Lin (1998), many studies have examined distributional thesaurus building. The semantic link considered between an entry word and its neighbors is varied: synonyms, hyperonymy, hyponymy or another (Budanitsky and Hirst, 2006; Adam et al., 2013, for a discussion). Despite their diversity, these links are interesting for many applications related to Natural Language Processing. The various aspects of the thesaurus building is therefore a research field still very active.

One first step concerns the definition of the distributional context of a given word. The graphical contexts simply consider the words appearing around the occurrences of the target word, while syntactic contexts are formed with the syntactic predicates and arguments of the occurrences of the target word. The latter, if it is considered more accurate, requires a prior parsing step which (i) is not always available, (ii) may be misleading.

There are many relationships between distributional semantics and IR. For example, vectorial representations of the contexts are often used (Turney and Pantel, 2010), but unrelated with weighting schemes and relevance functions used in IR (with the exception of Vechtomova and Robertson (2012) in the slightly different context of computing similarities between named entities). However, the weighting of contexts provides more relevant neighbors. Broda et al. (2009) thereby proposed to consider the ranks rather than directly the weights of contexts to overcome the influence of weighting functions. Some bootstrap methods were also proposed to modify the weight of the contexts of a word, by taking into account its semantic neighbors (Zhitomirsky-Geffet and Dagan, 2009; Yamamoto and Asakura, 2010). Another example of relationship between distributional semantics and IR is the use of search engines to collect co-occurrence information or contexts on the web (Turney, 2001; Bollegala et al., 2007; Sahami and Heilman, 2006; Ruiz-Casado et al., 2005). Finally, given that the "traditional" distributional representation of contexts is sparse and redundant (Hagiwara et al., 2006), several methods for dimension reduction were tested: from Latent Semantic Analysis (Landauer and Dumais, 1997b; Padó and Lapata, 2007; Van de Cruys et al., 2011) to *Random Indexing* (Sahlgren, 2001), through factorization by non-negative matrices (Van de Cruys, 2010).

The problem of the construction of distributional thesaurus may be expressed in a simple way as a conventional IR problem (Claveau et al., 2014). All contexts of a target word are then represented as a document (or query), and distributional neighbors of the target word are the sets of similar contexts. This formulation of distributional neighbors search process offers interesting research tracks and easily accessible tools.

2.2 Tested models

In this paper, several distributional models are tested. A first group of models, that may be called traditional distributional models are considered. In the following sub-section we report results obtained by a state-of-the art approach, hereafter denoted *base*, that uses a cosine similarity and weighting by mutual information (Ferret, 2013), an improved version (*rerank*) which uses machine learning technique to rerank neighbors (Ferret, 2013), and another version (*synt*) based on syntactic contexts (Ferret, 2014) rather than graphic ones are also tested.

As explained in Claveau et al. (2014), the problem of building a distributional thesaurus can be translated into a problem of searching similar documents and can therefore be carried out with IR techniques. In this context, all the contexts of a given word in a corpus are collected; this set of contexts forms what is considered as a document. Building an entry in the thesaurus, ie. finding the closest words (in a dis-

tributional sense) of a word w_i, is thus equivalent to finding documents (contexts) close to the document representing the contexts of w_i (seen as a query in the IR system). This has led to new distributional models, that differ from the previous ones by the way the similarity between two words (or their contexts) is computed. We also report the results of systems based on this IR approach. Several variants, each using a different way to compute the similarity between the sets of context, are considered: namely TF-IDF/cosine and Okapi-BM-25 (Robertson et al., 1998). In previous work, we also proposed an adjusted versions of them *adjusted-TF-IDF, adjusted-Okapi BM25*, in which the influence of the document size is reinforced in order to give more importance to the most discriminating context words (Claveau et al., 2014). Other IR systems are tested; they are based on probabilistic language modeling (denoted LM), with both Dirichlet smoothing (varying the values of the parameter μ) and Hiemstra smoothing (smoothing with the probabilities of occurrence of words throughout the collection; with different values of λ) (Claveau and Kijak, 2016). All these very classical IR models are not detailed further here; the interested reader will find the concepts and useful details (such as the role of the parameters) in the cited references or IR surveys (Manning et al., 2008, for example).

As a last group of models, we consider approaches based on dimensionality reduction. In such models, the data is represented in dense vector space, usually of small dimensionality (for instance, $\mathbb{R}^{500}$). We report results yielded by models based on usual dimension reduction techniques (LSI, LDA, Random projections (RP)), with different numbers of dimensions. In this group, we also consider the very popular embedding approaches, namely Word2Vec (Mikolov et al., 2013). Indeed, they have been shown to be equivalent to standard distributional models with an additional dimensionality reduction step (Levy and Goldberg, 2014). For comparison purpose, we also indicate the results of a word2vec model pre-trained on the Google News corpus (which is significantly larger than AQUAINT-2); it is freely available at `https://code.google.com/p/word2vec/`.

2.3 Evaluating distributional thesauri

As already mentioned, the evaluation of a thesaurus can be done in two ways: (i) the intrinsic evaluation consists in comparing the produced thesaurus with a reference resource; (ii) the extrinsic evaluation assesses the thesaurus through its use in a given task.

The intrinsic evaluation requires to have reference lexicons. Usual lexicons used as references are WordSim 353 (Gabrilovich and Markovitch, 2007), WordNet 3.0 (Miller, 1990) or Moby (Ward, 1996). The two latter exploit larger resources (as synonyms) and are those used in this work for the intrinsic evaluation, as in Ferret (2013). Other data sets, as the set of synonyms from the TOEFL test (Landauer and Dumais, 1997a) or the semantic relationships in BLESS (Baroni and Lenci, 2011), are not directly lexicons, but can also be used for direct evaluation. Given a reference lexicon, it is then easy to compute recall, accuracy or any other measure of quality.

If the intrinsic evaluation is simple, its relevance depends on the adequacy of the lexicons used as references. For this reason, several studies have suggested extrinsic evaluation through a task, such as the lexical substitution task proposed at SemEval 2007 (McCarthy and Navigli, 2009). The goal is to replace a word in a sentence by a neighbor (given by the evaluated thesaurus) and verify that it did not change the meaning of the sentence, by comparing the obtained results to the substitutions proposed by humans. In such a task, the exact synonyms are favored over other types of semantic relationships.

Several studies use distributional information within an IR framework (Besançon et al., 1999; Billhardt et al., 2002), like recent lexical representations such as word2vec (Huang et al., 2012; Mikolov et al., 2013). The aim is to improve the representation of documents and/or the Relevance Status Value function (RSV, ie. the function used in IR systems to rank the answers to a query according to their supposed relevance), by exploiting the similarities between word contexts. Nevertheless, the process of creating the distributional thesaurus is not dissociated from the IR process in these studies, which makes the evaluation of the only distributional information contribution impossible. Recently, we have proposed to specifically evaluate the distributional thesauri in IR by using semantic neighbors to expand the queries (Claveau and Kijak, 2016). In this paper, we adopt the same framework in Section 5.

3 Intrinsic Evaluation of distributional models

3.1 Principles and material

For the sake of comparison with published results, the data used for our experiments are those used in several studies. The corpus used to collect the contexts is AQUAINT-2 (Vorhees and Graff, 2008); it is composed of articles in English containing a total of 380 millions of words. The words considered for our thesaurus entries are common nouns occurring at least 10 times in the corpus, that is 25 000 different nouns. The contexts of all occurrences of these words are collected; in the experiments reported below, contexts are formed by the two words at the right and two words at the left of the target noun, along with their position. For example, in the sentence "... all forms of restriction on freedom of expression, threats ..." the words restriction-2, on-1, of+1, expression+2 are added to the set of contexts of freedom.

As we mentioned earlier, we use WordNet (WN) and Moby for intrinsic assessment of generated thesauri. These two resources have different, additional characteristics: WN identifies strong semantic links (synonyms or quasi-synonyms) while Moby identifies a greater variety of links (hypernyms, meronyms, co-hyponymy...). WN offers on average 3 neighbors for 10 473 nouns of AQUAINT-2, and Moby contains on average 50 neighbors of 9 216 nouns. Together, these resources cover 12 243 nouns of the corpus with 38 neighbors on average. These resources are used as reference for the evaluation; more details about the semantic links considered by these resources and their use for distributional thesaurus evaluation can be found in the literature (Ferret, 2013; Claveau et al., 2014). The number of nouns and the variety of semantic relations that they contain make these references a comprehensive evaluation data set, compared with other existing benchmarks (such as WordSim 353 (Gabrilovich and Markovitch, 2007) for instance).

3.2 Intrinsic evaluation results

Figure 1 presents the results obtained by different thesaurus building systems presented in Section 2.2, applied to the AQUAINT-2 corpus. The performance measures used to compare the generated thesauri with the reference (WordNet + Moby, denoted by WN+M) are those typically used for this task: precision at different levels (on the top 5, 10, 50, 100 neighbors), MAP (Mean Average Precision) and R-precision, expressed as a percentage, averaged on the 12 243 nouns in the WN+M reference. For all these distributional models, among all the parameters tested, we only report some of the best performing ones in terms of MAP (number of dimensions, size of the context window...).

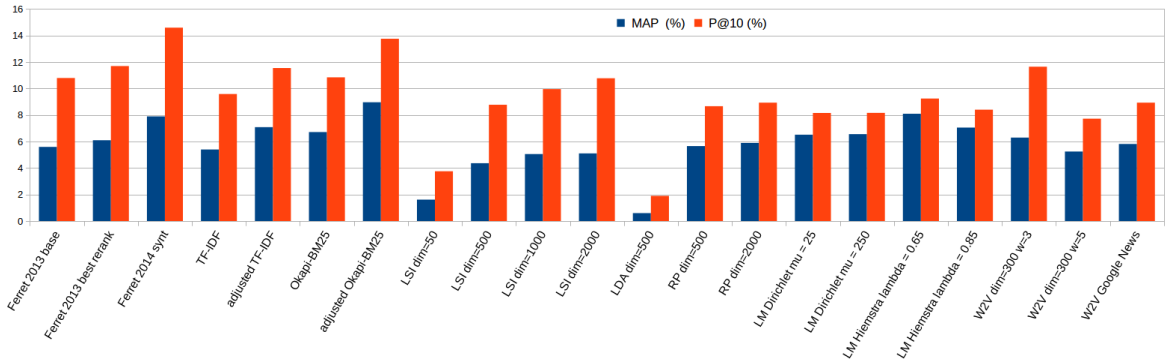

Figure 1: Performance of various distributional and embedding models for building distributional thesauri over the WN+M reference

As already mentioned in the literature, this kind of evaluation with reference lexicons leads to very severe conclusions about the quality of the evaluated distributional thesauri. For instance, the P@10 score states that, in average, 9 out the 10 first neighbors of an entry word are errors, whatever the model. Nonetheless, it is worth noting that some traditional models, and in particular recent IR-based ones such as adjusted Okapi-BM25, obtain better results than the popular word2vec ones. Overall, dimension reduction techniques yields low results: The lower the number of dimensions considered, the worse the

Method	Pearson's r	Spearman's ρ	Kendal's τ
adjusted Okapi	-0.0009 (p=0.9723)	0.3148 (p=5.0e-32)	0.2093 (p=2.5e-30)
W2V dim=300 w=3	0.0027 (p=0.9314)	0.2913 (p=1.4e-21)	0.1944 (p=9.7e-21)

Table 1: Correlation coefficients (with their p-values) between the Average Precision (AP) of each word on the WN+M dataset and its frequency

Method	Pearson's r	Spearman's ρ	Kendal's τ
adjusted Okapi	-0.0923 (p=0.0007)	0.0604 (p=0.0274)	0.0465 (p=0.0111)
W2V dim=300 w=3	-0.1218 (p=9.01e-05)	0.0657 (p=0.0352)	0.0479 (p=0.0213)

Table 2: Correlation coefficients (with their p-values) between the Average Precision (AP) of each word on the WN+M dataset and its polysemy

results. This negative result is in line with some conclusions of previous work (Van de Cruys, 2010). The occurrence of certain very specific contextual words is indeed a strong indicator of the semantic proximity of words. Aggregation of different words into a single dimension is then detrimental to distinguish the semantic neighbors. This is also confirmed by the fact that within a model family, the parameter settings leading to the best results are those which give more weight to discriminating words: squared IDF for Okapi, very few smoothing for language modeling (ie. low values of μ and λ).

3.3 Influence of data characteristics

It is interesting to examine how some characteristics of the data may influence the results. For instance, it has already been noted (Ferret, 2013) that the frequency of words for which we try to find the neighbors has a great influence on the final quality. This is easily explained by the fact that the more frequent the nouns are, the more contexts they have to describe them; and finally, the better the results are. In order to verify what is the actual effect on our results, given our data and methods, we estimate the correlation between the entry quality in the distributional thesaurus, measured by the Average Precision on the WN+M dataset, and the its frequency in the AQUAINT-2 corpus; results are given in Table 1.

As expected, these results confirm the effect of the frequency on the entry quality. Yet, it should be noted that this correlation is not perfect; other characteristics may interfere on the results.

Another data property that may influence the results is polysemy. Indeed, all the methods evaluated in Section 3.2 consider that all the occurrences of a word (or lemma) should result in one thesaurus entry, that is, no disambiguation is performed. Thus, one could suspect that the list of distributional neighbors of a polysemic word would be impacted. As we have done before, to verify this supposition, we estimate the correlation between the entry quality (AP on the WN+M reference) and the number of senses for that entry as encoded in WordNet. Results are given in Table 2. For comparison purpose, we also report the results obtained with the word2vec GoogleNews model.

The effect of polysemy on the thesaurus results is not obvious. On the one hand, one can observe that there is no correlation between the results and the number of word senses for the models trained on our corpus. On the other hand, the word2vec GoogleNews model shows a statistically significant negative correlation; it means that the less polysemic words tends to yield the best results.

4 Evaluating with specially crafted resources

The evaluation through reference lexicons, as presented above, has several shortcomings already mentioned in Section 2. In addition to these, it is worth noting that resources such as WordNet or Moby were not initially designed for evaluation, and choices made for their building are not necessarily adequate for our evaluation task. For instance, there is no graduation: for a given semantic relation two words are either related or not. In order to provide more relevant evaluation resources, other direct evaluation of distributional thesauri were proposed. In this section, we consider SimLex999 (Hill et al., 2014) that was specially developed to evaluate distributional models. One of its most interesting particularities is that,

according to the authors: "it explicitly quantifies similarity rather than association or relatedness, so that pairs of entities that are associated but not actually similar have a low rating".

4.1 Experimental setting

SimLex999 is a resource in which pairs of words (nouns, verbs, adjectives) are given a score according to their association strength. This score was given by a group of annotators with light instructions on what is to be considered as "association" (Hill et al., 2014, Sec. 3.3). This is intended to reflect the light formalization of the semantic links captured by distributional models.

The evaluation based on this resource aims at comparing the word pair list sorted by association strength and the word pair sorted according to the distributional score. In practice, the Spearman's ρ rank correlation is used. A review of the most recent results obtained with this dataset can be found at `http://www.cl.cam.ac.uk/~fh295/simlex.html`.

4.2 Results

Table 3 shows the SimLex999 results of the best traditional model (adjusted Okapi-BM25) and the best word2vec model. For comparison purpose, we also report the results obtained with the freely available word2vec model trained on the GoogleNews corpus. One can observe a very important difference between the Okapi model and the word2vec trained on the AQUAINT-2 corpus. The GoogleNews model also yields a good score, but one has to keep in my mind that it was trained on a larger corpus than ours.

Method	Spearman's ρ
adjusted Okapi	0.4511
W2V dim=300 w=3	0.3691
W2V GoogleNews	0.4419

Table 3: Correlation coefficients (with their p-values) of distributional models on the SimLex999 dataset

4.3 Influence of data characteristics

As done for the previous evaluation scenario, it is interesting to examine how the SimLex999 results are impacted by the data characteristics. In Figure 2, we report the evolution of Spearman's ρ according to the frequencies of the words considered; ρ is computed on subsets of the SimLex999 pairs whose frequencies are both under a given threshold. The model used here is word2vec trained on the AQUAINT-2 corpus with dim=300 and w=3. One can observe that there are some variations when considering the lowest frequencies; they are due to the small number of SimLex pairs which make the correlation computation very sensitive. Beside that, overall, the frequency does not seem to play an active role in the performance, which seems to contradict what was observed in Section 3.3. Yet, it is worth noting that the less frequent SimLex999 words are not rare in our corpus (more than 2,000 occurrences for the rarest one). SimLex999 contains only frequent or very frequent words and thus does not adequately evaluate the capacity of the model to handle rarer words.

Figure 3 adopts the same setting and presents the impact of polysemy on the SimLex999 performance: ρ is computed on subsets of the SimLex999 pairs whose sum of senses, as encoded in WordNet, is under a given threshold. Here, the effect of polysemy appears very clearly: polysemic words have a negative impact on the capacity of the model to encode the similarity between words as measured by the SimLex999 dataset. This result is not surprising, but it did not appeared in the previous lexicon-based evaluation scenario due to the protocol used.

Finally, these two direct evaluation scenarii, using reference lexicon or specially crated datasets, give dissimilar results, and are not impacted by the same data characteristics.

5 Indirect evaluation through query expansion

Following our previous work (Claveau and Kijak, 2016), in this section we use an IR task as a way to evaluate distributional models. More precisely, we use distributional thesauri to expand queries: for each

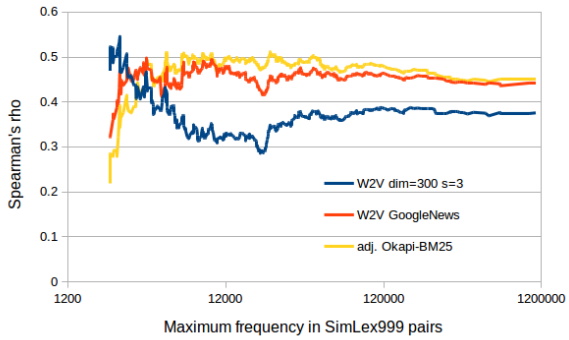

Figure 2: Performance on the SimLex999 dataset according to the frequency of the words considered; log-scale

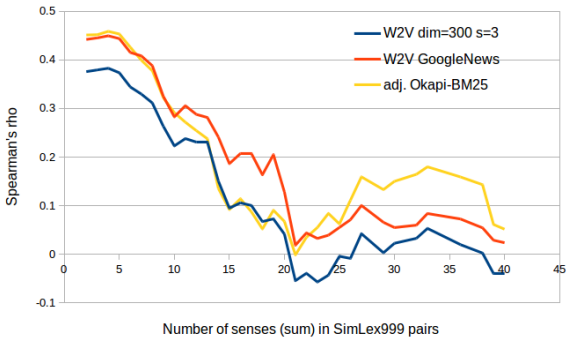

Figure 3: Performance on the SimLex999 dataset according to the sum of the sense of the words in the considered pairs

query noun, its neighbors found in the considered thesaurus are added to the query. The experimental framework and the results obtained are successively presented below.

5.1 Experimental setting

The IR collection used in the experiments comes from the Tipster project and was used as part of TREC. It contains more than 170 000 documents and 50 queries in English (the queries are structured: the query itself, a narrative field detailing the criteria of relevance; in the experiments reported below, we only use the query field). This collection is particularly suited since its documents come from the *Wall Street Journal* and are similar to those of AQUAINT-2.

The IR system used is Indri (Metzler and Croft, 2004; Strohman et al., 2005). This probabilistic system implements a combination of language modeling (Ponte and Croft, 1998) (as the ones used in Sect. 3) and inference networks (Turtle and Croft, 1991); it is known to provide state-of-the-art results. In the experiments reported below, we use its standard settings, ie. Dirichlet smoothing (with $\mu = 2500$ as recommended). In our case, Indri offers an additional advantage: it has a complex query language that allows us to include the words of the distributional thesaurus by making best use of the inference network model; in practice, the dedicated operator `'#syn'` is used to aggregate the counts of the words indicated as synonyms (see Indri documentation for details). To remove the effects of inflection on the results, the plural and singular forms of nouns of the queries are added, either in the non-extended, original queries or those extended with the semantic neighbors. As example, we give below a sample query, with its non-expanded form and its expanded form (adjusted Okapi top 5) using the inference network operators of Indri:

– query : `coping with overcrowded prisons`
– normal form : `#combine( coping with overcrowded #syn( prisons prison ) )`
– expanded form : `#combine( coping with overcrowded #syn( prisons prison inmate inmates jail jails detention detentions prisoner prisoners detainee detainees ) )`

The performance for this IR task is typically measured by precision at different thresholds (P@x), R-precision, and MAP. Therefore, to evaluate the thesaurus, we measure the gains in terms of precision, MAP, etc. between the results without and with expansion. We also indicate the average of the AP (Average Precision) gain by query, noted AvgGainAP (not be confused with the gain of MAP, which is the gain calculated from the AP averages over the query). Non statistically significant results (Wilcoxon and t-test with $p < 0.05$) are in italics.

5.2 Expansion results

Table 4 presents the performance gains achieved by expanding the queries with the words collected in the thesaurus (the ones used in the previous experiments). Here we only report results when expanding

with the top 10 nearest neighbors (other settings lead to similar conclusions ; see (Claveau and Kijak, 2016)). We also show the results obtained by expanding the queries with the reference lexicons (WN alone and WN+M).

Expansion	MAP	AvgGainAP	R-Prec	P@5	P@10	P@50	P@100
without	21.78	-	30.93	92.80	89.40	79.60	70.48
with WN	+12.44	+36.3	+7.01	+4.31	+7.16	+7.60	+10.87
with WN+M	+11.00	+28.33	+7.78	*+3.02*	+5.37	+6.53	+9.17
with adjusted Okapi top 10	+13.80	+24.36	+9.58	*+2.16*	+4.03	+5.58	+8.26
with W2V dim=300 s=3 top 10	+5.20	+17.83	+4.75	*+1.29*	*+2.68*	+4.32	+5.16
with W2V GoogleNews top 10	+13.70	+30.52	+9.52	*+3.02*	*+3.58*	+8.14	+10.19

Table 4: Relative gain of performance (%) when expanding queries with different thesauri

First, we note that for any thesaurus used, the query expansion brings a significant gain in performance. By the way, it contradicts the conclusions of (Voorhees, 1994) about the alleged lack of interest in using WN to expand queries. The most notable fact here is the excellent results obtained with the thesaurus built automatically (traditional or word2vec), that even exceed those of the reference lexicons. While its precision on the first 10 neighbors was evaluated under 14% in Section 3, the adjusted Okapi-BM25 and word2vec thesauri generate expansions yielding the better MAP gains. The average AP gain (AvgGainAP) also provides interesting information: it is maximum with WN, which therefore provides a stable improvement (gain for most queries). This is due to the fact that the words added to the query by WN are synonyms, which presents a low risk. This stability is lower with other thesauri; as the MAP gain remains generally good, it indicates that only certain queries benefit from significant absolute gains.

6 Comparing evaluation results

6.1 Overview

The results of the previous experiences raise questions about the consistency between the lexicon based, similarity-based and task-based evaluations. We want to know, for example, if the P@10 on the WN-based evaluation between two thesaurus construction methods, even if stated as statistically significant, is sensible when now using WN+M as a reference dataset, or in IR, or in the SimLex999 evaluation. We also add the results obtained on the lexical substitution framework proposed in SemEval 2007 (McCarthy and Navigli, 2009). In this task, the distributional thesauri are evaluated on their ability to provide words that are judged as similar in a specific context. In the experiments reported below, we use a very simple strategy: the 10 closest neighbors are proposed, whatever the context. The results are evaluated in terms of precision (referred as the out-of-ten precision in SemEval 2007).

Let us consider Figure 4. The performance on the different evaluation protocols is reported for four distributional models used before: the adjusted Okapi-BM25, word2vec (dim=300, w=3), word2vec (dim=300, w=9) and the GoogleNews word2vec model. Several things are worth noting from this figure. Some models (adjusted Okapi-BM25 for instance) outperform others (for instance, word2vec) on every evaluation protocol. Yet, large difference for one evaluation protocol does not lead to large margin in another evaluation (consider for instance P@10 on the IR task versus the SimLex999 correlation scores). When considering models with more similar results, one can even see that one model can be better at a task and worse at another, sometimes with significant margins (for instance, consider the two word2vec models with s=3 and s=9).

This latter point raises questions on the validity of certain evaluation protocols. In previous work (Claveau and Kijak, 2016), we have shown that the precision of the thesaurus, as measured by a comparison with exiting lexicons, is largely under-estimated when considering the IR-based evaluation. It is mainly caused by the incompleteness of the lexicons used in the intrinsic evaluation. Yet, in this previous work, there was a correlation between these two evaluation protocols (models obtaining the best results for IR yielded the best results for the lexicon-based evaluation, etc.). As seen in Figure 4 with the adjusted Okapi and GoogleNews models, this is not the case in general.

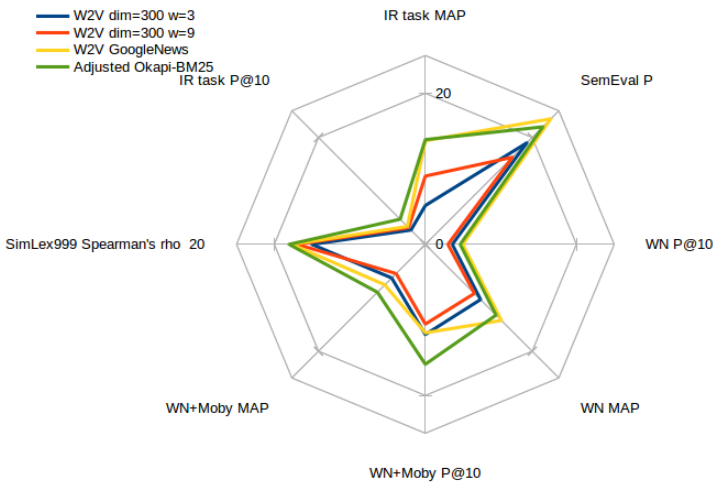

Figure 4: Performance of the adjusted Okapi and word2vec models trained on the AQUAINT-2 corpus; for comparison purpose, the results of the GoogleNews word2vec model are also reported.

6.2 Model parameters

One could argue that the previous results are due to the different approaches (or training corpus in the case of the GoogleNews model) used by these models. In order to confirm or infirm that, we study the evolution of all our evaluation scores according to one specific parameter for a given model (here, word2vec). Figure 5 shows the performance evolution on the different evaluation scenarii according to the dimensionality (respectively the size of the context window). Several points are worth noting. First, this figure highlights here again the fact that the best model (or set of parameters) for one evaluation scenario is not necessarily the best for another. A small context window yields the best results for SimLex999, while a maximum is reached at s=3 when evaluating with WN (strict synonymy) or WN+M (large range of semantic relations). Concerning the IR task, the window size has few effect on P@10 but has a great impact on the MAP. This is due to the fact that the terms used as expansion barely modify the 10 first documents retrieved by the search engines, but have a greater impact on the whole list of retrieved documents (expansion helps finding documents that share no common words with the original queries). Large windows help identifying words appearing in the same documents than the query words (much like LSI would do) and thus benefits to the MAP.
Using a small dimension is detrimental to every task; The resulting vector space cannot represent adequately the word semantics. Conversely, a large number of dimensions does not allow the necessary generalization needed for retrieving new documents (IR MAP) or the large variety of relations used in WN+M. Thus, for these evaluation scenarii, a dimension between 300 and 500 appears as a good compromise. But for the SimLex999 and the WN-based evaluation, a large number of dimension will allow a more precise description of the word: such setting is more suited to detect synonymy or close semantic links.

7 Conclusion

In this article, following the work of Claveau and Kijak (2016), we compared different scenarii to evaluate distributional and embedding models. Beside the intrinsic evaluation through reference lexicons (here, WordNet and WordNet+Moby) and specialy crafted data (SimLex999), we also rely on an extrinsic evaluation with an IR task, as initially proposed by Claveau and Kijak (2016).

In this work, several conclusions are worth noting. The main one is certainly that direct, or intrinsic, evaluation (be it with reference lexicons or specially crafted data) should be avoided if possible. Indeed, the thesaurus characteristics they evaluate are unclear and may be very different from one's specific need. This is particularly obvious when comparing the IR task results with those of the WN+Moby evaluation (Section 5 and see also (Claveau and Kijak, 2016) for further discussion). Indeed, the very weak results

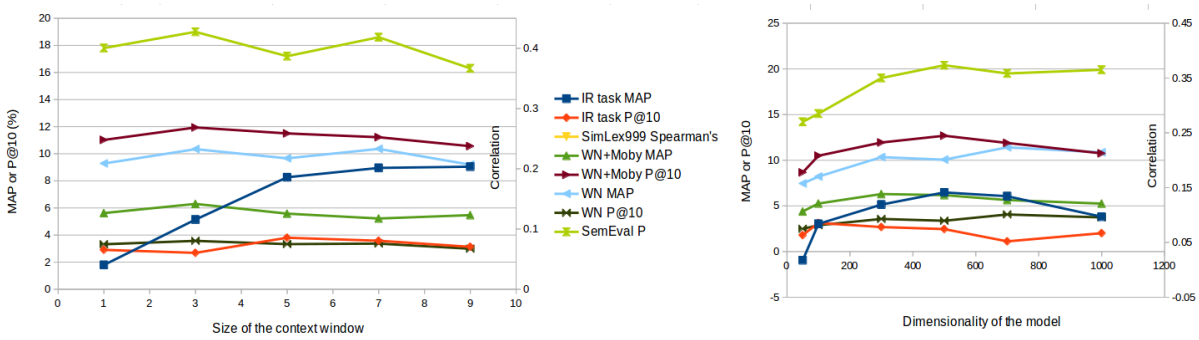

Figure 5: Influence of context size and dimensionality in word2vec models on the results of different evaluation protocols. On the left,the size of the context window is set to 3; on the right, the dimensionality is set to 300.

of the generated thesaurus at the lexicon-based evaluations are not confirmed in the third-party evaluation framework (in our case, query expansion for IR).

Beside that, the evaluation resources (WordNet, Moby or SimLex999) are not complete enough to provide reliable results. For instance, by showing that the thesaurus generated with our models obtains extrinsic results at least as good as the reference lexicons (WN and Moby) used for the intrinsic evaluation, we question previous conclusions of many studies only based on intrinsic evaluation. This incompleteness problem also exists with SimLex999 since it focuses on frequent words (cf. Section 4.3), which are known to be the easiest to model with distributional approaches, but are not necessarily the most interesting for one's needs. Indirect, or task-based, evaluation (lexical substitution or IR) seems conceptually more grounded, but the datasets used may suffer from the same problem of incompleteness or non-representativity. Another related conclusion remark, is that the model parameters have very different effects depending on the considered evaluation scenario (cf. Section 6.2). It is thus important to fine tune with respect to the final task rather than on unrelated datasets.

As a side results, all the experiments presented here confirm the interest of using the IR approaches for building distributional thesaurus (Claveau et al., 2014). In particular, the adjusted Okapi-BM25 model offers significant gains of performance over word2vec for most of the evaluation scenarii considered.

D-GloVe: A Feasible Least Squares Model for Estimating Word Embedding Densities*

Shoaib Jameel and Steven Schockaert
School of Computer Science and Informatics,
Cardiff University.
{JameelS1, S.Schockaert}@cardiff.ac.uk

Abstract

We propose a new word embedding model, inspired by GloVe, which is formulated as a feasible least squares optimization problem. In contrast to existing models, we explicitly represent the uncertainty about the exact definition of each word vector. To this end, we estimate the error that results from using noisy co-occurrence counts in the formulation of the model, and we model the imprecision that results from including uninformative context words. Our experimental results demonstrate that this model compares favourably with existing word embedding models.

1 Introduction

Several vector space models for word meaning have already been proposed (Lund and Burgess, 1996; Landauer and Dumais, 1997; Turney and Pantel, 2010; Mikolov et al., 2013; Pennington et al., 2014). While there are considerable differences in how these vector space models are learned, most approaches represent words as vectors. However, a few authors have proposed models that represent words as regions or densities in a vector space (Erk, 2009; Vilnis and McCallum, 2015), motivated by the view that region or density based representations are better suited to model the diversity of word meaning, and can thus capture e.g. hyponymy in a natural way. In this paper, we also use densities in a low-dimensional vector space to represent word meaning. In contrast to previous work, however, we use densities for modelling our lack of knowledge about the precise meaning of a word. This allows us to use a more cautious representation for rare words, and leads to better confidence estimates in downstream tasks. Note that this use of densities is indeed fundamentally different from its use in previous work. For example, increasing the corpus size in our case will lead to more precise estimates (i.e. distributions with lower variance) while the models from (Erk, 2009; Vilnis and McCallum, 2015) may arrive at distributions with higher variance, reflecting the broader set of context windows that may be found.

Our approach is based on the GloVe model for word embedding (Pennington et al., 2014). In particular, we also associate two vectors with each word i: the vector w_i, which intuitively represents the meaning of word i, and the vector $\tilde{w}_j$, which intuitively represents how the occurrence of i in the context of another word j affects the meaning of that word. Moreover, we also use a least squares formulation to constrain these vectors such that $w_i \cdot \tilde{w}_j$ reflects the co-occurrence statistics of words i and j. In contrast to GloVe, however, we explicitly model two factors that contribute to the residual error of this model: (i) the fact that corpus statistics for rare terms are not reliable and (ii) the fact that not all words are equally informative. This has two key advantages. First, it allows us to formulate the underlying optimization problem as a feasible generalized least squares problem. As we show in our experiments, this leads to word embeddings (as vectors) that substantially outperform those obtained from the GloVe model, and other baselines, in standard word similarity and analogy tasks. Second, it allows us to explicitly represent our uncertainty about the precise definitions of the word vectors. Rather than using w_i for modelling the meaning of word i, we then consider a density which is defined by the residual error model.

Specifically, the residual error model allows us to naturally associate a univariate density with each context vector $\tilde{w}_j$, given a target word i. A natural geometric interpretation can be obtained by fixing the

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1849–1860, Osaka, Japan, December 11-17 2016.

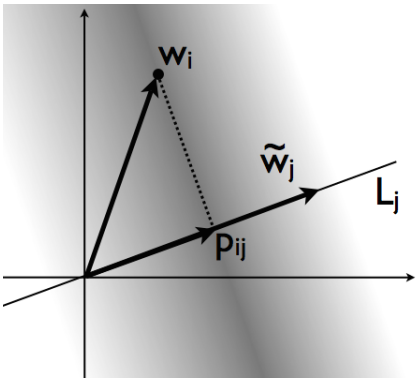

Figure 1: Density modelling the possible values of w_i, induced by a single context word $\tilde{w}_j$.

context vectors. The density associated with a given context word can then be viewed as a soft constraint on the possible values of the vector w_i, as illustrated in Figure 1. The variance of this density depends on the size of the corpus (larger corpora lead to more precise estimates) and on the informativeness of the context word, where densities associated with uninformative context words should have a high variance, reflecting the fact that they should not have a strong impact on the word embedding.

The remainder of this paper is structured as follows. In the next section, we give an overview of related work. Subsequently, in Section 3 we introduce our probabilistic model for word embedding and discuss its relationship with the GloVe model. Finally, we present our experimental results and conclusions.

2 Related work

Word embedding models construct vector space models of word meaning by relying on the distributional hypothesis, which states that similar words tend to appear in similar linguistic contexts (Harris, 1954). One class of methods relies on constructing a term-document (Landauer and Dumais, 1997) or, more commonly, a term-term (Lund and Burgess, 1996) co-occurrence matrix. Intuitively, we can think of the row vectors in these matrices as representing the contexts in which a given word occurs. Given the sparse and high-dimensional nature of these vectors, most approaches use some form of dimensionality reduction based on matrix factorization, such as singular value decomposition (SVD). An important factor in the performance of such methods is how co-occurrences are weighted, with Positive Pointwise Mutual Information (PPMI) generally considered to be a suitable choice (Bullinaria and Levy, 2007).

In the last few years, a number of neural network inspired methods have been proposed that formulate the problem of learning word embeddings as an optimization problem. The well-known skip-gram (SG) method (Mikolov et al., 2013), for example, aims to construct vectors, such that the log-probability that word c appears in the context of word w is proportional to $w \cdot c$. The related Continuous Bag of Words (CBOW) model uses a similar idea, but instead focuses on predicting the probability of a given target word, given its context. The GloVe model (Pennington et al., 2014), which our approach is based on, learns two word vectors w_i and $\tilde{w}_j$ and a bias b_i for each word i, using the following least squares regression formulation:

$$\sum_{i=1}^{n}\sum_{j=1}^{n} f(x_{ij})(w_i \cdot \tilde{w}_j + b_i + \tilde{b}_j - \log x_{ij})^2$$

where x_{ij} is the number of times words w_i and $\tilde{w}_j$ co-occur, $\tilde{b}_j$ is the bias for the context word j, and n is the number of different words in the considered corpus. The function f weights the terms of the model to limit the effect of small co-occurrence counts, as these are deemed to be noisy. It is defined as $f(x_{ij}) = \left(\frac{x_{ij}}{x_{max}}\right)^{\alpha}$ if $x_{ij} < x_{\max}$ and $f(x_{ij}) = 1$ otherwise. The purpose of x_{max} is to prevent common words from dominating the objective function too much.

An interesting property of the representations learned by SG, CBOW and GloVe is that they capture similarity as well as analogies and related linear relationships. As a result, both word similarity and word analogy tasks are now commonly used to evaluate the quality of word embeddings. Finally, note

that while methods such as SG might seem like a radical departure from matrix factorization based methods, it was shown in (Levy and Goldberg, 2014) that SG implicitly finds a factorization of a shifted-PMI weighted term-term co-occurrence matrix. It has been observed that, compared to the factorization model underlying SG, SVD remains a useful choice for modeling word similarity, but it is less suited for discovering analogies (Levy and Goldberg, 2014).

The standard word embedding models have recently been improved in various ways. For example, some authors have proposed so-called multi-prototype representations, where the idea is to deal with ambiguity by learning several vectors for each word (Reisinger and Mooney, 2010; Huang et al., 2012; Liu et al., 2015; Neelakantan et al., 2015), intuitively by clustering the contexts in which the word appears, as a proxy for word senses, and learning one vector for each context. Other authors have shown how word embeddings can be improved by taking into account existing structured knowledge, e.g. from lexical resources such as WordNet or from knowledge graphs such as Freebase (Yu and Dredze, 2014; Xu et al., 2014; Faruqui et al., 2015).

While most word embedding models represent words as vectors, a few authors have explored the usefulness of region and density based representations. For example, in (Erk, 2009), two models are proposed to induce regions from context vectors. Among others, it is shown that these regions can be used to encode hyponym relations. In (Vilnis and McCallum, 2015), a model is proposed which represents words as Gaussian densities, and the usefulness of this model for discovering word entailment is demonstrated. As already mentioned in the introduction, while our model also represents words as densities, our densities model the uncertainty about the true location of a word vector, rather than modelling the diversity of the underlying concept. As a result, for instance, Kullback-Leibler divergence is meaningful for modelling word similarity in the approach from (Vilnis and McCallum, 2015), but would not be appropriate in our model. To the best of our knowledge, the model presented in this paper is the first that explicitly models the uncertainty associated with the word vectors. Note that while several probabilistic models have been proposed for word embedding (Maas and Ng, 2010; Li et al., 2015), these works model the probability that a document has been generated, rather than the probability that a given vector is the correct representation of a given word.

3 Our model

Similar to the GloVe model, we propose to learn word embeddings by solving the following weighted least squares problem:

$$\sum_{i=1}^{n} \sum_{j \in J_i} \frac{1}{\sigma_{ij}^2} (w_i \cdot \tilde{w}_j + \tilde{b}_j - s_{ij})^2 \tag{1}$$

where n is the number of words in the vocabulary, $J_i \subseteq \{1, ..., n\}$, and $\tilde{b}_j$ and s_{ij} are constants. In particular, the GloVe model can be recovered by choosing $J_i = \{j \,|\, x_{ij} > 0\}$, $\sigma_{ij}^2 = \frac{1}{f(x_{ij})}$ and $s_{ij} = \log x_{ij} - b_i$. However, as we explain below, these choices are sub-optimal. First, in Section 3.1 we propose to use a Dirichlet-Multinomial language modeling approach and choose s_{ij} as the expectation of $\log P(j|i)$ in this model. Section 3.2 then explains how suitable estimates for σ_{ij}^2 can be obtained. The importance of these estimates is twofold: they should improve the quality of the word vectors that we obtain by solving (1) and they will enable us to precisely model our uncertainty about the exact location of each word vector. This latter point is discussed in more detail in Section 3.3, which explains how we can evaluate the likelihood that a vector is the correct representation of a given word.

3.1 Dealing with imperfect corpus statistics

Let us write $s_{ij}^{glove} = \log x_{ij} - b_i$. The idea behind the derivation of the GloVe model in (Pennington et al., 2014) is that s_{ij}^{glove} is an estimation of $\log P(j|i)$, with $P(j|i)$ the probability of seeing word j in the context of word i. Rather than fixing $b_i = \log \sum_l x_{il}$, in line with this view, it is assumed that $\log \sum_l x_{il}$ is absorbed in the bias term b_i. One of the main advantages of this choice is that it makes the model

symmetric w.r.t. the role of the target vectors w_i and context vectors $\tilde{w}_j$; e.g. in some experiments it was observed that using the average of w_i and $\tilde{w}_j$ can lead to a small increase in performance.

In our model, s_{ij} will be chosen as an estimation of $\log P(j|i)$. This will enable a more elegant modeling of the residual errors, and offer a more principled way of dealing with sparse frequency counts. It also leads to a clearer geometric interpretation. In particular, let us write p_{ij} for the orthogonal projection of w_i on the line $L_j = \{p \,|\, p = \lambda \cdot \tilde{w}_j, \lambda \in \mathbb{R}\}$ (see Figure 1), then $w_i \cdot \tilde{w}_j = \|\tilde{w}_j\| \cdot \|p_{ij}\|$. This allows us to write the residual error as $e_{ij} = \|\tilde{w}_j\| \cdot \|p_{ij}\| - s_{ij} + \tilde{b}_j$. We can think of $\|p_{ij}\|$ as the coordinate of word i in a one-dimensional word embedding, which is constrained by the model to correspond to a linear function of s_{ij}. The relation between this one-dimensional embedding and the full embedding is determined by $\|\tilde{w}_j\|$ and $\tilde{b}_j$, which only depend on the context word j. Another way to look at this geometric interpretation is that each context word j acts as a soft constraint on the possible choices of w_i, which is illustrated by the shaded area in Figure 1.

Clearly $\frac{x_{ij}}{\sum_l x_{il}}$ only gives us a reliable estimate of $P(j|i)$ if the number of occurrences of i is sufficiently large. This problem is well known and can be alleviated by various smoothing techniques (Zhai and Lafferty, 2004). In this paper, we will adopt Bayesian smoothing. In addition to smoothing the frequency counts, this will give us a way to estimate variance. In particular, we assume that for each target word i there is a multinomial distribution from which all words that appear in the context of i are drawn. A standard approach is to assume that the parameters of that multinomial distribution are drawn from a Dirichlet distribution. Specifically, let x_{ij} be the number of times word j appears in the context of word i in the considered corpus, as before, and let $x_i = \sum_l x_{il}$. Note that x_i is the total number of tokens that occur in the context of i. The probability that among these there are y_1 occurrences of word 1, y_2 occurrences of word 2, etc. is given by

$$P(\mathbf{y} \,|\, \alpha) = \frac{x_i B(\sum_j \alpha_j, x_i)}{\prod_{y_j > 0} y_j B(\alpha_j, y_j)}$$

where $\mathbf{y} = (y_1, ..., y_n)$, $\alpha = (\alpha_1 + x_{i1}, ..., \alpha_n + x_{in})$ and B is the Beta function. In the experiments, we will use the overall corpus statistics to set the parameters of the Dirichlet prior, i.e. we will choose $\alpha_i = \lambda \cdot \frac{n_i}{\sum_j n_j}$, where n_i is the total number of occurrences of word i in the corpus and $\lambda > 0$ is a parameter that will be chosen based on tuning data.

Using this Dirichlet-Multinomial model, we can set s_{ij} as the expectation of $\log \frac{Y_{ij}}{x_i}$, where the random variable Y_{ij} represents the number of occurrences of word j in the context of word i. We estimate this expectation using a Taylor expansion:

$$s_{ij} = E[\log Y_{ij}] - \log x_i \approx \log E[Y_{ij}] - \frac{\mathit{Var}[Y_{ij}]}{(2 \cdot E[Y_{ij}]^2)} - \log x_i$$

where

$$E[Y_{ij}] = \frac{x_i \alpha_j^*}{\sum_l \alpha_l^*} \qquad \mathit{Var}[Y_{ij}] = \Big(\frac{x_i \alpha_j^*}{\sum_l \alpha_l^*}\Big)\Big(1 - \frac{\alpha_j^*}{\sum_l \alpha_l^*}\Big)\Big(\frac{x_i + \sum_l \alpha_l^*}{1 + \sum_l \alpha_l^*}\Big)$$

with $\alpha_j^* = \alpha_j + x_{ij}$. This choice of s_{ij} has two advantages over s_{ij}^{glove}. First, by smoothing the raw frequency counts, we obtain more reliable estimates for rare terms. Second, context words j for which $x_{ij} = 0$ are completely ignored in the GloVe model. From the point of view of the proposed geometric interpretation, this means that valuable information is ignored. In particular, if we want $\|p_{ij}\|$ to reflect how strongly context word j is related to word i, we should require that it is small when $x_{ij} = 0$. On the other hand, evaluating (1) for every pair (i, j) is not feasible as it would make the complexity of the model quadratic. Therefore, we let J_i contain all indices j for which $x_{ij} > 0$, as well as a random sample of indices for which $x_{ij} = 0$. In our experiments, we choose the sample size such that the number of indices for which $x_{ij} > 0$ is equal to the number of indices for which $x_{ij} = 0$.

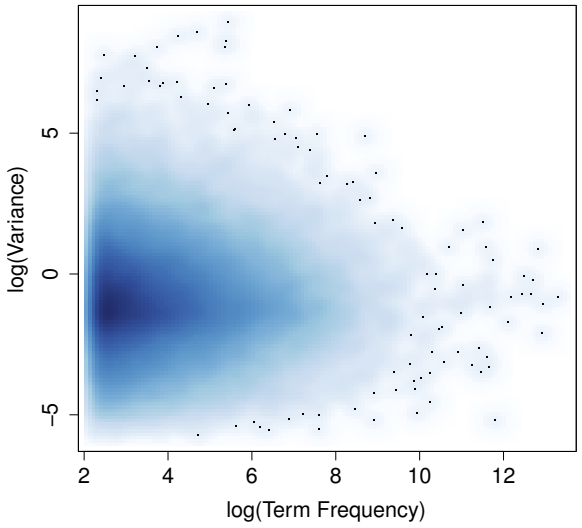

Figure 2: Scatter plot comparing term frequency with $\mathit{Var}[e_j^{\mathit{info}}]$.

3.2 Estimating the variance of residual errors

The choice of $f(x_{ij})$ as the weight for the term corresponding to target word i and context word j reflects the implicit assumption that $\frac{1}{f(x_{ij})}$ is a reasonable estimate of the variance σ_{ij}^2 of the residual error $e_{ij}^{\mathit{glove}} = w_i \cdot \tilde{w}_j + b_i + \tilde{b}_j - \log x_{ij}$. As we will see, this assumption is rather questionable.

A standard technique for selecting the weights in weighted least squares problems, called feasible generalized least squares, consists in estimating the variance of the residual errors in an initial solution (e.g. obtained using standard least squares). This allows us to reformulate the objective function by deriving appropriate weights from the estimated variances σ_{ij}^2. Solving the resulting optimization problem in turn allows us to obtain better estimates of the variances. This process is repeated for a fixed number of times, or until the estimated variances converge.

In our model, we will follow this strategy to estimate the variances σ_{ij}^2 from the observed residual errors e_{ij}. This requires us to make assumptions about which factors affect these variances, as we can clearly not estimate σ_{ij}^2 from e_{ij} alone. We will assume that e_{ij} is the sum of two independent errors, viz. $e_{ij} = e_{ij}^{\mathit{count}} + e_j^{\mathit{info}}$. Intuitively e_{ij}^{count} is the error that results from using unreliable co-occurrence statistics and e_j^{info} is the error that results when the target word j is uninformative. Again using a Taylor expansion, we can estimate $\mathit{Var}[e_{ij}^{\mathit{count}}]$ as follows:

$$\mathit{Var}[e_{ij}^{\mathit{count}}] = \mathit{Var}[\log Y_{ij}] \approx \frac{\mathit{Var}[Y_{ij}]}{E[Y_{ij}]^2}$$

where $E[Y_{ij}]$ and $\mathit{Var}[Y_{ij}]$ are evaluated as before. Furthermore, we can estimate $\mathit{Var}[e_j^{\mathit{info}}]$ from the observed residual errors, as follows:

$$\frac{\sum\{e_{ij}^2 : j \in J_i\} - \sum\{\mathit{Var}[e_{ij}^{\mathit{count}}] : j \in J_i\}}{|\{e_{ij}^2 : j \in J_i\}|} \tag{2}$$

This allows us to estimate σ_{ij}^2 as $\mathit{Var}[e_{ij}^{\mathit{count}}] + \mathit{Var}[e_j^{\mathit{info}}]$.

Figure 2 shows the relationship between $\mathit{Var}[e_j^{\mathit{info}}]$ and the number of occurrences of the context word j in the text collection (for a subset of Wikipedia[1]). As can be seen from the figure, the correlation

between these two quantities is very weak, e.g. high-frequency words can be very informative. For example, the words 'family' and 'service' are frequent in Wikipedia but were still found to be highly informative context words (i.e. $Var[e_j^{info}]$ is low for these words), while stop words such as 'were' and 'is' are found to be uninformative (i.e. $Var[e_j^{info}]$ is high for these words). Similarly, there are low-frequency words which are found to be uninformative, such as 'ga', 'scoula' and 'niggle' while other low-frequency words were found to be highly informative, such as 'compactness' and 'nasdaq'. Table 1 shows a number of additional examples of words with high/low frequency and high/low variance.

3.3 Evaluating likelihood

Explicitly modelling the residual error allows us to associate a density with each word. For example, the density shown in Figure 1 intuitively captures the evidence about the embedding of the word i that is provided by the context word j. In this section, we will assume that each target word is associated with a random vector. Note that the residual error e_{ij} then is a random variable. We will evaluate the likelihood that e_{ij} takes a given value by evaluating the likelihood that e_{ij}^{count} takes a given value s and that e_{ij}^{info} takes the value $r - s$. Let $S_{ij} \subseteq \mathbb{R}$ be the set of possible values that e_{ij}^{count} can take, i.e.:

$$S_{ij} = \{E[\log Y_{ij}] - \log P(Y_{ij} = k) : 0 \leq k \leq x_i\}$$

With each target word i and context word j we can associate the density f_{ij} defined for $r \geq 0$ as:

$$f_{ij}(r) = \frac{1}{|S_{ij}|} \sum_{s \in S_{ij}} P(Y_{ij} = k) \cdot f_{ij}^{info}(r - s) \tag{3}$$

Here $f_{ij}(r)$ is the likelihood that the residual error e_{ij} takes the value r, while $f_{ij}^{info}(s)$ is the likelihood that e_{ij}^{info} takes the value s. The variance σ_{ij}^{info} of f_{ij}^{info} is given by (2). If we furthermore assume that e_{ij}^{info} is normally distributed, we obtain:

$$f_{ij}^{info}(r - s) = \mathcal{N}(r - s, 0, \sigma_{ij}^{info})$$

If we treat each context word as an independent source of evidence, we obtain the following density g_i, modelling our knowledge about the possible choices of a word vector for word i ($w_i \in \mathbb{R}^s$):

$$g_i(w_i) = \prod_{j \in J_i} f_{ij}(w_i \cdot \tilde{w}_j - s_{ij} + \tilde{b}_j) \tag{4}$$

Note that we assume that the context vectors $\tilde{w}_j$ are given.

4 Evaluation

In this section we compare our method with existing word embedding models on a range of standard benchmark tasks.

4.1 Methodology

Corpora We have used the following text collections: Wikipedia[2] (1,335,766,618 tokens), the English Gigaword corpus[3] (1,094,733,691 tokens), a concatenation of the Wikipedia and Gigaword corpora (2,430,500,309 tokens), UMBC[4] (2,714,554,484 tokens) and ClueWeb-2012 Category-B[5] (6,030,992,452 tokens). Note that the first three text collections have also been used in (Pennington et al., 2014). We adopted a straightforward text preprocessing strategy. In particular, following (Pennington et al., 2014), we have removed punctuations, lower-cased the tokens, removed HTML/XML tags, and conducted sentence segmentation. For the ClueWeb collection, we used the preprocessing implementation of the reVerb tool[6], which was specifically designed to process ClueWeb, and only considered terms which occur at least 100 times in the collection, to offset the larger size of this collection. This led to a vocabulary size of 283,701 words. For the other collections, we used our own code, which is available along with the rest of our implementation[7], and used the NLTK library[8] for sentence segmentation. As these collections are smaller than the ClueWeb collection, we considered all words that appear at least 10 times. The resulting vocabulary sizes are 1,252,101 words for Wikipedia, 469,052 words for the Gigaword corpus, 1,524,043 words for Wikipedia+Gigaword and 541,236 words for UMBC. When counting word co-occurrence statistics, we do not cross sentence boundaries. Similar to GloVe, words in the context windows in our model were weighted using the harmonic function. For the baseline models, we used the context word weighting scheme from their original implementations.

Baseline methods and variants We consider the following state-of-the-art word embedding baselines: the Skip-Gram (SG) and Continuous-Bag-of-Words (CBOW) models from (Mikolov et al., 2013), GloVe (Pennington et al., 2014), and the Gaussian word embedding model (Gauss) from (Vilnis and McCallum, 2015). In all cases, we have used existing implementations of these models[9][10][11]. Furthermore, we have considered several variants of our model to better understand what components are responsible for the improvements over GloVe. In the standard version, we estimate the similarity between words w_i and w_j by evaluating the likelihood $g_i(w_j)$, as defined in (4). In variant DG-ZC we instead use cosine similarity, as in the GloVe model. In variant DG-C we also use the cosine similarity and in addition set J_i as in the GloVe model (i.e. we disregard pairs (i, j) for which $x_{ij} = 0$). Variant DG-UfL differs from the standard model by not considering the error term e_j^{info}.

Evaluation tasks We have evaluated the models on traditional word analogy and word similarity tasks (Levy et al., 2015). In particular, we have used an existing Google Word analogy dataset which we obtained from the GloVe project[12]. In addition, we have used the Microsoft Word analogy dataset[13] as well as twelve existing word similarity datasets[14]. The aim of these evaluation tasks has been explained in detail in (Levy et al., 2015). A new evaluation task for word embedding has recently been proposed

in (Camacho-Collados and Navigli, 2016), which we have also considered, using the evaluation script provided by the authors[15]. The aim of this task is to find the outlier in a given set of words. We refer to (Camacho-Collados and Navigli, 2016) for a detailed explanation of the task and the considered evaluation metrics.

Parameter tuning We select the parameters for each of the methods using a 25% validation set and report results on the remaining 75% of each evaluation set. The parameters were tuned separately for each of the evaluation tasks. For CBOW and SG, we chose the number of negative samples from a pool of {1, 5, 10, 15}. For GloVe, we selected the x_{max} value from {10, 50, 100} and α from {0.1, 0.25, 0.5, 0.75, 1}. For the Gaussian word embedding approach, we used the spherical Gaussian with KL-divergence model. For our model, we selected the Dirichlet prior constant λ from {0.0001, 0.001, 0.01, 0.1, 1000, 2000, 5000, 8000}. For all models, the number of dimensions was chosen from {100, 300}, the size of the context windows was chosen from {2, 5, 10}, and the number of iterations was fixed as 50. In our model, we re-estimate the variances σ_{ij}^2 every five iterations.

4.2 Results

We present our main results in Table 2. The word similarity datasets are indexed as: S1: EN-MTurk-287, S2: EN-RG-65, S3: EN-MC-30, S4: EN-WS-353-REL, S5: EN-WS-353-ALL, S6: EN-RW-STANFORD, S7-EN-YP-130, S8-EN-SIMLEX-999, S9-EN-VERB-143, S10-EN-WS-353-SIM, S11: EN-MTurk-771, and S12: EN-MEN-TR-3k. We can see from the results that our model consistently outperforms GloVe. To further understand what components are responsible for this improvement, Table 3 shows the result for some variants of our model, showing that each of the proposed adaptations of the GloVe model contributes to the overall result. Compared to the other baselines, the results in Table 2 show that our model performs substantially better for the semantic instances of the Google analogy datasets (Gsem), while it is outperformed by SG (and in some cases CBOW) for the syntactic instances (Gsyn) and for the Microsoft dataset (MSR), which contains only syntactic instances. Our model also outperforms the baselines for the outlier detection task. For the similarity test instances, the performance is mixed. What is noticeable is that our model performs comparatively better for large corpora (e.g. ClueWeb) and worse for smaller corpora (e.g. Gigaword).

In Table 4 we present a more detailed analysis of the similarity test sets for which our model performs worse than SG. In particular, the table shows the results of a modified test set that only considers the 30% most frequent terms and a modified test set that only considers the 30% least frequent terms. These results clearly show that our model outperforms SG for high-frequency terms and that it is outperformed by SG for low-frequency terms. Dirichlet-Multinomial model are indeed known to struggle with low-frequency terms (Sridhar, 2015), which can e.g. be addressed by the use of asymmetric Dirichlet priors (Wallach et al., 2009). Note that this observation also explains why our model performs comparatively better for larger corpora and why it performs worse for syntactic analogy instances (given that such instances tend to contain low-frequency terms). While this can be seen as a limitation of our model, the fact that our model treats low-frequency terms in a cautious way may actually be advantageous in downstream applications.

An advantage of our approach is that the likelihood based formulation naturally allows us to estimate the confidence that a given prediction is correct. In Figure 4.2 we show the accuracy for the k analogy

instances of the Google dataset about which our model was most confident, for varying values of k. Similarly, the figure also shows the accuracy of the predictions made by SG, ranked in terms of cosine similarity. As can be seen, our model is better able to identify those instances that it can answer correctly (e.g. the accuracy of the top 5000 instances remains close to 1).

5 Conclusions

We have proposed a new word embedding model in which each word is represented as a density, obtained by associating with each word i and each context word j a univariate density. These univariate densities are in turn obtained by explicitly modelling the residual error of the considered least squares optimization function. Our experiments reveal that the model consistently outperforms the GloVe model, on which it is based. The proposed model also outperforms skip-gram, and other baselines, for high-frequency terms. For low-frequency terms, our model takes a rather cautious approach, which means that it is often outperformed by skip-gram in standard evaluation settings.

Abstract

Most distributional lexico-semantic models derive their representations based on *external* language resources such as text corpora. In this study, we propose that *internal* language models, that are more closely aligned to the mental representations of words could provide important insights into cognitive science, including linguistics. Doing so allows us to reflect upon theoretical questions regarding the structure of the mental lexicon, and also puts into perspective a number of assumptions underlying recently proposed distributional text-based models. In particular, we focus on word-embedding models which have been proposed to learn aspects of word meaning in a manner similar to humans. These are contrasted with internal language models derived from a new extensive data set of word associations. Using relatedness and similarity judgments we evaluate these models and find that the word-association-based internal language models consistently outperform current state-of-the art text-based external language models, often with a large margin. These results are not just a performance improvement; they also have implications for our understanding of how distributional knowledge is used by people.

1 Introduction

How is semantic information encoded? How is similarity represented in the brain? And how can we capture this information computationally? One answer to this question involves distributional lexico-semantic models, which quantify the semantic similarity between lexical items based on their distributional properties in large samples of data. Recent models like `word2vec` (Mikolov et al., 2013) and GloVe (Pennington et al., 2014), which rely on external corpora as the source of data, increasingly appear to capture word meaning in ways that ever-more-closely resemble human representations. For instance, these models show systematic improvements over previous work in key benchmarks such as human similarity judgments of word pairs (Baroni et al., 2014). The strong performance of these models has also suggested to cognitive scientists that the learning mechanisms they embody might resemble how humans learn the meaning of some words (Mandera et al., in press).

In this study we show that using word-association data instead of corpus data improves performance substantially above the current state-of-the-art. We suggest that this is because data-intensive distributional models like `word2vec`, formidable though they are, may not capture word representations the way the average adult language speaker does. Their enormous, high-quality input data enables them to mimic human behavior, but they do relatively poorly compared to performance based on data that more accurately captures people's true representations of meaning.

The distinction between using text corpora or word association data maps onto the distinction made by Taylor (2012) between External language models (E-language) and Internal language models (I-language). An E-language model, like `word2vec`, treats language as an "external" object consisting of the all utterances made in a speech-community. An I-language model sees language as the body of knowledge residing in the brains of its speakers. Largely due to the easy availability of high-quality external corpora – for instance, there are over one trillion words in the Google n-gram corpus (Michel

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1861–1870, Osaka, Japan, December 11-17 2016.

et al., 2011) – computational linguists have traditionally focused on E-language models (Bullinaria and Levy, 2007; Baroni et al., 2014; Levy et al., 2015). Whether a similar distributional approach based on I-language might also be useful has received relatively less attention. One explanation could be purely on the basis of practical arguments, as it's not clear whether appropriate I-language resources are available. This paper fills that gap, by introducing an approximation of I-language using a new database of word associations considerably larger than previous ones and conducting a direct comparison of how both kinds of approaches predict human similarity judgments. It is valuable not just in demonstrating that models based on I-language greatly improve their performance. It also suggests that when people judge similarity, they may be relying more on networks of semantic associations than on statistics calculated from the distributional patterns of the words they hear.

Why should we expect to see (and why *do* we see) such improvements when the models use word associations data rather than high-quality large-scale text corpora data? After all, word association models generally incorporate far less data. Moreover, one might presume that word associations are themselves simply derived from the distribution of words in the external language: in that case, one would expect them to be an inferior and noisy measure.

However, several strands of research support the idea that word associations capture representations that cannot be fully reduced to the distributional properties of the E-language environment. Previous attempts to predict word associations from E-language have had limited success (Griffiths et al., 2007; Michelbacher et al., 2007; Wettler et al., 2005). E-language typically only predicts the strongest associate in the minority of cases and does even worse in predicting non-primary responses. Why is this? At least part of it is that E-language has the structure it does because people are using it to communicate to each other; it is not simply a reflection of their mental representations. For instance, the word "yellow" is a very strong associate of "banana", but the two words co-occur relatively infrequently since most bananas are yellow. As a result, modifying the word *banana* with *yellow* is uninformative, so most people leave it out when talking. Many of the divergences between the distributions of words in external language and the strength of internal associations may occur because so much of E-language is shaped by pragmatic and communicative considerations such as these. There is also evidence that meaning representations in the brain, as reflected in word associations, are shaped by far more than the distributional properties of the E-language. For instance, fMRI measures reveal that imagery-related areas like the precuneus are activated during word association tasks (Simmons et al., 2008).

The structure of this paper is as follows. In Part 2 we describe the origin and nature of the data we are using as the E-language source (text corpora) and I-language source (word association data). Part 3 describes the distributional models which we will apply to each data source, while Part 4 describes the multiple human similarity and relatedness judgments that each model and data source will be used to predict. Part 5, the results, demonstrates that models based on I-language consistently perform substantially better than the same model based on E-language.

2 Data sources

The central comparison in this paper is between model performance on E-language vs I-language data. The increasing number of online resources from which text can be extracted means that obtaining a representative E-language has become more straightforward. Furthermore, better balanced corpora that easily surpass the knowledge of the average human are readily available. We derived our E-language data based on four different kinds of existing text-based corpora, as described below.

Free word association data are used as the I-language data. Although there are certainly other possibilities, word association data are advantageous as they appear to tap directly into mental representations (Deese, 1965; McRae et al., 2012; Szalay and Deese, 1978). Moreover, we shall show that a new procedure and larger data sets address important shortcomings from previous work that relied on a relatively small number of cues words for which only a single association response was asked from the participant (Kiss et al., 1973; Nelson et al., 2004).

2.1 A text corpus to train E-language models

Our aim was to combine corpora that would provide us with a fairly balanced set of texts that is representative of the sort of language a person experiences during a lifetime – including both formal and informal language as well as spoken and written language. Four different corpora were combined.

1. Subtitles for English movies between 1970 and 2016 extracted from the OpenSubtitle corpus as described in Tiedemann (2012). Subtitle corpora have been frequently used in cognitive science because they capture daily language better than extremely large written corpora like the Google n-gram corpus (Brysbaert et al., 2011).

2. The Corpus of Contemporary English (COCA), as described in Davies (1990 present). It consists of a balanced set of formal and informal language including fiction, newspaper articles and spoken texts. We excluded the sub-corpus for academic texts.

3. The Global Web-Based English corpus (GlowBE), as described in Davies (2013). We included the sub-corpora of British, American, Canadian and Australian texts.

4. SimpleWiki, which presents knowledge that is likely available to the average person (18 million tokens in comparison to the 2.9 billion words in the full English Wikipedia).

Altogether, in compiling these corpora we aimed to be generous in terms of the quality and quantity of items so that models incorporating it would perform similarly to the existing state-of-the-art. For similar reasons, we used word-forms rather than lemmas: this matches previous work and provides the best possible match with the stimuli in the human benchmarks. The resulting corpus consisted of 2.16 billion tokens and 4.17 million types. Each sentence was uncased and stop words were removed. We further excluded words that did not occur at least 300 times, retaining 65,632 unique word types. This cut-off is larger than previous approaches using count models and word embedding models but allowed us to reduce the memory requirements for the count model we introduce later and to make sure that words in the evaluation sets were at least as frequent as the words in the association study for which we collected 300 responses. Moreover, we piloted different cut-offs and found it didn't affect our findings.

2.2 A novel word association dataset for I-language models

One of the shortcomings with previous word association studies of considerable size like the Edinburgh Association Thesaurus (Kiss et al., 1973) or the University of South Florida norms (Nelson et al., 2004) is that they only include the strongest associations (Aitchison, 2012) because only a single response is generated for each cue word. For example, in the case of *umbrella*, most participants would respond *rain*, which prevents the inclusion of weaker links. A better way to include weaker associates as well is by using a continued procedure where multiple responses for each cue word were collected (Szalay and Deese, 1978). Extending the response set to include weaker responses and including enough cue words to capture most words used in daily languages motivated us to set up a new large-scale study. The current data are collected as part of the *Small World of Words* project, an ongoing effort to map the mental lexicon in various languages [1]. Each participant was given a short list of cue words (between 15 and 20 words) and asked to generate three different responses to each cue. To avoid chaining responses, the instructions stressed to only give a response to the cue word. If a word was unknown or no secondary or tertiary response could be given, the participants were able to indicate this. Additional details on the procedure are available in (De Deyne et al., 2013).

The results reported here are based on 10,021 cue words for which at least 300 responses have been collected (100 primary, 100 secondary and 100 tertiary) for every cue. The study was presented as an online crowd sourced project in which fluent English speakers volunteered to participate. The responses were based on over 85,496 participants of which 82% were native speakers. Responses indicated as

[1] The word association task and details of the project can be accessed at `https://smallworldofwords.org/`. A paper describing an extension of these norms including over 12,000 cues is currently in preparation and the data will be made available on the same website.

unknown (1.17% of cue words) or missing, because a participant could not think of any secondary or tertiary associations (4.15% of responses), were excluded. In line with previous work, we constructed a semantic graph from these data. This graph closely resembles the bag-of-words count models but represented as a graph makes it possible to consider the spreading activation discussed in the next section. A graph $\mathbf{G}$ was constructed by only including responses that also occurred as a cue word. This converted the bimodal cue $\times$ response graph to a unimodal cue $\times$ response graph. In this weighted graph $\mathbf{G}$, g_{ij} counts the number of times that word j is given as an associate of word i. We extracted the largest strongly connected component by only keeping those cues that were also given at least once as a response. This way all words can be reached by both in- and out-going links. The resulting graph consists of 10,014 nodes, which retains 84% of the original data consisting of all responses. The average number of tokens per word is 267 and the number of different word types each word is connected to (i.e., its out-degree of) is 92, ranging from 12 (for the word *done*) to 169 (for *control*). As expected, the graph is also very sparse: only 0.92% of words are connected (i.e., $\mathbf{G}$ has 0.92% non-zero entries). Throughout the text we will refer to this graph as $\mathbf{G_{123}}$, since it incorporates all three responses given by participants.

3 Models

We consider four different models in this paper, two E-language models estimated from the text corpora, and two I-language models that use word association data. In both cases, one model is a simple count based model and the other aims to exploit the structure of the input data.

3.1 Count based model for text corpora

Count models of text corpus data use a simple representation: they track how many times a pair of words co-occur in a document or sentence. For our analyses, we applied a sliding window at the sentence level similar to Pennington et al. (2014). Specifically, we used a symmetric dynamic window that linearly weighted words as a function of the distance between them (Pennington et al., 2014). The resulting co-occurrence frequencies were transformed using the positive point-wise mutual information (PMI^+), given the evidence that this measure performs well in count models (Bullinaria and Levy, 2007; Levy et al., 2015). In particular, we follow Levy et al. (2015) in applying a discount factor in order to prevent very rare words from biasing the results (see their Equation 3), and unless otherwise stated we used the same discount factor (0.75) that they did.

3.2 Predicting structure from text corpora using word embeddings

An alternative approach to representing text corpora is to apply a lexico-semantic model that aims to extract the latent semantic structure embedded in the text corpus by learning to predict words from context. We focused on the word embeddings derived from the neural network approach in *word2vec* (Mikolov et al., 2013; Levy et al., 2015), using a continuous bag of words (CBOW) architecture in which the model is given the surrounding context for a word (i.e., the other words in a sliding window) and is trained to predict that word.

For our analyses, we used the *gensim* implementation of *word2vec* (Řehůřek and Sojka, 2010). Based on previous work (Baroni et al., 2014; Mandera et al., in press) the following settings were used: a negative sampling value of 10, and a down-sampling rate of very frequent terms of 1e-5. Additionally, the following hyper-parameters were manipulated, using the values reported by previous work (Levy et al., 2015) as a starting point. We considered window sizes between 2 to 10, and fitted models with between 100 and 500 dimensions with steps of 100. We will focus on the best fitting hyper-parameter values, but for the purposes of robustness we will also examine the performance of models using previously published semantic vectors.

3.3 Count based model for word associations

In an E-language model, the goal is to characterize the linguistic contents of a text corpus, whereas an I-language model aims to capture the mental representation that a human speaker might employ. The difference between these two goals motivates a difference in the kinds of data that one might use

(e.g., text corpora versus word associations) but there are commonalities between the two approaches. For example, there is evidence that the relationship between (observed) word association frequency and (latent) associative strength is nonlinear (Deese, 1965), an observation that suggests the PMI$^+$ measure might be reasonably successful as a simple count model for association strength. With that in mind our first model is a simple PMI$^+$ measure using the word association frequency as the input.[2]

3.4 A spreading activation approach to semantic structure

While the PMI$^+$ model captures the semantic information in the raw word association data, it does not attempt to capture any deeper semantic structure that these data encode. Inspired by classic work in human semantic memory by Collins and Loftus (1975), we use word association data to construct a network that connects associated words, and model semantic similarity using denser distributions derived from a *random walk* defined over this network, similar to the Katz index (Katz, 1953). The intuitive idea is that when a word is presented it activates the corresponding node in the graph, and starts a random walk (or many such walks) through the graph, activating nodes that the walk passes through. If there are many short paths that connect two nodes, then it is easy for a random walk through the graph to start at one node and end at the other, and the words are deemed to be more similar as a consequence.

To implement this idea we first normalize the word association matrix such that each row sums to 1, thus converting it to a transition matrix $\mathbf{P}$. Then, in order to construct an explicit model to derive new direct paths between words, we consider the following iterative procedure (Newman, 2010). First consider a walk of a maximum length r where $\mathbf{I}$ is the identity matrix and a "damping parameter" $\alpha < 1$ governs the extent to which new paths are dominated by short paths or by longer paths. During each iteration, indirect links reflecting paths of length r are added to the graphs, producing this sequence of "augmented" graphs:

$$\begin{aligned} \mathbf{G_{rw}}^{(r=0)} &= \mathbf{I} \\ \mathbf{G_{rw}}^{(r=1)} &= \alpha\mathbf{P} + \mathbf{I} \\ \mathbf{G_{rw}}^{(r=2)} &= \alpha^2\mathbf{P}^2 + \alpha\mathbf{P} + \mathbf{I} \end{aligned} \tag{1}$$

In these expressions, longer paths receive lower weights due to operation of the α parameter. The probability of an associative chain surviving across r links is thus α^r. The smaller the value of α, the larger the contribution made by very short paths. This "decay" parameter serves an important role to limit the spread of activation and avoid the entire network to become quickly activated. In the limit, where we consider paths of arbitrarily long length (and accordingly, arbitrarily low weight) we obtain the following expression:

$$\mathbf{G_{rw}} = \textstyle\sum_{r=0}^{\infty}(\alpha\mathbf{P})^r = \mathbf{I} - \alpha\mathbf{P}^{-1} \tag{2}$$

At this point, the "random walk graph" $\mathbf{G}_{\text{rw}}$ combines paths of various lengths obtained from the random walk. However, these paths do not precisely match the associative strength measure proposed earlier, and to address this we apply the exact same procedure that we have used for the other models, namely the PMI$^+$ transformation. Applying the PMI weighing function to $\mathbf{G_{rw}}$ reduces the frequency bias introduced by this type of walk (Newman, 2010) and also keeps the graph sparse.

To see how this spreading activation mechanism can be very powerful, consider the word *tiger*. Before applying spreading activation its meaning vector consists of 92 different association responses. When we apply the spreading activation measure we uncover nearly 559 new associations which ordered by their weights included *zebra*, *cheetah*, *claws*, *cougar* and *carnivore*, all of which seem meaningfully related to *tiger* but were not among the responses when *tiger* was presented as a cue word.

4 Comparing model predictions to human judgments

To assess how well each of these four models captures human semantic knowledge, we evaluate them using several standard data sets that measure human judgments of similarity and relatedness, and addi-

[2]We did not apply a discount factor for the word association data due to the different characteristics of text corpora and word associations: with smaller data sets the problem of rare words is less pronounced in word associations.

tionally introduce a new data set based on the "remote triad task". We used a variety of different data sets in order to provide insight into *why* some models perform well on some kinds of task and not on others.

4.1 Similarity and relatedness judgments

The data sets used to evaluate the models broadly fall into one of two classes. Two of the studies asked participants to judge the similarity between words, namely the WordSim-353 similarity data set (Agirre et al., 2009)[3] and the SimLex-999 data (Hill et al., 2016). In the remaining studies people were asked to judge relatedness. These include the WordSim-353 relatedness data set (Agirre et al., 2009), the MEN data (Bruni et al., 2012), the Radinsky2011 Amazon Mechanical Turk data (Radinsky et al., 2011), the popular Rubenstein and Goodenough (RG1965) data (Rubenstein and Goodenough, 1965) and the MTURK-771 data (Halawi et al., 2012).

4.2 Remote triads task

In addition to these data sets, we include data from a relatedness judgment task based on triadic comparisons using a procedure introduced in De Deyne et al. (2016). In this task, participants are asked to select the most related pair out of a set of three English nouns. An advantage of this task is that the third word acts as a context, which makes judgments less ambiguous. Critically, the triads were constructed by choosing words largely at random from the English word association data set. The only constraints were that the words in a triad had to be roughly matched on judged concreteness and word frequency. This was done to avoid simple heuristics such as grouping abstract or common words together. The consequence of this procedure is that the triads tended to consist of words that are only weakly related to each other, such as BRANCH - ROCKET - SHEET or CLOUD - TENNIS - SURGEON, and it is for this reason it is referred to as the "remote triads task". A total set of 100 triads was constructed this way and judgments were collected for 40 native English speakers [4].

4.3 Additional details

All four models represent word meanings as a semantic vector, and we used the cosine similarity measure in all cases. Only word pairs that were present in the text corpus and the word association data were included. As shown in Table 1 (columns 2 and 3), most words were retained. For the triads task model predictions were obtained by normalizing the similarities between the three words in each triad and correlating them with the frequencies of the choice preferences.

5 Results

The best performing parameters were a window size of 3 for the corpus count model, and a window size of 7 and 400 dimensions for *word2vec*, although the findings for other window sizes and dimensions were quite similar. The word association count model is based on $\mathbf{G_{123}}$ and has no free parameters, whereas for the random walk model we used a parameter value of $\alpha = 0.75$, similar to previous studies (De Deyne et al., 2016). Table 1 shows the performance of all models, and it is clear that the I-language models substantially outperform the E-language models in almost every case. It is also clear that extracting structure helps: *word2vec* generally outperformed the corpus count model, and the random walk model outperformed the word association count model. For the E-language models the magnitude of this effect was slightly smaller than reported elsewhere (Baroni et al., 2014; Mandera et al., in press), and the count model outperformed *word2vec* on the remote triads data.

5.1 Other versions of the I-language models

Given the superiority of the I-language models over E-language models in predicting human responses, it is natural to ask why this occurs. Our word association data arise from a task that elicited multiple judgments from each person. To estimate the effect of the multiple judgment procedure, we restricted the training data to the first associate only (using $\mathbf{G_1}$ rather than $\mathbf{G_{123}}$). After doing so the average

[3] Note that the items were determined by post-hoc raters who split the original WordSim-353 data set in related and similar items. As such, these judgments might not consist of "pure" similarity judgments.

[4] The data are available at `http://simondedeyne.me/data`

Table 1: Spearman rank order correlations between human relatedness and similarity judgments, and the predictions from all four models described earlier. Word association results presented here are based on $\mathbf{G_{123}}$. Further details for $\mathbf{G_1}$ are available in the text.

			Text Corpus		Word Associations	
Data set	*n*	*n(overlap)*	Count	*word2vec*	Count	Random Walk
WordSim-353 Related	252	207	.67	.70	.77	.82
WordSim-353 Similarity	203	175	.74	.79	.84	.87
MTURK-771	771	6788	.67	.71	.81	.83
SimLex-999	998	927	.37	.43	.70	.68
Radinsky2011	287	137	.75	.78	.74	.79
RG1965	65	52	.78	.83	.93	.95
MEN	3000	2611	.75	.79	.85	.87
Remote Triads	300	300	.65	.52	.62	.74
mean			.67	.69	.78	.82

correlation for the count model fell from .78 to .67, with a much smaller decline (from .82 to .78) for the random walk model. The difference is illuminating: $\mathbf{G_1}$ is much sparser than $\mathbf{G_{123}}$, allowing indirect paths to have a larger impact, which is why the random walk model is more robust than the count model.

A different question to ask is whether our new data set encoded in $\mathbf{G_{123}}$ produces better results than previous ones. There appears to be some modest evidence for this: when using the Edinburgh Association Thesaurus (EAT) consisting of 8,400 words (Kiss et al., 1973), the count model produced an average correlation of .65 to the test data, and the random walk model correlated at .74, both of which are smaller than the values obtained (.78 and .81) using a matched $\mathbf{G_{123}}$ that contains the same words as the EAT. A similar exercise using the USF association data (Nelson et al., 2004) produced correlations of .65 and .77 for the count and random walk model compared to .78 and .82 for the matched $\mathbf{G_{123}}$.

5.2 Other versions of the E-language models

Previous papers have discussed the performance of the E-language models (Levy et al., 2015), but a few additional comments are worth making. Analogous to the effect that the training data have on the I-language models, one might wonder if the poorer performance of *word2vec* was due to the text corpus we used to extract semantic vectors. To test this, we relied on recently published semantic vectors from Mandera et al. (in press)[5], Levy et al. (2015)[6] and Pennington et al. (2014)[7] including items part of $\mathbf{G_{123}}$. For the GloVe vectors based on 6 billion tokens from Pennington et al. (2014), the best result was found for 300 dimensions; the average correlation was .64. Using the GloVe vectors for a 64 billion tokens corpus improved the correlation to .67 and using the GloVe vectors for an enormous corpus of 840 billion tokens to .70. Compared with the published results from Levy et al. (2015), the average correlation was .65. Using the best-fitting vector spaces from Mandera et al. (in press), the correlation was .69 for the published vectors derived from English subtitles using 300 dimensions. Given this, it does not seem likely that the problem was our specific choice of corpus or hyperparameters.

6 Discussion

The goal of this study was to compare two kinds of semantic models: "I-language" models that encode mental representations, and "E-language" models that encode lexical contingencies. In one respect the superior performance of the I-language models is unsurprising: the training data directly reflect human mental representations, and as such *should* be more strongly linked to human semantic judgments. On the other hand, the I-language models were trained on a *much* smaller data set than the E-language models,

[5] http://zipf.ugent.be/snaut-downloads/spaces/english/predict/

[6] https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/

[7] http://nlp.stanford.edu/projects/glove/

with an average of 260 words contributing to the distributional representation of each word. Given this, it is worth considering the broader implications of the findings.

6.1 Cognitive plausibility of E-language models

Previous work has argued that the *word2vec* model is more cognitively plausible than count models due to its similarity to models of classical conditioning (Mandera et al., in press). This is contrasted with more statistical approaches such as Latent Semantic Analysis (Landauer and Dumais, 1997) and topic models (Griffiths et al., 2007). However, it is not clear that this holds up in light of the fact that we find very little difference in performance between count models and *word2vec*, or previous work arguing that word embedding models perform an implicit matrix factorization (Levy and Goldberg, 2014).

Perhaps more importantly, there is something strange about the claim that E-language models are cognitively plausible when the data sets upon which they are trained are as large as they are. If purely text based models are intended to stand as models for how humans acquire semantic structure, then they should be trained on a corpus small enough that it plausibly represents the language exposure of the young adults who participated in the benchmark tasks. If billions of tokens are required to produce adequate predictions while still being unable to match the performance of simple I-language models, it is not clear what claims can be made about human language acquisition.

6.1.1 Relation between relatedness and similarity

A final remaining question is how we can interpret the lower results for similarity judgments in one of the tasks (SimLex-999) across all models. Does this indicate a fundamental shortcoming in the models?

In this case, the answer depends. Similarity might be important in a NLP setting, for example in constructing thesauri, but the role of similarity in human semantic cognition is mostly an empirical matter. If anything, a variety of studies support a prominent role for relatedness. This includes semantic priming effects when processing a word proceeded by a related one (Hutchison, 2003), event-related potentials in EEG that are triggered by related but not similar words (Kutas and Hillyard, 1984) and fMRI studies that map the structure of the mental lexicon in a more thematic rather than taxonomic way based on similarity (Huth et al., 2016). Add to this that similarity can only be derived for certain concept combinations, and similarity ratings tend to be less reliable than relatedness ratings (Hill et al., 2016), suggests that relatedness judgments have broader use in studies of human semantic cognition.

6.2 Future directions

One obvious way to improve E-language models is by including non-linguistic information as well. As mentioned in the introduction, access to imagery contributes to the responses people give in a word association task and this might explain the fact that I-language models perform very well on the basis of a small number of words. While recent studies have shown some promising results by enhancing language models with visual representations, there's still room for improvement. For example, Bruni et al. (2012) reported findings of a multimodal model that uses word embeddings combined with features extracted from images. An evaluation using the MEN dataset resulted in a correlation of .78 for the best performing model, which is considerably lower than current results for the E-language and especially the I-language models.[8] On the upside, if I-language models do considerably better because they have a privileged access to imagery compared to E-language model, this would also suggest that further improvements by constructing more elaborate multimodal representations are possible. More generally, because the both I-language and E-language models use the same kind of symbolic language-based representations, determining what kind of features (perceptual or other) make the I-language models so successful with very little data might also provide us with valuable pointers towards further refining existing E-language models and NLP applications build from them.

Going forward will also require us to increase the discriminatory power of existing benchmarks, by including judgments that focus on finer perceptual distinctions, or by capitalizing on how humans infer additional structure beyond what's available in E-language. In this study, we have shown that the remote

[8] Unfortunately we did not have access to the semantic vectors from Bruni et al. (2012) so we could not verify whether this is due to the fact that some items were excluded in our experiments.

triad task might be ideally suited to test how well a model can generalize beyond the input and provide a benchmark capable of differentiating competing models. Apart from more sophisticated and more realistic approximating of the E-language environment, there's also a need for better I-language models. While the new word association data addresses some issues from previous studies, future work will aim to include at least 20,000 different cues. Furthermore, improvements might be achieved by looking at native speakers only, applying differential weights to the primary, secondary and tertiary responses, or designing more elaborate spreading activating mechanisms. As such, further gains for association based I-language models would not be a surprise and might help us bridge the external and internal language world.

Abstract

We propose a novel word embedding-based *hypernym generation* model that jointly learns clusters of hyponym-hypernym relations, i.e., hypernymy, and projections from hyponym to hypernym embeddings. Most of the recent hypernym detection models focus on a *hypernymy classification* problem that determines whether a pair of words is in hypernymy or not. These models do not directly deal with a hypernym generation problem in that a model generates hypernyms for a given word. Differently from previous studies, our model jointly learns the clusters and projections with adjusting the number of clusters so that the number of clusters can be determined depending on the learned projections and vice versa. Our model also boosts the performance by incorporating inner product-based similarity measures and negative examples, i.e., sampled non-hypernyms, into our objectives in learning. We evaluated our joint learning models on the task of Japanese and English hypernym generation and showed a significant improvement over an existing pipeline model. Our model also compared favorably to existing distributed hypernym detection models on the English hypernym classification task.

1 Introduction

Hypernym-hyponym relations, a.k.a. hypernymy, are important information for several NLP tasks such as question answering and ontology construction. Some manually-constructed semantic resources like WordNet contain hypernymy; however, they have limited coverage. Plenty of studies have been conducted to automatically detect hypernymy, e.g., (Hearst, 1992; Roller et al., 2014; Fu et al., 2015).

Hypernymy detection was traditionally often tackled with unsupervised methods using Hearst-style patterns (Hearst, 1992) or distributional inclusion hypothesis (Geffet and Dagan, 2005). These methods treat hypernymy pairs individually. Recent progress in the word representation allows to represent words in a shared low-dimensional vector space, and several models using the distributional word representation or word embeddings have been proposed for hypernymy detection (Roller et al., 2014; Weeds et al., 2014; Turney and Mohammad, 2015; Levy et al., 2015). Such models employ supervised learning. Most of the models focus on a *hypernymy classification* problem, i.e., whether a given word pair is in hypernymy or not, and they ignore a more practical *hypernym generation* problem to generate hypernyms for a given word.

Few studies have examined hypernym generation using word embeddings (Fu et al., 2015; Tan et al., 2015). Fu et al. (2015) proposed a two-step, pipeline model that partitions hypernymy pairs into several clusters and learns a projection matrix between words in a pair for each cluster separately. The projection matrix projects the embedding vector of a hyponym close to that of its hypernym. The incorporation of clustering allows representing several types of hypernymy and shows a higher performance than other traditional models in constructing semantic hierarchies. The clusters, however, may not be appropriate for hypernym generation since clustering is independent of hypernym generation.

This paper presents a novel hypernym generation model that jointly learns clusters of hypernymy and the projections from hyponyms to their hypernyms in the clusters . Unlike most previous supervised

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1871–1879, Osaka, Japan, December 11-17 2016.

models using word embeddings, we target the hypernym generation problem, not hypernymy classification. This paper has newly incorporated the following points into hypernym generation. First, our model performs the clustering of the relations with learning projection matrices jointly, to obtain appropriate clusters for hypernym generation. Second, motivated by DP-means (Kulis and Jordan, 2012), our model adjusts the number of clusters during training so that the model can fit the number of clusters to the training data. Third, the similarity measure in learning projection matrices is selected to be consistent with one in training word embeddings. Finally, we use sampled non-hypernym instances in learning projection matrices so that our model can distinguish hypernymy from non-hypernymy. We evaluated our model on hypernym generation tasks in Japanese and English, as well as a well-studied hypernymy classification task in English. Our joint learning model shows a significant improvement over a pipeline learning model (Fu et al., 2015) on the hypernym generation tasks. As for the hypernymy classification, our model showed a comparable performance to the state-of-the-art hypernymy classification model (Levy et al., 2015).

2 Related Work

In the task of detecting hypernym, traditional approaches focused on Hearst-style lexical patterns that indicate hypernymy (Hearst, 1992; Snow et al., 2005; Kozareva and Hovy, 2010). For instance, from a sentence ... *works by such authors as Shakespeare* ..., an "is-a" pair between *Shakespeare* and *author* can be detected by using a pattern that a word *A* is a hypernym of another word *B* when *A* and *B* are linked by *such A as B*. These methods typically show high precision but suffer from low recall because many hypernymy pairs are not explicitly mentioned in texts as such patterns.

To overcome the problems of the lack of explicit hypernymy mentions, several other traditional unsupervised methods are proposed based on distributional inclusion hypothesis. This hypothesis states that a term can only be used in contexts where its hypernyms can be used and that a term might be used in any contexts where its hyponyms are used (Geffet and Dagan, 2005; Kotlerman et al., 2010). These methods have shown limited performance because the hypothesis is not always correct and it cannot distinguish co-hyponymy and meronymy from hypernymy.

Recently, distributed word representation or word embeddings such as skip-gram (Mikolov et al., 2013) and ivLBL (Mnih and Kavukcuoglu, 2013) has been often employed for the task of detecting hypernymy, since such representation are shared among words. Most models using word embeddings focus on a hypernymy classification task where a model needs to predict whether a given word pair is in hypernymy or not. They take distributional vectors for a pair of a word x and its candidate *hypernym* y as input, calculate features from these vectors, and predict whether the pair is in hypernymy or not using a classifier like support vector machines (SVMs). For example, the *concat* model (Baroni et al., 2012) uses the concatenation of hypernymy pair $\langle \mathbf{x}, \mathbf{y} \rangle$, while the *diff* model (Roller et al., 2014; Weeds et al., 2014; Fu et al., 2015) uses $\langle \mathbf{y} - \mathbf{x} \rangle$. Here, $\mathbf{x}$ and $\mathbf{y}$ represent word embeddings of x and y, respectively. These classification-based models, however, have not been evaluated on hypernym generation, where a model generates hypernyms for a given word.

Less work has been done on hypernym generation using word embeddings (Fu et al., 2015; Tan et al., 2015). Fu et al. (2015) proposed a model of using the projection matrices, each of which projects x to y. They proposed a two-step, pipeline algorithm to detect hypernym. The first step is clustering. They partitioned training pairs into clusters using k-means so that pairs in each cluster are close in the sense of the differences (*offsets*) between x and y, i.e., $\langle \mathbf{y} - \mathbf{x} \rangle$. The second step is projection. They trained a projection matrix Φ_c for each cluster c. Φ_c is obtained by using the least squares objective:

$$\Phi_c^* = \arg\min_{\Phi_c} \frac{1}{N_c} \sum_{(x,y) \in P_c} \|\Phi_c \mathbf{x} - \mathbf{y}\|^2, \quad (1)$$

where P_c is a set of word pairs in c-th cluster and N_c is the number of word pairs in P_c. This model performs clustering and projection separately, so the performance of clustering depends on the *offsets* and their underlying embeddings and the clustering results also may not be appropriate for learning hypernymy. The similarity scores between instances in different clusters may not be comparable since

Algorithm 1: Jointly Learning Clusters and Projections of Hypernymy

input : $(x_1, y_1), \ldots, (x_n, y_n)$: input data, λ: threshold

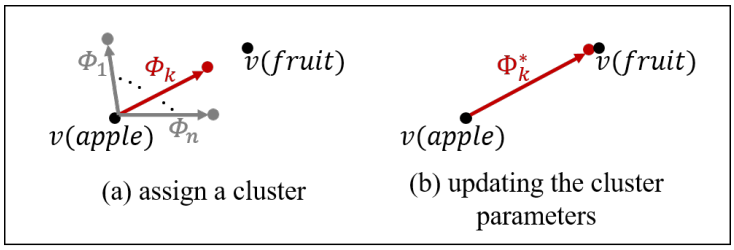

Figure 1: Overview of our proposed joint learning model

the projection matrices are trained independently. Further, this model does not consider non-hypernymy pairs during training, so it is not clear how the model performs on non-hypernymy pairs.

3 Jointly Learning Clusters and Projections of Hypernymy

This paper proposes a novel model that learns projections from words to their hypernyms and clusters of hypernymy jointly. Our model automatically estimates the number of clusters, motivated by DP-means clustering (Kulis and Jordan, 2012) that automatically estimates the number of clusters during clustering unlike k-means.

In learning the projections and clusters, our model receives d-dimensional word embeddings and training word pairs as its input, clusters the pairs with updating the cluster parameters ($d \times d$ projection matrices and bias terms in a similarity measure), and produces cluster parameters as its output. After the parameters are learned, our model generates hypernyms for a given word by projecting a word by using the projection matrices and selecting words that have the highest similarities with the projected word.

We will detail the learning and hypernym generation processes in the rest of this section.

3.1 Joint learning

Our joint learning model starts learning with a single cluster that includes all the training pairs and learns projection matrices with automatically increasing the number of clusters during learning. The entire algorithm is shown in Algorithm 1.

Our model updates the parameters of the cluster each training pair belongs to. The training pair consists of word x_i and its hypernym y_i. For each update, the model first finds (or generates) an appropriate

cluster for the target pair and then updates the parameters of the cluster as in Figure 1.

To find an appropriate cluster for a training pair, our model first calculates the similarity between the words in the pair for all the clusters and adds the pair to a cluster that achieves the highest similarity. Our similarity measure is based on an inner product, which is used in learning word embeddings. The similarity is defined as:

$$sim_c(x_i, y_i) = \sigma\left(\Phi_c \mathbf{x}_i \cdot \mathbf{y}_i + b_c\right). \tag{2}$$

Here, Φ_c denotes a $d \times d$ projection matrix for c-th cluster, b_c denotes bias of c-th cluster, σ denotes a logistic sigmoid function, and $\mathbf{x}_i$ and $\mathbf{y}_i$ are normalized word embeddings of x_i and y_i. This similarity measure calculates how close the matrix Φ_c projects x_i to y_i. Using the similarities, our model categorizes the pair into a cluster with the highest similarity if the similarity is beyond a threshold λ. If all the similarities are below the threshold and no matrix projects $\mathbf{x}$ close enough to $\mathbf{y}$, our model instead generates a new cluster and assign the cluster to the pair.

After a cluster is assigned to a pair, our model updates the cluster parameters (Φ and b) of the cluster for projection matrix and similarity measure. During the update of the parameters, motivated by negative sampling (Mikolov et al., 2013), our model generates pseudo negative non-hypernyms and penalizes the parameters so that the model do not generate the non-hypernyms in prediction. Our model maximizes the following objective function:

$$J = \sum_{c=1}^{k} \sum_{(x,y) \in P_c} \left(\log \mathrm{sim}_c\left(x, y\right) + \sum_{i=1}^{m} \log\left(1 - \mathrm{sim}_c\left(x, y_i'\right)\right) \right). \tag{3}$$

Here, k is the current number of clusters, $y_i' (\neq y)$ denotes a negative sample, and m denotes the number of negative samples. For the negative samples, our model selects the most confusing words that show the highest similarities with x because this selection produced better results than uniform sampling in our preliminary experiment.

Although our model employs clustering and projection matrices, it is substantially different from Fu et al. (2015). Our model newly incorporates the following points into hypernym generation:

- our model jointly learns clusters of hypernymy and the cluster parameters, i.e., projection matrices Φs and biases bs, so that the clusters and their parameters are well tuned to hypernymy generation and the cluster parameters are tuned so that similarity measures are consistent among all the clusters.
- our model automatically determines the number of clusters based on the similarity threshold λ in order to determine the appropriate number of clusters for the target data set.
- our model employs the same similarity measure as that used in training word embeddings, in order to keep consistency of word similarity in our model and word embedding training.
- our model uses negative non-hypernymy instances during training, which allows the model not only to keep the projection of hyponym far from wrong hypernyms but also to deal with non-hypernymy instances in prediction.

3.2 Hypernym generation

Since we do not know which cluster a pair of x and w belongs to, we check all the clusters and select the most appropriate cluster that produces the highest similarity for the pair. When generating hypernyms for a word x, we calculate the similarity score for each word w in our vocabulary as follows:

$$score_{gen}(x, w) = \max_c sim_c(x, w). \tag{4}$$

After obtaining the scores for all the words in our vocabulary, the words with the highest scores are selected as the hypernyms of x.

	Japanese	English

#vocabulary	1 million	3 million
#words	$\sim$10 billion	$\sim$100 billion

Table 1: Data and parameters in learning word embeddings

	Japanese (ALAGIN)	English (Baroni)
#train	14,814	970 (2,011)
#validation	1,752	69 (223)
#test	4,598	346 (536)
#total	21,164	1,385 (2,770)
#hypernyms / #hyponym	≈ 1	≈ 1.22

Table 2: The number of hypernymy relations and the average number of hypernyms per hyponym in the hypernymy data sets. The numbers in parentheses show the total number of positive and negative pairs in the English data set.

4 Evaluation Settings

We evaluate our model on Japanese and English hypernymy data sets. We will first explain resources for these two language data sets, and then explain the task settings.

4.1 Data sets

Our model requires word embeddings and training data of hypernymy pairs.

We obtained word embeddings for Japanese by applying ivLBL (Mnih and Kavukcuoglu, 2013) to texts crawled from Japanese Yahoo Answers (Yahoo Chiebukuro)[1]. As for English, we used a pre-trained Google News word embeddings[2] (Mikolov et al., 2013), which has shown high performance in several word similarity tasks. Table 1 summarizes the settings in learning word embeddings. We use the words in the word embedding as our vocabularies.

To obtain supervision for training hypernymy, we used ALAGIN typed hierarchies for Japanese[3], and the data by Baroni et al. (2012) for English. The statistics of the data are shown in Table 2. Word pairs in ALAGIN were made by automatically extracting word hierarchy from Wikipedia (Sumida et al., 2008), selecting the top-level pairs, and manually cleaning the selected pairs. Since this data deal with not only words but phrases, we selected hypernymy pairs that include only words and split the pairs into training, validation, and test pairs. Word pairs of Baroni's data were extracted from WordNet. While the data originally include 1,385 positives and 1,385 negatives that are from a random permutation of positive pairs, we used only positive pairs for training because our model generates negative pairs during training.

4.2 Task and evaluation settings

We optimized our model parameters with Adam (Kingma and Ba, 2015) with recommended parameters in their paper. We set the number of negative samples m to 1, according to the preliminary experiment. We tuned other hyperparameters, e.g., λ in our model and k in k-means, with the validation data. As a result of several preliminary experiments, we decided other hyperparameters as well. We consider only direct hypernymy in our experiment, differently from Fu et al. (2015). For instance, we consider only

	Japanese (ALAGIN)		English (Baroni)	
	pipeline	joint	pipeline	joint
#clusters	5	19	1	2
MRR	0.193	**0.349**	0.280	**0.339**

Table 3: MRR of our joint model and the pipeline model on the test parts of the Japanese ALAGIN data set and English Baroni's data set.

(*apple*, *fruit*) and (*fruit*, *plant*) pairs for the hypernymy hierarchy *apple* $\underset{H}{\longrightarrow}$ *fruit* $\underset{H}{\longrightarrow}$ *plant*, and do not consider (*apple*, *plant*). Here, *A* $\underset{H}{\longrightarrow}$ *B* means that *B* is a hypernym of *A*.

We evaluated our model on the task of *hypernym generation* using both the Japanese ALAGIN data set and the Baroni's data set. We generate hypernyms from our vocabulary in word embeddings.

To compare our model with the existing projection matrix-based pipeline model of Fu et al. (2015), we implemented their pipeline model, i.e., k-means clustering and projection matrix learning with the least square objective as explained in Section 2, but we did not include indirect hypernymy and employed Adam instead of stochastic gradient descent to optimize the model parameters (projection matrices). In generating hypernyms for a word x, we assigned a cluster c to the pair (x, w) by k-means for each word w in our vocabulary. We then selected words that had the lowest least square distances as the hypernyms of x. Here, the least square distances are defined as follows:

$$distance_c(x, w) = \|\Phi_c \mathbf{x} - \mathbf{w}\|^2, \tag{5}$$

where $\mathbf{w}$ denotes the word embedding of w. We call this model as a *pipeline* model, in contrast to our *joint* model.

We use Mean Reciprocal Rank (MRR) for the evaluation of hypernymy generation.

$$MRR = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{rank_i}, \tag{6}$$

where N is the amount of test data, $rank_i$ is the rank which correct hypernym is generated. MRR ranges from 0 to 1, and higher MRR indicates better performance of the model.

We also used the Baroni's data set to evaluate the performance of our joint model on a well-studied *hypernymy classification* task. We compared our model with the state-of-the-art supervised distributional model by Levy et al. (2015). Since our model is not classification-based, we performed the following simple threshold-based classification in order to judge whether a given word pair is in hypernymy or not:

$$score_{gen}(x, w) \begin{cases} \geq 0.5 & \Rightarrow \text{ positive} \\ otherwise & \Rightarrow \text{ negative.} \end{cases} \tag{7}$$

5 Evaluation

We present the results of hypernym generation evaluation in section 5.1 and those of hypernymy classification evaluation in section 5.2.

5.1 Hypernym generation

We compared MRRs of our joint model with those of the pipeline model on Japanese and English test data sets. The results, along with the numbers of clusters, are summarized in Table 3. These numbers of clusters are tuned using the validation data sets. In both Japanese and English test data sets, our joint model outperformed the pipeline model. Further, in our model, the number of clusters tends to be larger than that of the pipeline model. This may be partly because our joint model can capture more differences in hypernymy relations than the *pipeline* model, which used offsets, i.e., $\langle \mathbf{y} - \mathbf{x} \rangle$, in the clustering. Note that the small numbers of clusters in English data were considered to stem from the size of the data set;

Japanese (ALAGIN)		English (Baroni)	
pipeline (least squares)	joint (inner products)	pipeline (least squares)	joint (inner products)
0.215	**0.279**	0.321	**0.343**

Table 4: MRR of our model with inner product-based similarity measure and the pipeline model with least squares-based similarity measure without clustering on the validation parts of the Japanese ALAGIN data set and English Baroni's data set.

λ	0	0.1	0.15	0.2
#clusters	1	5	19	44
MRR	0.279	0.327	**0.368**	0.353

Table 5: MRR and the number of clusters on the validation part of the Japanese ALAGIN data set.

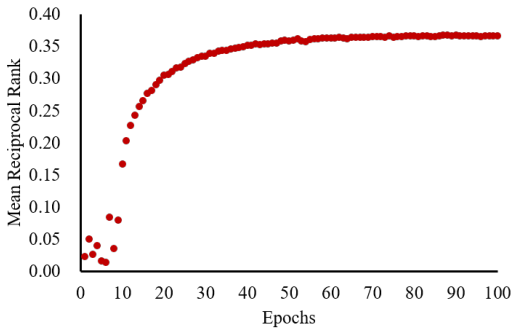

Figure 2: Learning curve of our joint model on the Japanese ALAGIN validation data set.

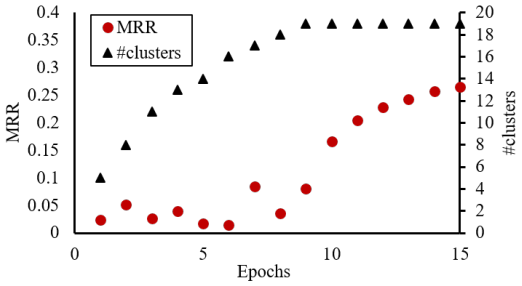

Figure 3: MRR on the validation set and the number of clusters of our joint model in the early learning stage on Japanese ALAGIN data set.

the English data set was about 6.5% of the Japanese data set in the number of positive instances as in Table 2.

We compare our model and the pipeline model without clustering on the Japanese validation data set in Table 4. Our model uses the inner product-based similarity in Equation 2 and negative sampling in Equation 3, while the pipeline model used the least square distance as in Equation 5. The results show that our model produces better results than the least square-based model.

The threshold of the clustering is a crucial parameter to decide the number of the clusters in our model. Table 5 shows the number of clusters and MRR on the Japanese validation data set when we varied the clustering threshold λ.

Figure 2 shows the learning curve of our joint model with the best hyperparameter on Japanese validation data set. This learning curve is stable except for the initial stage of learning (#epochs ≤ 9). To understand the behavior of the learning in the initial stage, we show MRR and the number of clusters in the first 15 epochs of learning our models in Figure 3. The number of clusters of our model increases in the initial learning stage (#epochs ≤ 9), and it stops to increase after several iterations. Due to this increase of clusters, MRR is unstable in the initial stage of learning. MRR starts to improve constancy after the number of clusters is fixed.

Our joint model and the pipeline model are different from other existing hypernymy classification models in that the former models can generate hypernyms from a given word. We present two examples of estimated hypernyms for given words in Tables 6 and 7.

5.2 Hypernym classification

We evaluated our model on the hypernym classification task using the Baroni's English data set. Our model produces 0.766 in F_1 score, while the model of Levy et al. (2015) compared several similarities

	joint		pipeline	
rank	estimated hypernym	$score_{gen}$	estimated hypernym	$\|\Phi\mathbf{x} - \mathbf{y}\|^2$
1	企業 “firm”	0.974	企業 “firm”	0.617
2	会社 “company”	0.752	有名企業 “famous firm”	0.696
3	グループ “group”	0.748	関連会社 “associated company”	0.726

Table 7: Examples of estimated hypernyms for a word 機械学習 “machine learning”.

measures and reported the state-of-the-art F_1 score of 0.802. In this comparison, we did not tune our hypernym generation model for the classification task. Instead, we directly applied our best hypernymy generation model in Table 3 to the task by using the hypernymy generation scores as classification scores (see. Equation 7). According to the results, our joint model compares favorably to the state-of-the-art model.

6 Conclusions

This paper proposed a novel word embedding-based hypernym generation model that clusters hyponym-hypernym relations and learns the parameters for the projection from hyponyms to their hypernyms in each cluster. Unlike many existing hypernym classification models, our proposed model can generate hypernyms from a given word. This generation will help to directly apply our model to several NLP tasks. Furthermore, the number of clusters is automatically determined according to the word embeddings and the training pairs.

We employ the inner product-based similarity measures so that word similarity can be consistent in training word embeddings and in our model. We also employ negative sampling so that the generated hypernyms can not be close to wrong hypernyms. We evaluate our model over Japanese and English data sets. Our proposed model significantly outperformed the other hypernym generation model on both Japanese and English data sets. We also evaluated our model on the hypernymy classification in English, and, without task-specific tuning, the result showed the F_1 score comparable to the state-of-the-art model.

In future work, we aim to extend our model for indirect hypernyms or hyponymy generation. This extension can improve the model performance and also widen the application areas of our model.

Incremental Fine-grained Information Status Classification Using Attention-based LSTMs

Yufang Hou
IBM Research Ireland, Dublin, Ireland
yhou@ie.ibm.com

Abstract

Information status plays an important role in discourse processing. According to the hearer's common sense knowledge and his comprehension of the preceding text, a discourse entity could be `old`, `mediated` or `new`. In this paper, we propose an attention-based LSTM model to address the problem of fine-grained information status classification in an incremental manner. Our approach resembles how human beings process the task, i.e., decide the information status of the current discourse entity based on its preceding context. Experimental results on the ISNotes corpus (Markert et al., 2012) reveal that (1) despite its moderate result, our model with only word embedding features captures the necessary semantic knowledge needed for the task by a large extent; and (2) when incorporating with additional several simple features, our model achieves the competitive results compared to the state-of-the-art approach (Hou et al., 2013) which heavily depends on lots of hand-crafted semantic features.

1 Introduction

Information status (IS) (Halliday, 1967; Prince, 1981; Nissim et al., 2004) accounts for the familiarity of a discourse entity according to its accessibility to the hearer at a given point in the text, e.g., `old` mentions[1] are known to the hearer and have been referred to previously; `mediated` mentions have not been mentioned before but are accessible to the hearer by reference to another `old` mention or to prior world knowledge; `new` mentions are "not being recoverable from the preceding discourse" (Halliday, 1967).

Information status has attracted a large amount of interests in theoretical linguistics under the framework of *information structure* (Halliday, 1967; Prince, 1981; Prince, 1992; Gundel et al., 1993; Lambrecht, 1994; Birner and Ward, 1998; Kruijff-Korbayová and Steedman, 2003). Many NLP tasks can benefit from knowing information status of discourse entities. Cahill and Riester (2009) improve the performance of generation ranking in German by incorporating features modeling IS. Rahman and Ng (2011) show that a coreference system can profit from IS classification. Baumann and Riester (2013) conduct an empirical study of information status in spoken German and demonstrate that IS can influence prosody in read speech. Hou et al. (2013) model bridging anaphora recognition as a subtask of learning fine-grained information status.

In this paper, we focus on classifying IS on written text because many applications which can benefit from IS concentrate on written texts. We follow the IS scheme for written text proposed by Markert et al. (2012). It adopts the three major IS categories (`old`, `new` and `mediated`) from Nissim et al. (2004) and distinguishes six subcategories for `mediated`. Section 2 provides a brief description of the scheme.

We address the task of fine-grained IS classification via an attention-based LSTM model in an incremental manner. The model resembles human beings' cognitive process of determining IS for discourse entities, i.e., during the process of reading a text from left to right, assign IS for each discourse entity according to its own property and its preceding context.

[1] A mention is a noun phrase which refers to a discourse entity and carries information status.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1880–1890, Osaka, Japan, December 11-17 2016.

Previous approaches on fine-grained IS classification (Markert et al., 2012; Hou et al., 2013) explore world knowledge by integrating hand-crafted semantic features extracted from manually and automatically constructed knowledge bases. One goal of this paper is to investigate in which extent word embeddings learned from large corpora can replace such hand-crafted semantic features. Experimental results on the ISNotes corpus (Markert et al., 2012) show that our model with only word embedding features achieves reasonable results for several IS categories. We further demonstrate that when incorporating with several additional simple features, our model achieves competitive results compared to the state-of-the-art approach (Hou et al., 2013) which heavily depends on lots of hand-crafted semantic features.

2 An Overview of Information Status in ISNotes

ISNotes (Markert et al., 2012) contains 10,980 mentions annotated for information status in 50 texts taken from the Wall Street Journal portion of the OntoNotes corpus (Weischedel et al., 2011). Below we briefly illustrate the definitions of eight IS categories with examples.

A mention is `old` if it is either coreferent with an already introduced entity, or if it is a generic or deictic pronoun.

`Mediated` mentions have not been mentioned before but are not autonomous, i.e., they can only be correctly interpreted by reference to another mention or to prior world knowledge. ISNotes distinguishes six subcategories of `mediated` mentions:

- `mediated/worldKnowledge` mentions are generally known to the hearer. This category includes many proper names, such as *Germany*.
- `mediated/syntactic` mentions are syntactically linked via a possessive relation, a proper name premodification or a PP (prepositional phrase) postmodification to other `old` or `mediated` mentions, such as:

  [[their]$_{old}$ liquor store]$_{mediated/syntactic}$,

  [the [Federal Reserve]$_{mediated}$ boss]$_{mediated/syntactic}$, and

  [the main artery into [San Francisco]$_{mediated}$]$_{mediated/syntactic}$.
- `mediated/bridging` mentions are inferable because a related entity or event (antecedent) has been previously introduced in the discourse, such as **the streets** in Example 1.
- `mediated/comparative` mentions usually include a premodifier that makes clear that this entity is compared to a previous one (antecedent), such as **others** in Example 2.
- `mediated/aggregate` mentions are coordinated mentions where at least one element in the conjunction is `old` or `mediated`, such as *[Not only [George Bush]$_{mediated}$ but also [Barack Obama]$_{mediated}$]$_{mediated/aggregate}$.*
- `mediated/function` mentions refer to a value of a previously explicitly mentioned function (e.g., **3 points** in Example 3). The function needs to be able to rise and fall.

(1) *Oranjemund, the mine headquarters*, is a lonely corporate oasis of 9,000 residents. Jackals roam **the streets** at night ...

(2) As the death toll from last week's temblor climbed to 61, the condition of *freeway survivor Buch Helm*, who spent four days trapped under rubble, improved, hospital officials said. Rescue crews, however, gave up hope that **others** would be found.

(3) IBM shares were down$_{function}$ **3 points**.

`New` mentions are entities that have not yet been introduced in the discourse and that the hearer cannot infer from either previously mentioned entities/events or general world knowledge.

Table 1 shows the IS distribution in ISNotes which contain 1,726 sentences in total.

Mentions	10,980	
old	3237	29.5%
mediated	3,708	33.8%
syntactic	1,592	14.5%
world knowledge	924	8.4%
bridging	663	6.0%
comparative	253	2.3%
aggregate	211	1.9%
func	65	0.6%
new	4,035	36.7%

Table 1: IS distribution in ISNotes. The last column indicates the percentage of each IS category relative to the total number of mentions.

3 The Attention-based LSTM Model

In this section we first briefly describe LSTMs in Section 3.1. We then detail our attention-based LSTM model for fine-grained IS classification in Section 3.2.

3.1 LSTMs

Recently, recurrent neural networks (RNNs) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) have been empirically shown to perform well in a range of NLP tasks, such as machine translation (Sutskever et al., 2014), parsing (Vinyals et al., 2015), and sentence compression (Filippova et al., 2015). LSTMs contain special units called memory blocks in the recurrent hidden layer. These memory blocks are designed to avoid vanishing gradients and to remember some long-distance dependencies from the input sequence. The vanilla LSTM model with hidden size k is defined as follows: given a sequence of input $(x_1, ..., x_T)$, LSTMs compute the *h*-sequence and the *m*-sequence using the following equations iteratively from t=1 to T:

$$i_t = sigm(W_1 x_t + W_2 h_{t-1}) \quad (1) \qquad f_t = sigm(W_2 x_t + W_3 h_{t-1}) \quad (2)$$

$$o_t = sigm(W_5 x_t + W_6 h_{t-1}) \quad (3) \qquad i_t\prime = tanh(W_7 x_t + W_8 h_{t-1}) \quad (4)$$

$$m_t = m_{t-1} \odot f_t + i_t \odot i_t\prime \quad (5) \qquad h_t = o_t \odot tanh(m_t) \quad (6)$$

The operator $\odot$ denotes element-wise multiplication, and $sigm$ and $tanh$ are computed element-wise. The matrices $W_1, \ldots, W_8$ and the vector h_0 are the parameters of the model.

3.2 Incremental IS Classification with Attention-based LSTMs

Model. In practice LSTMs still have difficulties to handle long-range dependencies because the model tries to encode the full input sequence into a fixed-length vector. To alleviate this problem, attention-based LSTMs allow the decoder to "attend" the different part of the input sequence when making the prediction. In an IS classification scenario, for each document, the attention-based LSTM model reads the mentions from left to right, and predicts each mention's IS output according to (1) the current mention's state cell and (2) weighted representation of the preceding mentions.

Figure 1 shows the high-level structure of our model. More precisely, for a mention m_i and its preceding t mentions, let two LSTMs read the mentions from left to right. The first LSTM uses the sum of word embeddings as mention representations, whereas the second LSTM uses one-hot vectors as mention representations[2]. Let k_1 and k_2 be the hyper-parameters denoting the size of mention representations and

[2]Another choice is to concatenate the sum of word embeddings with one-hot vectors and use only one LSTM. In practice, we find that encoding them with two LSTMs works better.

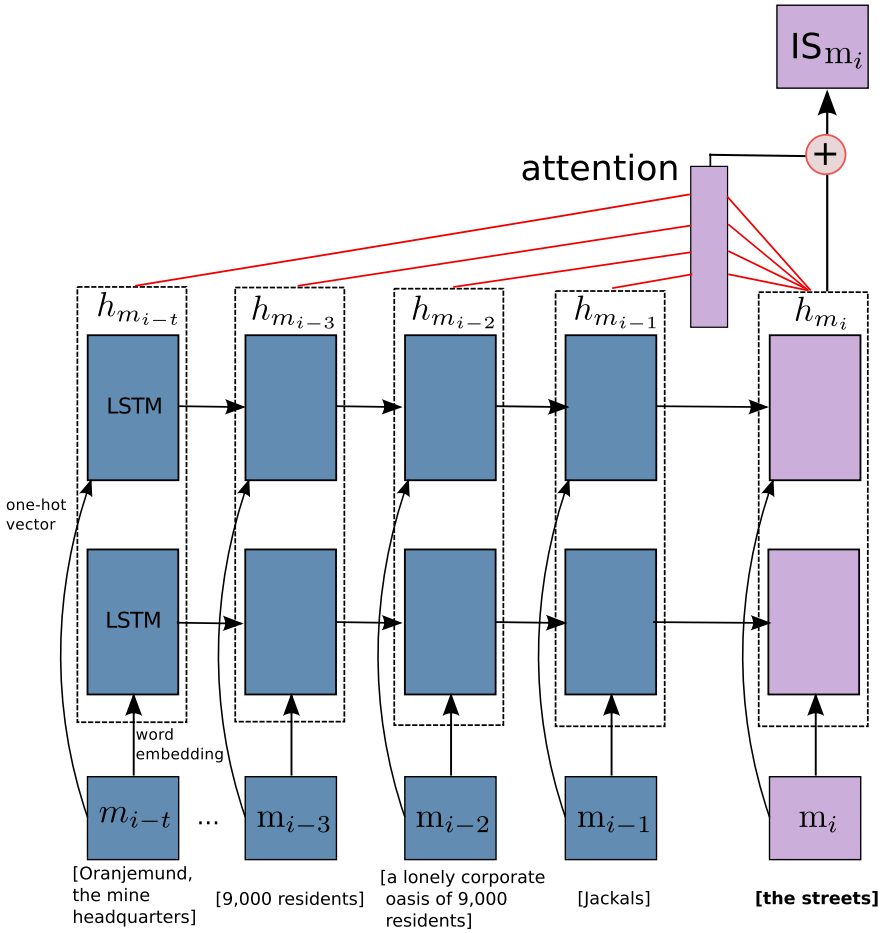

Figure 1: Fine-grained IS classification using attention-based LSTMs.

hidden layers in the two LSTMs respectively[3], and $H_1 \in \mathbb{R}^{k_1 \times (t+1)}$ and $H_2 \in \mathbb{R}^{k_2 \times (t+1)}$ to denote the output vectors from the first LSTM and the second LSTM. We then stack the first t output vectors from the two LSTMs:

$$H = \begin{bmatrix} H_1 \\ H_2 \end{bmatrix}, H \in \mathbb{R}^{(k_1+k_2) \times t} \tag{7}$$

Let $k = k_1 + k_2$, we define an attention vector α over the preceding t mentions and their weighted representation r as follows:

$$M = tanh(W_H H + [(W_{m_i} h_{m_i})_{\times t}]), M \in \mathbb{R}^{k \times t} \tag{8}$$

$$\alpha = softmax(W^T M), \alpha \in \mathbb{R}^t \tag{9}$$

$$r = H\alpha^T, r \in \mathbb{R}^k \tag{10}$$

where h_{m_i} is the stacked output vector of mention m_i from the two LSTMs, the matrices $W_H, W_{m_i} \in \mathbb{R}^{k \times k}$ and the vector $W \in \mathbb{R}^k$ (W^T denotes its transpose) are learned parameters of the model. Note that we repeat the linear transformation of the state cell of mention m_i (i.e., $W_{m_i} h_{m_i}$) t times. As a result, each column in M is the attention representation for each preceding mention $m_j (i - t \leq j < i)$ by combining the output vector h_{m_i} of mention m_i and the output vector of mention m_j (j's column vector in H).

[3]The size of the hidden layer in each LSTM is equal to its mention representation size.

We obtain the final representation of m_i using:

$$\hat{h}_{m_i} = tanh(W_1 r + W_2 h_{m_i}), \hat{h}_{m_i} \in \mathbb{R}^k \quad (11)$$

where the matrices $W_1, W_2 \in \mathbb{R}^{k \times k}$ are the model's parameters. Finally, we use a softmax layer to project $\hat{h}_{m_i}$ into the target space of eight IS classes.

Training instances. For all mentions in a document, we first add a dummy mention with the span of $[-1, -1]$ in the beginning of the document. We then order all mentions according to their end positions in ascending order; if two mentions have the same end position, we order them according to their start positions in descending order. This rule ensures that for embedded mentions, the inside mention is ordered before its parent. Such arrangement of embedded mentions is important because for `mediated/syntactic` and `mediated/aggregate`, a mention's IS label is dependent on the IS labels of its (syntactic) children. Table 2 shows several examples of how embedded mentions are ordered under this rule.

embedded mentions	result of ordering
(1) [[their] liquor store]	[their] – [their liquor store]
(2) [the [Federal Reserve] boss]	[Federal Reserve] – [the Federal Reserve boss]
(3) [the main artery into [San Francisco]]	[San Francisco] – [the main artery into San Francisco]
(4) [[he] and [[his] skilled team]]	[he] – [his] – [his skilled team]–[he and his skilled team]

Table 2: Results of ordering for embedded mentions.

After ordering, we create a training instance for each mention using its preceding mentions as the context. The training instances are created in an incremental manner. For instance, given a document containing the sentence shown in Example 1 (Section 2), the training instances will be (m_0 is the dummy mention):

- m_0 || **[the mine headquarters]**
- m_0*–[the mine headquarters]* || **[Oranjemund, the mine headquarters]**
- m_0*–[the mine headquarters]–[Oranjemund, the mine headquarters]* || **[9,000 residents]**
- m_0*–[the mine headquarters]–[Oranjemund, the mine headquarters]–[9,000 residents]* || **[a lonely corporate oasis of 9,000 residents]**
- m_0*–[the mine headquarters]–[Oranjemund, the mine headquarters]–[9,000 residents]–[a lonely corporate oasis of 9,000 residents]* || **[Jackals]**
- m_0*–[the mine headquarters]–[Oranjemund, the mine headquarters]–[9,000 residents]–[a lonely corporate oasis of 9,000 residents]–[Jackals]* || **[the streets]**
- m_0*–[the mine headquarters]–[Oranjemund, the mine headquarters]–[9,000 residents]–[a lonely corporate oasis of 9,000 residents]–[Jackals]–[the streets]* || **[night]**

Decoding. In the testing stage, given a document and its ordered mentions based on the rule described above, we predict IS classes for these mentions incrementally from left to right. Because a mention's IS could depends on the IS labels of its context mentions, we also encode the IS class as one-hot representation. The gold standard labels and the predicted IS labels of the context mentions are used for training and decoding respectively[4].

[4]The IS class one-hot representation for the target mention is a zero vector during training and decoding.

Network parameters. We use Adam (Kingma and Ba, 2015) for optimization with the learning rate of 0.01. We train all models with 10 epochs using cross-entropy loss. To avoid over-fitting, we apply dropout before and after the LSTM layer with the probability of 0.1. For each mention, we set the maximum number of its context mentions as 50[5]. Therefore we unfold the network 51 times and apply masking for the instances which have less than 50 context mentions.

We use GloVe vectors (Pennington et al., 2014) with 100 dimensions trained on Wikipedia and Gigaword as word embeddings, which we do not optimize during training. Out-of-vocabulary words in the training set and the testing set are set to fixed random vectors. We approximate mention representations fed into the first LSTM by summing embeddings of all words from a mention as Yu and Dredze (2015) show that sum of word embeddings achieves reasonable result to induce phrase embeddings. In ISNotes, around 30% of mentions contain only one word and around 70% of mentions contain less than four words. Mention representations fed into the second LSTM are one-hot vectors of the mentions' features and their IS classes.

4 Experiments

4.1 Experimental Setup

We perform experiments on the ISNotes corpus (Markert et al., 2012). Following Hou et al. (2013), all experiments are performed via 10-fold cross-validation on documents. We use gold standard mentions and the OntoNotes syntactic annotation layer for feature extraction. We report overall accuracy as well as precision, recall and F-measure per IS category. In the following, we describe the baseline and our model with different feature settings.

Baseline. Hou et al. (2013) report the state-of-the-art performance for fine-grained IS classification on ISNotes using collective classification. They explore a wide range of features (34 in total), including a large number of lexico-semantic features as well as a couple of surface features and syntactic features. Hou et al. (2013) observe that bridging anaphors are rarely marked by surface features. Therefore they carefully design discourse structure, lexico-semantic and genericity detection features to capture the phenomenon. The semantic features are extracted from manually or automatically constructed knowledge bases, such as WordNet (Fellbaum, 1998) and the General Inquirer lexicon (Stone et al., 1966).

LSTM. To test how well we can predict IS for mentions without using any hand-crafted features, we only use word embeddings and IS labels in our attention-based LSTM model described in Section 3.2. Specifically, we use mention embeddings (100 dimensions) as the input of the first LSTM. Mention embeddings are obtained by summing word embeddings of all words from a mention, where word embeddings are from GloVe vectors trained on Wikipedia and Gigaword. We use one-hot vectors (8 dimensions) to encode IS labels and use them as the input of the second LSTM.

LSTM+PAR. Hou et al. (2013) show that coordination parent-child relations and other syntactic parent-child relations among mentions are highly effective for `mediated/coordination` and `mediated/syntactic` classes. We use one-hot vectors (2 dimensions) to integrate such parent-child information into the LSTM model described above. Table 3 demonstrates two examples of one-hot representation for parent-child relations.

[[their] liquor store]	$[\text{their}]_{[1,0]} \parallel \textbf{[their liquor store]}_{[1,0]}$
[[he] and [[his] skilled team]]	$[\text{he}]_{[0,1]} - [\text{his}]_{[0,0]} - [\text{his skilled team}]_{[0,1]} \parallel \textbf{[he and his skilled team]}_{[0,1]}$

Table 3: one-hot representations for parent-child relations.

LSTM+PAR+FEAT. We hypothesize that knowledge about a mention's surface and syntactic properties can be useful to decide its information status. Therefore, we add a small feature set (see Table 4) from

[5]In practice, we find that in our model, the results are similar with the maximum number of context mentions as 10, 20, or 50.

Hou et al. (2013) into our attention-based LSTM model (*LSTM+PAR*) using one-hot representations. $f1$-$f5$ are surface and syntactic features, and $f6$-$f8$ are three simple lexical-semantic features. $f6$-$f8$ provide additional semantic knowledge for three mediated classes (i.e., `mediated/comparative`, `mediated/worldKnowledge` and `mediated/function`) that our current mention embedding representations do not capture well.

Feature	**Value**
$f1$ FullPrevMention	{yes, no, NA}
$f2$ PartialPreMention	{yes, no, NA}
$f3$ Determiner	{bare, def, dem, indef, poss, NA}
$f4$ NPtype	{pronoun, common, proper, other}
$f5$ GrammaticalRole	{subject, subjectPassive, pp, other}
$f6$ PreModByCompMarker	{yes, no}
$f7$ IsFrequentProperName	{yes, no}
$f8$ DependOnChangeVerb	{yes, no}

Table 4: A small feature set from Hou et al. (2013).

4.2 Results and Discussion

Results. Table 5 shows the results of our models compared to the baseline. Our model with word embeddings and only a couple of simple features (*LSTM+PAR+FEAT*) performs as good as the state-of-the-art approach (Hou et al., 2013) which explores a wide range of semantic features based on various knowledge resources. It is worth noting that the model with only word embeddings (*LSTM*) achieves an accuracy of 66.8. Also *LSTM* performs similar as the baseline for bridging anaphora recognition under the multi-class classification setting. This indicates that word embeddings in our model do capture certain semantics needed for the task. The improvement in *LSTM+PAR* over *LSTM* confirms the effectiveness of the two parent-child relations for `mediated/syntactic` and `mediated/aggregate` categories.

Comparing the results of *LSTM+PAR+FEAT* to *LSTM+PAR* and *LSTM+PAR+FEAT−wordEmb*, it seems that word embeddings and the small set of simple features (most of them are capturing the surface and syntactic properties of mentions) are complementary. Specifically, `mediated/function` and `mediated/bridging` benefit most from word embeddings which provide useful semantic knowledge to capture these two categories. On the contrary, the feature set (*FEAT*) provides better generalization capability for `old`, `mediated/worldKnowledge` and `mediated/comparative`.

acc		**78.9**			66.8			68.6			78.6			75.1	

Table 5: Experimental results of the attention-based LSTM models compared to the baseline. Bolded scores indicate the best performance for each IS class. There is no significant difference between *LSTM+PAR+FEAT* and the baseline at the level of $p < 0.01$ (Statistical significance is measured using McNemar's χ^2 test (McNemar, 1947)).

The incremental prediction mechanism in our model utilizes the (predicted) IS class information of previous mentions when predicting the IS class for the current mention. To gain a better understanding of such mechanism, we conduct an experiment by removing IS label information from our best model (thus *LSTM+PAR+FEAT - ISLabels*). This leads to a mild decrease in the overall accuracy (from

78.6 to 77.7). When looking at the results, we found that the decrease is centered on the categories of `mediated/syntactic`, `mediated/aggregate` and `new`. This confirms that our incremental decoding strategy helps the model to capture the IS label dependencies among mentions better.

Analysis of attention mechanism. We further analyze the attention mechanism in our model *LSTM+PAR* by manually checking some testing examples from one fold. We choose this setting because we want to investigate whether the model can capture long distance relations between mentions without being informed by the features which indicate whether a mention is fully or partially mentioned before.

Figure 2 shows heat maps of several examples that our model predicts correctly[6]. Note that we must take into account that the model only partially relies on representations obtained from attention, i.e., in Equation 11, the final prediction depends on the combination of attention representation as well as the long range contextual representation obtained from LSTM encoders.

It is interesting to see that in the first example, the model attends to several reasonable antecedents for the pronoun "[it]" when predicting its information status. In the second example, when predicting information status for "[the kingdom]", the model focuses on its antecedent "[Saudi Arabia]". In the third and the fourth examples, the model focuses on the syntactic children when predicting information status for "[its percentage share of OPEC production]" and "[Motorola and other companies]".

We also notice that for `old` mentions, when their antecedents do not appear in the preceding context mentions, the weights of attention are more uniformly distributed. Furthermore, for correctly predicted `mediated/comparative` and `mediated/bridging` mentions, we do not observe clear patterns in their attention weights. We assume this is because we have less training data for these two categories. In addition, only a few of them have antecedents occurring in the preceding ten mentions. Therefore, the model seems mainly uses the last output vector (h_{m_i} in Equation 11) for prediction.

5 Related Work

Automatic IS classification. Markert et al. (2012) applied joint inference for IS classification on the ISNotes corpus. Built on this work, Hou et al. (2013) proposed a cascading collective classification algorithm for bridging anaphora recognition with various semantic features. They report the state-of-the-art result for fine-grained IS classification using collective classification.

Rahman and Ng (2012) studied the fine-grained IS classification problem on the Switchboard dialogue corpus (Nissim et al., 2004). They first designed a rule-based system to assign IS classes to mentions. The rule-based system heavily depends on knowledge resources such as FrameNet (Baker et al., 1998), WordNet (Fellbaum, 1998), and ReVerb (Fader et al., 2011). They then applied an SVM^{multiclass} algorithm for this task by combining the prediction from the rule-based system, the ordering of the rules as well as two lexical features.

Another work on IS classification was carried out by Cahill and Riester (2012). They assumed that the distribution of IS classes within sentences tends to have certain linear patterns, e.g., *old* > *mediated* > *new*. Under this assumption, they trained a CRF model with syntactic and surface features for fine-grained IS classification on the German DIRNDL radio news corpus (Riester et al., 2010).

Our work differs from the above mentioned work in that we explore a new model which resembles human beings' cognitive process for the task and we replace hand-crafted semantic features with word embeddings which were learned from large corpora in an unsupervised manner.

Attention-based RNNs in NLP. Recently, RNNs with attention mechanisms have demonstrated success in various NLP tasks, such as machine translation (Bahdanau et al., 2015), parsing (Vinyals et al., 2015), image captioning (Xu et al., 2015), and textual entailment (Rocktäschel et al., 2016). Attention-based RNNs allow the model to access its internal memory when making predictions. This property is intuitive for our task because in order to decide a discourse entity's information status, we need to access its context and choose one (or none) discourse entity to attend.

[6]Due to the space limitation, we only show plots for maximum number of context mentions at ten. The patterns we observe here are similar for maximum number of context mentions at 20 or 50.

Figure 2: Attention heat maps.

6 Conclusions

We develop an attention-based LSTM model which draws on the recent advances in research on RNNs for fine-grained IS classification. The system imitates how human beings reason information status of a discourse entity based on its preceding context. The results indicate that our model with only pre-trained word embeddings captures semantic knowledge needed for the task by a large extent. Extending the model with several simple features improves the ability of the system, resulting in competitive results on the ISNotes corpus compared to the state-of-the-art approach which explores a broad variety of semantic features.

The model presented here is intuitive for understanding discourse entities. In the future, it would be worthwhile exploring how to extend the system to model other related discourse processing tasks, such as coreference resolution and bridging resolution.

{r02922036,hhchen}@ntu.edu.tw

Abstract

In this paper, we investigate four important issues together for explicit discourse relation labelling in Chinese texts: (1) discourse connective extraction, (2) linking ambiguity resolution, (3) relation type disambiguation, and (4) argument boundary identification. In a pipelined Chinese discourse parser, we identify potential connective candidates by string matching, eliminate non-discourse usages from them with a binary classifier, resolve linking ambiguities among connective components by ranking, disambiguate relation types by a multiway classifier, and determine the argument boundaries by conditional random fields. The experiments on Chinese Discourse Treebank show that the F1 scores of 0.7506, 0.7693, 0.7458, and 0.3134 are achieved for discourse usage disambiguation, linking disambiguation, relation type disambiguation, and argument boundary identification, respectively, in a pipelined Chinese discourse parser.

1 Introduction

Discourse relations represent how discourse units logically connect with each other. A discourse connective explicitly signals the presence of a discourse relation, and therefore it is an important clue for discourse analysis. There are several challenges in Chinese discourse parsing.

Firstly, there are more discourse connectives in Chinese than in English and their parts of speech have more varieties (Huang et al., 2014). Therefore, it is likely to encounter words that have the same surface forms as real connectives but do not function as discourse connectives.

Secondly, many Chinese connectives are parallel connectives that have multiple discontinuous components (Zhou and Xue, 2012). Each connective can be composed of one or more *connective components*. For example, "雖然-但" (although-but) consists of two connective components: "雖然" (although) and "但" (but). When multiple connectives are present in a paragraph, their components often link with each other in multiple possible ways. (S1) is an example. There are five possible connective candidates, including (1) "除了...還" (in addition to ... also), (2) "還...也" (also ... also), (3) "除了" (in addition to), (4) "還" (also), and (5) "也" (also). Figure 1 illustrates the ambiguous linking. Only candidates (1) and (5) are correct. Moreover, when spurious component candidates exist in a paragraph, they form many more spurious connective candidates by linking together in different ways. Finding the correct linking between correct components is useful for discourse analysis because they provide clues to determine the positions of the relations.

(S1) 除了投資環境優越，還在於這些企業所具有的產品優勢。(...) 對上海的產業優化也有很大的帶動作用。(In addition to superior investment environment, it's also due to the product advantages possessed by the enterprise. (...) It also has great effect in promoting the optimization of industries in Shanghai.)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1891–1902, Osaka, Japan, December 11-17 2016.

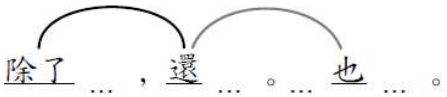

Figure 1: Ambiguous linking between connective components.

Thirdly, the sentence structures in Chinese texts are not clearly defined. Thus it is more challenging to detect the arguments for a given relation. Here, arguments of a discourse relation are the discourse units it involves. Since the relations form a hierarchical discourse structure, the arguments for relations higher in the hierarchy or lower in the hierarchy could span over ranges of various lengths.

In this paper, we aim at investigating these unique challenges at the same time. The goal of this research is to build an end-to-end system to analyse the explicit discourse relations in Chinese texts. In particular, we deal with four tasks together: (1) extraction of explicit discourse connectives, (2) linking resolution between the component candidates, (3) classification of the relation type for each discourse connective, and (4) extraction of the discourse arguments of a connective.

This paper is organized as follows. Section 2 surveys the related work. Section 3 describes the datasets used in this study. Section 4 presents our Chinese discourse parser. Section 5 shows and discusses the experimental results. Section 6 concludes the remarks.

2 Related Work

Rhetorical Structure Theory Discourse Treebank (RST-DT) (Carlson et al., 2001) and the Penn Discourse Treebank 2.0 (PDTB2) (Prasad et al., 2008) are two popular English discourse corpora for discourse analysis. Many groups have investigated different subtasks of English discourse parsing on PDTB2, including discourse connective identification, relation type disambiguation (Pitler and Nenkova, 2009; Wellner, 2009; Faiz and Mercer, 2013), and argument extraction (Wellner and Pustejovsky, 2007; Elwell and Baldridge, 2008; Ghosh et al., 2011; Ghosh et al., 2012; Kong et al., 2014). Lin et al. (2014) build an end-to-end discourse parser. As RST-DT provides hierarchical discourse structure annotations, there are also many attempts to construct the discourse structures automatically for sentences (Sporleder and Lapata, 2005; Fisher and Roark, 2007; Joty et al., 2012) and documents (Hernault et al., 2010; Feng and Hirst, 2012; Joty et al., 2013; Li, Li et al., 2014; Ji and Eisenstein, 2014).

Comparatively, there have been few large-scale Chinese discourse corpora until recently (Zhou and Xue, 2012; Zhou and Xue, 2015; Zhang et al., 2014; Li, Feng et al., 2014). Due to limited resource, early studies often used self-constructed corpora that made it difficult to compare between different works. T'sou et al. (1999), T'sou et al. (2000) and Chan et al. (2000) investigated connective detection in Chinese texts as a part of a tagging system. Hu et al. (2009) developed an automatic system to extract connective components from sentences. They used a rule-based method and found that the performance was sensitive to the connective lexicon. They improved their performance by removing words commonly used in non-discourse contexts. Zhou et al. (2012) and Li, Carpuat et al. (2014) employed cross-lingual information to deal with discourse usage ambiguity. Li, Carpuat et al. (2014) used 5-way classification to classify a connective between four relation types and non-discourse usage. Li et al. (2015) used CDTB to investigate detection and classification of connective components. They used maximum entropy and decision tree algorithms with various syntactic features. Chen et al. (2016) investigated fine-grained Chinese discourse relation labelling. Hu et al. (2011) dealt with linking ambiguity. However, they only focused on intra-sentential relations in sentences that have multiple clauses and assumed all connective components in the sentence have already been correctly identified.

As researchers start to focus on higher level problems for linguistic analysis, interest in discourse parsing also grows. The CoNLL-2015 Shared Task (Xue et al., 2015) and the CoNLL-2016 Shared Task (Xue et al., 2016) both focus on shallow discourse parsing. In particular, the CoNLL-2016 Shared Task features Chinese discourse parsing with Chinese Discourse Treebank 0.5 (Zhou and Xue, 2015), a PDTB-style annotated corpus.

3 Datasets

In this section, we briefly introduce the datasets used in this study and provide some statistics.

3.1 Chinese Discourse Treebank (CDTB)

In Chinese Discourse Treebank (CDTB) (Li, Feng et al., 2014), 500 documents selected from the Chinese Treebank (CTB) (Xue et al., 2005) were annotated. Totally, CDTB contains 2,342 paragraphs. Each paragraph was segmented into elementary discourse units (EDUs), and each paragraph is represented as a discourse tree as shown in Figure 2. Each relation is represented by an internal node, while each EDU is represented by a leaf node. The explicit and implicit relations between different spans of EDUs were annotated. In addition, discourse connectives for each relation were annotated. The exact positions of the arguments for a relation is heavily influenced by the complete discourse tree, and can range over multiple sentences in a paragraph.

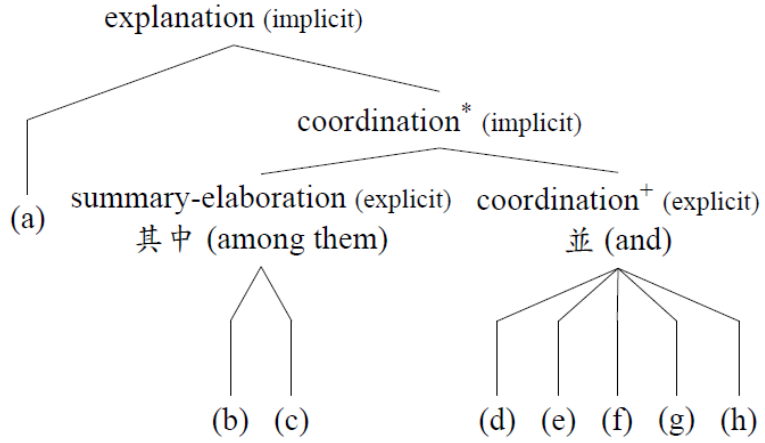

Figure 2: A discourse tree.

In CDTB, total 7,310 relations are annotated, and 1,814 of them are explicit. The set of discourse relation types is organized in a three-level hierarchy. In this paper, we only focus on the four top-level relation types, i.e., causality, coordination, transition, and explanation.

Some errors including duplicate annotations and erroneous positions are found in the corpus. After manual correction for explicit relation annotations, there are 1,813 explicit relations, each of which consists of exactly one connective instance. These 1,813 connectives are composed of 2,131 connective component instances.

The length distribution for the annotated connectives is shown in Table 1. The distribution is imbalance. There are totally 274 classes of connectives, but 147 of them appear only once.[1] Since some connectives share the same components, there are only 227 classes of connective components. Most of the connective classes only have one unique top-level relation type.

#Components	1	2	3	4	6	7
#Connective Classes	143	108	15	6	1	1
#Instances	1,544	235	24	8	1	1

Table 1: Lengths of connectives.

Table 2 shows the number of arguments for explicit relations. Most relations only have two arguments, but there are relations that have as many as 7 arguments. The number of arguments does not always match with the number of connective components. For example, single connective "并" (and) can have as many as 5 arguments because it connects multiple parallel segments together.

#Arguments	2	3	4	5	6	7
#Instances	1,688	85	33	4	2	1

Table 2: Number of arguments for each explicit relation.

Totally there are 3,802 arguments for explicit relations. Depending on the position the relation resides in the discourse tree, the length of an argument could vary greatly, but most of the arguments for

[1] These numbers are computed by their surface forms, i.e., instances of the same connective class may have different relation types.

explicit relation are composed of only one EDU. On average, each argument is composed of 1.6 EDUs, and the longest argument is composed of 20 EDUs.

3.2 NTU PN-Gram Corpus

Recently, efficient methods to learn word embeddings have been developed. In this paper, we investigate whether such word vectors are useful for dealing with discourse issues. NTU PN-Gram Corpus released by Yu et al., (2012), which was constructed by POS-tagging the Chinese texts extracted from the ClueWeb09 dataset (Callan et al., 2009). It has 21,217,147 unique sentences, containing 326,996,602 tokens. We used this corpus to create 400-dimensional embeddings using GloVe tool (Pennington et al., 2014) and word2vec tool (Mikolov et al., 2013a; Mikolov et al., 2013b) with skip-gram and continuous bag-of-words models.

3.3 Connective Component Dictionary

Discourse connectives serve as linking elements that connect discourse units. There are three kinds of linking directions (Li and Thompson, 1989): (1) forward-linking, (2) backward-linking, and (3) couple-linking. Such linking directions could be useful for identifying the positions of arguments for a given connective. We used the connective linking dictionary collected by Huang et al. (2014) as features for argument boundary identification. Totally, it contains 301 distinct connective components that are annotated with linking directions.

4 Chinese Discourse Parser

There are five modules in the proposed pipelined system. Each paragraph in CDTB is processed by the following modules: (1) identify connective candidates, (2) eliminate non-discourse usages from connective candidates, (3) resolve linking ambiguities, (4) disambiguate relation types, and (5) extract arguments.

4.1 Connective Candidate Extraction

We use string matching with the connective lexicon collected from CDTB to extract all possible instances. Directly matching with raw text would yield 12,498 candidate components[2] because many characters used for connectives appear in other unrelated words. Therefore, Stanford Chinese segmenter (Chang et al., 2008) is employed to segment paragraphs into tokens. Only the components composed of complete tokens are extracted.

Total 7,649 component candidates which recover 2,068 of 2,131 annotated components are extracted. These candidates form 7,976 connective candidates which recover 1,755 of 1,813 annotated connectives. While some correct instances are not extracted due to segmentation errors, it reduces the number of spurious candidates substantially while maintaining high recall.

4.2 Discourse Usage Disambiguation

A logistic regression classifier is trained to eliminate spurious connective candidates. The features are listed below:

P&N: We used a subset of the features selected from Pitler and Nenkova (2009). It includes four binary features for each connective component: (1) the highest category that dominates exactly the component itself, which is called self-category, (2) the parent, (3) the left-sibling, and (4) the right-sibling of the self-category. Null features are set when no such nodes exist. For example, in Figure 3, there is no node that dominates exactly the component "卻是" (but). For multi-component connectives, the union of the features is used. We have also experimented with the full feature set, but the performance does not increase.

CONNECTIVE: The string of the connective.

[2] Candidate components that could not form complete connectives are already eliminated. If we simply match with component lexicon without checking whether they could form connectives, 24,539 candidate components would be detected.

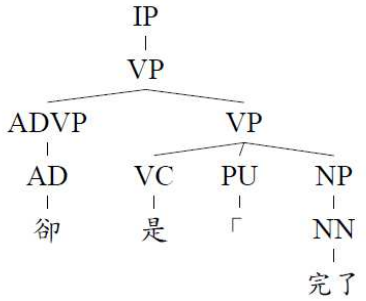

Figure 3: A sub-parsing tree for 卻是.

POS: The feature set contains: (1) POS tags for all tokens that constitute the connective component, (2) POS tag of the token to the left of the component, and (3) POS tag of the token to the right of the component. For multi-component connectives, the union of the features is used.

NUM: The feature set contains a one-hot encoded feature–the number of components. In addition, there are seven numerical features: (1) the number of overlapped connective candidates, (2) the number of connective candidates that enclose any components of the current connective, (3) the distance between the leftmost and the rightmost tokens of the connective measured by tokens, (4) the geometric mean of distances between all neighbouring connective components for the current connective candidate, (5) the distances from the leftmost component to a separating element including "!?:;, ◦ " or the paragraph boundary on the left, (6) the distance from the rightmost component to a separating element on the right, and (7) the minimum distance from any separating element to any connective component. We normalize the numerical features by scaling each to zero mean and unit variance.

VECTOR: This feature set is built using word embeddings. The vectors are used to construct three features for each connective component: (1) the mean of the vectors representing each token that constitutes the connective component, (2) the vector for the token to the left, and (3) the vector for the token to the right. Zero-valued vector is used when the vector does not exist. In total, it is a 1,200-dimensional vector for each component when the 400-dimensional embeddings are used. For multi-component connectives, we averaged the vectors.

4.3 Connective Linking Disambiguation

If we can classify discourse usage perfectly, we would have already solved the linking ambiguities because only the correct connectives remain. Due to imperfect classification, there may still exist some overlapped candidates. Here, we propose a greedy algorithm to resolve linking ambiguities among a set of connective candidates as outlined in Algorithm 1. The algorithm filters the candidate set C and produces a result set A that contains only non-overlapped connective candidates. All connective candidates are ranked under some criteria and the one with the highest priority is greedily accepted. We will use different ranking criteria to evaluate our models, including (1) Score: the probability obtained by logistic regression as described in Section 4.2, (2) Length: the number of components each connective candidate has, the larger the better, and (3) Position. Position is used mainly as a tiebreaker. In particular, we accept the left-most candidate first.

Algorithm 1. Linking Resolution Algorithm

Input C: A set of connective candidates
Output A: A set of accepted connectives

1. $A \leftarrow \{\}$
2. Rank all connective candidates in C
3. **while** C is not empty **do**
4. let c_i be the connective candidate that has the highest priority
5. $C \leftarrow C - \{c_i\}$
6. $A \leftarrow A \cup \{c_i\}$
7. Remove all connective candidates $c_j \in C$ that overlap with c_i
8. **end while**
9. **return** A

4.4 Discourse Relation Type Disambiguation

We use a logistic regression classifier to investigate whether the features we discussed in Section 4.2 are useful for relation type disambiguation.

4.5 Connective Argument Extraction

We formulate argument extraction as a sequence labelling problem. As we know the arguments span over a continuous interval, we use four labels for the EDUs: *before*, *start*, *inside*, and *after*. Each argument is represented by a *start* followed by zero or more *inside*s. Figure 2 is a discourse tree, where the explanation relation has two arguments (a) and (b-h), while the coordination$^+$ relation has five arguments (d), (e), (f), (g), and (h). Figure 4 shows the arguments and the corresponding labels for summary elaboration relation shown in Figure 2.

As our goal is to extract the arguments, only the argument boundaries must be determined. Although correct EDU segmentation is unavailable to our system because we attempt to extract arguments from raw texts, the EDU boundaries in CDTB only occur with certain punctuation symbols that separate phrases and sentences. Thus, we segment a paragraph by these symbols, and solve the sequence labelling problem on these segments instead of EDUs.

We use Conditional Random Fields (CRFs) to deal with the sequence labelling problem. CRFsuite (Okazaki, 2007) is adopted along with its default parameters. When training, each explicit relation with its corresponding labelling is used as a training case. When testing, CRFs are used to label the segments for each connective we extracted. Therefore, the same segments for a paragraph are labelled independently for each explicit relation inside the paragraph. The resulting argument boundaries are used to extract the connective's arguments.

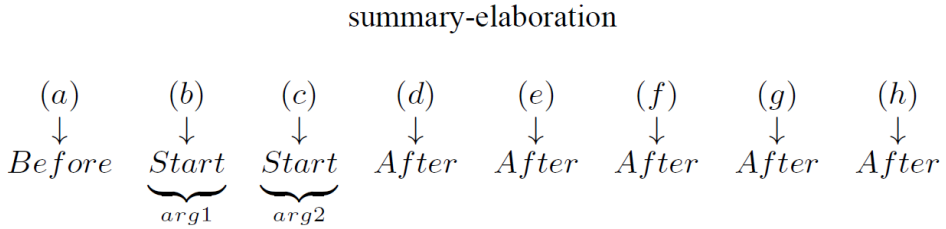

Figure 4: Sequence labelling for relation arguments identification.

The features, which are determined by the current connective being considered and the segment, are shown as follows.

CONTEXT: The concatenation of the self-category and the categories of the parent, the left-sibling, and the right-sibling is used as a binary feature as done by Kong et al. (2014).

PATH: The feature set is similar to the CON-NT-Path features of Kong et al. (2014). We use the path from the self-category of each connective component to the self-category of the segment as the feature.

POS: The POS tags for all tokens in the segment.

SUBJ: The SUBJ feature is set if a segment contains a subject.

ENDCHAR: The last token in the segment, i.e., the symbol that separates the current segment from the next one.

COMPONENT: The feature set contains the information about connective components: (1) whether the segment has a connective component, (2) the string of the component if it exists, (3) whether there exists a component at the beginning of the segment, (4) whether there exists a component at the end of the segment, (5) whether the segment contains only a component and the separating symbol, (6) whether the segment is before all connective components, (7) the distance to the first segment that contains a component as a binary feature, (8) whether the segment is after all connective components, and (9) the distance to the last segment that contains a connective component as a binary feature.

LINK: The feature set contains the linking directions a connective component could be used if it exists in the given segment. A connective component dictionary is consulted.

CONNECTIVE: This feature set contains connective related information, including the string of the connective and the number of connective components it has.

5 Results and Discussions

In the experimental setups, we first evaluate the performance of each individual disambiguation task and then examine the propagation effects in the pipelined system.

5.1 Discourse Usage Disambiguation

We evaluate our models using 10-fold cross-validation. The 2,342 paragraphs are divided into 10 splits while keeping the distribution for the number of explicit relations in each paragraph roughly equal. The averaged precision, recall, and F1 scores for the positive connective instances are reported. As there are many spurious connectives, we balance the training set by oversampling the correct instances for three times, but keep the original distribution when evaluating on test set.

For statistical significance, we use Wilcoxon signed-ranks test (Wilcoxon, 1945) as suggested by Demšar (2006) at confidence level 95%. For each experiment, we select the best model (denoted by bold), and * is used to denote the scores that are significantly different.

We firstly investigate the performance between different word embeddings as shown in Table 3. The vectors constructed by skip-gram model are the most useful. We will use them in the remaining experiments. Table 4 shows the results for all features. The best results are obtained with ALL-SKIP-GRAPM in discourse usage disambiguation. We also experiment with different learning models including Naive Bayes, SVM, decision trees, and random forest. Logistic Regression performs the best. For all models, we use default parameters provided by scikit-learn without tuning, i.e., C=1.0, penalty=l2 for Logistic Regression.

ALL	0.6682	0.8203	0.7363*

Table 4: Performance of discourse usage disambiguation using different features.

5.2 Connective Linking Disambiguation

To evaluate linking disambiguation individually, we first assume all correct connective components are already known. We use the 10-fold for paragraphs specified in Section 5.1 to evaluate our model using each connective as an instance. The results are reported in Table 5. We evaluate different ranking criteria and the combination. A baseline model that simply ranks the candidates by their positions is also reported. We find that the ambiguity among the components is low. The baseline model already achieves an F1 score of 0.8797. In fact, only 472 out of 2,131 components are involved in more than one connective candidate. Length is relatively weaker than Score reported by the logistic regression model. Moreover, we also evaluate linking disambiguation within the pipelined system. The results are shown in Table 6. Integrating both Score and Length criteria performs the best. The comparison shows that most of the linking ambiguity is caused by spurious linking with spurious connective component candidates.

Ranking Criteria	Precision	Recall	F1 Score
Baseline	0.8528	0.9084	0.8797*
Score	0.9770	0.9796	**0.9783**
Length	0.9760	0.9604	0.9681*
Length+Score	0.9793	0.9636	0.9714*

Li et al. (2015) DT	0.5680	0.4960	0.5230

Table 7: Performance of discourse connective disambiguation on the component level.

In the above evaluation, we consider a connective instance as an evaluation unit. To compare with the related work we also take a connective component as an evaluation unit. Table 7 summarizes the results of discourse connective disambiguation on this level. The first model is for discourse usage disambiguation without linking disambiguation. The second model eliminates additional candidates by resolving linking ambiguity. The experimental results of Li et al. (2015) are listed for reference because they use the same dataset as us. The best results for Maximum Entropy (ME) and Decision Tree (DT) classifiers with automatic parsing tree features are selected. Although linking disambiguation has small effect for identifying individual components, it effectively improves the performance of connective extraction as shown in Table 6. The result is also important for argument extraction, because the positions of connective components provide clues for the positions of the arguments of an explicit relation.

5.3 Discourse Relation Type Disambiguation

At first, we evaluate the relation type disambiguation by assuming connectives are known. We use 10-fold cross-validation with the 1,813 explicit connectives to evaluate our model. We keep the distribution for the relation types roughly equal for each fold. While the NUM features have some discriminative power for discourse usage disambiguation, it does not help for relation disambiguation. When used independently, the performance is the same as always predicting the major category. On the other hand, the string of the connective provides strong clues for the relation type. When used individually, it already achieves a micro average F1 of 0.9308. In addition, the SKIP-GRAM feature is also useful for this task, achieving a micro average F1 of 0.9473. In Table 8, we show the performance for different relation types using ALL-NUM as features. We can find that the number of instances affects the performance of the learning model. The lesser the instances, the worse the performance. To compare with Li et al. (2015), we also evaluate the results on component level. Table 9 shows that we also achieve better performance on relation type classification.

Relation Type	Precision	Recall	F1 Score	#instances
causality	0.9634	0.9504	0.9561	465
coordination	0.9575	0.9723	0.9645	974
transition	0.9372	0.9131	0.9234	173
explanation	0.9754	0.9450	0.9588	201
macro average	0.9584	0.9452	0.9507	1,813

Table 8: Performance of relation type disambiguation when connectives are known.

	Our Model			Li et al. (2015)		
Relation Type	P	R	F1	P	R	F1
causality	0.9584	0.9420	0.9490	0.8380	0.6840	0.7510
coordination	0.9566	0.9734	0.9645	0.8250	0.9360	0.8770
transition	0.9504	0.9178	0.9318	0.7850	0.5960	0.6700
explanation	0.9754	0.9407	0.9563	0.8970	0.8280	0.8590

Table 9: Performance of relation type disambiguation on component level.

We further evaluate the relation type classification on the pipelined system. We predict the relation type with features ALL-NUM for each connective candidate extracted by using the Length+Score approach. The 10-fold for paragraphs specified in Section 5.1 is used. We obtain micro-averaged F1 score of 0.7458. Compared with the F1 score of 0.7693 shown in Table 6, the performance only decreases a little when one more module is integrated into the pipelined system. That shows the effectiveness of our model for relation type disambiguation.

5.4 Connective Argument Extraction

To evaluate argument extraction individually, we first assume all connectives are already correctly identified. The 10-fold for paragraphs specified in Section 5.1 is used for cross-validation. The precision, recall, and F1 scores for the argument boundaries are computed. In addition, accuracy scores evaluated on 1,813 connective instances are computed. Each instance is counted as correct only when all boundaries are all correctly identified. The averaged results over all folds are reported in Table 10. While the best F1 for argument boundaries is 0.7848, the accuracy for the connectives as evaluation units is only 0.4074. It means that for each connective, we are able to recover most of its argument boundaries, but it is challenging to recover all of them at the same time.

An analysis on the errors reveals that our model can handle the relations that have exact two arguments. For more arguments, the error rates are almost close to 1. In addition, out of the 1,074 error cases, there are only 164 cases that both sides of the interval the arguments span over are incorrect. The reason behind this is probably due to the fact that the existence of a connective often gives strong hint on at least one side of the interval. On the contrary, there is often no explicit indication on the boundary of the other side of the interval.

Finally, we evaluate the performance of the pipelined Chinese discourse parser. Here, the Length+Score approach is used for connective extraction, the ALL-NUM features are used to disambiguate the 4 top-level relation types, and the CRF models with ALL features are used for argument boundary detection. Each explicit relation is counted as true positive only when the three tasks are all correctly done; otherwise, it is counted as false positive. Under the rigorous evaluation, precision, recall, and F1 score are 0.2917, 0.3389 and 0.3134, respectively. We also evaluate on a relaxed partial match for argument extraction. An F1 score is computed for each argument tokenwise, and an instance is treated as correct when the number of arguments is correct and the averaged tokenwise F1 score is above a threshold.[3] The F1 scores computed with 0.3, 0.5, 0.7, and 0.9 as thresholds are 0.6013, 0.5782, 0.5063 and 0.3455, respectively.

Features	Precision	Recall	F1 Score	Accuracy

6 Conclusion

In this paper, we investigate four issues regarding Chinese discourse analysis at the same time. We propose four types of features for discourse usage disambiguation. A greedy algorithm is also developed to resolve linking ambiguities. Besides, we also investigate relation type disambiguation and argument extraction. These modules are integrated into a pipelined system that extracts explicit discourse relations and their arguments from the raw text. The pipelined system achieves an overall F1 score of 0.3134.

There still exist some issues that need to be further investigated. Firstly, a closer integration between discourse usage disambiguation and linking disambiguation may be valuable. In our work, these two stages are pipelined. Although some linking information is used as features, the greedy algorithm still ranks each candidate individually. We expect that utilizing global relationship between conflicting candidates may improve the performance for both tasks. Secondly, the arguments for a relation may be useful for relation type recognition. However, the accuracy for argument extraction must be improved before the extracted arguments are used as features. Finally, implicit relations must be dealt with to construct the full discourse structure. Resolving these issues will be helpful to construct a complete Chinese discourse parser.

Abstract

We experiment with different ways of training LSTM networks to predict RST discourse trees. The main challenge for RST discourse parsing is the limited amounts of training data. We combat this by regularizing our models using task supervision from related tasks as well as alternative views on discourse structures. We show that a simple LSTM sequential discourse parser takes advantage of this multi-view and multi-task framework with 12-15% error reductions over our baseline (depending on the metric) and results that rival more complex state-of-the-art parsers.

1 Introduction

Documents are not just an arbitrary collection of text spans, but rather an ordered list of structures forming a discourse. Discourse structures describe the organization of documents in terms of discourse or rhetorical relations. For instance, the discourse relation CONDITION holds between the two discourse units (marked with square brackets) in example (1a) and a relation MANNER-MEANS holds between the segments in example (1b).[1]

(1) a. [The gain on the sale couldn't be estimated] [until the "tax treatment has been determined."]

b. [On Friday, Datuk Daim added spice to an otherwise unremarkable address on Malaysia's proposed budget for 1990] [by ordering the Kuala Lumpur Stock Exchange "to take appropriate action immediately" to cut its links with the Stock Exchange of Singapore.]

Different theories of discourse structure exist. For instance, Rhetorical Structure Theory (RST) (Mann and Thompson, 1988) analyzes texts as constituency trees covering entire documents. This theory has led to the RST Discourse Treebank (RST-DT) (Carlson et al., 2001) for English and the development of text-level discourse parsers (Hernault et al., 2010; Joty et al., 2012; Feng and Hirst, 2014; Ji and Eisenstein, 2014b). Such parsers have proven to be useful for several downstream applications (Taboada and Mann, 2006; Daumé III and Marcu, 2009; Thione et al., 2004; Sporleder and Lapata, 2005; Louis et al., 2010; Bhatia et al., 2015; Burstein et al., 2003; Higgins et al., 2004). Another corpus has been annotated for discourse phenomena in English, the Penn Discourse Treebank (Prasad et al., 2008) (PDTB). In contrast to RST-DT, PDTB does not encode discourse as tree structures and documents are not fully covered. In this study we focus on the RST-DT, but among other things, we consider the question of whether the information in PDTB can be used to improve RST discourse parsers.

Discourse parsing is known to be a hard task (Stede, 2011). It involves several complex and interacting factors, touching upon all layers of linguistic analysis, from syntax, semantics up to pragmatics. Consequently, also annotation is complex and time consuming, and hence available annotated corpora are sparse and limited in size. The aim of this paper is to address this training data sparsity by proposing to leverage different views of the same data as well as information from related auxiliary tasks. We aim at investigating which source of information are relevant for the discourse parsing task.

[1] The examples are taken from the RST Discourse Treebank, documents 1179 and 0613, respectively.

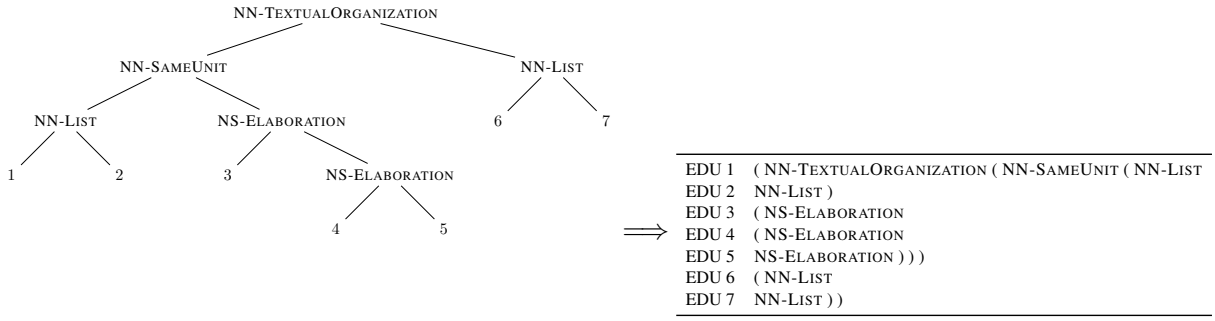

Figure 1: From RST-DT discourse trees to constituency sequence labels.

Specifically, we draw upon the recent success of deep learning methods and present a novel multi-view multi-task hierarchical deep learning model for discourse parsing. Our model, a bidirectional Long Short-Term Memory (bi-LSTM) model, learns joint text segment representations for predicting RST-DT discourse trees and learns from several auxiliary tasks. We encode RST-DT trees as sequences of bracket and label n-grams, and exploit multiple views of the data (such as RST-DT structures as dependencies) as well as multi-task learning through auxiliary tasks (such as modality information from TimeBank, or discourse relations as annotated in the PDTB). Our multi-view learning is different from the standard notion of multi-view learning. Jin et al. (2013), for example, combine multi-view and multi-task learning, but here, multiple views refer to multiple, independent feature sets describing the datapoints. We are, to the best of our knowledge, the first to use multiple views *on the output structures* to effectively regularize learning.

Contributions We present a hierarchical multi-task bi-LSTM architecture for multi-task learning, enabling better learning of discourse parsers with other views of the data and related tasks. Our approach achieves competitive performance compared to previous state-of-the-art models by making use of auxiliary tasks. We make the code and preprocessing scripts available for download at `http://bitbucket.org/chloebt/discourse`.

2 Baseline RST parser

Discourse parsing is a prediction problem where the input is a document, i.e., a sequence of elementary discourse units (EDUs) consisting of text fragments. The output of the task is a binary tree[2] with EDUs at the leaf nodes. The non-terminal nodes are labeled with two sets of information: (a) discourse relations and (b) an indication of whether the daughters are nucleus or satellite. A nucleus is being considered as the most important part of the text whereas a satellite presents secondary information. A discourse relation may involve a nucleus and a satellite (mononuclear relation) or two nuclei (multinuclear relation).

2.1 From sequences to trees

Our approach is to learn sequential models with transfer from models from related tasks, but the output structures are trees. For this purpose, we encode trees as sequences in a very simple way that preserves all the information from the original trees: Every EDU is labeled with its local surrounding discourse structure. More precisely, the first EDU is labeled by the entire path of the root of the tree to itself. Then, the following EDUs are labeled as beginning a new relation (using the opening bracket and the relation name) or ending one or more relations (using the relation name and closing brackets). For example, the EDU 1 in the tree in Figure 1 will be labeled with: "NS-TEXTUALORGANIZATION (NS-SAMEUNIT (NN-LIST".[3] Then, the EDU 2 ends a LIST relation, and the EDU 3 begins an ELABORATION relation. See Figure 1 for a complete conversion.

[2] As in all the previous studies on the RST-DT, we binarize the trees using right-branching.

[3] 'N' means nucleus and 'S' satellite, a relation is thus labeled 'NS' if its first argument is the nucleus of the relation and its second argument, the satellite.

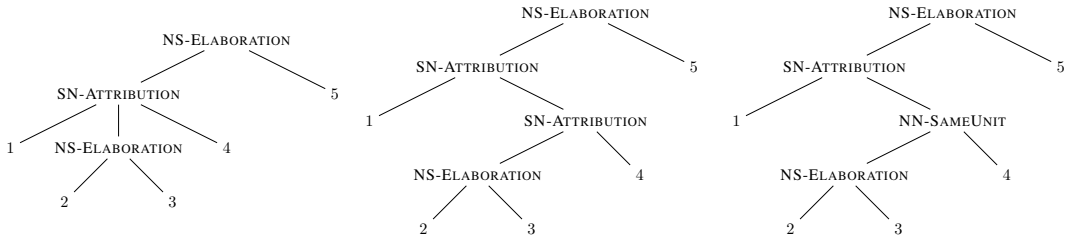

Figure 2: RST predicted, corrected and gold trees for document 1129 from the RST-DT.

Our output will be labeled trees, but below, in our multi-task learning models, we will consider unlabeled parsing and labeled parsing with only nuclearity or relations as auxiliary tasks. Note, however, that in a sequence prediction model we have no guarantee that our output structures form well-formed discourse trees. Therefore we use the following heuristics to guarantee well-formed output structures:

Heuristics The first three heuristics are enough to guarantee well-formed trees in practice: 1) If the first predicted label only contains closing parenthesis, we replace them by opening ones. 2) We remove any right hand side bracket that ends the tree too early, i.e., leads to a well-formed tree only covering a left subsequence of the sequence of EDUs. 3) We add right hand side brackets at the end if there are unclosed brackets after processing the sequence of labels.

However, we not only need to produce well-formed trees, we need to produce well-formed binary trees. Hence, we add the following two heuristics: 4) We first transform them to Chomsky Normal Form.[4] 5) We then remove unary nodes as follows:

- If the unary node is the root, an internal node whose child is a relation node, or a pre-terminal node (its child is a leaf and an EDU node), we replace it by its child.
- If the unary node is an internal node and its child an EDU node (but not a leaf node), then the EDU node becomes its left daughter and the daughter of the EDU node becomes its right daughter.

For example, the document 1129 in the RST-DT is predicted by our baseline model as the sequence in (2a), corrected first using the steps from 1) to 3). Here, we only need to remove a closing parenthesis after EDU 4. We obtain the sequence (2b) corresponding to the first tree in Figure 2. This tree only needs to be binarized, we thus end with the second tree in Figure 2 that can then be compared to the gold tree (third tree in Figure 2).

(2) a. (NS-ELABORATION (SN-ATTRIBUTION (1) (NS-ELABORATION (2)(3)) (4))) (5))

b. (NS-ELABORATION (SN-ATTRIBUTION (1) (NS-ELABORATION (2)(3)) (4)) (5))

3 Auxiliary tasks

We consider two types of auxiliary tasks: first, tasks derived from the RST-DT (multi-view), that is dependency encoding of the trees and additional auxiliary tasks derived from the main one; second, we consider tasks derived from additional data, namely, the Penn Discourse Treebank (Prasad et al., 2008), Timebank (Pustejovsky et al., 2003; Pustejovsky et al., 2005), Factbank (Saurí and Pustejovsky, 2009), Ontonotes (Hovy et al., 2006) and the Santa Barbara corpus of spoken American English (Du Bois, 2000).

All the auxiliary tasks are, as the main one, document-level sequence prediction tasks. In Table 1 we report the number of documents and single labels for each task. We hypothesize that such auxiliary information is useful to address data sparsity for RST discourse parsing.

[4] Using the implementation available in NLTK.

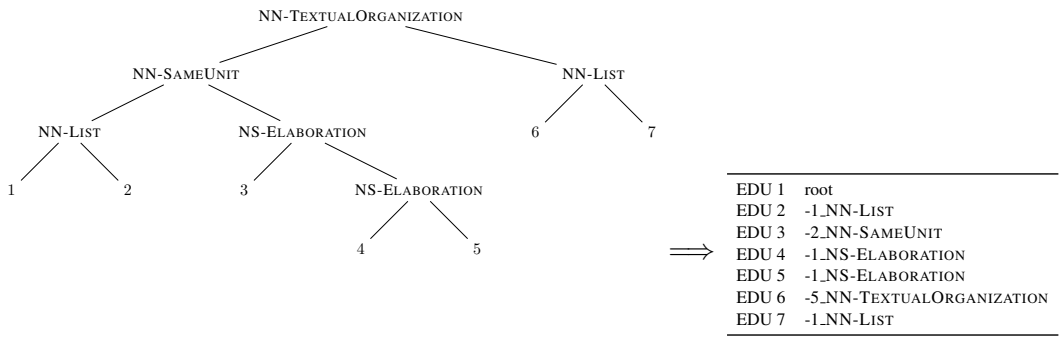

Figure 3: From RST-DT discourse trees to dependency sequence labels. The numbers indicate the position of the head of the EDU, e.g. EDU 2 and EDU 3 have the root EDU 1 as head.

3.1 Building other views of the RST-DT trees

Binary dependencies We first use a representation of the RST-DT trees as binary dependencies (RST-Dep). We roughly do the same transformation as (Muller et al., 2012; Li et al., 2014) but contrary to the latter, we choose as root the nucleus of the root node of the tree rather than the first EDU of the document. More precisely, we associate each node with its saliency set as defined in (Marcu, 1997): The nucleus is the salient EDU of a relation, and the nuclei can go up in the tree with possibly several nuclei in the saliency set of a node. Like Li et al. (2014), we replace all multi-nuclear relations (NN) by mono-nuclear ones choosing the left DU as the nucleus (NS). We thus have only one nucleus in each saliency set. Figure 3 illustrates the conversion of an RST tree into dependency sequence labels.

Nuclearity and relations We further add two alternative views that simply correspond to the main task with one label information removed, keeping either only nuclearity labels (Nuc) or discourse relations (Lab). The idea here is to break up the labeling task, since with the set of 18 discourse relations traditionally used, adding the nuclearity information leads to a large number of 41 labels.

Fine-grained labels Finally, we also use the main task with the original 78 fine-grained relations as an auxiliary task, the idea being of helping the model to learn finer distinctions between the relations.

3.2 Using additional annotations

As we already discussed, discourse relation identification is a hard task that requires access to high-level information. Previous work has shown that and indication about the *events* involved in the discourse units aids identification or constrains the set of inferable relations (Asher and Lascarides, 2003; Danlos and Rambow, 2011; Taboada and Das, 2013). Consider our examples given in the introduction. For instance, modals can indicate conditional relations as in example (1a). Similarly, in example (1b) two asynchronous successive events can be an indication for a causal relation, and besides marking temporal relations, the presence of a present participle may trigger a causal or a manner relation.

In this work we consider time and factuality auxiliary tasks in a multi-task setup. We use two resources for this, Factbank and Timebank, described next. We also include information concerning co-reference using Ontonotes annotations, and use the Santa Barbara corpus that contains conversations split into speaking turns. Finally, we incorporate some annotations from the PDTB, another corpus for discourse that however follows a different annotation scheme than the RST-DT. We describe below the different resources used, as well as how we convert the annotations into sequence labeling tasks in order to use them into the multi-task framework. See Table 1 for dataset characteristics.

Factbank and Timebank FactBank (Saurí and Pustejovsky, 2009) is a corpus of news reports that links events to their degree of factuality. The factuality corresponds to four modality values ('certain', 'probable', 'possible', 'unknown') combined to a polarity value ('positive', 'negative', 'unknown'). Factbank has been annotated on top of TimeBank and a part of AQUAINT TimeML, corpora that provide an annotation of the events according to the TimeML specifications (Pustejovsky et al., 2005). Each event is

annotated with several types of information, among which, of particular interest for discourse, are tense ('infinitive', 'pastpart', 'past', 'future', 'prespart', 'present', 'none'), aspect ('perfective', 'progressive', 'perfective_prog', 'none'), polarity ('positive', 'negative', 'none') and modality (e.g. 'have_to', 'would have to', 'should have to', 'possible', 'must', 'could', ...).

In order to build a sequence prediction task upon FactBank and TimeBank annotations, we choose to use sentences as minimal units. We then simply label each sentence in a document with its most frequent tag for each dimension (tense, aspect, modality and factuality). A more fine grained approach would be to retrieve the clause for each event.

Ontonotes OntoNotes (Hovy et al., 2006) contains, among other layers, the annotation of coreference links between entities in documents. Coreference and rhetorical relations are linked, as shown in (Ji and Eisenstein, 2014a). We only keep the English texts. We use sentences as minimal units. The first sentence of the document is annotated as root. We then label each sentence as coreferent to the immediately previous one, to one preceding sentence or as no coreferent.

Santa Barbara corpus We use the Santa Barbara corpus of spoken American English (Du Bois, 2000) to get a sequence labeling task corresponding to turns in a conversation, the idea being that rhetorical structure could share similarities with the structure of conversations. Specifically, we segment the dialogues by pauses and label the first turn-taking utterance as beginning a new turn. All other utterances are labeled as inside the turn of the current speaker. We randomly split the data into documents containing 100 turns.

Penn Discourse Treebank The PDTB (Prasad et al., 2008) is another corpus annotated at the discourse level for English. Contrary to the RST-DT, the annotation is theory neutral: the spans of text are not necessarily all connected, there is no specific structure representing a document. However, the PDTB contains much more data than the RST-DT, with more than two thousands documents annotated against around four hundreds in the RST-DT, making it interesting to try to take advantage of this relatively large amount of discourse annotated data. Since the PDTB and the RST-DT follow different annotation guidelines (i.e. different definitions of the minimal discourse units, of the relations, of the structures involved), multi-task learning is a relevant framework to try to combine them.

In PDTB, EDUs are the arguments of connectives and adjacent sentences inside paragraphs. The EDUs are mainly clauses, but the annotators are free to choose a span not covering an entire clause, or covering more than one sentence. In this paper, we use sentences as EDUs rather than the manually identified segments: if a relation links more than two sentences, we keep the relation between the last sentence of the first argument and the first sentence of the second argument; if a relation links two fragments belonging to two different sentences, we expand the text of each argument to cover the entire sentences. We ignore intra-sentential explicit relations.[5]

We use a BIO annotation scheme for relations between adjacent sentences. More precisely, a sentence is labeled with a BIO label and a discourse relation R_i among the 16 corresponding to the second level in the PDTB hierarchy of sense[6] and the pseudo relation EntRel corresponding to a link between entities. A sentence labeled with "B-R_a" is the first argument of a relation R_a whose second argument is the following sentence. If this following sentence is also the first argument of a relation R_b, it is labeled as "B-R_b", else, it is labeled as ending the current relation, thus "I-R_a". A sentence that is not linked to the previous or following sentence is labeled with "O".

4 Hierarchical bi-LSTMs and baselines

Our main technical contribution is a hierarchical bi-LSTM that composes embeddings for a sequence of words from lower-level word bi-LSTMs, and uses these to predict sequences of labels, encoding especially discourse tree structures.

[5]Preliminary experiments including non overlapping intra-sentential relations did not show improvements against only keeping inter-sentential ones. However, including intra-sentential instances requires more pre-processing and it makes necessary to decide which intra-sentential relations to keep to avoid overlaps.

[6]We only keep the first relation annotated for a pair of arguments.

Task	# Doc	# Labels
Constituent	322	1955
Nuclearity	322	284
Relation	322	1159
Dependency	322	708
Fine grained	322	2,700
Aspect	208	4
Factuality	208	7
Modality	208	10
Polarity	208	3
Tense	208	7
Coreference	2,361	4
PDTB	2,065	35
Speech	446	2

Table 1: Number of documents (# Doc) and labels (# Labels) per task (training data). The main task corresponds to the first line (Constituent).

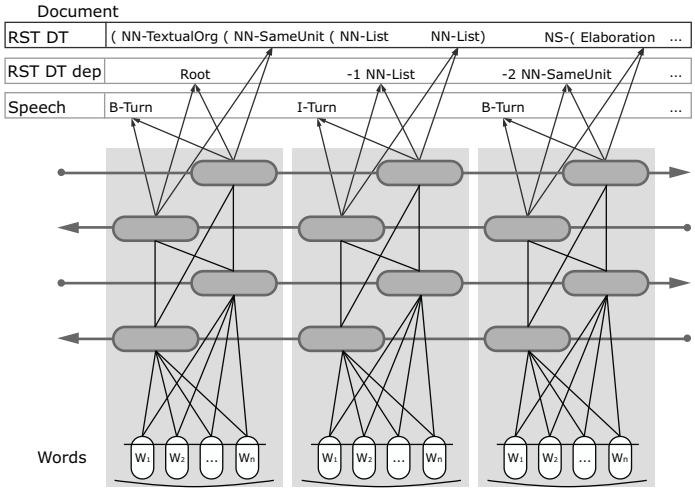

Figure 4: Multi-task learning, hierarchical bi-LSTM network architecture (with 2 layers).

In regular bi-directional recurrent neural networks (bi-RNNs), sequences are read in both regular and reversed order, enabling conditioning predictions on both left and right context. Below, in the forward pass, we run the input data through an embedding layer and compute the predictions of the forward and backward states, which are connected in one or more feed-forward layers, from which we compute the softmax predictions for the sequence based on a linear transformation. We then calculate the objective function derivative for the sequence using cross-entropy (logistic loss) and use backpropagation to calculate gradients and update the weights accordingly. LSTMs (Hochreiter and Schmidhuber, 1997) replace the cells of RNNs with LSTM cells, in which multiplicative gate units learn to open and close access to the error signal.

The overall architecture is shown in Figure 4: each input sequence in the document (i.e. a discourse unit, a speaking turn, a sentence, depending on the task) goes through the hierarchical bi-LSTM that outputs a sequence of labels for the entire document. In particular, an input sequence is represented as a sequence of word embeddings. This sequence goes first through the bi-directional LSTM at the lower level, and the final states (forward, backward) of the bi-LSTMs is taken as input representation for the document-level bi-LSTM at the upper level, which consists of two stacked layers.

For multi-task learning, each task is associated with a specific output layer, whereas the inner layers – the stacked LSTMs – are shared across the tasks. At training time, we randomly sample data points from target or auxiliary tasks and do forward predictions. In the backward pass, we modify the weights of the shared layers and the task-specific outer layer. Except for the outer layer, the target task model is thus regularized by the induction of auxiliary models.

Bi-LSTMs have already been used for syntactic chunking (Huang et al., 2015) and semantic role labeling (Zhou and Xu, 2015), as well as other tasks. Our model differs from most of these models in being a hierarchical model, composing word embeddings into sentence embeddings that are the inputs of a bigger bi-LSTM model. This means our model can also be initialized by pre-trained word embeddings. We implemented our recurrent network in CNN/pycnn,[7] fixing the random seed. We use standard SGD for learning our model parameters.

5 Experiments

Data The RST-DT contains 385 Wall Street Journal articles from the Penn Treebank (Marcus et al., 1993), with 347 documents for training and 38 for testing in the split used in previous studies. We

[7] https://github.com/yoavg/cnn/

follow previous works in using gold standard segmentation (Joty et al., 2012; Ji and Eisenstein, 2014b). Discourse segmentation on the RST-DT can be performed with performance above 95% in accuracy (Xuan Bach et al., 2012). The RST-DT contains newswire articles from the Wall Street Journal.

Baseline As baseline, we train a standard bi-LSTMs on the RST-DT corpus without any auxiliary task information.

Systems As our system, we use hierarchical bi-LSTMs with task supervision from other related tasks. We experiment with using pre-trained embeddings in both baselines and systems.

Competitive systems We compare our approach with the state-of-the-art text-level discourse parser DPLP (Ji and Eisenstein, 2014b). In our comparison, we reproduced the best results reported, including both proposed approaches for DPLP – DPLP concat (*concatenation form* for the projection matrix) and DPLP general (*general form*).

Parameter tuning We used a development set of 25 documents randomly chosen among the training set. We optimized the number of passes p over the data ($p \in [10, 60]$), the value of the Gaussian noise ($\sigma \in \{0.0, 0.2\}$), the number of hidden dimensions ($d \in \{200, 400\}$), the number of stacked layers ($h \in \{1, 2, 3, 4, 5\}$), and the auxiliary tasks to be included and combined. In the end, we report results using 2 feed-forward layers with 128 dimensions, a Gaussian noise with sigma of 0.2, 200 hidden dimensions, 20 passes over the data, 2 layers and Polyglot embeddings (Al-Rfou et al., 2013)[8].

Metrics Following (Marcu, 2000b) and most subsequent work, output trees are evaluated against gold trees in terms of how similar they bracket the EDUs (Span), how often they agree about nuclei when predicting a true bracket (Nuclearity), and in terms of the relation label, i.e., the overlap between the shared brackets between predicted and gold trees (Relation).[9] These scores are analogous to labeled and unlabeled syntactic parser evaluation metrics. The exact definitions of the three metrics are:

- Span: This metric is the unlabeled F_1 over gold and predicted trees, and identical to the PARSEVAL metric in syntactic parsing. This metric reflects a correct bracketing and ignores nuclearity and relation labels.
- Nuclearity: This metric is the labeled F_1 over gold and predicted discourse trees, disregarding the discourse relations.
- Relation: This metric is the labeled F_1 over gold and predicted discourse trees, disregarding the nuclearity information.

6 Results

Our results are summarized in Table 2. We note that the bi-LSTM baseline that only receives task supervision from RST-DT discourse trees achieves scores comparable to the state-of-the-art for the unlabeled structure (Span), but lower scores for the other metrics.

More importantly, multi-task learning, i.e., combining different representations of the data, leads to substantial improvements over our baseline for 8 out of the 11 tasks tested. We found that it is much more beneficial to have multiple views, thus, interestingly using different views on the data, with all the tasks derived from the main one leading to improvements (RSTFin, RSTDep, Nuc+Lab). Especially, the model takes advantage of using the data from the main task but with fine grained relations, with 82.88% in unlabelled F_1 (Span), 67.46% in labelled F_1 considering nuclearity (Nuclearity), and 53.25% in labelled F_1 considering relations (Relation). This auxiliary view helps the model to discriminate between the relations.

Most of the tasks derived from additional annotations also lead to improvements. Especially, we found that the speech data (Speech) leads to good results: this confirms our assumption that the turns

Table 2: Parsing results of different models on the RST-DT test data. Prior work results are reprinted (DPLP) (Ji and Eisenstein, 2014b). The auxiliary tasks are: RST-DT sequences from trees but keeping only the relations (Lab) or the nuclearity information (Nuc), RST-DT dependency parsing (RSTDep), sequence labels from Factbank using modality information (Mod), and inter-sentential relation from the PDTB (PDTB).

of speech and the structures involved share some similarities with the rhetorical units and structures. Moreover, factuality (Fact), aspect (Asp), modality (Mod) and polarity (Pol) information prove to be useful for discourse parsing. On the other hand, the tasks derived from tense (Ten) and coreference (Coref) annotations do not lead to improvements. These information, crucial for the task, would probably benefit from a finer grained encoding at the sentence level. The task derived from the PDTB, taken alone, lowers slightly the results.

Finally, we experiment with task combinations. Our best system only uses the views based on nuclearity and label (Nuc+lab), the encoding of the tree as dependency (RSTDep), the modality information (Mod) and the task derived from the PDTB data. This combination leads to substantial improvements, with 83.62% in unlabelled F_1 (Span), 69.77% in labelled F_1 considering nuclearity (Nuclearity), and 55.11% in labelled F_1 considering relations (Relation). This closes 60,7% of the gap to human performance on unlabelled discourse parsing. It is slightly better than state-of-the-art in discourse parsing for Span. Feng and Hirst (2014) proposed a system with better scores for these metrics, but the comparison to their system is not entirely fair, since they add common-sense constraints that are not clearly explained and post-editing. Besides, there is no single approach that does best for all metrics.

Our results indicate that our architecture learns useful representations capturing some of the syntactic and contextual information needed for the task.

7 Related work

Some of the first text-level discourse parsers were based on hand-crafted rules and heuristics, making mainly use of the connectives as indication of the relations and using constraints to build the entire RST trees (Marcu, 2000a; Le Thanh et al., 2004).

More recent works proposed learning based approaches inspired by syntactic parsing. Hernault et al. (2010) (HILDA) proposed a greedy approach with SVM classifiers performing attachment and relation classification at each step of the tree building. Joty et al. (2012) (TSP) built a two-stage parsing system, training separate sequential models (CRF) for the intra and the inter-sentential levels. These models jointly learn the relation and the structure, and a CKY-like algorithm is used to find the optimal tree. Feng and Hirst (2014) noticed the inefficiency of TSP and proposed a greedy approach inspired by

HILDA but using CRF as local models for the inter- and intra-sententials levels, allowing to take into account sequential dependencies.

Last studies also focused on the issue of building a good representation of the data. Feng and Hirst (2012) introduced linguistic features, mostly syntactic and contextual ones. Ji and Eisenstein (2014b) (DPLP) proposed to learn jointly the representation and the task, more precisely a projection matrix that maps the bag-of-words representation of the discourse units into a new vector space. This idea is promising, but a drawback could be the limited amount of data available in the RST-DT, an issue even more crucial for other languages.

Discourse parsing has proven useful for many applications (Taboada and Mann, 2006), ranging from summarization (Daumé III and Marcu, 2009; Thione et al., 2004; Sporleder and Lapata, 2005; Louis et al., 2010), sentiment analysis (Bhatia et al., 2015) or essay scoring (Burstein et al., 2003; Higgins et al., 2004). However, the range of applications and the improvement allowed are for now limited by the low performance of the existing discourse parsers.

We are not aware of other studies trying to combine various encodings of the RST-DT trees or to leverage relevant information through multi-task learning to improve discourse parsing. To the best of our knowledge, multi-task learning has only been used for discourse relation classification (Lan et al., 2013) on the Penn Discourse Treebank to combine implicit and explicit data.

We are not the first to propose using bi-LSTMs for tree structure prediction problems. Zhou and Xu (2015), for example, use bi-LSTMs to produce semantic role labelling structures. Zhang et al. (2015) did the same for relation extraction. None of them considered multi-task learning architectures, however. Multi-task learning in deep networks was first introduced by Caruana (1993), who did multi-task learning by doing parameter sharing across several deep networks, letting them share hidden layers. The same technique was used by Collobert et al. (2011) for various NLP tasks, and for sentence compression in (Klerke et al., 2016). Hierarchical multi-task bi-LSTMs have been previously used for part-of-speech tagging (Plank et al., 2016).

8 Conclusion and future work

We presented the first experiments exploiting different views of the data and related tasks to improve text-level discourse parsing. We presented a hierarchical bi-LSTM model allowing to leverage information from various sequence prediction tasks (multi-task learning) that achieves a new state-of-the-art performance on unlabeled text-level discourse parsing, and competitive performance in predicting nuclearity and discourse relations.

For relation prediction, future work includes adding additional information at the sentence level, such as syntactic information used in most of the studies identifying discourse relation on the PDTB (Pitler et al., 2009; Lin et al., 2009; Rutherford and Xue, 2014), or better representation of the combination between the arguments (Ji and Eisenstein, 2014b).

Abstract

For the task of implicit discourse relation recognition, traditional models utilizing manual features can suffer from data sparsity problem. Neural models provide a solution with distributed representations, which could encode the latent semantic information, and are suitable for recognizing semantic relations between argument pairs. However, conventional vector representations usually adopt embeddings at the word level and cannot well handle the rare word problem without carefully considering morphological information at character level. Moreover, embeddings are assigned to individual words independently, which lacks of the crucial contextual information. This paper proposes a neural model utilizing context-aware character-enhanced embeddings to alleviate the drawbacks of the current word level representation. Our experiments show that the enhanced embeddings work well and the proposed model obtains state-of-the-art results.

1 Introduction

It is widely agreed that in a formal text, units including clauses and sentences are not isolated but instead connected logically, semantically, and syntactically. Discourse parsing is a fundamental task in natural language processing (NLP) that analyzes the latent relation structure and discovers those connections across text units. It could benefit various downstream NLP applications such as question answering (Chai and Jin, 2004; Verberne et al., 2007), machine translation (Hardmeier, 2012; Guzmán et al., 2014), sentiment analysis (Bhatia et al., 2015; Hu et al., 2016b), and automatic summarization (Maskey and Hirschberg, 2005; Murray et al., 2006).

For discourse parsing, Penn Discourse Treebank (PDTB) (Prasad et al., 2008) provides the lexically-grounded annotations of discourse relations. Each discourse relation consists of two abstract object arguments and the corresponding sense annotations, which can be roughly characterized according to whether explicit connectives could be drawn from the texts. In *Explicit* relations, explicit connectives can be found in the texts; when such indicators are not given directly, an inferred connective expression could be inserted, forming *Implicit* relations. The following two examples describes these two kinds of discourse relations: the former has an explicit connective *"so"* which reveals the *Explicit* relation, while in the latter case, an inferred *Implicit* connective *"that is"* has to be inserted to express the relation.

(1) **Arg1:** We're standing in gasoline.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 1914–1924, Osaka, Japan, December 11-17 2016.

clauses are effectively indicated by explicit connectives like *"but"* and *"so"*, implicit discourse relation recognition is much more difficult. Without effective indicators, the relations could only be inferred from indirect plain texts, which makes implicit discourse relation recognition the bottleneck of the entire discourse parsing system (Qin et al., 2016a; Li et al., 2016; Chen et al., 2015). This paper attempts to deal with this challenging task.

The challenge stems from the fact that, without connective cues, recognizing implicit relation has to rely solely on two textual arguments, and it must capture latent semantic and logical relationship between two arguments in discourse-level. First, given limited amount of annotated corpus, both the traditional indicator feature based methods and the recent embedding based neural methods (Wang et al., 2015) can suffer from insufficient data. The training is especially difficult for rare words, which appear rarely in the corpus but generally take up a large share of the dictionary, making it hard to effectively learn their representations, resulting in high perplexities for discourse relation recognition. Moreover, implicit relation recognition calls for semantic understanding, which needs to encode the word meaning in the context and the sentence-level understanding for the argument pairs. Considering the complexity of natural language, the task is quite nontrivial and requires more effective encoding of the arguments.

Conventional methods for implicit discourse relation recognition are based on manually specified indicator features, such as bag-of-words, production rules, and other linguistically-informed features (Zhou et al., 2010; Park and Cardie, 2012; Biran and McKeown, 2013; Rutherford and Xue, 2014). Recently, embedding based neural models have been proved effective to address the data sparsity problem that is not well solved in traditional methods. The key techniques include real-valued dense embeddings for feature representations and non-linear neural models for feature combinations and transformations. However, most of the neural models take words as the smallest processing units, which can suffer a lot from insufficient training on rare words. Discourse parsing, as the highest level language processing at present, covers word and sentence levels for feature representation. This work extends the current word-level representation onto more fine-grained character-level which is helpful for encoding morphology information and alleviating the rare word problem.

In summary, this paper presents a neural model with context-aware character-enhanced embeddings to address implicit discourse relation recognition task. Recently, character-aware models have been popular for English and other morphologically rich languages (Kim et al., 2016; Zhang et al., 2015b; Ling et al., 2015). The proposed model enhanced the word embeddings with character-aware representations learned from stacked convolutional and recurrent neural models. Utilizing these enhanced embeddings, the model covers information of three levels from character, word, to sentence. Through extensive experiments on standard discourse corpus, we analyze several models and show the superiority of the proposed method.

The remaining of the paper is organized as follows: Section 2 discusses related work; Section 3 describes the proposed model; Section 4 provides the details of experiments and model analysis; and Section 5 concludes the paper.

2 Related work

Implicit discourse relation recognition is the subcomponent of the end-to-end discourse parsing system, which is also used as the share-task in CoNLL 2015 and CoNLL 2016 (Xue et al., 2015; Xue et al., 2016). In the share-task, the classification task concerns other Non-Explicit types including *EntRel* and *AltLex*, in addition to the *Implicit* relations.

Early work for implicit discourse relation recognition focuses on typical machine learning solutions with sparse indicator features and linear models. Pitler et al. (2009) use several linguistically informed features, including polarity tags, Levin verb classes and length of verb phrases. Zhou et al (2010) improve the performance through predicting connective words as extra features. Park and Cardie (2012) propose a method using a locally-optimal feature set. Biran and McKeown (2013) collect word pairs from arguments of explicit examples to help the learning. Rutherford and Xue (2014) employ Brown cluster pairs to represent discourse relation and incorporate coreference patterns to identify the meaning in text. Li and Nenkova (2014) introduce a syntactic representation to reduce sparsity. Rutherford and

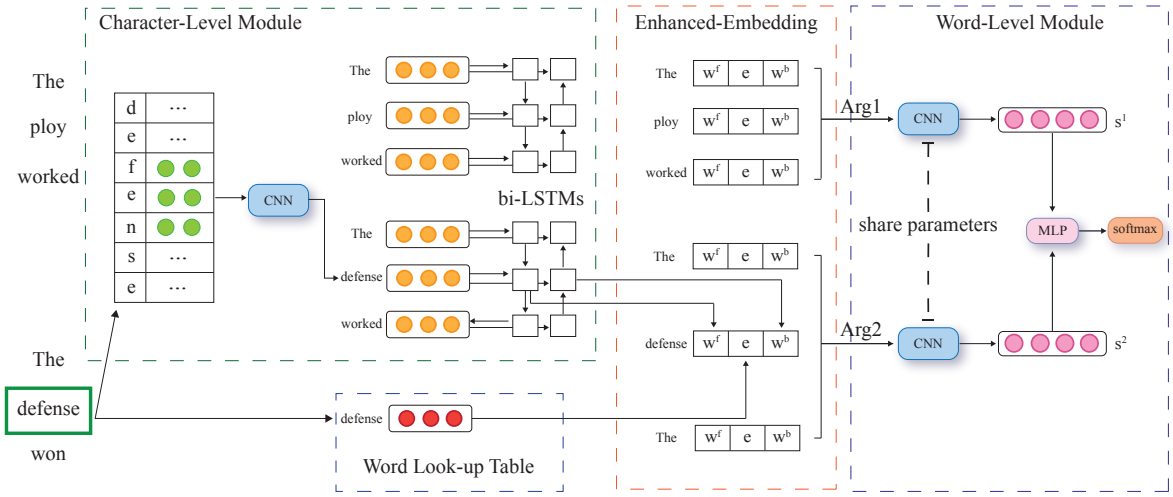

Figure 1: Architecture of the proposed model.

Xue (2015) and Ji et al. (2015) add automatically-labeled instances to expand data. Fisher and Simmons (2015) incorporate a mixture of labeled and unlabeled data to reduce the need for annotated data.

More recently, neural network models have been proved effective for NLP tasks (Wang et al., 2016; Zhang et al., 2016; Cai and Zhao, 2016; Hu et al., 2016a) and also utilized for implicit discourse relation recognition. Ji and Eisenstein (2015) adopt recursive neural network and incorporated with entity-augmented distributed semantics. Zhang et al. (2015a) propose a simplified neural network which contains only one hidden layer and use three different pooling operations (max, min, average). Chen et al. (2016) adopt a deep gated neural model to capture the semantic interactions between argument pairs. Ji et al. (2016) propose a latent variable recurrent neural network architecture for jointly modeling sequences of words. (Qin et al., 2016b) propose a stacking neural network model to solve the classification problem. In their model, convolutional neural network is utilized for sentence modeling and a collaborative gated neural network is proposed for feature transformation.

3 Model

3.1 Architecture

The architecture of our model is shown in Figure 1. The model is a hybrid neural network including a character-level module and a word-level module. The character-level module receives inputs of character-level embeddings followed by stacked CNN and bidirectional LSTMs layers. First, the convolutional and max-pooling operations perform local information encoding and feature selection, obtaining a fixed-dimensional representation of the character-based word representation sequence. Then via bidirectional LSTMs, the sequence is transformed to a new sequence which encodes the rich contextual information. This new sequence is the output of the character-level module which models context-aware character-level information, and will be utilized in later layers. In the word-level module, the character-based word representations will be concatenated to ordinary word embeddings, forming enhanced embeddings which integrate both character-level and word-level information. Later CNN will be utilized again to obtain sentence-level representations for the two arguments, followed by conventional hidden layers and a softmax layer for the final classification.

3.2 Character-Level Module

This module aims to get the most out of the character sequence and obtain the character-based word representations, utilizing an architecture of stacked CNN and LSTM. Modeling from character level could alleviate rare words problem and useful capture morphological information, like the prefixes and suffixes of words.

Character Embedding The character representation will still be in the form of embeddings. In this task, we define an alphabet of characters which contains uppercase and lowercase letter as well as numbers and punctuation. The input word will be decomposed into a character sequence. Through a character look-up table, a word will be projected to a sequence of character vectors: $[\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_n]$, where $\mathbf{c}_i \in \mathbb{R}^{d_c}$ is the vector for the i-th character in the word with dimension d_c and n is word length. For the convenience of notation, the character vectors for a word can be regarded as a character matrix $\mathbf{C}$:

$$\mathbf{C} = [\mathbf{c}_1; \mathbf{c}_2; \ldots; \mathbf{c}_n]$$

Convolutional Neural Network A convolutional operation followed by a max-pooling operation will be applied to the character matrix $\mathbf{C}$ of each word. The convolutional layer is used to extract and combine local features from adjacent characters and the following max-pooling layer forms the representations for the current word. For the convolutional operation, k groups of filter matrices [$\mathbf{F}_1$, $\mathbf{F}_2$, ..., $\mathbf{F}_k$] with variable sizes $[l_1, l_2, \ldots, l_k]$ and biases [$\mathbf{b}_1$, $\mathbf{b}_2$, ..., $\mathbf{b}_k$] are utilized. Each of them transforms the character matrix $\mathbf{C}$ to another sequence. The transformed sequences $\mathbf{C}'_j (j \in [1, k])$ will be obtained as follows:

$$\mathbf{C}'_j = [\ldots; \tanh(\mathbf{F}_j \cdot \mathbf{C}_{[i:i+l_j-1]} + \mathbf{b}_j); \ldots]$$

Here, i indexes the convolutional window. Next, a one-max-pooling operation is adopted and the representation $\mathbf{w}$ for a word is obtained through concatenating all the mappings after pooling as follows:

$$\mathbf{w}'_j = \mathbf{max}(\mathbf{C}'_j)$$
$$\mathbf{w} = [\mathbf{w}'_1 \oplus \mathbf{w}'_2 \oplus \ldots \mathbf{w}'_k]$$

Bidirectional LSTM The character-based word representation obtained through CNN can be directly utilized in the word-level module, however, each word vector from the CNN is individually obtained and lacks of the encoding of contextual information. In a sentence, word can never be understood independently without context. Nearby words can offer important cues to the current word as suggested by N-gram language model and context-aware sentence modeling. Motivated by this, we propose to utilize bidirectional LSTMs to encode the character-based word vectors.

Given the character-based word representations $[\mathbf{w}_1, \mathbf{w}_2, \ldots, \mathbf{w}_n]$ as the input sequence, an LSTM computes the state sequence $[\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n]$ by applying the following formulation for each time step:

$$\mathbf{i}_t = \sigma(\mathbf{W}^i_w \mathbf{w}_t + \mathbf{W}^i_h \mathbf{h}_{t-1} + \mathbf{W}^i_c \mathbf{w}_{t-1} + \mathbf{b}_i)$$
$$\mathbf{f}_t = \sigma(\mathbf{W}^f_w \mathbf{w}_t + \mathbf{W}^f_h \mathbf{h}_{t-1} + \mathbf{W}^f_c \mathbf{w}_{t-1} + \mathbf{b}_f)$$
$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot tanh(\mathbf{W}^c_w \mathbf{w}_t + \mathbf{W}^c_h \mathbf{h}_{t-1} + \mathbf{b}_c)$$
$$\mathbf{o}_t = \sigma(\mathbf{W}^o_w \mathbf{w}_t + \mathbf{W}^o_h \mathbf{h}_{t-1} + \mathbf{b}_o)$$
$$\mathbf{h}_t = \tanh(\mathbf{c}_t) \odot \mathbf{o}_t$$

Here the σ denotes the sigmoid function and the $\odot$ denotes element-wise multiplication. $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{c}_t$, $\mathbf{o}_t$ and $\mathbf{h}_t$ stand for input gate, forget gate, memory cells, output gate and the current state, respectively. Finally, the state sequence $[\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n]$ will be utilized as the context-aware word representations. Recent works (Graves et al., 2013; Graves et al., 2005) show that backward LSTM can also effectively encode the context by modeling the word sequence backward, combined with the ordinary forward LSTM, the so-called Bidirectional LSTM could effectively capture the information from both past and future words, and we will utilize it in this module. We will denote the output state sequence (originally noted as $\mathbf{h}$) of forward LSTM as $[\mathbf{w}^f_1, \mathbf{w}^f_2, \ldots, \mathbf{w}^f_n]$ and the one of the backward LSTM as $[\mathbf{w}^b_1, \mathbf{w}^b_2, \ldots, \mathbf{w}^b_n]$.

3.3 Word-Level Module

In recent neural models, words are represented as real-valued dense vectors. With the prevalence of deep learning methods in NLP, continuous space word vectors have been found an effective means for word

representations. Unlike the traditional model in which words usually represent as one-hot vectors and are independent with each other, vector space models reveal the relationship and capture the intuition among words which different or similar to others along a variety of dimensions (Mikolov et al., 2013). However, embeddings considering only at word level is usually not good for rare words as discussed above and we introduce character-level embedding to enhance the current word embedding.

Enhanced Word Embedding For obtaining word representations, we enhance ordinary word vectors with the character-based vectors obtained from the character-level module by concatenating all the representations on words. Thus a sequence of enhanced word embeddings could be obtained, which could cover contextual information from character-level to word-level, and the character-based embedding could alleviate rare word problems in some way. Formally speaking, an argument could be represented as a sequence as follows:

$$\mathbf{M} = [\mathbf{w}_1^f \oplus \mathbf{e}_1 \oplus \mathbf{w}_1^b; \mathbf{w}_2^f \oplus \mathbf{e}_2 \oplus \mathbf{w}_2^b; \ldots; \mathbf{w}_n^f \oplus \mathbf{e}_n \oplus \mathbf{w}_n^b]$$

where $\oplus$ is the concatenation operator. $\mathbf{w}^f, \mathbf{e}, \mathbf{w}^b$ stand for the state of forward LSTM, word embedding and the state of backward LSTM, respectively.

Convolutional Neural Network In the word-level module, CNN is utilized again to extract local context features. Like the convolutional layer in character-level module, several groups of filter matrices with various filter window sizes are utilized to extract features from different ranges. This procedure is quite similar to the one in character-level module and we will leave out the formulas. Unlike the character-level CNN, here the convolutional operation is applied on the arguments and the following max-pooling layer will produce the sentence vectors. Via parameter sharing, this feature extraction procedure become same for both arguments. We will note the sentence vectors for the two arguments as $\mathbf{s}^1$ and $\mathbf{s}^2$.

Softmax Getting the sentence-level representations, we can concatenate the sentence vectors and feed them to the conventional softmax layer for the final classification.

$$\mathbf{v} = \mathbf{s}^1 \oplus \mathbf{s}^2$$

$$\Pr(y_i) = \frac{\exp \mathbf{w}^i \times \mathbf{v}}{\sum_j^l \exp \mathbf{w}^j \times \mathbf{v}}$$

Here, $\Pr(y_i)$ means the probability of assigning the instance to label i, $\mathbf{w}$ indicates the parameters in the final softmax layer. Additionally, multilayer perceptron (MLP) hidden layers could be added between sentence vectors and the final softmax layer, and we will leave out the descriptions for brevity.

3.4 Training

For training, the object is the cross-entropy error with *L2* regularization:

$$E(\hat{y}, y) = -\sum_j^l y_j \times \log(\Pr(\hat{y}_j))$$

$$J(\theta) = \frac{1}{m} \sum_k^m E(\hat{y}^{(k)}, y^{(k)}) + \frac{\lambda}{2} \|\theta\|^2$$

where $y^{(k)}$ is the gold labels and $\hat{y}^{(k)}$ is the predicted ones. For the optimization process, we apply the diagonal variant of AdaGrad (Duchi et al., 2011) with mini-batches.

4 Experiment

PDTB 2.0[1], which is one of the largest manually annotated corpus of discourse relation, is utilized for the experiments. Annotated on Wall Street Journal corpus with one million words, the data contain

[1] http://www.seas.upenn.edu/ pdtb/

16,224 implicit relations. It provides three hierarchies of relations: Level 1 *Class*, Level 2 *Type*, and Level 3 *Subtypes*. The first level consists of four major relation *Class*: COMPARISON, CONTINGENCY, EXPANSION and TEMPORAL. There are 16 Level 2 relation types of implicit relations. The third level of *Subtypes* is types that are only available for specific types.

For the evaluation of implicit relation classification, there are two settings in previous works: one is multi-class classification for second-level discourse relations (Lin et al., 2009); the other is the "One-Versus-Others" setting which employs binary classification only for Level 1 $Class$, which is first used by Pitler et at. (2009). Note that the results for the latter setting can be also derived from the specific statistics over the results of the former setting. In this paper, we will focus on the more practical multi-class classification, which is a necessary component for building a complete discourse parser such as that for the shared tasks of CoNLL-2015 and 2016 (Xue et al., 2015; Xue et al., 2016). For the model analysis, we perform the experiments with the multi-classification setting. In order to compare with previous results, we will also evaluate our system on the binary relation classification task.

4.1 Multi-class classification

Following (Lin et al., 2009), we adopt the standard PDTB splittings as follows: Sections 2-21 as training set, Section 22 as development set and Section 23 as test set. We will denote this dataset as the PDTB Standard setting *PDTB-STD*. In order to be in consistence with previous setting, we also remove 5 *Types* which are too few in the corpus: CONDITION, PRAGMATIC CONCESSION, PRAGMATIC CONCESSION, PRAGMATIC CONTRAST and EXCEPTION. Thus, we use the remaining 11 Level 2 *Types* in our experiments. In addition, for nearly 2% of the implicit relations have more than one type during annotating in PDTB, we consider these relations as two relation types with the same argument pairs when training. During testing, the predictions which match one of the gold types will be considered as correct. To compare with the state-of-the-art system (Ji and Eisenstein, 2015), which uses a slightly different setting: Sections 2-20 as training set, 0-1 as development set, and 21-22 as testing set. We also run experiments on this setting (noted as the PDTB Alternative setting *PDTB-ALT*) and show the comparisons.

4.1.1 Hyper-Parameters

For the hyper-parameters of the model and training process, we fix the lengths of both arguments (number of words) to be 80 and the lengths of the words (number of characters) to be 20, and apply truncating or zero-padding when necessary. The dimensions for character embeddings and word embeddings are 30 and 300 respectively. The word embeddings are initialized with pre-trained word vectors using *word2vec*[2] (Mikolov et al., 2013) and other parameters are randomly initialized by sampling from uniform distribution in [-0.5, 0.5] including character embeddings. The learning rate is set as 0.002.

In the character-level module, the CNN part uses three groups of 128 filters, with filter window sizes of (2, 3, 4); while the output dimensions of bidirectional LSTMs is set to 50. In the word-level module, the CNN part also contains three groups of filters. For we need more parameters to accurately model the sentence level information, each group has 1024 filters and their filter window sizes are (2, 4, 8). We also add another hidden layer above the concatenated sentence vectors and its dimension is set to 100.

4.1.2 Models

In this sub-section, we will describe the models in the comparisons of our main experiments, which show the effectiveness of the proposed neural model with enhanced embeddings. Our experiments mainly concerns four group of models: Baseline Models, Word-level Only Neural Models, Character-level Only Neural Models and Combined Models. The proposed model, namely **Char+Word-Enhanced**, falls into the last group and many other models can be considered as partial models of it.

Baseline Models These include simplified models or previous traditional model.

- **Majority Baseline** The most commom *Type* class is CAUSE, which accounts for 26.1% of the implicit relations in the PDTB test set.

Char+Word-Enhanced	**45.04**

Table 2: Comparisons on test set of *PDTB-ALT* for multi-class classification.

- **Word Representation** This model just utilizes sum of word vector as sentence vectors, for showing how the model with only word vector embeddings can work.
- **Lin et al. (2009)** Traditional linear model with manually specified features, including production rules, dependency rules, word pairs and context features.

Word-level Models These models only utilize conventional word vectors through a word-level embedding table looking-up process and does not use the character-level module.

- **Word-level CNN** This model adopts CNN with conventional word embeddings, which does not utilize the character-level module.
- **Word-level BiLSTMs** This model replaces CNN to Bidirectional LSTMs, also with conventional word embeddings. The sentence vectors will be the last state vector of the LSTMs.

Character-level Models These models only make use of the word representations learned from the Character-level module. For the word-level module (from word-level representations to sentence-level ones), CNN will be used.

- **Char-level CNN** This model utilizes only the embeddings from character-level module (without concatenating the word-level embeddings), and in the character-level part BiLSTMs are not utilized and the word representations are directly from CNN.
- **Char-level CNN+BiLSTMs** This model integrates BiLSTMs in the character-level module, which could encode the context information in the character-level embeddings.

Combined Models These combine the Char-level and Word-level modules (**Char-level CNN+BiLSTMs** and **Word-level CNN**) through concatenation on different levels.

- **Char+Word-Concat** This model combines the two modules at the sentence representation level, by concatenating the sentence vectors.
- **Char+Word-Enhanced** This is the proposed model, which combines the modules at the word embedding level, forming enhanced embeddings.

4.1.3 Model Analysis

The analysis of the models will be based on the results of Table 1 and we will discuss them in groups. First, the traditional linear model performs well, but it needs manually specified features. Simply adding word vectors is not a very good idea, because it ignores the crucial information of word order. In the second group, we could see that CNN performs well, for it provides the capacity of modeling local word sequences (via convolutional operations) and capturing sentence-level features (via max-pooling operations). Somewhat surprisingly, the model of BiLSTMs seems not good for this sentence-pair modeling task, the reason might be that using the last states of LSTMs ignores too much information of the

Competitive System	COMP.	CONT.	EXP.+	TEMP.	AVG.
Pitler et al. (2009)	21.96	47.13	76.42	16.76	40.57
Zhou et al. (2010)	31.79	47.16	70.11	20.30	40.32

Table 3: Comparisons of F_1 scores (%) for binary classification. (symbol **+** means EXP. with *Entrel*)

previous words of the sequence. Thus, for the rest models, CNN will be selected to compute sentence vectors. In the third group, we will explore how the character-based embeddings will perform without conventional word-level embeddings. The character-based embeddings learned from **Char-CNN** model are individually calculated and lacks of the information of surrounding words, thus stacking BiLSTMs improves the accuracies because the recurrent layer could effectively capture rich context characteristics. Not surprisingly, utilizing only character-level embedding performs not that good, even the simple adding-word-vectors method gives better accuracies. This suggests that conventional word-level embeddings should not be abandoned because a word is only meaningful at the word-level. However, the character forming of a word could be also helpful, especially when we are dealing with rare words. Thus in the fourth group, we will explore the combination of character-level and word-level representations. The **Char+Word-Concat** model that concatenates the sentence vectors (from different CNNs) indeed improves the performance. The proposed model, **Char+Word-Enhanced**, combines the two modules at the word representation level, this is different from the **Concat** model because the influence of character-level representations are directly integrated into the final word representations before fed to CNN. The proposed model outperforms all the others, which shows the character-based representations do make extra helps.

4.2 Binary Classification

In order to compare with some previous work, we run our model on the binary implicit relation classification task. The dataset is also from PDTB and conventional splitting for binary classification is followed: Section 2-20 for training, 0-1 for development and Section 21-22 for testing. For the training set, since the number of negative examples is much greater than the number of positive examples, extra negative examples are extracted randomly to provide balanced training set. All examples in sections 21 and 22 are included for testing. Following previous work, the evaluation metric for binary classification will be Macro-F1 score. The hyper-parameters of our model are roughly the same as in multi-class classification expect that learning rate is set to 0.0002 for the binary classification task.

4.3 Results

As shown in Table 1, 2 and 3, the proposed model **Char+Word-Enhanced** outperforms most of the previous models, both for multi-class and binary classification task. This shows the effectiveness of context-aware character-enhanced embeddings and that these enhanced embeddings corporate well with sentence-level neural models.

5 Conclusion

In this paper, we propose a character-level neural module to obtain context-aware character-based embeddings for implicit discourse relation recognition. Utilizing the combined character-enhanced embeddings, our model performs well, which shows that the character-level information captured by the

proposed model may effectively improve this semantic understanding task.

Abstract

This paper introduces a novel method for measuring non-cooperation in dialogue. The key idea is that linguistic non-cooperation can be measured in terms of the extent to which dialogue participants deviate from conventions regarding the proper introduction and discharging of conversational obligations (e.g., the obligation to respond to a question). Previous work on non-cooperation has focused mainly on non-linguistic task-related non-cooperation or modelled non-cooperation in terms of special rules describing non-cooperative behaviours. In contrast, we start from rules for normal/correct dialogue behaviour – i.e., a dialogue game – which in principle can be derived from a corpus of cooperative dialogues, and provide a quantitative measure for the degree to which participants comply with these rules. We evaluated the model on a corpus of political interviews, with encouraging results. The model predicts accurately the degree of cooperation for one of the two dialogue game roles (interviewer) and also the relative cooperation for both roles (i.e., which interlocutor in the conversation was most cooperative). Being able to measure cooperation has applications in many areas from the analysis – manual, semi and fully automatic – of natural language interactions to human-like virtual personal assistants, tutoring agents, sophisticated dialogue systems, and role-playing virtual humans.

1 Introduction

This paper describes a general method for measuring the degree of cooperation of dialogue participants' behaviour. Central to the method is the idea, following Traum (1994) and Matheson et al. (2000), that in dialogue obligations are continually created and resolved. Our contribution is a proposal for measuring non-cooperation in terms of the degree to which dialogue participants deviate from the obligations that they acquire during the course of the dialogue. We focus on an application of the proposed method to political interviews in order to evaluate its validity. We developed this method to extend the state-of-the-art of computational dialogue modelling to cases in which the conversational flow is compromised to some extent but without reaching complete breakdown. Shedding light on the nature of linguistic non-cooperation in dialogue promises to yield a better understanding of conversation. The method can be used for the analysis – manual, semi and fully automatic – of natural language interactions and for applications such as human-like virtual personal assistants, tutoring agents, sophisticated dialogue systems, and role-playing virtual humans.

In the remainder of this paper, we proceed as follows. In Section 2, we look at recent research in computational modelling of non-cooperative dialogue. We highlight the similarities and differences with the approach proposed in this paper. The next two sections then describe the two principal steps of our method. In Section 3, we introduce the first step. This step consists of segmentation of dialogue transcripts and coding of the speakers' contributions. We describe the segmentation and annotation schemes, and report on their reliability. In this step, the individual annotations are neutral with regards to cooperation. Section 4 introduces a fully automated method for combining the annotations from the first step with a model of the dialogue game (specific to the dialogue genre in question). The result of

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1925–1936, Osaka, Japan, December 11-17 2016.

this automatic analysis is a dialogue marked up with cooperative and non-cooperative features. These features lead to a score for each speaker that indicates the extent to which they behaved according to the obligations associated with their role in the dialogue, which we interpret as the degree of cooperation of the participant with respect to the conversational setting. The dialogue game model, in this case for political interviews, is extracted from descriptive accounts in the linguistics literature of the dialogue genre. Next, in Section 5, the validity of the method is assessed by analysing the correlation between the resulting scores and human judgement on the same set of political interview transcripts. Finally, Section 6 presents our conclusions and some suggestions for further work.

2 Related Work on Computation and Annotation of Non-cooperation in Dialogue

Possibly the earliest computational model of non-cooperation is presented by Jameson (1989). It includes an extensive study for modelling bias, individual goals, projected image and belief ascription in conversation. Jameson implemented some of these ideas, in the context of used car sales, by means of a dialogue system that can assume different roles (Jameson et al., 1994). These contributions show that user-model approaches to dialogue modelling are flexible enough to account for situations of an arbitrary degree of intricacy. However, as noted, e.g., by Taylor et al. (1996) the level of detail required in the characterisation of the user and the complexity of mechanism for reasoning about user models can lead to problems like infinite regress in nested beliefs (speaker's beliefs about the hearer's beliefs about the speaker's beliefs...).

More recently, Traum (2008) brought attention to the need for computational accounts of dialogue situations in which a broader notion of cooperation is not assumed. Traum's work on non-cooperative dialogue is mainly aimed at creating virtual humans – or embodied conversational agents (Cassell, 2001) – with abilities to engage in adversarial dialogue. Traum et al. (2005; 2008) present a model of conversation strategies for negotiation, implemented as a virtual human that can be used for teaching negotiation skills. A recent version of the system (Plüss et al., 2011; Traum, 2012) supports cooperative, neutral and deceptive behaviour, and also is able to reason in terms of secrecy in order to avoid volunteering certain pieces of information. However, their model the adversarial scenarios by means of a set of rules that the interlocutors follow. Our approach contrasts with this in that it models non-cooperation in terms of systematic deviation from the rules of the dialogue game.

Along lines similar to Traum et al., the work of Kreutel and Matheson (2001; 2003) accounts for non-cooperative behaviour at the level of the task, what the authors call *strategic acting*. At the conversational level, however, their models – as well as those of Traum and Allen (1994) and Matheson et al. (2000) – always discharge a speaker's obligations before considering their private goals. This also holds for the recent work on learning non-cooperative dialogue behaviours using statistical methods (Efstathiou and Lemon, 2014): conversational or linguistic cooperation is assumed (i.e., dialogue participants honour their discourse obligations), whereas non-linguistically, participants fail to cooperate. The method we describe in this paper is complementary to this work in that we aim to characterise, analyse and measure *conversational/linguistic* non-cooperation.

Previous research on dialogue annotation for non-cooperation is scarce. The only instances of complete research we know of are those of Davies (1997; 2006) and Cavicchio (2010) – see also Cavicchio and Poesio (2012).[1] Both are in the context of task-oriented dialogues, and more specifically the HCRC Map Task domain (Anderson et al., 1991; Carletta et al., 1997).

Davies (1994; 1997; 2006) proposes a direct approach to annotating cooperation in order to analyse its relation with effort and task success. Her annotation approach shares some characteristics with ours, but cooperation is judged directly by the annotators, as "positive codings (i.e., finding an instance of the behaviour in an utterance), and negative codings (i.e., finding an instance where we believe a particular behaviour should have been used)" (Davies, 2006, p. 43). In her doctoral thesis, Cavicchio (2010) applies Davies's coding scheme to a multi-modal corpus of the Map Task domain and studies the relation

[1] Additionally, two short papers by Asher et al. (2012) and Afantenos et al. (2012) report on ongoing data collection and preliminary annotation of negotiation dialogues surrounding a board game, following a theory of strategic conversation proposed by Asher and Lascarides (2013).

between (non-)cooperation and emotions. Her focus is not however on how to assess cooperation in dialogue, but on to what extent psychophysiological indicators of emotion (e.g., heartrate and facial expressions) correlate with cooperative behaviour.

The key difference between Davies's and our approach is that the former already includes the normative notion of dialogue game we use later in the assessment of cooperation. This reduces the flexibility of the coding scheme, as the assessment of cooperation is part of the annotation process. By detaching these steps, the method proposed here allows for assessment of cooperation of the same annotated data using different dialogue games, e.g., to explore how the same behaviour would be perceived by audiences with different cultural backgrounds.

3 Corpus Annotation

The degree of cooperation of dialogue participants is determined in two steps. The input for the process is a dialogue transcript. In the first step, this transcript is manually segmented and annotated. In this manual step, the annotators are *not* required to make any judgements about the cooperation of the interlocutors. The actual determination of the extent of cooperation takes places in the second fully automated step.

In this section, we describe the first step by briefly introducing the annotation schemes and providing our results on their reliability. The complete annotation guidelines, tool, and fully annotated corpus are available online.[2]

3.1 The Corpus

In order to test our approach, we applied it to a corpus of six political interviews with a total of 88 turns (3556 words). The number of turns and words in each fragment is shown in Table 1.

Table 1: Political interview fragments in the corpus annotation study

Interview	Turns	Words
1. Brodie and Blair	16	734
2. Green and Miliband	9	526
3. O'Reilly and Hartman	19	360
4. Paxman and Osborne	16	272
5. Pym and Osborne	10	595
6. Shaw and Thatcher	18	1069
Total	88	3556

The fragments were selected from a larger set of 15 interviews collected from publicly available sources (BBC News, CNN, Youtube, etc.). We selected this particular set with the aim of including behaviours at different levels of cooperation for both interviewer and interviewee role. At the same time, we avoided extreme cases in which the exchange broke down or turned into a dialogue of an entirely different type (e.g., confrontation or debate). A second criterion was to ensure coverage of the annotation scheme, with special attention to the dialogue act taxonomy.

3.2 Segmentation and Dialogue Act Annotation

We followed the recommendations put forward in the ISO standard proposal by Bunt et al. (2009; 2010; 2012), simplifying the terminology and some aspects of the scheme when needed. For this we drew on work by Carletta et al. (1997), Allen and Core's (1997) DAMSL, Traum and Hinkelman's (1992) Conversation Acts theory – following Poesio and Traum (1997; 1998) and proposed as a standard by the Discourse Resource Initiative (Initiative, 1997) –, and Stoyanchev and Piwek (2010a; 2010b). We consider two main classes of functions for dialogue acts: Initiating and Responsive. Initiating dialogue acts are primarily meant to provoke a response by the other speaker as opposed to being themselves responses to previous dialogue acts. Responsive dialogue acts are mainly reactions of the speaker to a previous (initiating or responsive) action of the other party. These are distinguished by the prefixes **Init** and **Resp** in Table 3. Initiating dialogue acts are further divided into information giving and information

[2] At `http://mcs.open.ac.uk/nlg/non-cooperation/`.

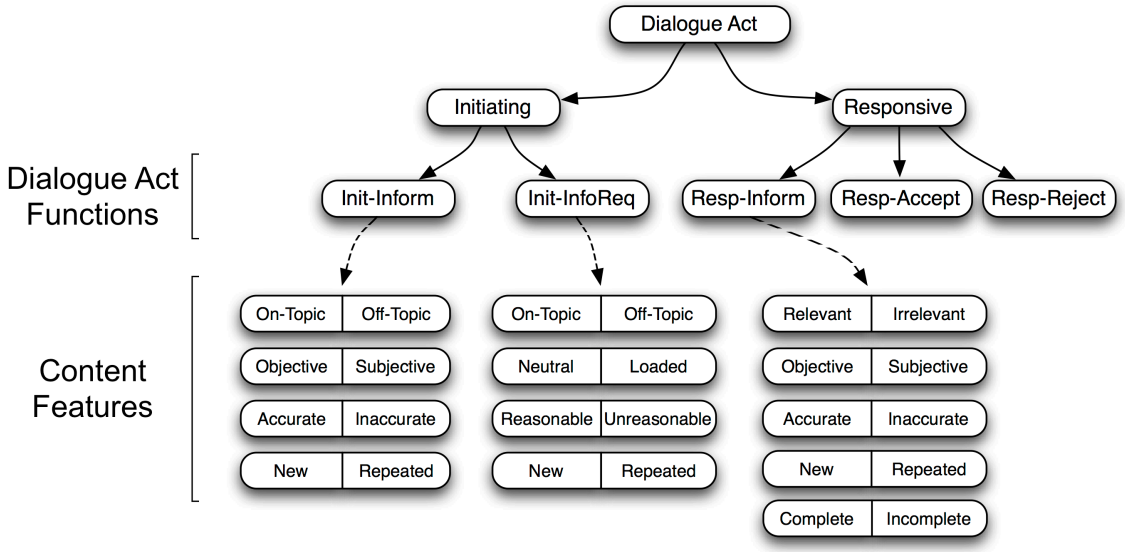

Figure 1: Annotation scheme for dialogue act functions and content features

requesting dialogue acts (**Init-Inform** and **Init-InfoReq**, respectively). Responsive dialogue acts are further divided into information giving, accepting and rejecting dialogue acts (**Resp-Inform**, **Resp-Accept**, and **Resp-Reject**, respectively). The entire annotation scheme, including dialogue act functions and content features, is shown in Figure 1.

For the segmentation and dialogue act annotation stage, four annotators (one of the authors and three native English-speaking researchers with previous experience in dialogue annotation) received transcripts of the corpus and were asked to segment the turns in each dialogue and to annotate each segment with dialogue act functions and, when applicable, with referent segments (i.e., a segment in a previous turn of the other speaker to which the current segment responds). A *segment* is defined as a stretch of a turn that can be labelled with a single dialogue act function. Stretches of a turn can belong to only one segment - i.e., segments do no overlap - and some stretches can remain unannotated. The instructions for segmenting and dialogue act functions for each turn in a dialogue are summarised as follows:

1. Segment the turn by selecting the stretches of speech that have a clear dialogue act function.

2. Assign a dialogue act function to each segment, identifying whether the dialogue act is initiating an exchange (i.e., requesting information, giving information as context for an upcoming question, etc.), or responding to a previous dialogue act (i.e., accepting a question or an answer, answering a question, rejecting a premise, providing additional information, etc.).

3. For each responsive segment, select the segment that caused the response.

Furthermore, when choosing the stretches of a turn that constitute separate segments two criteria are followed: (*a*) the stretch has to be of a length such that it can be assigned one of the available dialogue act functions, and (*b*) its contents have to request for or convey a clearly identifiable, ideally unique piece of information, or several pieces of information on the same topic.

We measured inter-annotator agreement for segmentation using Krippendor's α_U coefficient (Krippendorff, 1995), which was adapted for segmentation of transcribed dialogue. In general, agreement for segmentation, see Table 2, is high, i.e., "substantial", in terms of Landis and Koch (1977). Consistent with intuition, disagreement is greater in dialogues with longer turns.

Annotators independently segmented the turns and selected dialogue act functions for these segments in the same annotation step. This means that the units for annotation identified by one coder can differ from those identified by another coder. These differences make it possible to analyse the reliability of

Table 2: Inter-annotator agreement for segmentation (Krippendorff's α_U)

Interview	α_U	D_o	D_e
1. Brodie and Blair	0.802	3.217	16.251
2. Green and Miliband	0.618	3.276	8.565
3. O'Reilly and Hartman	0.773	4.138	18.219
4. Paxman and Osborne	0.92	0.993	12.468
5. Pym and Osborne	0.672	4.0	12.184
6. Shaw and Thatcher	0.653	7.951	22.890
Overall	0.74	23.574	90.577

Table 3: Inter-annotator agreement for dialogue act functions (Krippendorff's α)

Label	α	D_o	D_e
Init-Inform	0.409	0.040	0.068
Init-InfoReq	0.893	0.009	0.089
Resp-Inform	0.645	0.038	0.107
Resp-Accept	0.606	0.011	0.029
Resp-Reject	0.635	0.018	0.050
Overall	0.657	0.059	0.171

the original annotation data only in terms of Krippendorff's α,[3] which supports missing annotations for some of the items. The value of this coefficient for each label (i.e., regarding the rest of the categories as **Other**) and for entire dialogue act taxonomy is given in Table 3. Agreement ranges from "moderate" to "perfect", with overall agreement being "substantial".

Finally, for responsive dialogue acts, we also asked annotators to indicate which dialogue segment they were a response to. Inter-annotator agreement for referent segment annotations is "substantial" at $\alpha = 0.732$ and $(D_o, D_e) = (0.038, 0.141)$.

3.3 Content Feature Selection

For the second stage, we identified a set of dimensions on which the content of a contribution is judged (see Figure 1). These are based, in part, on Bull and Mayer's (1993) and Bull's (1994; 2003) extensive work on the micro-analysis of equivocation in political discourse.

Annotations from the previous stage were automatically aggregated to produce a single segmented and partially annotated version of each dialogue. These were used in the second stage of the study in which seven annotators (the four coders that took part in the first stage, plus another linguistic expert, with near native English, and two native English speakers with no background in linguistics or experience in dialogue analysis) were asked to select content features.

When judging the content of a segment, annotators had to consider – to the best of their knowledge – several elements of the context of the conversation (e.g., topical, political, historical), as well as common sense, world knowledge, etc. They also had to take into account previous contributions of both participants, and in some cases contributions made later on in the dialogue. Every time annotators made a judgement, they were instructed to ask themselves the following question: 'Do I have any evidence to make this choice?' If the answer was 'Yes', they could go ahead with their choice. Otherwise, they had to be *charitable*. This means that, for instance, if it is not possible to determine whether the information provided in a segment was accurate or not, the first option was chosen. Similarly, if whether a question is reasonable or not cannot be decided, then it is considered reasonable.

Table 4 shows the values of agreement for Krippendorff's α, observed and expected disagreement, observed (or average) agreement A_o, and multi-rater versions of Cohen's κ and Scott's π (or Siegel and Castellan's K) with their respective expected agreements A_e – observed agreement is the same for both coefficients and as given under A_o.[4] We report on agreement for the content features individually, aggregated for each dialogue act function, and overall for the entire corpus. Overall agreement is moderate ($\alpha = 0.454$).

[3]Krippendorff's α is a family of reliability coefficients (Krippendorff, 2003, Chapter 11) defined in terms of the ratio between the disagreement observed among the coders and the disagreement expected by chance: $\alpha = 1 - \frac{D_o}{D_e}$, where D_o and D_e are, respectively, the observed and expected disagreements.

[4]In addition to Krippendorff's α, we report reliability of the annotation of content features using multi-rater versions of Cohen's κ (Cohen, 1960; Davies and Fleiss, 1982) and Scott's π (Scott, 1955; Fleiss, 1971) – called K by Siegel and Castellan (1988). This is because these measures are often found in the literature when discussing the results of dialogue annotation exercises. The general form for both coefficients is: $\pi, \kappa = \frac{A_o - A_e}{1 - A_e}$, where A_o and A_e are, respectively, the observed – or average – agreement and the agreement expected by chance. The observed agreement A_o is the same for both coefficients and equal to the ratio between the number of instances in which any two annotators agreed in the classification of an item and the total number of pairs of annotations of each item. See discussions by Artstein and Poesio (2008) and Plüss (2014, Chapter 4) on the applications of these coefficients to studies in computational linguistics.

Table 4: Inter-annotator agreement for content features

4 Computing Cooperation

4.1 From Annotations to Actions Labels

As a first step, the dialogue act functions and content features in the annotations are mapped to *action labels*. The rules of a dialogue game are formulated in terms of the actions that participants perform during a conversation. These actions are represented as labels that capture those aspects of the speakers' contributions that are necessary for applying the rules.

The mapping, see Table 5, is carried out automatically, based on rules that are tailored to a specific dialogue game and coding scheme pair. This approach allows for a separation between the prescriptive nature of the dialogue game and the descriptive character of the coding scheme. Such independence facilitates, for instance, changing the rules of the dialogue game so that it better relates to the social norms, conventions and expectations of different cultural backgrounds, while keeping the coding scheme unchanged and using the same annotated data. It is worth noting that this mapping is independent of the set of interviews in the corpus and, like the dialogue game, was devised based on the linguistics literature for political interviews (Bull and Mayer, 1993; Bull, 1994; Heritage, 1998; Clayman and Heritage, 2002; Heritage, 2005). Also, given the formalisation of the dialogue game (see Figure 2 below), the application of the rules for mapping annotated dialogue into action labels is straightforward.

Table 5: Mapping annotations to action labels in political interviews

Annotation Scheme: Dialogue Act	Content Features	Dialogue Game: Action Label
Init-Inform	**On-Topic** *and* **Objective** *and* **Accurate** *and* **New**	`valid-statement`
Init-Inform	**Off-Topic** *or* **Subjective** *or* **Inaccurate** *or* **Repeated**	`invalid-statement`
Init-InfoReq	**On-Topic** *and* **Neutral** *and* **Reasonable**	`valid-question`
Init-InfoReq	**Off-Topic** *or* **Loaded** *or* **Unreasonable**	`invalid-question`
Resp-Inform	*Any*	`invalid-reply`
Resp-Accept		`acceptance`
Resp-Reject		`rejection`

(a) Interviewer segments

Annotation Scheme: Dialogue Act	Content Features	Dialogue Game: Action Label
Init-Inform	*Any*	`invalid-statement`[a]
Init-Inform	**On-Topic** *and* **Accurate** *and* **New**	`valid-statement`[b]
Init-Inform	**Off-Topic** *or* **Inaccurate** *or* **Repeated**	`invalid-statement`[b]
Init-InfoReq	*Any*	`invalid-question`
Resp-Inform	**Relevant** *and* **Accurate** *and* **New**	`valid-reply`
Resp-Inform	**Irrelevant** *or* **Inaccurate** *or* **Repeated**	`invalid-reply`
Resp-Accept		`acceptance`
Resp-Reject		`rejection`

(b) Interviewee segments

[a] If the interview starts with a question by the interviewer.
[b] In the first turn of an interview that starts with a statement by the interviewee.

4.2 Cooperative and Non-Cooperative Feature Computation

Linguistic cooperation of a dialogue participant with respect to a conversational setting equates to the participant following the rules of the dialogue game for that conversational setting. Figure 2 shows the dialogue game of political interviews that we used for the current study, derived from the descriptive accounts in the linguistics literature (Heritage, 1998; Clayman and Heritage, 2002; Heritage, 2005). Each turn in a dialogue is associated with an amount of cooperation and an amount of non-cooperation. These are given by the number of dialogue rules that the turn, respectively, conformes with and violates. The instances in which rules are conformed with are called *cooperative features* and those in which rules are broken are called *non-cooperative features*.

Participants can break the rules of the game in two ways: (*a*) by performing a conversational action that is not allowed for their role and (*b*) by failing to perform an action they were obliged to perform. Instances of (*a*) are violations of static obligations, which we call *static non-cooperative features*. Instances of (*b*) are violations of dynamic obligations, which we call *dynamic non-cooperative features*. An analogous distinction is made for cooperative features, called, respectively, *static cooperative features* and *dynamic cooperative features*. The *degree of cooperation* of each dialogue participant is thus the ratio between the number of cooperative features – static and dynamic – and the total number of features of that participant. In general, this value can be obtained for the entire conversation and for any continuous fragments. The complete algorithms for computing these features, given an annotated transcript and dialogue game, is available online.[5]

In each turn, we check whether the actions performed by the speaker are allowed for his or her role as specified in the dialogue game. If an action is in the the speaker's set of allowed actions, then it constitutes a static cooperative feature, otherwise it becomes a static non-cooperative feature.

In each turn, we look at the speaker's obligations pending after and discharged in that turn. If an obligation on the speaker has been discharged within the turn, then it constitutes a dynamic cooperative feature, otherwise it becomes a dynamic non-cooperative feature.

Once we have computed the static and dynamic features for each turn, we can regard the proportion of these that are cooperative as an indicator of the extent to which each participant acted within the rules of the game. This is the *degree of cooperation* of a dialogue participant with respect to a dialogue game. Formally, for speaker s and dialogue $D = \langle t_1; \ldots; t_n \rangle$ this is:

$$dc_{D,s} = \frac{cf_{D,s}}{cf_{D,s} + ncf_{D,s}}$$

where $cf_{D,s}$ is the number of cooperative features – both static and dynamic – of participant s and $ncf_{D,s}$ is the analogous for non-cooperative features. This is[6]:

$$cf_{D,s} = \sum_{\substack{i=1 \\ [s_i=s]}}^{n} |sf_i(2)| + |df_i(2)| \qquad ncf_{D,s} = \sum_{\substack{i=1 \\ [s_i=s]}}^{n} |sf_i(3)| + |df_i(3)|$$

Note that, although these definitions are here expressed for the complete dialogue, the same applies to any contiguous subsequences of turns.

The *degree of non-cooperation* of a dialogue participant s in dialogue D is: $dnc_{D,s} = 1 - dc_{D,s}$.

5 Evaluation

We obtained judgements on the behaviour of participants in the political interviews in the corpus by means of an online survey constructed using SurveyMonkey.[7] Observers were shown transcripts of the dialogues and asked to rate the performance of the participants on a 5-point scale (from Incorrect to Correct), based on their intuitions on how interviewers and politicians *ought* to behave.[8]

[5] See `http://mcs.open.ac.uk/nlg/non-cooperation/`.

[6] The elements in the sequences of both static and dynamic features $SF_D = \langle sf_1; \ldots; sf_n \rangle$ and $DF_D = \langle df_1; \ldots; df_n \rangle$ are triples (s_i, C_i, NC_i), where s_i is the speaker in turn t_i, and C_i and NC_i are the associated sequences of, respectively, cooperative and non-cooperative features.

&[*\text{-}\texttt{question}\ \mathbf{N} \succ \texttt{acceptance}], && (17)\\
&[*\text{-}\texttt{reply} \succ \texttt{acceptance}]\} && (18)
\end{aligned}$$

Figure 2: Dialogue game G_{PI} for political interviews, consisting of (*i*) $Allow_{PI}$, which specifies the actions allowed for the interviewer (ir) and interviewee (ie), respectively; (*ii*) $Introduce_{PI}$, which stipulates which actions by a specific participant give rise to obligations – e.g., (4) says that a new (**N**) valid question by the interviewer obliges the interviewee to accept that question and (5) says that after accepting a question an interviewee is obliged to provide a complete (**C**) valid reply; (*iii*) $Discharge_{PI}$ specifies how certain actions can count as other actions for (implicitly) discharging obligations – e.g., (15) says that repetition (**R**) of any questions counts as discharging the obligation for a rejection dialogue act and (16) says that a (valid or invalid) statement counts as discharging the obligation for an acceptance dialogue act; so, for instance, an obligation for acceptance by ie that has been created through application of rule (3), can be discharged by ie by producing a statement, in accordance with rule (16).

We used the six interviews in the corpus described above in Section 3.1. Judges (54 respondents in total) were shown the same context and transcript as the annotators.

We studied the relation between human judgement resulting from the survey and the degree of cooperation obtained from the method described above by means of a correlation analysis (see Figure 3).We carried out the correlation analysis separating interviewers from interviewees. The rationale for this step is that some of the rules of the dialogue game are role-specific, making the method strictly different for each participant in an interview. A similar argument applies to the way human observers are expected to judge the behaviour of interviewers and politicians. The two sets of six points are shown in Figure 4, with separate regression lines and values for Pearson's r. The results show that correlation is significantly better for interviewers ($r = 0.753$) than for interviewees ($r = 0.271$). Statistical significance is also stronger for interviewers ($p = 0.084$) indicating a trend towards positive correlation between the results of our method and human judgement. For the interviewees the correlation is not statistically significant ($p = 0.603$). With a sample of this size, correlation analysis is fairly sensitive to outliers, which could explain such a high p-value for the interviewees. Take, for instance, the interviewee in Interview 3 (O'Reilly and Hartman) which corresponds to the point furthest up from the regression line for interviewees (blue) in Figure 4. Coincidentally, Interview 3 has been described by one of the annotators as more like a debate than a political interview which could explain the unexpected value given by the method.

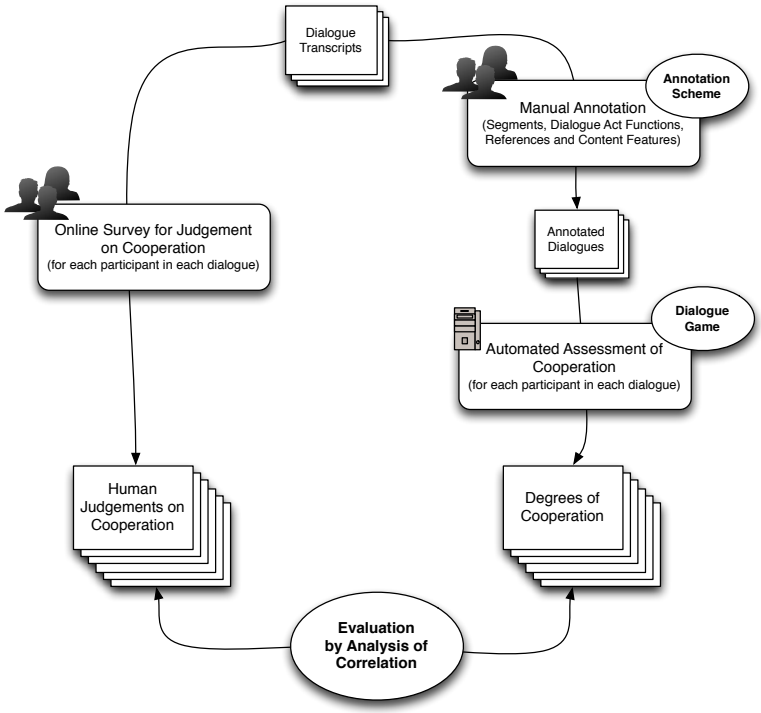

Figure 3: Evaluating the semi-automatic measure of cooperation via correlation with human judgement

6 Conclusions and Further Work

The method presented above is, to date and to our best knowledge, the most elaborate attempt at annotating and analysing naturally occurring dialogue in the light of linguistic cooperation. Also novel is the application of such an approach to a corpus of real political interviews, especially in that both speakers received the same amount of attention and that the method was subject to an extensive evaluation.

The results of the evaluation for reliability are encouraging and indicate that the method is suitable for the systematic analysis of non-cooperation. They also expose some of its weaknesses, such as the difficulties with applying some of the criteria in the manual annotation, a degree of vagueness in the definition of a few of the concepts and the inherent subjectivity of many of the judgements involved in properly characterising non-cooperation.

The evaluation of validity produced fairly good results, especially considering how little information was given to observers in the survey as to what was meant by linguistic cooperation and the total absence of a reference to the specific dialogue game adopted as part of the semi-automatic measure.

It is worth pointing out that the method, in its current form, was able to predict accurately in the six interviews of the corpus which of the participants behaved better with respect to their interlocutors. Beyond the correlation of the precise scores, the ability to determine this binary judgement without mistakes in all cases is of great interest and an indication of the adequacy of the approach.

It is unfortunate that the size of the sample in the corpus prevented from obtaining statistically significant results for each speaker role, particularly the interviewee. A larger sample, including more interview fragments would help in setting this right. Given the relative ease in collecting human judgements, the inclusion of new fragments should start with one or more surveys similar to the one described above. This would allow a decision on the choice of subset of interviews that offers the best coverage of the range of possible behaviours.

6.1 Further work

The method proposed in this paper can be extended to include further aspects of dialogue, like prosody, gestures and other multi-modal aspects of dialogue interaction, as well as sub-utterance elements such as interruptions, incomplete and overlapped speech, etc.

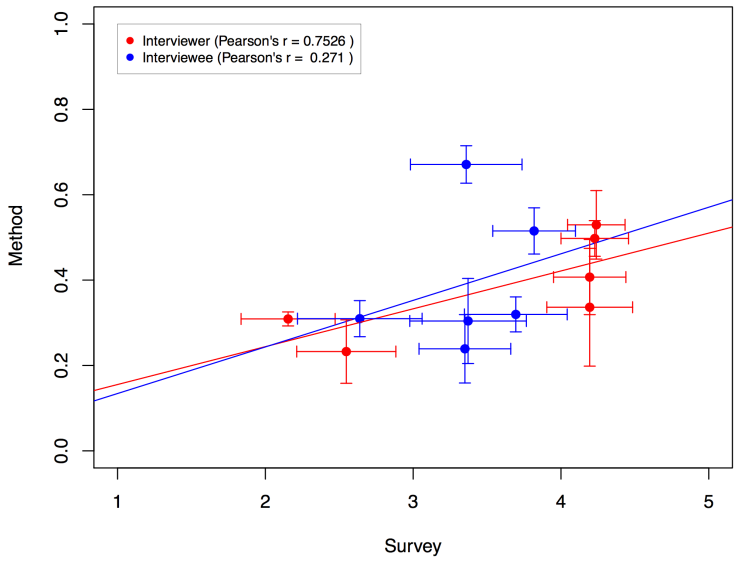

Figure 4: Survey results and the degree of cooperation for interviewers and interviewees (means with error bars, regression line and Pearson's r correlation coefficient)

A further line of work is towards full automation. Data-driven techniques using machine learning can be used to automatically annotate the dialogues with the labels needed to assess the degree of cooperation. Further, we speculate that the rules of the dialogue game could be learned from a sufficiently large corpus of interviews that are deemed conventional.

Our decoupling of the dialogue game from the annotations allows for further evaluation of the approach with participants from cultures with different conventions for political interviews (using the current corpus or a translation of it). Similarly, although the method has been described and evaluated in detail for political interviews, the approach is generally domain-independent. Applications to other conversational domains in which it is possible to identify a set of rules of expected interaction would allow further assessment of the approach. Such domains include courtroom interrogations, tutoring sessions, doctor-patient discussions, customer services, and many more.

Representation and Learning of Temporal Relations

Leon Derczynski
Department of Computer Science
University of Sheffield
S1 4DP, UK
leon.d@shef.ac.uk

Abstract

Determining the relative order of events and times described in text is an important problem in natural language processing. It is also a difficult one: general state-of-the-art performance has been stuck at a relatively low ceiling for years. We investigate the representation of temporal relations, and empirically evaluate the effect that various temporal relation representations have on machine learning performance. While machine learning performance decreases with increased representational expressiveness, not all representation simplifications have equal impact.

1 Introduction

Textual accounts often contain descriptions of events, times, and how they relate to one another temporally. To connect events and times to each other, we need to know the kind of temporal ordering between them. This ordering can be modeled with **temporal relations** that hold between pairs of entities, each of which may be an event or time. Extracting these relations is critical to understanding the text: for example, given an almanac of presidents of the USA, there are likely to be many indications of different people being president – but only one will be factual at any given time. In order to reason about events and the applicability of information in a document, linguistic expressions of time need to be converted to a formal representation. This task is temporal relation annotation.

To annotate temporal relations for reasoning or information extraction, one must to select a way of representing temporal relations. Such representations typically comprise a **set of temporal relations**, with each member describing a different temporal ordering. Building such representations is a key artificial intelligence task in reasoning and planning, and proposed solutions have amounted to major work in the field; e.g. Allen (1984), Freksa (1992).

Temporal relation annotation has two key parts. One must decide which entity pairs to relate, and then determine the nature of their relation. These are referred to as temporal relation **identification** and temporal relation **typing**.

These may be approached as a joint task, especially when it is possible for the type of one link to influence the type of another. For example, if event A is before event B and that event B is before event C, due to transitivity, the choice of relations between A and C may be constrained. Choosing how to represent the types of temporal relations is the focus of this paper.

Machine learning of temporal relations is hard. Mani et al. (2007) detail experiments with features annotated in TimeML (Pustejovsky et al., 2004), and reach around 75% accuracy at overall relation typing,[1] using gold-standard relation identification.[2] This pattern repeats in subsequent literature. Many others reach a similar performance, or perhaps even exceed it by 1-2% (Mirroshandel et al., 2011; Do et al., 2012); some do well by focusing on specific sub-parts of the problem (e.g. relations that are expressed by tense shifts (Derczynski and Gaizauskas, 2013b); relations between events in the same verb clause construction (Bethard et al., 2007)), or in contrast by taking a holistic whole-graph approach (Chambers

[1] Calculated by weighing the event-event and event-timex relation scores in their paper according to the distribution in the dataset used.

[2] This is typically made up of around 70% for event-event relations and 80% for event-time relations.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1937–1948, Osaka, Japan, December 11-17 2016.

Relation	Symbol	Explanation of A-relation-B
before	<	A finishes before B starts
after	>	A starts after B ends
equals	=	A and B happen at the same time
meets	m	A happens immediately before B
is met by	mi	A happens immediately after B
overlaps	o	A is an interval during which B starts but does not finish
is overlapped by	oi	A starts within B but finishes after
during	d	A happens between B's start and finish
contains	di	A starts before, and finishes after, B
starts	s	A and B start at the same time, but B continues past A's end
is started by	si	A starts at the same time as B, but then goes on for longer
finishes	f	A starts after B, but they finish at the same time
is finished by	fi	A starts before B, and they finish at the same time

Table 1: Temporal interval relations, using Allen's symbols

et al., 2014); or relations where a temporal conjunction is present (Derczynski and Gaizauskas, 2013a)); but no general breakthrough appears to be on the horizon.

Indeed, the top systems in each of the TempEval challenges had tightly-clustered scores showing some 5-10% error reduction over the most-common-class baseline, despite the work being spread over years of active research (Verhagen et al., 2009; UzZaman et al., 2013; Bethard et al., 2016).

When one considers how human annotators cope with the task as it is often cast, it is unsurprising that machine performance is not high. Choosing from a set of abstract temporal relation types to fit an arbitrary pair of event mentions in a given document is difficult. For the largest TimeML corpus, inter-annotator agreement on relation types was just 0.71 (kappa) between a set of experts familiar with temporal annotation.[3] In this case, they had to assign one of a set of fourteen different temporal ordering types to the pair of events.

Problems may lie in the schema of temporal relation types. Assigning types requires annotators to perform abstract reasoning often with incomplete information; systems must do the same. Thus, the choice of representation for temporal relation types is critical. The more relation types to choose from, the more reasoning is required, and so the potential for error increases.

The bulk of work has concentrated on describing the order of two events by using relations from Allen's interval algebra. However, no work has directly investigated the effect of temporal relation representation design on performance of machine learning systems.

This paper investigates temporal relation type representations, in the framework of TimeML when possible. It compares a range of existing relation sets and discuss two dimensions for relation representation design. Following this is a general comparison of the impact that relation set choice can have on machine learning performance. Next follows discussion of techniques commonly used to improve training sets, including relation type mapping, and examine their impact. Finally, the paper investigates how discriminable often-conflated relations are, providing insight into the difficulty added by using finer-grained relation sets, and reports on research on human aspects of temporal relation representation.

2 Temporal Representation Schemes

This section introduces fundamental temporal relation type sets for linguistic annotation. Standards for representing temporal relations are then described in the context of these fundamental relation sets.

[3] See http://timeml.org/site/timebank/documentation-1.2.html

Relation	Illustration	TimeML relation type disjunction
X is *older* than Y Y is *younger* than X		X [BEFORE, IBEFORE, ENDED_BY, INCLUDES, DURING] Y
X is *head to head* with Y		X [BEGINS, SIMULTANEOUS, IDENTITY, BEGUN_BY] Y
X *survives* Y Y is *survived by* X		X [INCLUDES, BEGUN_BY, IAFTER, AFTER] Y
X is *tail to tail* with Y		X [ENDED_BY, SIMULTANEOUS, IDENTITY, ENDS] Y
X *precedes* Y Y *succeeds* X		X [BEFORE, IBEFORE, ENDED_BY, INCLUDES, DURING_INV] Y
X is a *contemporary* of Y		X [INCLUDES, IS_INCLUDED, BEGUN_BY, BEGINS, DURING, DURING_INV, SIMULTANEOUS, IDENTITY, ENDS, ENDED_BY] Y
X is *born before death* of Y Y *dies after birth* of X		X [IS_INCLUDED, ENDS, DURING_INV, BEFORE, IBEFORE, INCLUDES, DURING, ENDED_BY] Y

Table 2: Semi-interval relations. Adapted from Freksa (1992). The superset of relations is omitted here, but related in that work.

2.1 A Very Simple Relation Set

A Very Simple set of relations for representing temporal relations could have just three members: BEFORE, OVERLAP, and AFTER. These are mutually exclusive; before means wholly before, and after means wholly after, precluding any ambiguity once a relation type has been assigned. No specific model of events is required here.

However, this representation is too simplistic to describe many of the temporal relations that are often explicitly conveyed in language. For example, there is no way to represent the distinction between *after* and *just after*, or between *I opened the door yesterday* and *I held the door open all day yesterday*.

2.2 Interval Relations

Allen (1983) introduces a richer relation set which models the events (or times) that are related as **temporal intervals**. Each interval consists of a start and end point, which correspond to when the item in question began and ended. Based on this, thirteen possible interval arrangements are identified and given names. The relations are shown in Table 1. This model can be used to model relations between events and times, both those observed and those described in natural language (Allen, 1984).

2.3 Semi-Interval Relations

Freksa (1992) describes a relation set based on semi-intervals, with temporal reasoning based on natural language as one of its intended uses. In this semi-interval relation set and algebra, events and times are still modelled as temporal intervals, but one is not required to fully specify the bounds of both related intervals in order to describe the relation between them. Rather, different relation types apply depending on both the order and the degree of specification. This allows for a more expressive representation. A subset of these underspecified interval relations are demonstrated in Table 2.

Its relation types (or "conceptual neighbourhoods") can be thought of as disjunctions of Allen interval relation types. For example, Freksa's TAIL-TO-TAIL relation corresponds to any situation where both

intervals end simultaneously (in Allen's terms, $\texttt{fi} \vee = \vee \texttt{f}$). The CONTEMPORARY relation is analogous to our Very Simple relation set's OVERLAP type (Section 2.1). If A is the set of Allen interval relation types and F the set of Freksa semi-interval relation types, then $F \subset \mathcal{P}(A)$. This semi-interval relation set is flexible, but this comes at a cost. Annotators and relation typing systems have a greater selection of relation types to choose from: there are total 31 types.

These three representations provide most of the concepts required to understand the other major relation type sets.

2.4 Annotation Standards

TimeML TimeML uses the Allen relations (although slightly renamed), and adds a IDENTITY relation to indicate co-reference. This extra relation is temporally equivalent to SIMULTANEOUS. Interpretation of TimeML's DURING and DURING_INV relations has been ambiguous; this work adopts the TimeML-strict definitions (Derczynski et al., 2013), which map directly to Allen's overlap and overlap-inverse.

As with Allen's temporal interval relations, TimeML requires full specification of both intervals and established versions only permit assignment of a single relation type. Links in newer prototype versions of ISO-TimeML (Pustejovsky et al., 2010) permit selection of disjunctions of interval relation types.

TempEval TempEval-1 and TempEval-2 (Verhagen et al., 2009; Verhagen et al., 2010) used the same three types as the Very Simple scheme, plus two less-specific types – BEFORE-OR-OVERLAP and AFTER-OR-OVERLAP – and the relaxed VAGUE. TempEval-3 used TimeML relations.

STAG The STAG annotation scheme (Setzer and Gaizauskas, 2000) – a precursor to TimeML – specifies three basic relations: SIMULTANEOUS, BEFORE and INCLUDES. Representation of "after" and "is-included-by" relations can be achieved by swapping the order of arguments (i.e. A BEFORE B vs. B BEFORE A). This intuitive, simple scheme cannot express Allen-style overlap, and the STAG INCLUDES relation is vague in that it subsumes BEGINS and STARTS Allen relation types.

Narrative Containers Pustejovsky and Stubbs (2011) attempt to reduce the scope of temporal relation typing task by defining narrative containers over sets of event mentions in documents. These containers represent a time interval during which groups of events occur. The containing time interval may either be explicit and reified with a narrative time, or implicit, with the exact bounds determined by context and text type. Containers reduce the amount of uncertainty in relation typing by grouping related events into local contiguous temporal scopes. This reduces annotator load and provides a basis for the temporal structure of a given document, without requiring specification of the type of every temporal relation. The narrative container approach is designed to support event-to-time relation typing, and succeeds in doing so directly for 50% of events with more informative relation descriptions. Empirical work (Miller et al., 2013) indicates that these containers can be annotated by humans sufficiently well to learn an initial automated approach. However, in the absence of a large general-purpose corpus annotated with them, this paper does not include narrative containers.

For a general overview and history of temporal annotation standards, see (Strötgen and Gertz, 2016).

3 Analysing temporal relation sets

This section investigates selected sets of temporal relation types. The sets are chosen to demonstrate key differences, though the list is not exhaustive. A graph-based comparison of three sets can also be found in (Denis and Muller, 2010).

3.1 Expressiveness and Specificity

We qualitatively describe temporal relation sets in two dimensions: The first dimension, *expressiveness vs. simplicity* details the range of different combinations of event orderings they can capture. The second, *specificity vs. laxness* details how much constraint the relation set's types imply, and how much one needs to know before typing a relation.

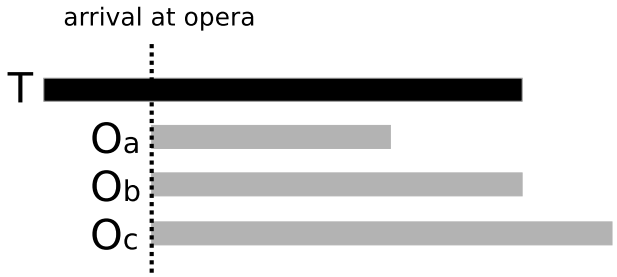

Figure 1: The Opera problem: Linguistic ambiguity leads to inability to choose a single interval relation. Here, we know the time of arrival at the opera but not of the departure, making it hard to relate intervals O and T.

For example, the Very Simple relation set is not very expressive – it has only three relations. The interval set is specific – one must describe relations using both endpoints of both intervals. Compared to the interval set, semi-interval relations are more expressive and less specific, because less information is required to choose a relation type.

3.2 Precision and Annotation

When describing the order of events and times, it is important to get the right degree of precision. Time can be thought of as a unidirectional, continuous dimension. This continuous aspect of time permits relatively small differences in the alignments of events, which may be at best useless and at worst counter-productive when reasoning.

However, lacking an inherent temporal quantisation or discretisation framework (such as chronons (Lévi, 1927)), we have no objective ground for ignoring small discrepancies in event timing. Instead, cues come from the temporal scale at which events take place (Gaizauskas et al., 2012).

A pragmatic approach suits this situation. Annotations over a text should match the information expressed. So, in *"I smiled when she entered the room"*, whether the smiling and the entrance were delayed by a few fractions of a second is unlikely to be salient. Rather, the language indicates that these events happened at the same time, and so this is the best thing to annotate. Texts regarding quantum events or star formation would both use different temporal scales.

3.3 The Opera Problem

The interval-based relation set is a richer representation than the Very Simple one, but has the disadvantage that the order of both related intervals' start and end (i.e. four points in total) must be known before a single relation type can be chosen. It is desirable to choose a single relation type when annotating linguistic data in order to keep down the number of choices that annotators need to make, which in turn affects the quality of output. The linguistic ambiguity in natural language texts can make it hard to choose a single interval relation type. This can be illustrated using the Opera problem, as put forward in Derczynski (2017)

Given the statement *Irene went to the opera today*, assume interval O is the visit to the opera and interval T is today.[4] Without knowing when Irene left, one cannot choose a single interval relation out of (a) O is included in T, (b) O and T end at the same time, or (c) O overlaps T – see Figure 1.

Underspecifying the endpoints of intervals allows ambiguity to be captured in a single relation type. The semi-interval relation set offers a solution the Opera problem using a relation where the start of O is specified but its end is not. In this representation it is O YOUNGER-CONTEMPORARY-OF T, which corresponds to the disjunction of Allen relations $\texttt{f} \vee \texttt{d} \vee \texttt{oi}$.

Similarly, the Very Simple set can give a lossy representation for this problem with its OVERLAP relation. It is lossy because the text describes more than can be represented by this relation type.

Confusions like the one the Opera problem presents occur frequently in TimeML annotation when linking events to the document time stamp, which is typically a one-day interval. For example, news

[4]This treats O as an eventuality which represents the state of Irene being at the opera; (Hobbs and Pustejovsky, 2003) examines the semantics of events in the context of temporal interval representations.

stories – the bulk of the TimeML annotated data in existence – refer to the day in which they are reported, but as one cannot see into the future and determine whether or not assertions and events in the news will persist past the end of the day, it is not always possible to accurately assign a single relation type with certainty.

4 Machine Learning and Temporal Relation Types

There are specific problems when applying machine learning to the temporal relation typing task. When approached as a classification task, the assumption made by most tools is that classes are independent. However, this is not correct in this case, for two reasons.

Firstly, relation types are not all equally different. TimeML's "immediately after" relation, IAFTER, is more like AFTER than it is INCLUDES. In fact, this non-orthogonality is critical to the construction and behaviour of Freksa's conceptual neighbourhood relations. The connected nature of relation types offers nuance in training, classification and evaluation of machine learning approaches to temporal relation typing.

Secondly, relation typing is a highly structured task, with local and global dependencies. Not only should local relation constraints (e.g. through transitivity and commutativity) be taken into account, as noted by Hovy et al. (2012); also, the annotation of a well-formed document should be globally temporally consistent, otherwise it will detail an impossible sequence of events.[5]

This interdependent aspect of temporal relations is hard to model, partially due to the underlying computational complexity (Vilain and Kautz, 1986). Nevertheless, including features for local dependencies give modest accuracy improvements (Chambers and Jurafsky, 2008; Yoshikawa et al., 2009).

5 Evaluating Learning of Relation Sets

Using a variety of temporal relation sets, machine learning of temporal relations is evaluated over the same data. This is achieved by mapping TimeML gold-standard relations to other relation sets thus:

Simple – before: BEFORE, IBEFORE; after: AFTER, IAFTER; overlap: everything else.

STAG – add inverses of the before and includes types, to make five relations. before: BEFORE, IBEFORE; after: AFTER, IAFTER; simultaneous: SIMULTANEOUS, DURING, DURING_INV, IDENTITY; is-included: IS-INCLUDED; includes: everything else.

Allen – One change: TimeML IDENTITY becomes Allen's "=" (equal, i.e. simultaneous).

TimeBank 1.2 (Pustejovsky et al., 2003) is the corpus, which has 6 418 temporal relations (TimeML TLINKs) in 183 documents. This is merged with the AQUAINT TimeML corpus, which has 2 340 TLINKs in 73 documents.[6] The AQUAINT corpus is structured in four themes, each of which contains multiple documents tracking the same story over time.

A 75%/25% split training and evaluation split is used. To avoid information that could be extracted through inference leaking between documents, splits are made at document and not TLINK level.

When evaluating learning of temporal information, one must also be wary of **timeline pollution** (Bergmeir and Benítez, 2012) – that is, introducing later knowledge into the training set that might give clues as to the contents of an earlier document in the test set. This pollution concern is offset by avoiding duplicating text across splits. These factors work against each other: avoiding timeline pollution, by only including later-dated documents in the test split, increases the risk of these documents re-using fragments of earlier articles on the same topic. Avoiding re-use is probably more important from a basic NLP point of view, so splits are arranged to reduce this. The solution adopted in the AQUAINT corpus is to split at theme-level, as a lot of similar text is repeated across each theme.

The feature set is the same as that in Mani et al. (2007). These are the attributes and values of the TimeML annotations, plus the strings they annotate, and in addition: the string of the conjunction coordinating the relation, if present; and two flags indicating whether, in a relation between two verb events, the verbs have the same tense or same aspect. Following previous work (Mani et al., 2007), experiments use a maximum entropy classifier (MegaM (Daumé III, 2004)), which has consistently provided stable

[5] This requirement makes the assumption that the author has written a temporally consistent story.

Relation set	MCC baseline	MaxEnt	ID3
Simple	44.79	73.96	57.65
STAG	38.00	60.36	51.13
Allen	26.08	58.58	46.01
TimeML	26.08	57.08	45.51

Table 3: Relation typing precision using a variety of temporal relation sets, compared to a most-common-class baseline.

Relation set	MCC baseline	MaxEnt	ID3
TempEval-2	55.61	59.25	61.73
TimeML	33.87	50.43	33.03

Table 4: Relation typing precision on a smaller set of links, using the TempEval-2 relations.

results in this task, and a decision tree classifier, ID3 (Quinlan, 1986), for its different inductive bias – i.e., away from the independence assumption. The goal here is to highlight relative performance using various relation representations. Results are given in Table 3.

Some relation sets could not be directly mapped from TimeBank. The TempEval-2 data uses a subset of TimeBank, but due to its relation set's multiple levels of specification, cannot be directly mapped. In a second set of experiments, the TempEval-2 dataset is compared with the corresponding TimeML relations. Performance using TimeML is included for comparison. Results are given in Table 4.

Generally, results suggest automatic relation typing is easier on smaller and simpler relation type sets. Greater expressiveness leads to both lower baselines and lower ML performance. Note the performance difference between Allen and TimeML relations sets – these are identical except for the addition of a co-reference relation in TimeML, for which relations are slightly harder to learn. Our Very Simple relation set of just three coarse-grained temporal arrangements was the easiest to assign using the existing data.This anti-monotone relation between increased expressiveness and lower machine learning performance held over all representations and algorithms tested.

6 Adapting Training Data

This section examines techniques for improving machine learning of temporal relations: simplifying the problem, and increasing available training data. Taking transitive closures is omitted, as it does not help (Mani et al., 2007).

6.1 Folding

Many relation types used in both TimeML and Allen's relation sets have a corresponding inverse relation. Mapping between these can be achieved by inverting the relation type and the argument order. For example, BEFORE*(Monday, Tuesday)* is equivalent to AFTER*(Tuesday, Monday)*. This relation **folding** simplifies classification by reducing the number of target classes, and is common in temporal relation classification, e.g. Mani et al. (2007); Mirroshandel et al. (2011).

6.2 Doubling

Doubling the reverse of folding: instead of using a relation type mapping to reduce the number of classes, use the mappings to double the number of examples. In controlled evaluation, it is possible to reverse the order of arguments in the evaluation set so the set only contains relation types the classifier has seen in folded training data. This is not possible where the relation type is never known, as one does not have control over argument order. E.g. if all AFTER relations are removed from the training data by swapping their arguments and changing them to BEFORE, when faced with the previously-unseen relation C AFTER D, a classifier trained on folded data will fail.

To solve this, instead of reducing the set of available relations, one can increase training data size by using the folding mappings to create new training instances instead of altering existing ones. That is, given an example A AFTER B one automatically adds an extra B BEFORE A. This is relation doubling.

Data set	MCC baseline	MaxEnt	ID3
Unfolded TimeML	26.08	57.08	45.51
Doubled TimeML	26.08	28.68	18.58
Folded TimeML	42.12	70.48	59.93

Table 5: Relation typing precision on a smaller set of links, using folding and doubling.

6.3 Closure

Many relation sets have types that exhibit properties of transitivity or commutativity. While a useful technique for increasing the volume of available data, the results of adding training data generated through closure can be unpredictable, and it is not always a suitable technique to apply; therefore, we omit effects of temporal graph closure here.

For example, in the interval relations, if A BEFORE B and B BEFORE C, then by transitive closure A BEFORE C. These properties allow the automatic addition of temporal relations to an existing set through inference. The set of links resulting from inferring as many possible relations from a source document is called that document's temporal closure.

While a useful technique for increasing the volume of available data, the results of adding training data generated through closure can be unpredictable, and it is not always a suitable technique to apply. For further reference, results on the use of closed data are presented by Mani et al.; extended discussion can be found in Verhagen (Verhagen, 2004).

6.4 Evaluation

Machine learning performance on folded training data using the TimeML relation set is evaluated as above. Results are in Table 5. Folding offers a big improvement over other methods, in terms of both error reduction above most-common-class baseline and also absolute accuracy. However, it is not applicable to real-world data. While doubling overcomes this critical deficiency, it overall reduces performance.

7 Relation Distinctions

As relation sets become more complex, categories of temporal relation are subdivided. For example, TimeML distinguishes between immediately before, IBEFORE, and before with an interceding gap, BEFORE, whereas neither our simple set, the STAG set or the TempEval-2 set do. It may be that some of these distinctions are easier to learn than others. To investigate, subgroups of relations that may be (or have been) sources of potential confusion are identified, and classifiers trained just on relations of the types in the group. These were then evaluated on the relations in the group from the test examples. As these subdivisions result in small amounts of training data, folded relations are used to simplify the problem and improve the examples to classes ratio.

The confusion between TimeML DURING and INCLUDES relations is also investigated. These were identified by annotators as confusing during TempEval-3 and cursory examination during TempEval-3 revealed many questionably annotated examples in TimeBank.

Results are shown in Table 6. Many of the finer distinctions can be successfully made in these situations, though there is significant variation. Unsurprisingly, accuracy on each relation type is higher the more examples are seen, with most having accuracies above 80% and some in the high 90s. The *overlap* group was hardest, at an accuracy of 55.23%. It also has one of the least skewed class distributions. It is interesting to note that relations in the STAG *includes* group, while sharing much with the *overlap* group, was generally easier to distinguish from one another. The co-reference relation added to the Allen relations by TimeML is also relatively easy to distinguish from non co-referent simultaneity, with the classifier reaching 30% – 50% error reduction above baseline. Indeed, (Glavaš and Šnajder, 2013) achieve F1 scores as high as 0.95 using graph kernels on this problem. With regard to the TimeML INCLUDES/DURING confusion, binary classification accuracy is lower than the most-common-class baseline; an indication of a difficult problem, or of poor-quality data – which uncertain annotators would generate.

Coarse relation	TimeML rel'n	Data %	Acc.
Before (3 300 instances)	BEFORE	97.17	99.65
	IBEFORE	2.83	31.34
	Overall	-	97.72
After (1 590 instances)	AFTER	95.34	99.12
	IAFTER	4.66	20.00

8 Human Factors in Temporal Annotation

When it comes to designing new representations, human factors can have bearing on design choices. Scheuermann et al. (2013) provide valuable insights into annotator preferences in temporal annotation. They report that experts prefer more expressive representations, at the cost of simplicity, whereas non-experts lean towards perceived user-friendliness at the cost of expressivity. This matches the anti-monotone interaction between machine learning performance and representational expressiveness: the simpler the representation, the easier it is to annotate and to learn.[7] Large variation was seen across all annotators. Schaeken and Johnson-Laird (2000) show that agreement and success of humans annotating timelines can be perturbed by even slight changes in text phrasing, which perhaps explains the variations seen in Scheuermann et al.'s work.

These findings are worth considering in the construction of relation representations and human temporal annotation tasks. One caveat, as Allen (1991) points out, is that the presence of parallels between natural language and a given representation is not always indicative of its suitability for automated reasoning. Freksa's relation set may be a better target for human annotation: it is intended to better reflect the usage of temporal relation expression in natural language, and only requires judgment over pairs of points rather than intervals, for construction. For example, one may decompose interval relations into point relations, and ask "Does A begin before B ends?". We already know that simpler questions yield better results from annotators (Sabou et al., 2014), and so a decomposed, less constrained approach to annotation may be fruitful. Certainly, the 13-way Allen (or 14-way TimeML) task has been tough, and it is reasonable that some disagreements come from annotators having to chose a particular relation type when in fact many (or none) seem appropriate to them.

9 Conclusion

This paper has investigated choices in representation of temporal relations. Human annotation agreement is often low in relation typing, and the task is also difficult for automatic systems. The expressivity of a representation has an inverse correlation with automatic temporal relation typing performance.

However, more expressive representations are required in order to accurately capture temporal structure, or even to reduce annotator confusion. It was shown that decisions over fine distinctions between

[7] The effect agreement has on training data is not measured here, but is stable across sets at around kappa 0.7.

temporal relation types in more expressive systems are of varying difficulty. This finding fits the observation that not all temporal relation types are equally different from each other.

In summary, expressivity is lacking in popular temporal relation representations, but large relation types sets are harder to annotate. It is important to get specificity right in a given relation set, and to select carefully the groupings made when creating coarser relation sets. Therefore, being aware of the expressiveness of different representations is critical to choosing how to represent temporal relations effectively for a given scenario.

Revisiting the Evaluation for Cross Document Event Coreference

Shyam Upadhyay Nitish Gupta Christos Christodoulopoulos Dan Roth

University of Illinois at Urbana-Champaign, IL, USA

Abstract

Cross document event coreference (CDEC) is an important task that aims at aggregating event-related information across multiple documents. We revisit the evaluation for CDEC, and discover that past works have adopted different, often inconsistent, evaluation settings, which either overlook certain mistakes in coreference decisions, or make assumptions that simplify the coreference task considerably. We suggest a new evaluation methodology which overcomes these limitations, and allows for an accurate assessment of CDEC systems. Our new evaluation setting better reflects the corpus-wide information aggregation ability of CDEC systems by separating event-coreference decisions made across documents from those made within a document. In addition, we suggest a better baseline for the task and semi-automatically identify several inconsistent annotations in the evaluation dataset.

1 Introduction

Understanding events is crucial to natural language understanding and has applications ranging from question answering (Berant et al., 2014; Narayanan and Harabagiu, 2004), to causal reasoning (Do et al., 2011; Chambers and Jurafsky, 2008) to headline generation (Sun et al., 2015). The task of Cross Document Event Coreference (CDEC) determines if two event mentions (which belong to different documents) refer to the same event (Bagga and Baldwin, 1999; Bejan and Harabagiu, 2014). Figure 1 shows an example of two events whose mentions co-refer across 3 documents,

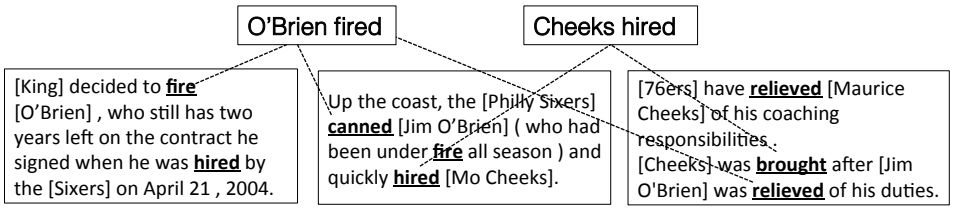

Figure 1: Event coreference across 3 documents. Event mentions are shown in **bold** and its participants are enclosed by brackets, []. Note that there are multiple **firing** events, but only a few co-refer.

An efficient CDEC system enables corpus-level aggregation of event attributes, which can prove valuable for tasks such as information extraction and aggregation (Humphreys et al., 1997; Zhang et al., 2015), topic detection and tracking (Allan et al., 1998), multi-document summarization (Daniel et al., 2003) and knowledge discovery (Mayfield et al., 2009).

In this work, we analyze whether existing CDEC evaluations reflect a system's ability to predict cross document links. Past works have adopted different evaluation methodologies which either make simplifying assumptions about the coreference task, such as ignoring singletons, or overlook certain coreference mistakes made by a CDEC system (as discussed in §4). Furthermore, under existing evaluations, a system which only predicts *within* document coreference links can score higher than a system which

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1949–1958, Osaka, Japan, December 11-17 2016.

predicts both within and cross document links. However, the latter system is clearly useful at aggregating information at corpus-level by finding across document links.

We address these issues by lifting the aforementioned assumptions, and proposing a new setting which enables accurate evaluation of the cross document coreference performance (§ 4.1). Lifting these assumptions also allowed us to semi-automatically identify several inconsistent annotations in the dataset. As the current evaluation dataset is the only available dataset with cross document coreference annotations, it is prudent to improve its annotation quality. We describe these annotation errors in § 7.3.

2 Related Work

Work on event coreference deals primarily with coreference within document, mostly building on insights gained from the entity coreference literature (Ng and Cardie, 2002; Bengtson and Roth, 2008; Lee et al., 2012; Peng et al., 2015). Recent approaches (Liu et al., 2014; Araki et al., 2014; Peng et al., 2016) have shown improvements in within document event coreference by exploiting event specific sub-structure (viz. sub-event or information propagation to arguments) and new event representations.

In comparison, cross document event coreference has been a less well-studied problem. Early work on cross document event coreference was done by Bagga and Baldwin (1999), who showed preliminary results on small exploratory datasets. To encourage research in this direction, Bejan and Harabagiu (2010) created the Event Coreference Bank (ECB), the first dataset with both within and across document event coreference annotations. ECB contained 482 documents, obtained from the Google News archive. Bejan and Harabagiu (2010) also showed encouraging results on ECB with several unsupervised Bayesian approaches. Later, ECB was augmented by Lee et al. (2012), to include entity level coreference annotations as well. On the new dataset, which they named EECB, they showed how entity and within document event coreference can benefit from making joint coreference decisions. Using EECB, Wolfe et al. (2015) formulated event coreference as an predicate alignment problem. Cybulska and Vossen (2014) noted that ECB and EECB did not have enough lexical diversity, thus oversimplifying the cross document coreference task. To get around this, they augmented the ECB corpus with 502 documents and released a larger corpus with event coreference annotations, named ECB+.

While there have been other works which use multi-modal supervision signals (Zhang et al., 2015) for CDEC, at present, ECB+ is the sole public dataset with cross document coreference annotations for events, leading to its popularity (Bejan and Harabagiu, 2014; Cybulska and Vossen, 2015; Yang et al., 2015). The most recent work using the ECB+ corpus is that of Yang et al. (2015), who developed a novel Bayesian clustering framework, which clusters event within and across documents, by modeling the clustering process as a Hierarchical Distance Dependent Chinese Restaurant Process (HDDCRP).

3 Cross Document Event Coreference

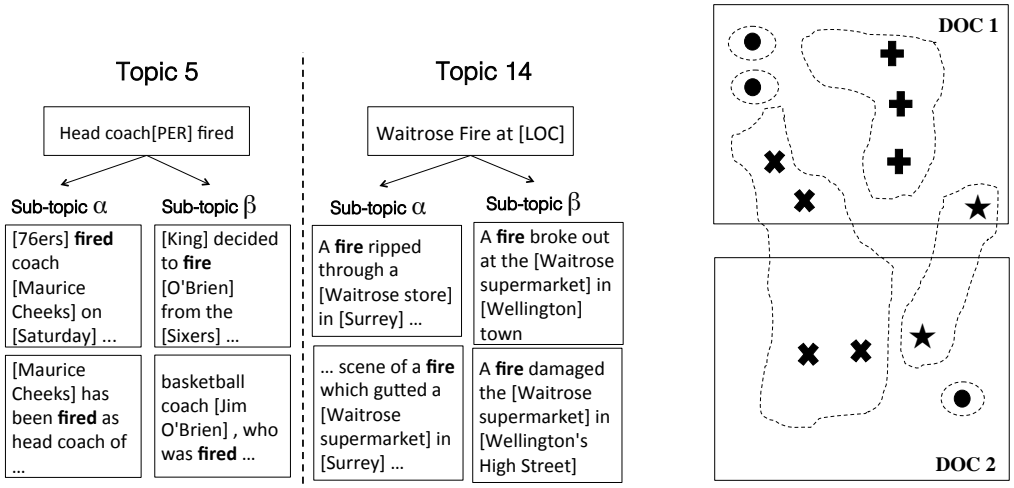
We view CDEC as a clustering task aimed at event-specific information aggregation. The clustering generated by a CDEC system allows one to examine all appearances of an event over a large corpus, shedding light on how the same event gets described in different documents.

We first describe our notation and the layout of the ECB+ dataset, and use Figures 2a and 2b to illustrate our definitions. Some statistics for the splits are shown in Table 1. We use the train, dev and test splits of Yang et al. (2015).

Event Mention A phrase which describes the action associated with an event. eg, in Figure 2a, *fired* is the event mention of the event "76ers fired coach Maurice Cheeks". We denote event mentions in **bold**.

Event Argument An event can have several arguments associated with it, describing its participants, location, or time of occurrence. eg., in Figure 2a, for the event "76ers fired coach Maurice Cheeks", "76ers" and "Maurice Cheek" are participant arguments and "Saturday" is the time argument. We collectively refer to these as the event arguments associated with the event mention (shown in [brackets]).

Event An event mention together with its arguments constitute an event, which describes an action and its arguments (location, time, participant etc.). An events in ECB+ can be in one of 3 categories:



(a) Layout of the ECB+ corpus.

(b) Event Types

Figure 2: (a) Documents in ECB+ are divided into topics and sub-topics, and coreference links can exist across documents in the same sub-topic. However, a coreference system is not aware of the topic (or sub-topic) partition at test time. (b) Coreference clusters are enclosed by a dotted line. Solid circles denote singleton mentions, solid crosses and stars denote cross document mentions, and solid plus denotes within document mentions.

(a) *Singleton Event* - an event with only one mention in the entire corpus. Shown as solid circles in Figure 2b, **(b)** *Within-Document (WD) Event* - an event with multiple mentions all of which appear in *one* document *only*. Shown as solid plus signs in Figure 2b, **(c)** *Cross-Document (CD) Event* - an event with multiple mentions spanning several documents. Shown as solid crosses and stars in Figure 2b.

Two events are *coreferent* if they represent the same situation. In particular, the text representation of the event should involve the same action and (some of the) arguments (Yang et al., 2015).

3.1 The ECB+ Corpus

In this section we discuss the specifics and layout of the ECB+ corpus.

Topics The documents in ECB+ are partitioned into several topics $\{T_1, T_2, ..., T_k\}$ each of which contains documents describing events of the same *event type*. For example, topic T_5 contains documents describing the firing of the head coach of a sports team. Figure 2a shows topics T_5 and T_{14} and the event types they described ("Head Coach [PER] fired" and "Waitrose Fire at [LOC]").

Sub-Topics A collection of documents that describe the same event within a topic, constitute a sub-topic. For example, the α sub-topic in topic 5 in Figure 2a, contains all documents describing the "firing of Maurice Cheeks", while those in the β sub-topic describe the "firing of O'Brien". Every topic T_i contains two sub-topics.[1] The documents in the β sub-topic were added by Cybulska and Vossen (2014) to increase the difficulty of the task, as a naive cross document event coreference system may incorrectly link a mention of the "O'Brien fire" event with a mention of the "Cheek fire" event.

3.2 Problem Formulation

Input: A collection of documents, each of which containing several event mentions.
Output: The system outputs an assignment of a cluster-id to each event mention, such that event mentions belonging to different documents but sharing the same cluster-id are coreferent.

Note that at test time, the CDEC system is not aware of the layout of the dataset so that it does not exploit the partitioning of documents into topics and sub-topics when making coreference decisions. As a result, a system can (incorrectly) link two event mentions across topics (or sub-topics), for which it should be appropriately penalized in evaluation. However, we will see in the next section that current evaluations do not meet this requirement.

[1] In principle, we can have more than 2 sub-topics per topic, but this does not occur in ECB+.

	Train	Dev	Test	Total
docs	462	73	447	982
topics	20	3	20	43
sub-topics	40	6	40	86
ev. mentions	5443	608	8951	14874
singleton	1866	167	5572	7605
WD	23	0	89	112
CD	3554	441	3290	7285
WD chains	2502	316	2138	4956
CD chains	691	47	479	1217

Table 1: Statistics of the ECB+ dataset. WD, CD refer to within document and cross document mentions respectively. WD (CD) Chains count the number of mention clusters that refer to the same event within (across) document(s). See text for details.

4 Evaluation Settings

All evaluation settings transform the cross document coreference problem to a within document coreference problem, by merging documents to create meta-document(s), such that cross document event coreference chains correspond to within document chains in the meta-document(s). We first revisit the evaluation settings that have been used in previous work. All these rely on the layout of the corpus, which affects their strictness.

Bejan and Harabagiu (2014) (B&H) In this case, the documents belonging to each topic are merged together to form a single meta-document $M(T_i)$. In this way, we have k meta-documents, one for each topic. Each meta-document is then evaluated separately for within document coreference, and the scores are aggregated by taking the micro-average. This evaluation is also followed by other works (Cybulska and Vossen, 2014; Cybulska and Vossen, 2015).

In this setting each topic's meta-document is evaluated in isolation, assuming that there were no coreference links made by a system across topics. However, a system can potentially link mentions across topics, as the input to the system does not describe the topic (or sub-topic) layout. As a result, this evaluation is oblivious to incorrect coreference made across topics. For example, it will ignore a (incorrect) link between the fire event mentions in topic T_5 and topic T_{14} in Figure 2a.

Yang et al. (2015) (YCF) In their case, all documents which belong to the same sub-topic (say α) of topic T_i are merged to create a meta-document $M(T_i, \alpha)$ for each sub-topic. Each such meta-document is then evaluated separately for within document coreference. In addition, all singleton event mentions are removed from the keys of all documents. [2]

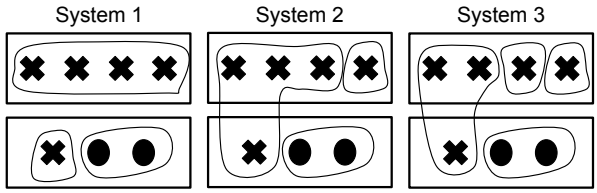
This setting implicitly makes two simplifying assumptions. First, it ignores singletons (referred to as I.S.) during evaluation, this making the coreference task considerably simpler (singletons constitute over 60% of the test mentions) as the system does not get penalized for making incorrect links to mentions of singleton events. Furthermore, by creating separate meta-document per sub-topic, this setting disregards the inclusion of documents from the β sub-topic into the corpus (see § 3), since incorrect coreference links across the sub-topics will not be penalized. This limitation (referred in Table 2 as S.T.) is similar, but more lenient, to the one in the B&H setting. (see § 7).

4.1 Our Proposals

We now discuss our proposed evaluation methodologies which address the limitations discussed above.

Proposal 1 (SIMPLE-CDEC) In this case, we merge all documents, across topics, into a single meta-document M. Unlike (Yang et al., 2015), we consider all event mentions (including singletons) in the corpus, and do not create a separate meta-document for each sub-topic, making our evaluation closer to what Cybulska and Vossen (2014) envisioned.

[2] We confirmed the YCF setting through personal communication with the authors and also examining the key and response files they provided.



(a) Enclosing rectangles denote documents, solid crosses (and circles) denote coreferent mentions of the same event (gold clustering). Polygon regions denote system response.

	MUC	B^3	$CEAF_e$	BLANC
System 1	88.8	87.0	75.5	80.5
System 2	88.8	87.0	75.5	80.5
System 3	74.9	74.9	58.3	63.7

(b) Performance of different systems as evaluated under SIMPLE-CDEC. Systems performing WD coreference are awarded equally or more than system performing CD coreference.

Figure 3: (a) Outputs of three different systems. System 1 only performs within-document (WD) coreference. System 2 and 3 performs cross-document(CD) coreference and correctly identify the cross document link of the solid cross event, but make mistake in the WD coreference. (b) SIMPLE-CDEC evaluation awards System 1 and System 2 same scores, and System 3 lower scores. Note that this issue is not limited to SIMPLE-CDEC, but also B&H and YCF.

SIMPLE-CDEC fulfills the requirement that the evaluation of a CDEC system should not be aware of the corpus layout into topics (as in ECB+) and all output links should be appropriately evaluated, unlike what is currently done in B&H and YCF. [3]

However, the SIMPLE-CDEC setting (just like B&H and YCF) does not distinguish the cross document performance from the within document performance. For example, in Figure 3a, a system which performs only within document coreference can get the same score as a system that performs both within and across document coreference (see Table 3b). However, it is desirable to have an evaluation setting that facilitates this distinction, and focuses on the ability of a CDEC system to aggregate information *across* documents in a large corpus, that is, evaluate on purely cross document coreference links. A CDEC system which performs within document event coreference only is not fully exploiting the large corpus and does not discover links between documents.

Proposal 2 (PURE-CDEC) In this setting, we first preprocess each document so that all within document mentions of the same event are reduced to a single meta-mention in that document. In this way, we discount the within document coreference links and focus on the cross document coreference links. Then, we follow the SIMPLE-CDEC setting to evaluate a single meta-document M generated from the preprocessed system response and the gold key documents.

5 Evaluation Metrics

We briefly describe the coreference evaluation metrics that are used in our experiments.

MUC (Vilain et al., 1995) A link-level metric, MUC counts the minimum number of edge-insertions or edge-deletions required to obtain the gold clustering (key) from the predicted clustering (response). A known limitation of MUC is that it does not reward a system for correctly identifying singletons.

B^3 (Bagga and Baldwin, 1998) A mention-level metric, B^3 calculates precision and recall for each mention by measuring the proportion of overlap between the predicted and gold coreference chains. The final score is an average over the scores for all mentions. Although it overcomes the limitations of MUC, it uses mentions of the same entity (coreference chain) more than once.

$CEAF_e$ (Luo, 2005) An entity-level metric which first finds an optimal alignment between entities in the key to the entities in the response by maximizing an entity similarity objective. This alignment is then used to calculate the CEAF precision and recall.

Blanc (Luo et al., 2014) First described in (Recasens and Hovy, 2011) and later extended in (Luo et al., 2014). Blanc is based on the Rand Index (Rand, 1971), and computes two F-scores, one evaluating the quality of coreference decisions (Pairwise) and another evaluating the quality of the non-coreference

[3] While evaluation should not rely on the corpus layout, we do not in any way suggest that this is the ideal approach for performing coreference. Indeed, considering coreference decisions over the entire corpus will be prohibitively expensive.

decisions (Pairwise-Negative). The Pairwise (PW) and the Pairwise-Negative (PWN) F-scores are then averaged to compute the final Blanc F-score.

Each of the above metrics have some drawbacks. B^3 and CEAF scores rapidly approach 100 if many singletons are present, and the same can drive the Blanc-PWN score to dominate the Blanc-PW score (Recasens and Hovy, 2011). This is why the entity coreference literature reports the CoNLL average, which is average of MUC, B^3 and $CEAF_e$ F-scores (Pradhan et al., 2011). Following previous work, we report CoNLL F1 and also the F-score averaged across all metrics.

Coreference Scorers For running evaluations under the YCF and B&H setting we use the standard within-document coreference scorer of Pradhan et al. (2014). However, in the SIMPLE-CDEC and PURE-CDEC setting, creating a single meta-document for the entire test split leads to a document with over 8000 mentions, which causes runtime issues for metrics like $CEAF_e$ and Blanc with Pradhan et al. (2014)'s scorer.[4] We use Hachey et al. (2014)'s scorer instead, which provides more efficient implementations.[5]

6 Baselines

We evaluate the following event coreference baseline models under the different evaluation settings,

Lemma In this model two events are coreferent if the head lemmas of their event mentions match.

Lemma-WD In this model we consider two event mentions coreferent if their head lemmas match and they belong to the same document. This is the within document variant of the Lemma model.

Lemma-δ In this model two event mentions are considered coreferent only if their head lemmas match and the *tf-idf* document similarity of the documents containing them exceeds a threshold (we use $\delta = 0.3$ after tuning on dev). For $\delta = 0$ this reduces to the Lemma baseline.

Supervised Agglomerative Clustering (SAC) Performs greedy agglomerative clustering, using a learned pairwise classifier to score if two cluster of mentions are coreferent. Inter-cluster similarity score is computed as the average of the similarity score of their mentions. Like Lemma-δ, two clusters are considered for linking if the document similarity exceeds a threshold (we use 0.3 as above).

We re-implemented the pairwise classifier of Yang et al. (2015) using the same feature set. Mention heads were found using dependency parses obtained by Stanford CoreNLP (Manning et al., 2014). We identify the Framenet (Baker et al., 1998) frame evoked by an event mention, we use the SEMAFOR (Das and Smith, 2011). For identifying the arguments for an event mention we use Illinois-SRL (Punyakanok et al., 2008). The pairwise classifier was trained using the Illinois-SL package (Chang et al., 2015).

7 Experiments

We first show the limitations of using current evaluation settings by showing how they can produce a wide range of results for the same baseline system. Next, we show the value of isolating the performance on predicting cross document coreference links. Finally, we assess the quality of the dataset and describe how we semi-automatically detected different types of annotation errors. Since we focus here on evaluation and not on developing an end-to-end CDEC system, we use the gold event mentions provided.

7.1 Comparing Evaluation Settings

We evaluate the lemma baseline under B&H, YCF, and SIMPLE-CDEC as described in §4. We aim to show that the same baseline approach can achieve highly variable results depending on the evaluation setting employed. We also isolate the effect of the two assumptions made by the YCF setting – first by creating a meta-document per sub-topic (S.T. in Table 2), and then by ignoring singletons (I.S. in Table 2) in SIMPLE-CDEC setting.

The results are shown in Table 2. Compared to SIMPLE-CDEC, all other settings assign the lemma baseline unrealistically high scores. B&H does not penalize links predicted across topics and therefore the F-score of the lemma baseline across all metrics increases. In addition to above, S.T. does not

[4]The $CEAF_e$ and Blanc evaluation did not finish after > 30 hours.

Table 3: **Comparing the baseline approaches under SIMPLE-CDEC and PURE-CDEC**. Best values in each column under different settings are shown in **bold**.

penalize cross sub-topic predictions as well, which boosts the performance further. This confirms that settings like B&H do not penalize certain incorrect coreference links by exploiting the corpus layout.

Next, we compare the settings that ignore singleton event mentions (which constitute over 60% of the test data) during evaluation. When ignoring singletons (I.S.), the F-score for all metrics improves compared to SIMPLE-CDEC. Under I.S., incorrect coreference links to singleton events are discounted, resulting in high scores. Finally, with YCF, which combines the assumptions of I.S. and S.T., the scores again improve dramatically.

This experiment clearly shows that the assumptions made by B&H and YCF lead to lenient evaluations. SIMPLE-CDEC is a more appropriate evaluation setting since it remains unaware of the corpus layout and correctly penalizes all incorrect coreference link predictions when evaluating a CDEC system.

7.2 Understanding Cross Document Coreference Performance

In this experiment we evaluate all the baselines using SIMPLE-CDEC and PURE-CDEC. The aim is to show that if we do not evaluate the cross document coreference separately, a system can exploit the evaluation by only focusing on correctly predicting within document coreference links.

The results are shown in Table 3. Lemma-WD predicts lots of singletons as it only links mention in the same document. This results in high B^3 and CEAF scores in both SIMPLE-CDEC and PURE-CDEC since over 60% event mentions in the test data are singletons.

For SIMPLE-CDEC, the lemma-WD baseline performs surprisingly well, second to the SAC model. All metrics reward Lemma-WD for identifying the within document links, which leads to the high CoNLL score. Surprisingly, its CoNLL score is slightly higher than Lemma-δ, which is a model which does both within and across linking. This is because the latter may incorrectly link some singletons across documents. Note that this behavior is not exclusive to the SIMPLE-CDEC – a system which exclusively

predicts within document links can achieve such high scores under the B&H and YCF settings.

However, we can get a clearer assessment of cross document coreference performance by evaluating the models under the PURE-CDEC setting. As this evaluation only rewards finding correct cross document links, Lemma, Lemma-δ and SAC model are the only models which get non-zero MUC and Blanc-PW scores. As a result, the Lemma-WD average F-score drops considerably (by almost 10%) in comparison to the Lemma-δ and SAC model (around 6%), revealing that these models indeed do better cross document coreference. It is evident that to accurately assess the cross document coreference performance, we should report *both* PURE-CDEC and SIMPLE-CDEC results.

It should be noted that Lemma performs worse than Lemma-WD because it makes incorrect cross document links, due to the naive nature of the lemma match. On the other hand, Lemma-WD does not make *any* across document links, avoiding incurring these penalties. It gets rewarded for "identifying" singletons as described earlier in SIMPLE-CDEC. This conservative nature of Lemma-WD gets better average scores than Lemma, even in the PURE-CDEC setting. Overall, SAC and Lemma-δ are the two best models in Table 3.

Choice of Baseline Besides the aforementioned insights, Table 3 offers a better choice of baselines. Bejan and Harabagiu (2014) and Yang et al. (2015) claimed that Lemma is a strong baseline for CDEC. We believe that this claim held in these works only due to the lenient evaluation settings of B&H and YCF, which did not appropriately penalize the incorrect across topic (and sub-topic) links made by the Lemma baseline. However, the SIMPLE-CDEC and PURE-CDEC evaluations show that Lemma-δ is a stronger baseline. For future comparisons, using Lemma-δ as a baseline is more appropriate.

7.3 The Annotation Quality of ECB+

Evaluating with singletons also helped in discovering annotation errors in the dataset. In addition to identifying annotation errors, as described below, we found that several documents were partially annotated,[6] which is consistent with a similar observation made in (Liu et al., 2014).

We used the approach of Goldberg and Elhadad (2007) to semi-automatically detect annotation errors, by training an anchored SVM. First, for each pair of mention (m_i, m_j) in the training data, we added a unique anchor feature a_{ij}, thus making the data linearly separable. Next, we trained a SVM classifier on all of the data with a high penalty parameter C. The classifier uses the anchor features to memorize the hard to classify examples, which are either genuine hard coreference pairs, or incorrect annotations. By thresholding the features weights for the anchor features $|a_{ij}| > \delta$ (we use $\delta = 0.95$), we generated a short-list of these hard cases, which we then examined by a annotator for mistakes. The errors we found can be categorized as one of:

Missing Singleton-to-Singleton Link Two gold event mentions which should have been marked as coreferent, but were marked as singletons. For example:

Aceh was hit extremely hard by the massive Boxing Day **earthquake** and **tsunami** in 2004, killing 170,000 people
A massive **quake** struck off Aceh in 2004 , sparking a **tsunami** that killed 170,000 people ...

Both mention pairs (*earthquake*,*quake*) and (*tsunami*,*tsunami*) refer to the same event, but their coreference links were missing in the annotation. Both the enclosing documents belong to the same topic.

Missing Singleton-to-Cluster Link A singleton event mention which should have been linked to an existing cluster of mentions describing the same event.

LaRue , a Mississippi oil heir who became the first person found guilty of participating in the **Watergate** coverup
... strategy for capturing Southern votes and then a significant participant in the **Watergate scandal** .

The *Watergate scandal* mention is marked as singleton. However, the watergate scandal event appears in several other documents to which the *Watergate* mention is marked as being coreferent. Again, both the mentions belong to documents in the same topic.

We found over 300 such annotation errors which were incorrectly not linking singleton mentions. The list of errors detected is available at `http://cogcomp.cs.illinois.edu/page/publication_view/801`.

[6]For example, Only 5 sentences out of 40 in a document were marked with events.

8 Conclusion

Accurate evaluation and high-quality annotations are crucial to our ability to measure progress in any task. We showed that past work for CDEC have resorted to widely different evaluation approaches, making several implicit assumptions, which simplify the coreference task and lead to overlooking coreference mistakes. In particular, as we showed, excluding singleton mentions from the evaluation does not seem justified. Furthermore, current evaluation methods heavily rely on the corpus being organized into topics and sub-topics, but this may not always be available, especially for evaluation corpora. To accurately measure CDEC performance, it is necessary to drop these assumptions. We recommend that future evaluations report results using both SIMPLE-CDEC and PURE-CDEC settings.

Beyond these assumptions, the annotations in the current dataset are incomplete in several respects. Indeed, we showed that over 300 annotation errors in the dataset can be detected semi-automatically, and also noted that many documents were partially annotated. As this dataset is presently the only dataset with cross document coreference annotations for events, such annotation errors make evaluation difficult. We believe that to correctly evaluate this task and make progress, efforts must be made to create thoroughly annotated datasets with high quality annotations.

Abstract

This study proposes a computational model of the discourse segments in lyrics to understand and to model the structure of lyrics. To test our hypothesis that discourse segmentations in lyrics strongly correlate with repeated patterns, we conduct the first large-scale corpus study on discourse segments in lyrics. Next, we propose the task to automatically identify segment boundaries in lyrics and train a logistic regression model for the task with the repeated pattern and textual features. The results of our empirical experiments illustrate the significance of capturing repeated patterns in predicting the boundaries of discourse segments in lyrics.

1 Introduction

Lyrics are an important element of popular music. They provide an effective means to express the message and emotion of music. Similar to prose text, lyrics are a discourse: i.e., they are, typically, a sequence of related lines, rather than an unconnected stream of lines of arbitrary order. Thus, like texts, lyrics also have a discourse structure consisting discourse segments. Each discourse segment exhibits an individual topic in discourse, and the transition of topics over successive discourse segments constitutes a flow (Austin et al., 2010; Watanabe et al., 2014). Unlike prose text, lyrics have their own peculiar properties, such as frequent repetition of identical or similar phrases and extensive use of rhyme and refrain (Austin et al., 2010), as illustrated in Figure 1. Analogous to prose text, the lyrics in Figure 1 can be viewed as a sequence of discourse segments, wherein each segment is depicted by a colored box. Segments ① and ③ appear repeatedly (e.g., segments ④ and ⑧ are identical to segment ①), which is not typically observed in prose text.

Our goal is to reveal the discourse structure of lyrics in popular music by quantitatively analyzing a large-scale lyrics corpus. The motivations behind the goal are as follows. First, there are hardly any studies that have focused on the data-oriented research of the discourse structure of lyrics; however, multiple studies have focused on the structure of music audio (Paulus et al., 2010, for a review). Second, a better understanding of the nature of lyrics structure combined with the existing theories of music audio could lead to a more comprehensive theory of the overall nature of popular music. Third, understanding the nature of lyrics structure will allow us to devise a variety of useful computer systems, such as systems that automatically generate lyrics, assist human lyrics writers, or evaluate the quality of lyrics.

As a first but crucial step toward achieving this goal, this study explores the nature of the discourse structure of lyrics with a focus on the rbyof repeated patterns as an indicator of segment boundaries. We choose discourse segments as our primary focus because exploring discourse segments is a necessary step toward a comprehensive understanding of lyrics structure. To address this issue, we consider the task of computationally predicting the boundaries of discourse segments in lyrics under the assumption that a better prediction model would allow us to better understand the nature of the discourse structure of lyrics.

By conducting a large-scale data analysis, we examine our primary hypothesis that *discourse segments in lyrics strongly correlate with repeated patterns*. For example, if a sequence of lines in lyrics has a

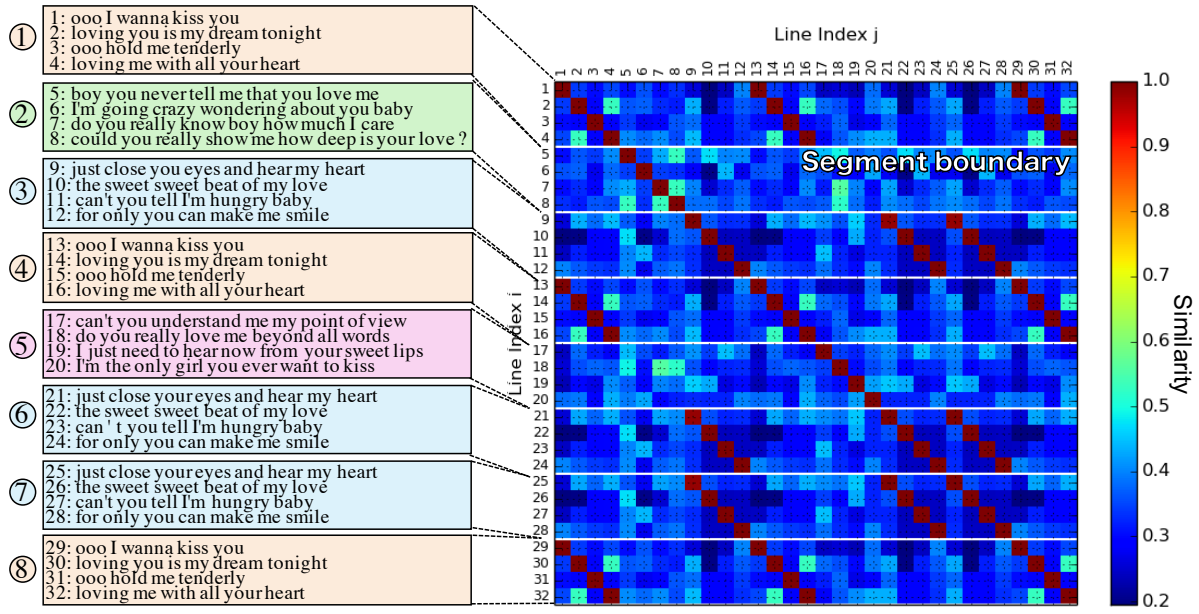

Figure 1: An example of lyrics and corresponding self-similarity matrix (title of lyrics: *How Deep Is Your Love?* (RWC-MDB-P-2001 No. 81 from RWC Music Database (Goto et al., 2002)))

repetition, such as *abcdefabc* (each letter represents a line, with repeated letters being repeated lines), we expect the boundaries of the discourse segments tend to agree with the boundaries of the repeated parts as in |*abc*|*def*|*abc*|, where "|" indicates a boundary.

To examine the extent to which these repeated patterns capture the segment structure of lyrics, we use a large-scale corpus of popular music lyrics that contains more than 140,000 songs. This is, to the best of our knowledge, the first study that takes a data-driven approach to exploring the discourse structure of lyrics in relation to repeated patterns.

One issue to be addressed before conducting the corpus study is that no existing corpus has annotated the discourse structure of lyrics. In this study, we preliminarily assume that discourse segment boundaries are indicated by empty lines inserted by lyrics writers. We admit that empty lines may not be "true" discourse segment boundaries and discourse segments may exhibit a hierarchical structure (e.g., verse–bridge–chorus structure). These issues could be better addressed by combining the analysis of the discourse structure of lyrics with the structural analysis of music. We believe this direction of research will open an intriguing new field for future exploration.

The remainder of this study is organized as follows. Section 2 reviews related work into the discourse structure of lyrics, with particular focus on the segmentation using repeated patterns. Section 3 presents the first quantitative analysis of the distribution of repeated lines and segments in lyrics and suggests cues that could help to identify the segment boundaries. Section 4 describes our computational model, which predicts the boundaries of discourse segments in lyrics using repeated patterns. Section 5 presents experimental results that show the importance of repeated patterns in predicting the boundaries of discourse segments in lyrics. Section 6 concludes and discusses future work. Note that throughout this study, we use the term *segment* to refer to a discourse segment in lyrics.

2 Related work

This section reviews related work into the discourse structure of lyrics, with particular focus on the segmentation of lyrics using repeated patterns.

Text segmentation is a classic text retrieval problem, and there exists a rich body of research into text segmentation in natural language processing. Various linguistic cues have been suggested to identify text boundaries such as expressions that frequently appear at the end of segments (Beeferman et al., 1999), contextual/topical changes (Choi, 2000; Malioutov and Barzilay, 2006; Riedl and Biemann, 2012),

and word/entity repetition (Kan et al., 1998; Reynar, 1999).

Although we share the same motivation as these studies, these text segmentation methods do not consider repeated patterns of phrasal segments because this type of repetition is nearly always absent in prose text. On the other hand, segments in lyrics often have repetitions (Austin et al., 2010) as shown in Section 3.1. We aim to capture the segment structure of lyrics using repeated patterns.

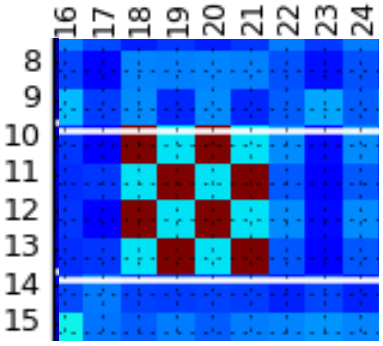

Figure 2: Negative example against pattern (1)

Previous computational work into lyrics segmentation has focused on identifying the segment labels of lyrics that are already segmented. For example, the structure of lyrics can be represented using labels A–B–C–A–B in which each letter refers to a group of lines; e.g., A might represent a chorus that appears twice. Barate et al. (2013) proposed a rule-based method to estimating such structure labels of *segmented* lyrics. Our task differs from this task in that we aim to estimate the segment boundaries of *unsegmented* lyrics using machine learning techniques.

In contrast to the segmentation of lyrics, much previous work has analyzed and estimated the segment structure of music audio signals using repeated musical parts such as verse, bridge, and chorus (Foote, 2000; Lu et al., 2004; Goto, 2006; Paulus and Klapuri, 2006; McFee and Ellis, 2014). To automatically identify these repeated musical parts in music audio signals, a self-similarity matrix (SSM) as shown in Figure 1 is often used. Repeated segments lead to high-valued lines in the off-diagonals of the matrix, and these patterns are used to identify the structure. To capture segments in lyrics using repeated patterns, we apply the SSM to lyrics. Lyrical repetition is known to be an important property of lyrics (Austin et al., 2010), and we expect that repetition patterns would also appear in lyrics as they do in audio signals.

In summary, no previous computational work has exactly focused on the segmentation of lyrics using repeated patterns. Section 3 presents the first quantitative analysis of the distribution of repeated lines and segments in lyrics, and suggests cues that help identify segment boundaries.

3 Statistics of repeated patterns and segment boundaries

As an initial step toward modeling the discourse structure of lyrics, we examine the distribution of segments in lyrics by focusing on repeated patterns. We first show the basic distributions of lyrics and suggest potential cues to indicate segment boundaries in lyrics. To examine the distribution of repeated patterns in lyrics and their relation to segment boundaries, we use a large scale lyrics database that contains 144,891 songs[1].

3.1 The basic distribution of lyrics

Among the 144,891 songs in the lyrics database, there are 5,666,696 lines and 969,176 segments in total, with segment breaks inferred from empty lines. Per song, there are 39.11 lines and 6.69 segments on average. Most songs have at least one repeated line (84.79% using an exact criterion; 90.34% using a lenient matching criterion of normalized edit distance ≥ 0.8, explained in the next section). A fair number of songs also have at least one repeated segment (exact match: 37.73%, lenient match: 54.57%). Per song, 13.73 lines and 0.52 segments (both exact match) are repeated at least once on average. These distributions show that repetition of lines and segments occurs frequently in lyrics, in line with our expectations. Next, we suggest potential repeated patterns to help in identifying segment boundaries.

3.2 Correlation between repeated patterns and segment boundaries

To examine what kinds of repeated patterns would help identify segments in lyrics, we use the SSM, similar to previous work into the segmentation of music audio signals (Section 2). Figure 1 shows an example SSM. Throughout this study, we represent the i^{th} line in lyrics as l_i ($1 \leq i \leq L$), where L is the number of lines of the lyrics. A degree of similarity between l_i and l_j, i.e., $\text{sim}(l_i, l_j)$, is represented

	P(Boundary does not appear | within a diagonal line)	**0.9273** (751195/810098)
Pattern (3)	P(Adjacent lines appear within a segment)	0.8507 (4697520/5521806)
	P(Adjacent lines appear within a segment | adjacent lines are similar)	**0.9439** (218524/231518)
Pattern (4)	P(Boundary appears after l_i)	0.1455 (824286/5666696)
	P(Boundary appears after l_i | l_i is similar to the last line of lyrics)	**0.4230** (125659/297069)
	P(Boundary appears after l_i | l_{i+1} is similar to the first line of lyrics)	**0.4189** (46531/111079)

Table 1: Correlation between each repeated pattern and segment boundary

as an intensity at a cell where the i^{th} row and j^{th} column overlap. Using the normalized edit distance $\text{NED}(l_i, l_j)$, we compute the degree of similarity (Yujian and Bo, 2007): $\text{sim}(l_i, l_j) = 1 - \text{NED}(l_i, l_j)$. The red diagonal lines in Figure 1 are the result of exact line repetitions [2]. The white horizontal lines in Figure 1 indicate the true segment boundaries.

After manually examining more than 1,000 lyrics and their SSMs, we suggest the following four types of repeated patterns as indicators of segment boundaries.

(1) The Start and end points of a diagonal line are segment boundaries. Some repeated segments correspond to the red diagonal lines. For example, in Figure 1, segment ① is repeated twice (segments ④ and ⑧), and each repetition ,starting at l_{13} and l_{29}, can be observed as a diagonal line from l_1 to l_4. This suggests that some segments could be divided at the start and end points of such a diagonal line.

(2) A segment boundary does not appear within a diagonal line. This is related to (1). A segment boundary does not normally appear within a diagonal line because each diagonal line often corresponds to a segment.

(3) Similar adjacent lines appear within a segment. Line-level repetitions that are adjacent, such as rhymes and refrains, tend to occur within a segment. For example, line l_7 rhymes internally with l_8 where these lines appear within a segment because $\text{sim}(l_7, l_8)$ indicates moderate similarity.

(4) A line similar to the first or last line of a song is an indicator of a segment boundary. Lines similar to the first or last line of lyrics tend to be repeated at segment boundaries. For example, in Figure 1, the first and last lines of the song, i.e., l_1 and l_{32}, are exactly the same as the first and last lines of segments ④ and ⑧. This is because the first and last lines of lyrics tend to be part of a chorus section that is often repeated throughout the lyrics.

To examine the extent to which these four patterns correlate with segment boundaries, we compute the prior and conditional probabilities of each pattern using the full lyrics database. Table 1 shows that all conditional probabilities are greater than their corresponding prior probabilities. These results suggest that the above repeated patterns reasonably capture segment boundaries, supporting the use of repeated patterns for modeling the segment structure of lyrics.

Note that pattern (1) does not hold for many cases. Figure 2 illustrates a typical negative example against pattern (1). This figure includes three diagonal lines, but the shorter lines do not agree with a segment boundary at either end. Similar cases are abundant partly because even a repetition of a single line is identified as a diagonal line in this experiment. This problem implies that a single occurrence of our local repeated pattern is not a sufficient clue for identifying a segment boundary. The conflict between patterns (1) and (2) is also shown in Figure 1, where a segment boundary implied by pattern (1) bisects a diagonal line from (l_{25}, l_9) to (l_{32}, l_{16}), which goes against pattern (2). This motivates us to build a machine learning-based model to capture combinations of multiple clues. The subsequent section describes how we represent these repeated patterns as features for predicting segment boundaries.

[2]The diagonal line of $\text{sim}(l_i, l_i)$ is ignored for analysis because it conveys no information.

4 Computational modeling of segment patterns in lyrics

To confirm the validity of our four repeated patterns for segment structures, we address the novel task of detecting segment boundaries in lyrics. Given the lyrics of a song where all segments are concatenated (no empty lines), the task is to identify the segment boundaries of the lyrics reproducing the empty lines. We formalize this task as a binary classification problem to predict the end ($y = 1$) or continuation ($y = 0$) of a segment between lines l_i and l_{i+1}. We model the conditional probability $p(y|i)$ using logistic regression with two different types of features: (1) *repeated patterns in lyrics* and (2) *textual expressions appearing at the line boundaries*.

4.1 Repeated patterns

We propose four subtypes of repeated pattern features (RPF1, RPF2, RPF3, and RPF4) corresponding to the four hypotheses presented in Section 3.2. Here, matrix M denotes the SSM of the lyrics. Each element $m_{i,j}$ represents the similarity between lines l_i and l_j, i.e., $m_{i,j} = \mathrm{sim}(l_i, l_j)$.

RPF1 The first repeated pattern (*the beginning or end point of a diagonal line in an SSM is a clue for a segment boundary*) is formalized as follows. Given two lines i and j, we expect that there exists a boundary after both of these lines if the lines are similar/dissimilar, but $i + 1$ and $j + 1$ are opposite (dissimilar/similar). For a given line i, Equation 1 enumerates a set of lines j ($1 \leq j \leq L$) where there may be boundaries after line i and every line j:

$$g_\lambda(i) = \{j \mid (m_{i,j} - \lambda)(m_{i+1,j+1} - \lambda) < 0\} \tag{1}$$

Here, λ is a threshold for detecting similarity and dissimilarity. The left side of Figure 3 illustrates four likely boundaries for line $i = 24$ with the threshold $\lambda = 0.6$: $g_{0.6}(24) = \{8, 12, 20, 28\}$.

Using the function $g_\lambda(i)$, we define feature functions $f_\lambda^{(\mathrm{RPF1\#})}(i)$ and $f_\lambda^{(\mathrm{RPF1v})}(i)$ that assess how likely it is that line i is located at the beginning or end points of diagonal lines in the SSM:

$$f_\lambda^{(\mathrm{RPF1\#})}(i) = |g_\lambda(i)| \tag{2}$$

$$f_\lambda^{(\mathrm{RPF1v})}(i) = \frac{1}{|g_\lambda(i)|} \sum_{j \in g_\lambda(i)} |m_{i,j} - m_{i+1,j+1}| \tag{3}$$

To sum up, $f_\lambda^{(\mathrm{RPF1\#})}(i)$ counts the number of likely boundaries after line i and other lines j, and $f_\lambda^{(\mathrm{RPF1v})}(i)$ computes the mean of the similarity differences at likely boundaries after line i and other lines j. We define multiple features with different threshold values λ.

RPF2 The second repeated pattern (*a segment boundary does not appear inside of a diagonal line of an SSM*) is formalized analogously to RPF1. Given two lines i and j, we expect that lines i and j are *points of continuity* if lines i and j are similar and $i + 1$ and $j + 1$ are also similar. For a given line i, Equation 4 enumerates a set of lines j ($1 \leq j \leq L$) where i and j are points of continuity:

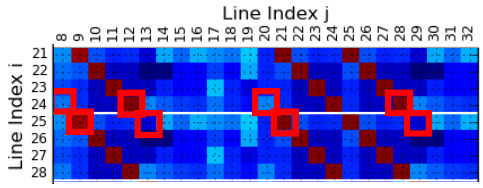
$$c_\lambda(i) = \{j \mid m_{i,j} \geq \lambda \wedge m_{i+1,j+1} \geq \lambda\} \tag{4}$$

The middle of Figure 3 shows an example of continuous points (here, $c_{0.6}(10) = \{22, 26\}$ in this example).

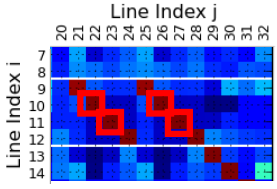
Similar to RPF1, Equations 5 and 6 count the number of continuous points and the mean of the similarity differences at continuous points, respectively.

$$f_\lambda^{(\mathrm{RPF2\#})}(i) = |c_\lambda(i)| \tag{5}$$

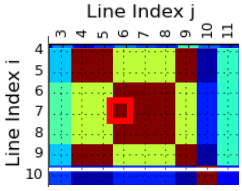
$$f_\lambda^{(\mathrm{RPF2v})}(i) = \frac{1}{|c_\lambda(i)|} \sum_{j \in c_\lambda(i)} |m_{i,j} - m_{i+1,j+1}| \tag{6}$$



Some diagonal lines end at line 24 and begin at line 25. A segment boundary is likely to appear between lines 24 and 25.



Two diagonal lines span over lines 9 to 12. Lines 9 to 12 are not likely to divide.



Lines 6 and 7 are similar. A segment boundary is unlikely to appear between lines 6 and 7.

Figure 3: Repeated pattern features: RPF1, RPF2, and RPF3

TF2_Uni-gram(-3) = "UH"	TF2_Bi-gram(-2) = "UH_UH"	TF2_Tri-gram(-2) = "UH_UH_SYM"
TF2_Uni-gram(-2) = "UH"	TF2_Bi-gram(-1) = "UH_SYM"	TF2_Tri-gram(-1) = "UH_SYM_PRP"
TF2_Uni-gram(-1) = "SYM"	TF2_Bi-gram(0) = "SYM_PRP"	TF2_Tri-gram(1) = "SYM_PRP_VBP"
TF2_Uni-gram(1) = "PRP"	TF2_Bi-gram(1) = "PRP_VBP"	TF2_Tri-gram(2) = "PRP_VBP_PRP"
TF2_Uni-gram(2) = "VBP"	TF2_Bi-gram(2) = "VBP_PRP"	
TF2_Uni-gram(3) = "PRP"		

Textual Feature 2 (TF2): 15 Part of speech N-grams

Figure 4: Textual features: TF1 and TF2

RPF3 (similarity with a subsequent line) RPF3 encodes the third repeated pattern, i.e., similar adjacent lines belong to the same segment. For a given line index i, this is quantified by the similarity $\mathrm{sim}(l_i, l_{i+1})$:

$$f^{(\mathrm{RPF3})}(i) = m_{i,i+1} \tag{7}$$

The right of Figure 3 shows an example where RPF3 indicates a continuation between lines 6 and 7.

RPF4 (similarity with the first and last lines) The fourth repeated pattern (i.e., *a line similar to the first line of the lyrics is likely to be the first line of a segment*, and *a line similar to the last line of the lyrics is likely to be the last line of a segment*) is encoded by two feature functions $f^{(\mathrm{RPF4b})}(i)$ and $f^{(\mathrm{RPF4e})}(i)$:

$$f^{(\mathrm{RPF4b})}(i) = m_{i,1} \tag{8}$$

$$f^{(\mathrm{RPF4e})}(i) = m_{i,n} \tag{9}$$

4.2 Textual expressions

Some textual expressions appear selectively at the beginning or end of a segment. For example, the phrase "So I" often appears at the beginning of a line but rarely appears at the beginning of a segment. To exploit such indications of the beginnings/ends of lines, we propose two textual features (TF1 and TF2).

TF1 (word n-grams at a line boundary) A phrase like "oh oh !!" tends to appear at the end of a segment. In contrast, a phrase like "I'm sorry" may appear at the beginning of a segment. Previous work on sentence boundary estimation has often used n-grams to detect segment boundaries (Beeferman et al.,

Method	P_k (%)	WD (%)	Precision (%)	Recall (%)	F-measure (%)

Table 2: Results of ablation tests

1999). Thus, we define word n-gram features (for $n = 1, 2, 3$) around a line boundary. More specifically, we define 15 n-gram features at different positions, listed and illustrated with an example in Figure 4.

TF2 (part of speech n-grams around a line boundary) Parts of speech (POS), such as *particles* or *determiners* do not tend to appear at the end of a sentence, and *conjunctions* do not appear at the beginning of a sentence. We exploit these tendencies by defining features for POS. Similar to TF1, we define POS n-gram features (for $n = 1, 2, 3$) around a line boundary. Specifically, we define 15 POS n-gram features at different positions, as shown in Figure 4.

5 Experiment

We sampled 105,833 English songs from the Music Lyrics Database v.1.2.7 so that each song contains at least five segments. The resulting dataset includes 2,788,079 candidate boundaries and 517,234 actual boundaries. We then split these songs into training (60%), development (20%), and test (20%) sets. For feature extraction, we used the Stanford POS Tagger (Toutanova et al., 2003). To train the segment boundary classifiers, we used the Classias implementation (Okazaki, 2009) of L2-regularized logistic regression. By employing multiple threshold values of λ from 0.1 to 0.9 with a step size of 0.1, we used them all together.

5.1 Performance evaluation metrics

We used two sets of metrics to evaluate the performance of each model for the task. One was standardly used in audio music segmentation, i.e., the precision, recall, and F-measure of identifying segment boundaries. Precision is the ratio of correctly predicted boundaries over all predicted boundaries, recall is the ratio of correctly predicted boundaries over all true boundaries, and F-measure is the harmonic mean of precision and recall. The other set was standardly used in text segmentation literature: P_k (Beeferman et al., 1999) and WindowDiff (*WD*) (Pevzner and Hearst, 2002). P_k is the probability of segmentation error that evaluates whether two lines l_i and l_j in lyrics fewer than k lines apart are incorrectly concatenated or divided by a segmentation model. P_k is considered a more suitable measure than F-measure in text segmentation because it assigns partial credit to nearly correct estimations. *WD* is a variant of P_k that resolves a problem of P_k by penalizing false positives. We set the window size k of P_k and *WD* to

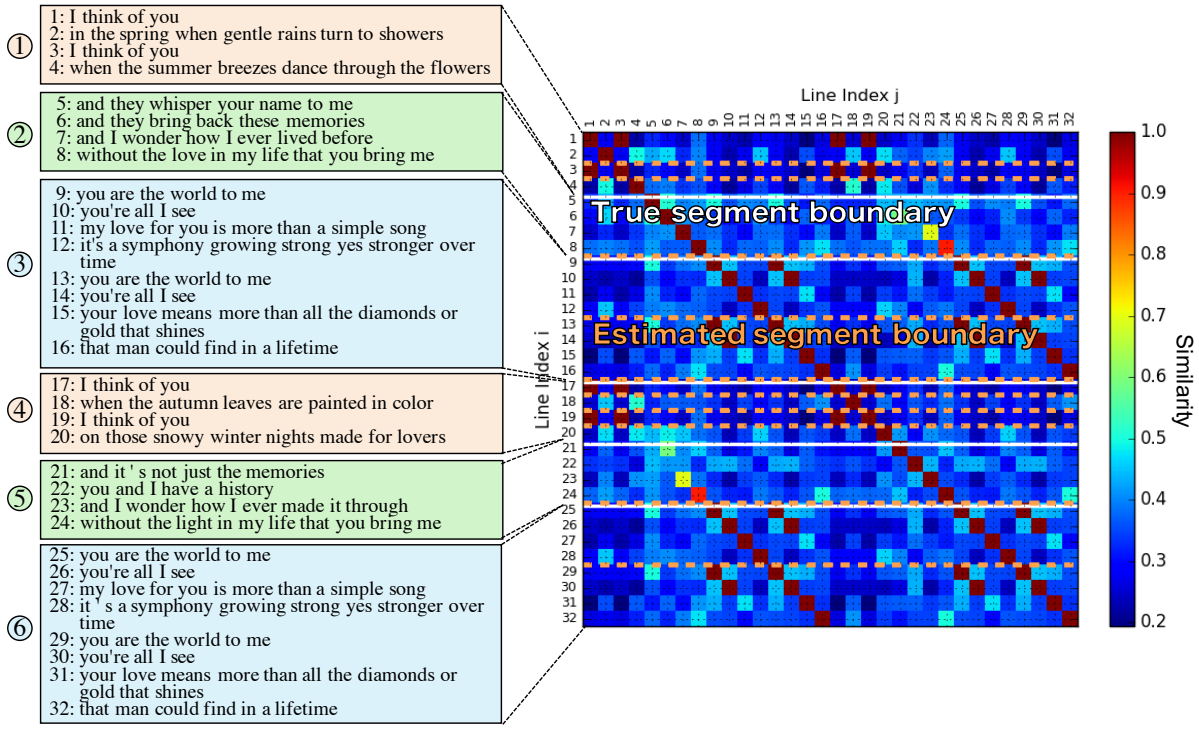

Figure 5: Examples of false positives (title of lyrics: *I think of you* (RWC-MDB-P-2001 No.87 from RWC Music Database (Goto et al., 2002))). White horizontal lines indicate true segment boundaries. Orange horizontal dashed lines indicate predicted boundaries.

one-half the average line length of the correct segments for each song in the test set.

5.2 Contributions of different features

We investigated the contribution of each feature set by conducting ablation tests over different combinations of feature sets. The results are shown in Table 2. **Random** denotes our baseline, a model selecting boundaries with uniform probability $P = 0.186$, the true frequency of boundaries ($P = 517,234/2,788,079$). RPF$*$ and TF$*$ denote the models with all repeated pattern features and all textual features, respectively. **Proposed** indicates the performance of the model with all proposed features. At the top of Table 2, the F-measure of the proposed method was 58.44, or 45 points higher than that of the random baseline.

The results of the ablation tests are shown in the bottom of Table 2. For example, "$-$RPF1" indicates that we ablated the feature RPF1 from the proposed method, which uses all of the features. Our best-performing model achieved an F-measure of 59.24 by excluding the TF1 unigram and bigram and TF2 trigram features.

The table shows that each type of our RPF features contributes to performance. Note that these four types are not redundant, and each of our hypotheses yielded positive results. Note that removing RPF1 and RPF2, which are intended to capture long-range repeated patterns, decreased the F-measure by 6.92 and 5.45 points, respectively. This result supports the hypothesis that sequences of repeated lines (diagonal lines in the SSM) are important clues for modeling lyrics segmentation.

In contrast to results reported in text segmentation literature (Beeferman et al., 1999), TF features turned out to be ineffective for lyrics segment boundary estimation, except for TF2 unigram features. One possible reason is that there is a larger variety of expressions used at the beginning or end of a segment in lyrics compared with prose texts. Still, the inclusion of some textual features did lift the performance of the RPF* model by nearly 2 points. Further investigation of TF features is left for our future work.

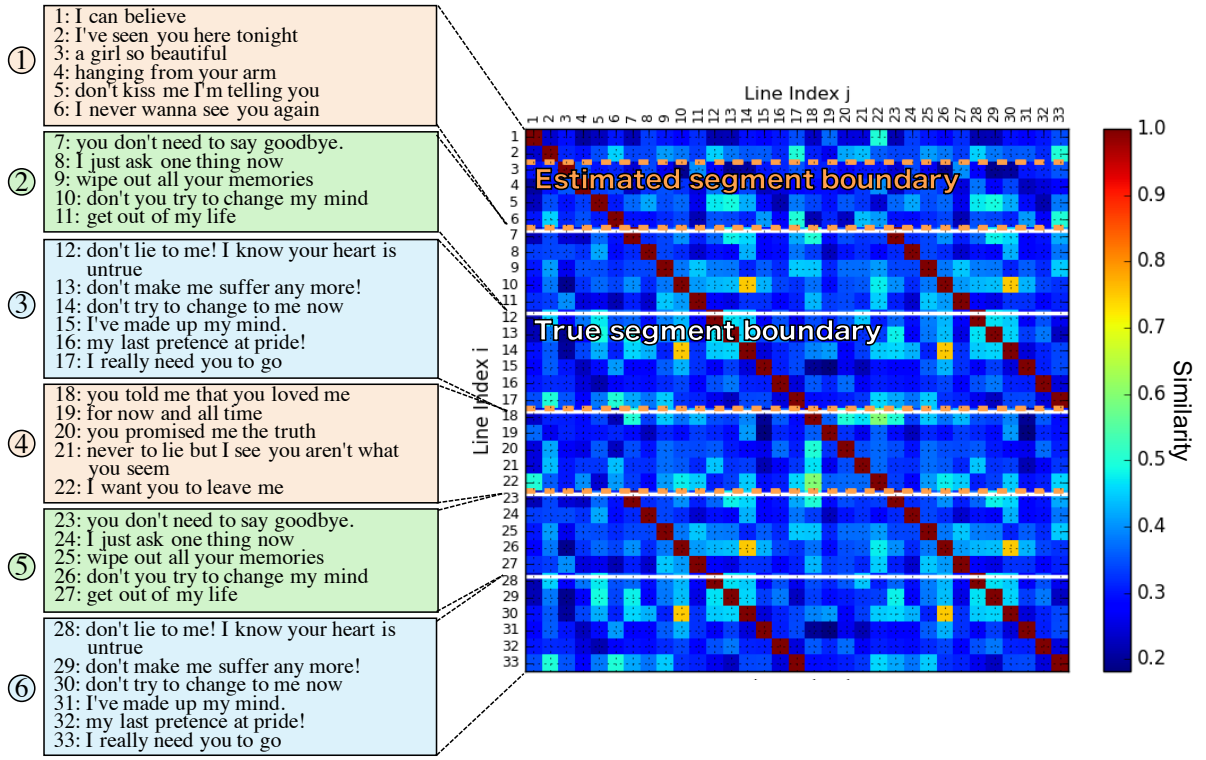

Figure 6: Examples of false negatives (title of lyrics: *Don't lie to me* (RWC-MDB-P-2001 No.97 from RWC Music Database (Goto et al., 2002))). White horizontal lines indicate true segment boundaries. Orange horizontal dashed lines indicate predicted boundaries.

5.3 Error analysis

Figures 5 and 6 give two examples of lyrics and SSMs that illustrate typical errors of our best model. Horizontal dashed lines depict predicted boundaries. As shown in Figure 5, the model sometimes overly divides a true segment into segments as small as single lines, false positives that appear to be due to occurrences of repeated single lines (here, lines 1, 3, 17 and 19). This is not a trivial problem because repetitions of single lines sometimes serve as an important clue. In fact, when restricting diagonal lines to be of the length of two or more lines, we considerably lose recall while gaining precision. More investigation is needed for further improvement.

In contrast to the case of Figure 5, Figure 6 shows a typical example of false negatives. We missed a boundary between, for example, lines 11 and 12. For this boundary, we cannot find any clear repeated pattern indicator. Such cases suggest a limitation of repeated pattern features and the need for further refinement of the model. One direction is to incorporate semantics-oriented state-of-the-art techniques for prose text segmentation such as topic tiling (Riedl and Biemann, 2012).

6 Conclusion and future work

This study has addressed the issue of modeling discourse segments in lyrics in order to understand and model the discourse-related nature of lyrics. We first conducted a large-scale corpus study into the discourse segments of lyrics, in which we examined our primary hypothesis that discourse segmentations strongly correlate with repeated patterns. To the best of our knowledge, this is the first study that takes a data-driven approach to explore the discourse structure of lyrics in relation to repeated patterns. We then proposed a task to automatically identify segment boundaries in lyrics and explored machine learning-based models for the task with repeated pattern features and textual features. The results of our empirical experiments show the importance of capturing repeated patterns in predicting the boundaries of discourse segments in lyrics. In future, we plan to refine the model further by incorporating topic/semantic

information, to extend the modeling of lyric discourse by combining it with audio musical structure, and to embed a resulting model into application systems, such as lyrics generation systems and lyrics composition support systems.

Abstract

In this paper we focus on the problem of dialog act (DA) labelling. This problem has recently attracted a lot of attention as it is an important sub-part of an automatic dialog model, which is currently in great demand. Traditional methods tend to see this problem as a sequence labelling task and deal with it by applying classifiers with rich features. Most of the current neural network models still omit the sequential information in the conversation. Henceforth, we apply a novel multi-level gated recurrent neural network (GRNN) with non-textual information to predict the DA tag. Our model not only utilizes textual information, but also makes use of non-textual and contextual information. In comparison, our model has shown significant improvement over previous works on the Switchboard Dialog Act (SWDA) data by over 6%.

1 Introduction

Dialog act labelling is one of the ways to find the shallow discourse structures of natural language conversations. It represents the meaning or intention of each short sentence within a conversation by giving a tag to each sentence (Austin and Urmson, 1962; Searle, 1969). DA can be of help to many tasks, for example, the DA of the current sentence provides very important information for answer generation in an automatic question answering system. This converts a complex system into a classification problem, enabling many existing systems to fit in the problem.

Traditional methods apply classifiers with rich human-crafted features to tag the sentences. One can view each sentence in the dialog as a separate one and label it accordingly, such as the work of (Silva et al., 2011), but this results in the loss of sequential information in the conversation context. Stolcke et al. (2000) used a segmented version of switchboard dialog act (SWDA) (Godfrey et al., 1992) with 43 tags based on the DAMSL labelling system , and proposed to use a hidden Markov model with rich features to predict the DA of each sentence. Although their model produces relatively good results, the feature construction and tuning consume too much human effort, and also make the adaptation between tasks difficult.

Using the deep learning framework, researchers have developed various systems to deal with DA and related problems like sentiment analysis and sentence classification. One can build a simple CNN architecture like Kim (2014) to do the labelling work. However, the sentences in a conversation are highly variant in length, some of which can be as short as one to two words or may even include nothing but some telephone script symbols. For example, a lot of sentences consist of nothing but "<*laughter*>." and "*Okay*". To be specific, in the SWDA data, 3,253 sentences consist of a single word and the length of 41.4% sentences are under 5 words. Figure 1 shows the distribution of sentence lengths in detail. As is shown in the figure, most of the sentences (61%) are under 10 words, which implies that a significant portion of the overall accuracy can be attributed to short sentences.

Most of previous models tend to do poorly on these extremely short sentences because of the lack of information. To deal with short texts, one must uncover more information, such as context sentences,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1970–1979, Osaka, Japan, December 11-17 2016.

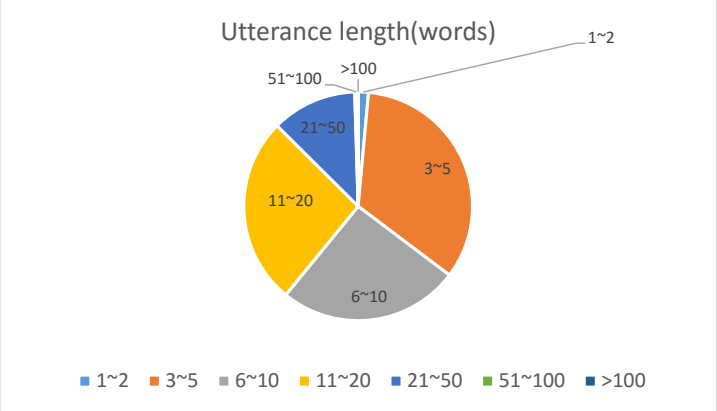

Figure 1: Sentence length distribution in the SWDA corpus

to facilitate the labelling process. In fact, the most important character of DA labelling that is different from simple sentence classification is that utterances appear sequentially in a conversation. Lee and Dernoncourt (2016) tried to make use of historical information by feeding previous sentences in a fixed window together with the current one to a feed forward neural network. This makes a good attempt in applying contextual information. However, this approach loses long distance dependency, thus giving very little improvement when compared with the CNN baseline. Zhou et al. (2015) tried to capture sequential information with the conditional random field (CRF) on the basis of a heterogeneous neural network. While their model works very well, we must also be keen to note that the RNN family models surpass CRF in sequence prediction tasks, as pointed out by Irsoy and Cardie (2014) and Yao et al. (2014).

Apart from textual and contextual information, non-textual information can also be considered. Hu et al. (2013) applied a restricted Boltzmann machine to combine textual and non-textual features in a community question answering problem. Their work makes good use of the non-textual features by combining them with textual features in an unsupervised manner.

To deal with the limitations of previous works, we propose a multi-level GRNN with non-textual features to predict the DAs. Our contributions can be highlighted in the following aspects:

- We apply a two-level GRNN to predict the DA. The low level GRNN is designed for modelling textual information of each sentence, and the top level GRNN is designed to make use of historical information in a conversation. This method produces an obvious improvement over the previous works as it automatically selects what information in the context to remember and forget.

- We use a feed forward neural network to capture the non-textual information. Then we feed the hidden layer as sentence level non-textual information to the top level GRNN.

- We conduct extensive experiments for DA labelling on the open SWDA corpus by exploiting different neural network models. With the new framework applied, our model achieves a significant improvement over previous works in SWDA task by over 6% from 73.1 to 79.37.

2 Related Work

2.1 Traditional methods on dialog act labelling

Dialog acts are to represent the intention of each sentence within a conversation. Allen and Core (1997) proposed the Dialog Act Markup in Several Layers (DAMSL) scheme to provide a top level structure for

anotating dialogs, which was applied by many dialog annotation systems (Jurafsky et al., 1997; Dhillon et al., 2004). Bunt et al. (2012) gave a detailed summary over the standard of dialog acts annotation in semantic annotation framework.

Dialog act labelling was traditionally viewed as a sequence labelling or sentence modelling problem. Most of the previous works try to predict the DA by calculating the probability of each label. Reithinger and Klesen (1997) used a language model to predict the probability of a certain DA. However, the effort to predict probability using a language model results in a severe loss of information, thereby leading to a poor result. Louwerse and Crossley (2006) introduced n-gram features to predict the DA, which is widely used in NLP tasks. This model uncovers more information from the text, but it fails to capture long-distance dependency. Surendran and Levow (2006) used SVM on individual sentences then viterbi decoding to make use of contextual information in a HMM style. This model builds a rather good framework for sequential labelling, as it not only feeds each sentence to a strong classifier SVM, but also makes use of context information in a probability graph. (Kim et al., 2010) further proposed to use CRF to deal with the problem, using both traditional bag of words features and new features such as dialog structures and dependencies between utterances. The common weakness of these methods is that they depend heavily on the features selected, and the feature construction process consumes much human effort.

2.2 Deep Learning models

As deep learning becomes increasingly popular, researchers have been trying to apply deep learning frameworks to deal with natural language processing and understanding tasks, including sentence modelling, DA labelling and many other tasks. Collobert and Weston (2007), Collobert and Weston (2008) and Collobert et al. (2011) constructed deep neural network structures for natural language processing tasks, which project one-hot word representations into distributed representations with a look-up table (or a projection layer) and build either feed forward or convolutional neural network upon them. This type of models seek to free researchers from laborious feature engineering, and allow the systems to easily adapt to different tasks.

Kalchbrenner et al. (2014) proposed a dynamic convolution neural network with multiple layers of convolution and k-max pooling to model a sentence. As imagined, this model is computationally expensive due to the many layers. Conversely, the CNN model proposed by Kim (2014) takes just one convolution and pooling layer with multi-channel word embeddings, followed by a softmax classifier. This model succeeded in many NLP tasks, such as sentence classification, sentiment analysis and so on.

Apart from CNN like architectures, researchers also applied recurrent neural network (RNN) and its variants to model sentences. Originally proposed by Elman (1990), RNN is expected to propagate information through time, which means one can make use of past information as latent variables. Mikolov et al. (2010) applied RNN to language modelling and got some very interesting results for word embedding. However, this vanila RNN suffers from the same problem as other deep neural networks, the problem of vanishing gradient. More specifically, gradients can either explode or vanish through time (Bengio et al., 1994). To tackle this problem, Hochreiter and Schmidhuber (1997) proposed long short term memory (LSTM), which uses a cell with input, forget and output gates to prevent the vanishing gradient problem. This makes RNN family networks much more powerful by memorizing information from long distance.

Recently, inspired by the gating idea, Cho et al. (2014) proposed another variant of RNN named gated recurrent neural network, which only uses a reset gate and a update gate to encode and decode sentences in a translation system. As reported in Chung et al. (2014), GRNN can achieve better results than LSTM in most tasks.

Palangi et al. (2015) proposed to sequentially take each word in a sentence, extract its information, and embed it into a semantic vector. This way, one can access the sentence level vector and use it to deal with other tasks such as information retrieval. Shen and Lee (2016) introduced one type of attention mechanism to sentence modelling based on LSTM, they also tested their model on SWDA task, which we will reference as a baseline. Their model performed better on longer sentences by highlighting the important parts of the sentence. But, as aforementioned, the most important part of this problem is

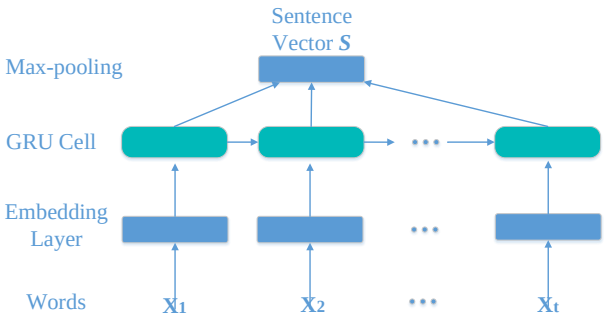

Figure 2: Gated recurrent neural network for sentence representation based on textual information

not about long sentences, but the short ones, which take the majority share of the corpus. Lee and Dernoncourt (2016) regarded this problem as a sequential short text classification problem, which is a good direction. However, although they tried to capture the historical information, they failed to seize long distant information in a conversation, because they only feed a fixed window to the neural network and the capability of the feed forward neural network is very limited.

3 Our Approach

In this paper, we propose to utilize a multi-level GRNN architecture to mine the information from both within the sentence and between the sentences. Gated recurrent neural network is a variant of the recurrent neural network. The GRNN allows information to flow over time without the problem of vanishing gradient, and is expected to memorize long distance dependency.

Equations 1 to 2 show the method to calculate the output h_t at time stamp t, with the input x_t and history information h_{t-1}, which is the output at time stamp $t-1$. In each gated recurrent unit, the *reset gate* (Equation 1) and the *update gate* (Equation 2) are designed to decide which latent information is to be discarded and which is to be held. Equation 3 calculates the candidate unit similar to vanilla RNN unit, except that it uses a *reset gate* to filter history information, and Equation 4 uses the *update gate* and the candidate unit to get the final output unit.

In our model, we first use the low level GRNN on the scale of words to learn sentence level vector, then we use GRNN to propagate the information between sentences over time within the same conversation. To discover more information on the sentence level, we also apply a feed forward neural network to capture the non-textual information such as the length of the sentence, the index of the utterance and so on.

$$z_t = \sigma(W_z x_t + U_z h_{t-1}) \quad (1)$$

$$r_t = \sigma(W_r x_t + U_r h_{t-1}) \quad (2)$$

$$\tilde{h}_t = tanh(W x_t + U(r_t \odot h_{t-1})) \quad (3)$$

$$h_t = (1 - z_t) h_{t-1} + z_t \tilde{h}_t \quad (4)$$

3.1 Textual information

Textual information is the basis of our end-to-end labelling system. We use a GRNN with max-pooling to encode the sentence into a vector.

As is shown in Figure 2, we treat each word as a separate unit. We first look up the corresponding embedding in a lookup table, which gives a matrix of $D * L$, D is the dimension of word embedding and L is the sentence length. Then we feed each word in the sentence into the low level GRNN, one word per time step, and then perform max pooling on the output of the GRU cells over the whole sentence.

caller	utterance index	sub-utterance index	act tag	text
A	5	2	qy	{F Um, } {F uh, } do you live right in the city itself? /
B	6	1	nn	No, /
B	6	2	sd	I'm more out in the suburbs, /
B	6	3	sd	{C but } I certainly work near a city. /
A	7	1	bk	Okay, /
A	7	2	qy	{C so } [ca-, +

Table 1: Utterance examples in SWDA corpus

3.2 Non-textual information

Although the aforementioned low level GRNN can capture the textual information within the sentence itself, it fails to make use of information from a higher level. For instance, in our DA labelling , the length of sentence plays an important role in identifying the tag of sentence, because the distribution of sentence length varies between different DAs. For sentences under the label of *acknowledge*, most sentences are below 10 words; whereas for sentences under the label of *statement non-opinion*, the sentences have more varied length distribution. As a matter of fact, it is shown in our experiment that this sentence length feature alone gives a much better prediction than random guesses.

Feed forward neural network (FFNN) is one of the simplest form of deep neural networks, and does a good job in many tasks. In this part of the neural network, we feed four shallow non-textual features to a FFNN. We use the hidden layer as the vector representing the non-textual information of the sentence. The four features we used are listed below. To better understand the features, Table 1 shows some examples from the original scripts.

- **Utterance index**: A conversation consists of multiple natural utterances, which are further split into lines of sentences for the convenience of tagging. Utterance index is the index of utterances, which can span multiple sentences. For example in Table 1, caller B says three sentences, and these three sentences share the same utterance index (6), but have different sub-utterance index. This feature may help when different acts take place in different parts of the conversation, for instance, conversations tend to begin with greetings.

- **Sub-utterance index**: Utterances can be broken across lines, sub-utterance index gives the internal position of the current sentence in the utterance. For example, in Table 1, the 6th utterance has three sentences or sub-utterances indexing from 1 to 3. This feature helps when different acts appear in different parts of an utterance. For example, questions tend to appear at the end of each utterance.

- **Same speaker**: This feature is a boolean feature of 0 or 1, indicating whether the identity of the speaker changes. Unlike the features above, this feature is deduced from the sub-utterance index. If the sub-utterance index is 1, then this feature is set to 1, otherwise 0.

- **Sentence length**: As explained earlier, the length of sentence plays an important role in predicting the label. As sentence lengths vary a lot, we normalize the lengths using Equation 5, where l is the word-wise sentence length.

$$l_{norm} = \frac{l - range(l)/2}{std(l)} \tag{5}$$

After we have the vector for textual and non-textual information aforementioned, we concatenate them together to get a combined vector for the sentence, as shown in the lower part of Figure 3.

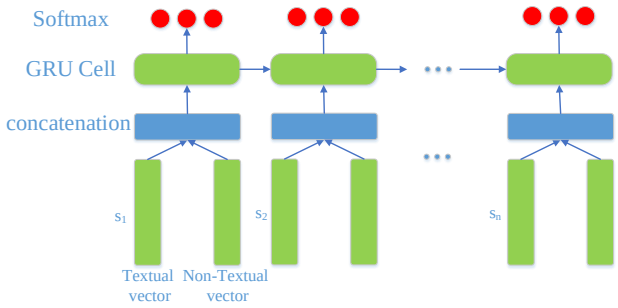

Figure 3: Gated recurrent neural network on sentence feature

3.3 Context information

GRNN is designed to remember valuable information while discarding useless information. In the DA labelling problem, the segmentation of sentences is not very strict. Many sentences are very short, which makes it very difficult to classify a sentence based on only little textual information and sentence level non-textual information. Therefore, GRNN can fit this problem very well.

In our model, we try to use GRNN to capture the structure between sentences, as shown in Figure 3. This enables our model to utilize information from longer distances, unlike the structure proposed by (Lee and Dernoncourt, 2016), which uses a fixed window to capture history information. Learning distant information is crucial for the fact that the dialog turn changes with no pattern, whereas some utterances consist of a single sentence while others consist of multiple sentences, which makes it impossible to learn the words from both speakers within a fixed window, as words of one speaker in the current sentence can be distant from the last words from the other speaker.

4 Experiment

4.1 Settings

We conducted experiments on the switchboard dialog act corpus, which extends the Switchboard-1 Telephone Speech Corpus with turn/utterance-level dialog-act tags. The tags summarize syntactic, semantic, and pragmatic information about the associated turn. There are over 200 tags in the corpus. Jurafsky et al. (1997) defines a system for collapsing them down to 44 tags.

In our experiments, we use the same data version as Stolcke et al. (2000), where there are 1,115 conversations (1.4M words, 198K utterances) in the training set, and 19 conversations (29K words, 4K utterances) in the test set. We use the same valid set as Lee and Dernoncourt (2016), which consists of 19 randomly chosen conversations. [1]

In our experiment, we build our model upon tensorflow by Abadi et al. (2015) [2], which is a popular package developed by Google for deep learning.

We use all the tokens of the utterances including texts and other telephone related symbols to train word embeddings with word2vec [3] (Mikolov et al., 2013), and set the dimension of word embeddings to 300. We use the Adam stohastic optimization method (Kingma and Ba, 2014) to minimize the negative log-likelihood cost with fine-tuning on the word embeddings. To try to avoid the over-fitting problem, we run each experiment for 10 epochs, and use the hyper-parameters from the epoch with the highest validation accuracy. We use rectified linear unit (relu) as the activation function.

4.2 Baselines

We conduct extensive experiments on the SWDA corpus by utilizing various neural network models.

[1] The train/validation/test splits were found at https://github.com/Franck-Dernoncourt/naacl2016

[3] available in https://code.google.com/archive/p/word2vec/

Method	Accuracy
Sequential short-text classification (Lee and Dernoncourt, 2016)	73.1
Neural attention (Shen and Lee, 2016)	72.6
Our model	79.37

Table 2: Experimental results compared with previous state-of-the-art methods

- **CNN**: We implemented a convolutional neural network following the framework of (Kim, 2014). We use filters of length 2,3 and 4, and for each window length there are 100 feature maps. So each sentence has a vector of 300 real numbers. After the convolution and max-pooling layer, there is a softmax layer to predict the DA of each sentence.

- **non-textual**: We feed the four non-textual features to a typical three-layer feed forward neural network as described in Section 3.2. We set the unit number of the hidden layer to 300 and use the output of the softmax layer to predict the label.

- **CNN+non-textual**: This model is a combination of CNN and non-textual. We concatenate the pooled feature maps of CNN and the hidden layer of non-textual FFNN, and feed this new combined vector to a softmax layer to predict the label.

- **single-level GRNN**: This model follows the description in section 3.1. We feed the word embedding to the GRU cells, each word per cell. After we get the output of the GRU cells from each time step, we perform a max-pooling over them and get the sentence vector. Then we feed the sentence vector to a softmax layer to predict the tag.

- **single-level GRNN + non-textual**: This model combines the max-pooled sentence vector from single-level GRNN and the hidden layer of non-textual FFNN in the same way as CNN+non-textual. Then the concatenated vector is fed to a softmax layer to predict the tag.

- **non-textual+GRNN**: We feed the hidden layer of the non-textual FFNN to a GRNN. Then we feed the output of each GRU cell to the softmax layer to predict the labels.

- **CNN+GRNN**: We feed the sentence vector from CNN to GRNN. Then we feed the output of each GRU cell to the softmax layer to predict the labels.

- **multi-level GRNN**: We feed the sentence vector from lower level GRNN to the upper level GRNN. Then we feed the output of each GRU cell to the softmax layer to predict the labels.

- **CNN+non-textual+GRNN** We feed the combination of sentence vector from CNN and hidden layer from non-textual FFNN to a GRNN. Then we feed the output of each GRU cell to the softmax layer to predict the labels.

- **multi-level GRNN+non-textual**: This is our model in this paper. In this model, we feed the combination of sentence vector from lower level GRNN and hidden layer from non-textual FFNN to the upper level GRNN. Then we feed the output of each GRU cell to the softmax layer to predict the labels.

4.3 Comparison with previous models

Table 2 shows our result compared with other state-of-the-art results. By utilizing information from previous time stamp with GRNN, we achieve significant improvement over the previous works. As seen in Table 2, we improve the performance by 6.27% over Lee and Dernoncourt (2016) and 6.77% over Shen and Lee (2016), as we better capture both the sentence level knowledge and contextual information in a conversation.

Method	Accuracy
CNN	68.25
single-level GRNN	69.75
non-textual	43.60
CNN+non-textual	70.86
single-level GRNN + non-textual	71.90
non-textual+GRNN	48.09
CNN+GRNN	77.14
multi-level GRNN	77.65
CNN+non-textual+GRNN	78.40
multi-level GRNN+non-textual	79.37

Table 3: Results of different neural networks in our experiment

Text	standard	single-level GRNN	final model
{F Um, } {F uh, } do you live right in the city itself? /	qy	qy	qy
No, /	nn	nn	nn
I'm more out in the suburbs, /	sd	sd	sd
{C but } I certainly work near a city. /	sd	sd	sd
Okay, /	bk	**fo_o_fw_by_bc**	bk
{C so } [ca-, +	qy	**sd**	qy

Table 4: The tagging DA results using two different neural network models, where "standard" means the golden standard tag in the data.

4.4 Comparison with baseline models

The experimental results in Table 3 show that both CNN and single-level GRNN with textual information can give relatively good results (68.25 & 69.75) for the DA labelling task.

Non-textual information can further improve the accuracy as they provide information about the whole sentence, instead of just individual words. This is verified by the fact that CNN+non-textual improves 2.61% over CNN and single-level GRNN+non-textual improves 2.15% over single-level GRNN. In fact, non-textual itself gives a surprisingly good result compared with random guess.

It is the GRNN which captures long distance dependency from context that produces the most significant improvement to the problem. As a matter of fact, the role of GRNN is so important that GRNN based on the weak classifier non-textual FFNN improves the result by almost 5% over the non-textual FFNN alone, and GRNN on the basis of CNN improves the result by almost 10% over the raw CNN. Altogether, our model of "multi-level GRNN+non-textual" surpasses the CNN baseline significantly by over 11%.

4.5 Analysis

In Table 4 we show the tagging results of the examples listed in Table 1. These results are from the single-level GRNN (one of our baselines) and our final model, respectively. The sentences are selected from the first conversation in the test set.

From the examples, we can observe that sentences with obvious features can be easily recognized by both models, for instance the first sentence "*do you*" is correctly tagged as "*qy*" (*Yes-No-Question*). However, when the sentence is short and ambiguous or can appear in multiple circumstances, such as "*Okay*", the simpler model mistakes the "*bk*" (*Response Acknowledgement*) for "*fo_o_fw_by_bc*" (*other*), while our final model which utilizes contextual information succeeds in predicting the right tag.

5 Conclusion

In this paper, we propose a multi-level GRNN model combined with non-textual features to deal with the dialog act labelling problem. We manage to mine multi-level information out of the conversation. Our model does a very good job on predicting short sentences in the SWDA corpus. Our results surpass previous state-of-the-art results significantly without much feature engineering, which makes our model easier to adapt to similar tasks. In the future, we hope to introduce the attention mechanism into our model and make better use of contextual information.

Multimodal Mood Classification - A Case Study of Differences in Hindi and Western Songs

Braja Gopal Patra, Dipankar Das, and Sivaji Bandyopadhyay
Department of Computer Science and Engineering,
Jadavpur University, Kolkata, India
{brajagopal.cse,dipankar.dipnil2005,sivaji.cse.ju}@gmail.com

Abstract

Music information retrieval has emerged as a mainstream research area in the past two decades. Experiments on music mood classification have been performed mainly on Western music based on audio, lyrics and a combination of both. Unfortunately, due to the scarcity of digitalized resources, Indian music fares poorly in music mood retrieval research. In this paper, we identified the mood taxonomy and prepared multimodal mood annotated datasets for Hindi and Western songs. We identified important audio and lyric features using correlation based feature selection technique. Finally, we developed mood classification systems using Support Vector Machines and Feed Forward Neural Networks based on the features collected from audio, lyrics, and a combination of both. The best performing multimodal systems achieved F-measures of 75.1 and 83.5 for classifying the moods of the Hindi and Western songs respectively using Feed Forward Neural Networks. A comparative analysis indicates that the selected features work well for mood classification of the Western songs and produces better results as compared to the mood classification systems for Hindi songs.

1 Introduction

Global digitization has led to music being available in the form of CDs, DVDs or other portable formats. With the rapid growth in Internet connectivity over the last decade, the audio or video music files are easily available and accessible over the World Wide Web. The number of music compositions created worldwide already exceeds a few millions and continues to grow. Similarly, the popularity of downloading and purchasing of music from online music shops has also been increased at the same pace. Thus, the organization and management of the music files are the important issues to be tackled carefully. Recently, studies on music information retrieval (MIR) have shown that moods are desirable access keys to music repositories and collections (Hu and Downie, 2010a).

In order to find out such access keys, most of the experiments on music mood classification of Western music have been performed based on the audio (Lu et al., 2006; Hu et al., 2008), lyrics (Zaanen and Kanters, 2010) and combination of both (Laurier et al., 2008; Hu and Downie, 2010b; Hu and Downie, 2010a). In case of the Indian music, few tasks have been performed on the Hindi music mood classification based on the audio (Ujlambkar and Attar, 2012; Patra et al., 2013a; Patra et al., 2013b; Patra et al., 2016b), lyrics (Patra et al., 2015c) and combination of both (Patra et al., 2016a). The maximum F-measure achieved for the multimodal system for Hindi songs was 68.6% in Patra et al. (2016a).

Indian music can be divided into two broad categories namely, "classical" and "popular" (Ujlambkar and Attar, 2012). Further, classical music tradition of India has two main variants; namely Hindustani and Carnatic. The prevalence of Hindustani classical music is found largely in north and central parts of India whereas Carnatic classical music dominates largely in the southern parts of India. Hindi or Bollywood music, also known as popular music, is mostly present in Hindi cinemas or Bollywood movies. Hindi is one of the official languages of India and is fourth most widely spoken language in the World[1]. Hindi songs make approximately 72% of the total music sales in India (Ujlambkar and Attar, 2012).

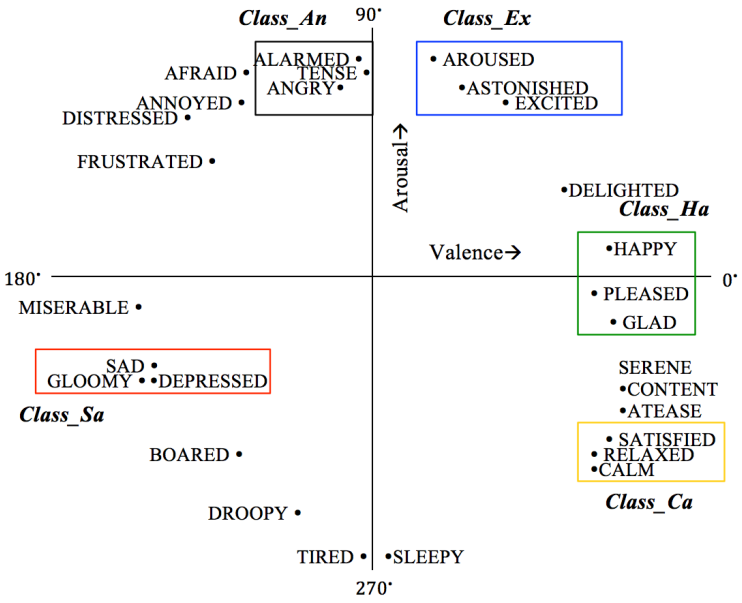

Figure 1: Russell's circumplex model of 28 affect words (Russell, 1980)

In order to deal with the above mentioned issues, the contributions of the authors are given below.

1. We employed our earlier proposed mood taxonomy for music mood classification in Hindi and Western songs (Patra et al., 2015c; Patra et al., 2016a; Patra et al., 2016b).

2. We annotated the audio and lyrics of the Hindi and Western songs using the above mood taxonomy.

3. We observed difference in mood while annotating the mood at the time of listening to the music and reading its corresponding lyric in case of the Hindi songs.

4. We identified important features using correlation based feature selection technique.

5. The Feed Forward Neural Networks (FFNNs) is implemented for mood classification purpose.

6. We have developed a multimodal system based on the audio and lyrics of the songs.

This paper is organized as follows: Section 2 introduces the mood taxonomy and describes the process of dataset preparation. Section 3 describes the audio and lyrics features. The FFNNs and the developed systems with comparison are described in the section 4. Finally, the conclusion is drawn in Section 5.

2 Mood Taxonomy and Dataset

2.1 Mood Taxonomy

We chose the *Russell's circumplex model* (Russell, 1980) to build our own mood taxonomy. The *circumplex model* and a subset of this dimensional model have been used earlier for several mood classification studies (Ujlambkar and Attar, 2012; Patra et al., 2013a; Patra et al., 2013b; Patra et al., 2015c; Patra et al., 2016a; Patra et al., 2016b). The *circumplex model* is based on *valence* and *arousal*, which is widely accepted by the research community. *Valence* indicates the positivity and negativity of emotions whereas *arousal* indicates the emotional intensity. The mood taxonomy is prepared by clustering the similar affect words of the *circumplex model* into a single class and each class contains three affect words of the *circumplex model* as shown in Figure 1. Each of our mood classes has distinct positions in terms of *arousal* and *valence*. We considered the five coarse mood classes, namely "*Class_An*", "*Class_Ca*", "*Class_Ex*", "*Class_Ha*", and "*Class_Sa*" for our experiments.

2.2 Dataset

All audio files of Hindi and Western song were collected from CDs bought from registered stores. The lyrics of the corresponding songs were collected from the web. The lyrics of the Hindi songs were written in *Romanized English* characters while essential resources like Hindi sentiment lexicons and list of stop words are available in *utf-8* character encoding. Thus, we transliterated the *Romanized* Hindi lyrics to *utf-8* characters using the transliteration tool available in the English to Indian Language Machine Translation (EILMT) project[2]. We observed several errors in the transliteration process. For example, words like 'oooohhhhooo' 'aaahhaa' were not transliterated due to the presence of repeated characters. Again, the words like 'par' and 'paar', 'jan' and 'jaan' were transliterated into different words 'पर' and 'पार', 'जन' and 'जान', but, the above pairs are the same words 'पर' and 'जान'. Hence, these mistakes were corrected manually.

Related research suggests that the state-of-the-art experiments on music mood classification have been performed on audio clips of 30 seconds (Hu et al., 2008; Ujlambkar and Attar, 2012; Patra et al., 2013b). In case of the Hindi songs, it is difficult to annotate mood of 30 second song clips since the annotators get confused in between adjacent mood classes while annotating short duration audio files. Thus, we sliced each of the audio files into 60 second clips. Each of the audio clips and lyric files of the Hindi and Western songs were annotated by three different annotators. The undergraduate students and research scholars belonging to the age group of 18-35 served as annotators.

From the annotation, we observed that different mood classes were chosen by the annotators during listening to the audio and reading the corresponding lyrics. The difference between listener's and reader's perspectives for the same song motivated us to investigate the root cause of such discrepancy. The authors believe that the subjective influence of music modulates the perception of lyric of a song in the listeners. For example, a song "Bhaag D.K.Bose Aandhi Aayi"[3] has mostly sad words like "dekha to katora jaka to kuaa (*the problem was much bigger than it seemed at first*)" in the lyric. This song was annotated as "*Class_Sa*" while reading the lyric, whereas it was annotated as "*Class_An*" while listening to the corresponding audio as it contains mostly rock music and arousal is also high. Similarly a song "Dil Duba"[4] was annotated as "*Class_Sa*" and "*Class_Ha*" while reading the lyric and listening to the corresponding audio, respectively. This song portrays negative emotions by using sad or negative words like "tere liye hi mar jaunga (*I would die for you*)", however, this song contains high valence. The above observations emphasize that the combined effect of lyric and audio plays a pivotal role in indicating the final mood inducing characteristics of a music piece. Moreover, the intensity of the emotion felt during listening to a song is much more than the intensity of the emotion while reading a lyric. The main reason behind this may be that the music with the voice induces the emotion.

We did not notice such differences in mood for the Western music. However, the intensity of the emotion was less while reading a lyric as compared to listening to the corresponding music in case of both Hindi and Western music. The confusion matrix of the Hindi song mood annotation is shown in Table 1. Detailed statistics of the annotated Hindi and Western songs are given in Table 2. We considered only those Hindi songs for our experiments, which were annotated with the same class both after listening to it and reading the corresponding lyric.

We calculated pairwise inter-annotator agreements on the dataset by computing Cohen's κ coefficient (Cohen, 1960). The inter-annotator agreements were calculated separately for audio clip annotation and lyric annotation. The overall inter-annotator agreement scores with five mood classes were found to be 0.94 and 0.84 for Hindi audio and lyrics, respectively. In case of the Western songs, the inter-annotator agreement scores with five mood classes were 0.91 and 0.87 for audio and lyrics, respectively. These correlation coefficients can be interpreted as almost perfect agreements.

3 Feature Extraction

This section describes the process of extracting features from both audio and lyrics. Feature extraction and selection play an important role in machine-learning frameworks. The important features from audio and lyrics were identified using correlation based feature selection technique. We considered different audio and textual features for mood classification in Hindi and Western songs.

3.1 Audio Features

We considered the key audio features like *intensity*, *rhythm* and *timbre* for the mood classification task. These features had been used by researchers for music mood classification in Indian languages (Ujlambkar and Attar, 2012; Patra et al., 2015b). These features were extracted using the jAudio (McKay et al., 2005) toolkit. In addition to these features, *chroma* and *harmonics* features were extracted from the audio files using the openSMILE (Eyben et al., 2010) toolkit.

3.2 Lyric Features

We adopted a wide range of textual features such as sentiment words, stylistic features and N-gram based features which are discussed in the following subsections.

Preprocessing: First we cleaned the lyrics dataset by removing the junk characters and HTML tags. Subsequently we removed the duplicate lines as it was observed that the starting stanza is usually repeated in the song at least a few times. Therefore, we removed these duplicate sentences to remove the biasness in the lyric.

3.2.1 Sentiment Lexicons (SL)

The emotion or sentiment words are one of the most important features for mood classification from lyrics. These words in the Hindi lyrics were identified using three lexicons - Hindi Subjective Lexicon (HSL) (Bakliwal et al., 2012), Hindi SentiWordnet (HSW) (Joshi et al., 2010) and Hindi Wordnet Affect (HWA) (Das et al., 2012). Similarly, we used two lexicons - SentiWordNet (Baccianellaet al., 2010) (SWN) and WordNetAffect (Strapparava and Valitutti, 2004) (WA) for identifying the sentiment words from the lyrics of the Western songs. It was observed that the number of sentiment words found in the lyrics of Hindi songs was less than the number of sentiment words found in the lyrics of Western

songs. The main reason was that the the performances of the POS tagger and stemmer/lemmatizer for Hindi language were not up to the mark. The CRF based *Shallow Parser*[5] is available for POS tagging and lemmatization, but it also did not perform well on the lyrics data because of the free word order nature of Hindi language. Most of the inflected sentiment words in Hindi lyrics were not matched with the sentiment words available in the Hindi sentiment or emotion lexicons. Thus, the number of words matched with sentiment or emotion lexicons are considerably less. In case of the Western songs, we used the RitaWordNet [6] to get the stemmed words and the parts-of-speech (POS) tags for the lyric words. The statistics of the sentiment or emotion words identified by these lexicons are given in Table 3.

Table 3: Statistics of unique sentiment and emotion words present in the lyrics of Hindi and Western songs

Classes	HWA	WA	Classes	HSL	HSW	SWN
Angry	248	312	**Positive**	1185	872	7853
Disgust	17	32				
Fear	20	52				
Happy	352	412	**Negative**	963	735	5271
Sad	110	231				
Surprise	39	81				

3.2.2 Text Stylistic Features (TSF)

Text stylistic features are widely used in text stylometric analysis such as authorship identification, author identification, etc. These features were also been used for mood classification from Hindi lyrics (Patra et al., 2015c) and Western music lyrics (Hu and Downie, 2010b). It was observed that these features reduce the performance of the system. The TSF such as the number of unique words, number of repeated words, number of lines, etc. were considered for our experiments.

3.2.3 N-Grams (NG)

It was noted by researchers that N-gram based features work well for mood classification using lyrics as compared to the stylistic or sentiment features (Zaanen and Kanters, 2010; Hu and Downie, 2010b; Patra et al., 2015c). The term frequency and document frequency (TF-IDF) scores of unigram, bigram and trigram were considered for the present study. The higher order N-grams tend to reduce the performance of the system. The N-grams having document frequencies more than one were considered to reduce the sparsity of the document vectors. We also removed the stopwords while considering the N-grams as it was observed that the stopwords do not contain any information related to the classification.

3.3 Feature Selection

Feature level correlation (Hall, 1999) was used to identify the most important features as well as to reduce the feature dimension in (Patra et al., 2015a). Thus, we used the correlation based supervised feature selection technique implemented in Weka toolkit [7] to find out the important contributory feature set for audio and lyrics.

A total of 445 audio features were extracted from Hindi and Western music audio files using jAudio and openSMILE. We also collected 12 sentiment features, 12 textual stylistic features and 6832 N-gram features from Hindi lyrics, whereas 8 sentiment features, 12 textual features and 8461 N-gram features were collected from the Western music lyrics. The feature selection technique implemented using Weka yields 154 important audio features for both Hindi and Western songs. 12 sentiment, 8 stylistic, and 1601 N-gram features from Hindi lyrics and 8 sentiment, 8 stylistic and 3175 N-gram features from Western music lyrics were extracted using feature selection technique. We subsequently used these features for the classification purpose.

[7] http://www.cs.waikato.ac.nz/ml/weka/

4 Classification Framework

We used the FFNNs for the mood classification purpose. It was observed that the FFNNs give better accuracy as compared to other machine learning algorithms like Support Vector Machines (SVMs) and Decision Trees (Patra et al., 2015b). Patra et al., (2015a) achieved low root mean square value for *arousal* and *valence* calculation using FFNNs. Moreover, they (Patra et al., 2015b) also reported higher F-measure for Hindi music mood classification based on audio.

4.1 Feed Forward Neural Networks (FFNNs)

Feed Forward Neural Networks refer to a special topology of neural networks in which each neuron belonging to a layer is connected to all the other neurons in the next layer. Neural networks are widely used for several classification and regression problems for its structural simplicity. The network is divided into multiple layers namely *input layer*, *hidden layer* and *output layer*. The *input layer* consists of inputs to the network. Then, the network follows a *hidden layer* which may consist of any number of *neurons* placed in parallel. Each neuron performs a weighted summation of the inputs which is then passed on to a nonlinear *activation function* (σ), also called the *neuron* function. Mathematically, the functionality of a hidden *neuron* is described as: $\sigma = \sum_{j=1}^{n}(w_j x_j + b_j)$, where the weights $\{w_j, b_j\}$ are symbolized with the arrows feeding into the neurons. The network output is formed by another weighted summation of the outputs of the neurons in the hidden layer (Mathematica Neural Networks- Train and Analyze Neural Networks to Fit Your Data, 2005). This summation on the output is called the output layer. The gradient descent learning principle is used to update the weights as the errors are back-propagated through each layer by the well-known back-propagation algorithm (Rumelhart et al., 1986). The updation rule can be stated as $\theta = \theta - \partial E/\partial\theta$.

4.2 Results Analysis and Discussion

We used FFNNs and LibSVM, a variant of the support vector machines (SVMs) implemented in Weka for the classification purpose. Several systems were developed using the audio features, lyric features and a combination of both. All experiments were conducted on the features selected by the correlation based feature selection technique. To obtain reliable accuracy, a 10-fold cross validation was performed for each of the classifiers.

4.2.1 Mood classification based on Audio

Initially, we performed experiments using only the timbre features and then added the other features incrementally. First we developed LibSVM based mood classification systems for Hindi and Western music. For Hindi music, the audio features based system achieved F-measure of 59.0, whereas for the Western music, the system achieved F-measure of 70.5 using all the audio features. The audio feature based Western music mood classification system achieved better F-measure (11.5 points absolute, 19.5% relative) than the Hindi-one. However, there were less number of instances present in the Western music as compared to the Hindi music. Therefore, we developed another pair of mood classification systems using the same number of instances for both the Hindi and Western music. In this case, the maximum F-measure of 56.8 and 64.5 were achieved for Hindi and Western music mood classification respectively using only audio features. The F-measure of the Western music mood classification system was 7.7 points absolute higher than the one for the Hindi music mood classification system developed on the same number of instances.

In the next phase, we developed audio based mood classification systems using FFNNs on the same set of 154 features. The maximum F-measure of 65.2 and 75.7 were achieved for the Hindi and Western music mood classification systems. The performance of the audio based systems are given in Table 4.

4.2.2 Mood classification based on Lyrics

We performed experiments using sentiment features initially and sequentially added other features incrementally. First, we used LibSVM for the classification purpose for feature ablation study. Subsequently, then we used the FFNNs using all the features together. We observed that the text stylistic features reduced the performance of the system. Thus, we removed text stylistic features from all other systems.

The lyric features based mood classification systems achieved the maximum F-measure of 55.3 and 68.2 for Hindi and Western song lyrics, respectively. The Western song mood classification achieves better F-measure of around 13.0 points absolute than the Hindi song mood classification system based only on lyric features. It was observed that the N-gram features yield good F-measure alone in case of the mood classification systems for Hindi and Western songs. The relative improvement of F-measure in case of Hindi song mood classification was much more than the mood classification system for Western songs. The main reason may be that the Hindi is free word order language and the Hindi lyrics are also more free in word order than the Hindi language itself.

We also developed lyric based systems for both song categories using the FFNNs. The corresponding mood classification systems achieved the maximum F-measure of 57.1 and 69.2 for Hindi and Western songs respectively. The performance of the lyric based systems are reported in Table 4.

4.2.3 Multimodal Music Mood classification

We developed multimodal music mood classification systems using LibSVM and FFNNs. The multimodal music mood classification system based on both audio and lyric features achieved F-measures of 68.9 and 80.4 for Hindi and Western songs using LibSVM. The multimodal music mood classification system for Western songs performs 11.5 points absolute better than the one for Hindi songs in terms of F-measure.

The FFNNs based multimodal music mood classification systems achieved the maximum F-measures of 75.1 and 83.5 for Hindi and Western songs, respectively. The performance of the multimodal systems are shown in Table 4 and the confusion matrices for these multimodal music mood classification systems are given in Table 5.

From the confusion matrix, it is observed that multimodal mood classification system for Hindi songs performs better in case of "*Class_Sa*" and performs poorly in case of "*Class_Ha*". This is obvious since the number of instances are more in case of "*Class_Sa*". The maximum number of instances from "*Class_Ha*" are classified as other classes because of the similar audio and lyric features. We also observed that the systems for Hindi songs are quite biased towards the "*Class_Sa*". In case of the Western songs, the "*Class_Ca*" contains the maximum number of instances and thus maximum number of instances are classified correctly for "*Class_Ca*". The system performs better in case of the "*Class_An*" and performs poorly in case of the "*Class_Ex*". It was also observed that some of the instances from each of the classes have tendency to go towards its neighboring classes. The main reason may be the similar features in between the neighbor classes.

4.2.4 Comparison with other systems

The proposed mood classification system for Hindi songs performs poorly as compared to the system of (Ujlambkar and Attar, 2012) which achieved F-measures of 75 to 81 using only audio based features. They used different mood taxonomy and they sliced the songs into 30 second clips. Unfortunately, their dataset is not freely available for research purpose. The features used for the experiments in (Ujlambkar and Attar, 2012) are a subset of our features. The audio based Hindi music mood classification system performs poor as compared to the system developed in (Patra et al., 2015b). Patra et al., (2015b) used more number of instances, but used a subset of our featureset. The audio based mood classification system outperformed other audio based systems reported in (Patra et al., 2013a; Patra et al., 2013b), but they developed their systems using smaller dataset and less number of features.

Our lyrics based mood classification system for Hindi songs outperformed the system reported in (Patra et al., 2015c) by 18.6 points absolute in terms of F-measure. We used similar features, but the number of instances were more in case of the present system. The significant difference in experimental setup is that their dataset was annotated with mood classes after listening to the corresponding audio files, whereas our lyrics dataset was annotated after reading the lexical content of lyrics. To the best of our knowledge, currently there is no other lyrics based mood classification system for Hindi music available in the literature. Patra et al., (2016a) developed multimodal mood classification system for Hindi songs using LibSVM and achieved F-measure of 68.6, which is 0.3 point absolute less than our multimodal mood classification system for Hindi songs using the same LibSVM. The main reason may be that we

Table 4: Performance of the mood classification systems with respect to different features using LibSVM and FFNNs

		Hindi Music			Western Music		
Systems	**Features**	P	R	F	P	R	F
Audio Features using LibSVM	**Timbre**	55.2	54.5	54.8	63.7	63.2	63.4
	Timbre+Intensity	55.7	55.3	55.5	66.9	66.6	66.8
	Timbre+Intensity+ Rhythm	58.8	57.8	58.2	70.3	70.0	70.2
	All audio features	58.9	59.1	59.0	70.5	70.5	70.5
Audio Features using FFNNs	**All audio features**	65.3	65.1	**65.2**	75.8	75.7	**75.7**
Lyrics Features using LibSVM	**SL**	41.3	39.4	40.4	60.0	59.6	59.8
	SL+TSF	38.6	38.7	38.6	59.7	59.9	59.8
	NG	46.3	46.7	46.5	60.2	60.3	60.2
	SL+TSF+NG	55.3	52.8	54.1	68.2	68.3	68.2
	SL+NG	55.9	54.7	55.3	68.2	68.3	68.2
Lyrics Features using FFNNs	**SL+NG**	57.2	57.0	**57.1**	69.3	69.1	**69.2**

Multimodal using FFNNs	**Audio+ Lyrics(Excluding TSF)**	76.8	73.5	**75.1**	84.8	82.2	**83.5**

used more number of instances for the present system. Till date, to the best of the author's knowledge, no other multimodal system has also been developed for Hindi songs based on audio and lyric features.

Table 5: Confusion matrix for multimodal systems using FFNNs

	Hindi Songs					Western Songs				
Classified as –>	**a**	**b**	**c**	**d**	**e**	**a**	**b**	**c**	**d**	**e**
Class_An = a	**153**	11	18	7	14	**195**	2	23	3	7
Class_Ca = b	1	**185**	3	35	28	0	**208**	2	12	25
Class_Ex = c	37	10	**192**	12	7	25	2	**192**	12	5
Class_Ha = d	5	35	10	**170**	12	3	9	16	**182**	8
Class_Sa = e	14	37	2	8	**224**	9	12	2	6	**151**

For Western music, it is very difficult to compare our mood classification system with other systems available in the literature, as our mood taxonomy is totally different from the mood taxonomy proposed by the existing multimodal mood classification systems (Hu and Downie, 2010a; Hu and Downie, 2010b). The number of mood classes present in their taxonomy is much higher (eighteen) than ours. Taking this into consideration, our present Western music mood classification system performed better than those systems. We used almost similar audio and lyric features as compared to the above mentioned systems. They used sentiment lexicons like General Inquirer, ANEW and WordNet-Affect, whereas we used SentiWordNet and WordNet-Affect for identifying the sentiment words.

4.2.5 Observations

Each mood classification system for Western songs outperforms the corresponding mood classification system for Hindi songs developed with the same classifier. The reasons for such results are listed below.

1. The moods experienced during listening to audio and reading the corresponding lyric are different in case of Hindi songs.

2. The mood is not very clear in the first 60 seconds clip of a Hindi song. Starting 20-30 seconds of the first clip of a song is mostly calm.

3. Western songs are usually much more rhythmic than Hindi songs.

4. The intensity of the mood felt in case of reading a lyric is less than the intensity of the mood felt at the time of listening to the audio in both song types.

5. We need more sophisticated features for audio to identify the mood in case of the Hindi music.

5 Conclusions

We developed mood annotated multimodal (lyrics and audio) datasets for Hindi and Western songs. Based on these multimodal datasets, we developed automatic multimodal music mood classification systems using LibSVM and FFNNs. The best performing systems developed using FFNNs achieved the maximum F-measures of 75.1 and 83.5 for Hindi and Western songs, respectively. It was observed that the different moods were perceived by the annotators while listening to audio and reading the corresponding song lyric in case of the Hindi songs. The main reason for such difference may be that the audio and lyrics were annotated by different annotators. Another reason may be that the mood is not transparent in lyrics as compared to the mood present in the audio of the corresponding song. In future, we intend to perform deeper analysis of the listener's and reader's perspectives of mood aroused from songs. We would also like to collect more instances for mood annotated datasets. We are also planning to use bagging and voting approach for the classification purpose.

Abstract

While automatic response generation for building chatbot systems has drawn a lot of attention recently, there is limited understanding on when we need to consider the linguistic context of an input text in the generation process. The task is challenging, as messages in a conversational environment are short and informal, and evidence that can indicate a message is context dependent is scarce. After a study of social conversation data crawled from the web, we observed that some characteristics estimated from the responses of messages are discriminative for identifying context dependent messages. With the characteristics as weak supervision, we propose using a Long Short Term Memory (LSTM) network to learn a classifier. Our method carries out text representation and classifier learning in a unified framework. Experimental results show that the proposed method can significantly outperform baseline methods on accuracy of classification.

1 Introduction

Together with the rapid growth of social media such as Twitter and Weibo, the amount of conversation data on the web has tremendously increased. This makes building open domain chatbot systems with data-driven approaches possible. To carry on reasonable conversations with humans, a chatbot system needs to generate proper response with regard to users' messages. Recently, with the large amount of conversation data available, learning a response generator from data has drawn a lot of attention (Ritter et al., 2011; Shang et al., 2015; Vinyals and Le, 2015).

A key step to coherent response generation is determining when to consider linguistic context of messages. Existing work on response generation, however, has overlooked this step. They either totally ignores linguistic context (Ritter et al., 2011; Shang et al., 2015; Vinyals and Le, 2015) or simply considers context for every message (Sordoni et al., 2015b; Serban et al., 2015). The former case is easy to lead to irrelevant responses when users' input messages rely on the context information in previous conversation turns, while the latter case is costly (e.g., on memory and responding time) for building a real chatbot system and has the risk of bringing in noise to response generation especially when users want to end the current conversation topic and start a new one. According to our observation, there are two types of messages in a conversational environment. The first type is context dependent message, which means to reply to the message, one must consider previous utterances in the dialogue[1], while the second type is context independent message, which means even without the previous utterances, the message itself can still lead to a reasonable response. Table 1 compares the two types of messages using examples. In Case 1, "why do you think so" is a context dependent message. In order to reply to the message, one cannot ignore its linguistic context "I think it will rain tomorrow". On the other hand, in Case 2, "Well, what time is it now" is a context independent message, as one can give a reasonable response without looking at the previous turns. Distinguishing context dependent messages from context independent messages is important for building a good response generator. Missing linguistic context for context dependent

[1]Broadly speaking, context may not be limited to linguistic context. For example, a user's interest could also be a kind of context. As the first step, in this work, we only focus on "linguistic context".

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 1990–1999, Osaka, Japan, December 11-17 2016.

Table 1: Two types of messages

Case 1 : a context dependent message	Case 2 : a context independent message
User : What will the weather be like tomorrow?	User : What are you doing?
Chatbot : I think it will rain tomorrow.	Chatbot : I am waiting for you to watch NBA.
User : ***Why do you think so?***	User : ***Well, what time is it now?***

messages will lead to nonsense response. For example, "because I love you" could also be a response for the message "why do you think so" if we only look at the message itself, but it is nonsense appearing in the dialogue of Case 1. Incorporating context information into context independent messages will increase the workload of a generation system and has the risk of bringing in noise to the generation process. For example, if we consider the context "NBA" for the message "Well, what time is it now", the chatbot will probably say something about "NBA" rather than answer the question with a time answer. Although detecting context dependent messages is crucial for building chatbot systems, there is limited understanding about it.

In this paper, we study this important but less explored problem. Instead of answering how to incorporate context information, we try to understand when we need the information. Therefore, our effort is complementary to the existing work on response generation. It can keep the existing generation algorithms context-aware and improve their efficiency and robustness to noise. The task is challenging, as messages in a conversational environment are usually short and informal, and evidence that can indicate a message is context dependent is scarce. For example, on 3 million post-response pairs crawled from Weibo, the average length of messages is 4.65. On such short texts, classic NLP tools such as POS Tagger and Parser suffer from bad performance (Derczynski et al., 2013; Foster et al., 2011) and it is difficult to explicitly extract features that are discriminative on the two types of messages. More seriously, there are no large scale annotations available for building a supervised learning procedure.

We consider leveraging the large amount of human-human conversation data available on the web to learn a message classifier. Our intuition is that a context dependent message has different linguistic context in different conversation sessions, therefore its responses could be more diverse on content than responses of a context independent message. To verify this idea, we study the distributions of responses of messages using conversation data crawled from social media and find that the length distribution of responses and the word distribution of responses are quite discriminative on the two types of messages. Based on this observation, for each message in the crawled data, we estimate the average length of responses, the entropy of the word distribution of responses, and the maximum mass of the word distribution of responses, and take these characteristics as weak supervision signals to learn a classifier. The classifier takes a message as input and can make prediction for any messages in a real conversation environment, even though the messages do not appear in the crawled data and characteristics like entropy are not available for them. We propose using a Long Short Term Memory (LSTM) architecture to learn the classifier. Our model represents message texts in a continuous vector space using a one-layer LSTM network. The text vectors are then provided as input to a two-layer feed-forward neural network to perform classification. The neural network architecture carries out feature learning and model learning in a unified framework, and thus can avoid explicit feature extraction which is difficult on short conversational messages. Our method leverages large scale weak supervision signals extracted from responses in social conversation data and can reach a satisfactory accuracy with only a few human annotations.

We conduct experiments on large scale English and Chinese conversation data mined from Twitter and Weibo respectively, and test the performance of our method on thousands of messages annotated by human labelers. Experimental results show that our method can significantly outperform baseline methods on accuracy of message classification on both of the two data sets.

We make the following contributions in this paper: 1) proposal of detecting context dependent messages in a conversational environment; 2) proposal of learning weak supervision signals from responses of messages using large scale conversation data; 3) proposal of using an LSTM architecture to learn a message classifier; 4) empirical verification of the proposed method on human annotated data.

2 Related Work

Our work lies in the path of building chatbot systems with data-driven approaches. Differing from traditional dialogue systems (cf., (Young et al., 2013)) which rely on hand-crafted features and rules to generate reply sentences for specific applications such as voice dialling (Williams, 2008) and appointment scheduling (Janarthanam et al., 2011) etc., recent effort focuses on exploiting an end-to-end approach to learn a response generator from social conversation data for open domain dialogue (Koshinda et al., 2015; Higashinaka et al., 2016). For example, Ritter et al. (Ritter et al., 2011) employed a phrase-based machine translation model for response generation. In (Shang et al., 2015; Vinyals and Le, 2015), neural network architectures were proposed to learning response generators from one-round conversation data. Based on these work, Sordoni et al. (Sordoni et al., 2015b) incorporated linguistic context into the learning of response generator. Serban et al. (Serban et al., 2015) proposed a hierarchical neural network architecture to building context-aware response generation. In this paper, instead of studying how to incorporate context into response generation, we consider the problem that when we need context in the process. Our work can keep the existing generation algorithms context-aware and at the same time improve their efficiency and robustness.

We employ a Recurrent Neural Network (RNN) architecture to learn a message classifier. RNN models (Elman, 1990), due to their capability of modeling sequences with arbitrary length, have been widely used in many natural language processing tasks such as language modeling (Mikolov et al., 2010) and tagging (Xu et al., 2015) etc. Recently, it is reported that Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014) as two special RNN models which can capture long term dependencies in sequences outperform state of the art methods on tasks like machine translation (Sutskever et al., 2014) and response generation (Shang et al., 2015). In this paper, we apply the LSTM architecture to the task of context dependent message detection. We append LSTM with a two-layer feed-forward neural network, thus feature learning and model learning can be carried out simultaneously.

Our work belongs to the scope of short text classification (Song et al., 2014). Existing applications of short text classification include query classification (Kang and Kim, 2003), tweet classification (Sriram et al., 2010), and question classification (Zhang and Lee, 2003). We study a new problem in short text classification: distinguishing context dependent messages from context independent messages in a conversational environment. The task is important for building open domain chatbot systems and has its unique challenges (e.g., new data structure). We tackle the challenges by leveraging the responses of messages and utilizing an LSTM network to conduct feature learning and model learning simultaneously.

3 Learning to Detect Context Dependent Messages

Suppose that we have a data set $\mathcal{D} = \{(m_i, y_i)\}_{i=1}^{N}$ where m_i is a message composed of a sequence of words $(w_{m_i,1}, \ldots, w_{m_i,n_i})$ and y_i is an indicator whose value reflects whether m_i is context dependent or not. Our goal is to learn a function $g(\cdot) \in \{-1, 1\}$ using $\mathcal{D}$, thus for any new message m, $g(\cdot)$ predicts m a context dependent message if $g(m) = 1$. To this end, we need to answer two questions: 1) how to construct $\mathcal{D}$; 2) how to perform learning using $\mathcal{D}$.

For the first question, we can crawl conversation data from social media like Twitter and ask human labelers to annotate the messages in the data. The problem is that human annotation is expensive and time consuming and therefore we cannot obtain a large scale data set for learning. To solve the problem, we automatically learn some weak supervision signals using responses of messages in social conversation data, and take the signals as $\{y_i\}$ in $\mathcal{D}$. For the second question, one straightforward way is first extracting shallow features such as bag-of-words and syntax from messages and then employing off-the-shelf machine learning tools to learn a model. The problem is that shallow features are not effective enough on representing semantics in short conversation messages, which will be seen in our experiments. We propose using a Long Short Term Memory (LSTM) architecture to learn a model from $\mathcal{D}$. The advantage of our approach is that it can avoid explicit feature extraction and large scale human annotations, and carry out feature learning and model learning in a unified framework.

3.1 Learning Weak Supervision Using Responses

Instead of requiring human annotations, we consider creating signals that are discriminative on the two types of messages from large scale social conversation data available on the web. Our intuition is that a context dependent message has different linguistic context in different conversation sessions, therefore, its responses could be more diverse on content than responses of a context independent message (one message may appear multiple times, and therefore it may correspond to multiple responses). Table 2 illustrates our idea with some examples from Twitter. The last column of the table represents the frequency of the message or the frequency of the response under the message. For each message, we show the top 5 most frequent responses. From the examples, we can see that a context dependent message tends to have divergent and uniformly distributed responses corresponding to different linguistic context, while the responses of a context independent message share relatively similar content and some content dominates the distribution.

Table 2: Responses of the two types of messages

Context dependent message : why	2196	Context independent message : Good night	644
Response 1 : I am kidding	7	Response 1 : Good night	47
Response 2 : He can be like mcdaniels for sixer	5	Response 2 : Goodnight	44
Response 3 : Because I say no	5	Response 3 : Night	23
Response 4 : I am tired	5	Response 4 : Sleep well	10
Response 5 : U will become dependent on them	5	Response 5 : Thank you	9

The examples inspire us to investigate some statistical characteristics that can reflect the diversity of responses. These characteristics could be good indicators of context dependent messages, and we can construct $\{y_i\}$ in $\mathcal{D}$ using the characteristics. We estimate the following statistical characteristics for each message using its responses, and examine how the characteristics are discriminative on the two types of messages using 1000 labeled messages from Twitter and Weibo respectively. The details of the labeled data will be described in our experiments.

Entropy: the first characteristic we investigate is the entropy of the word distribution of responses, which is a common measure for diversity. Given a word distribution $P = (p_1, p_2, \ldots, p_n)$, the entropy of the distribution is defined as

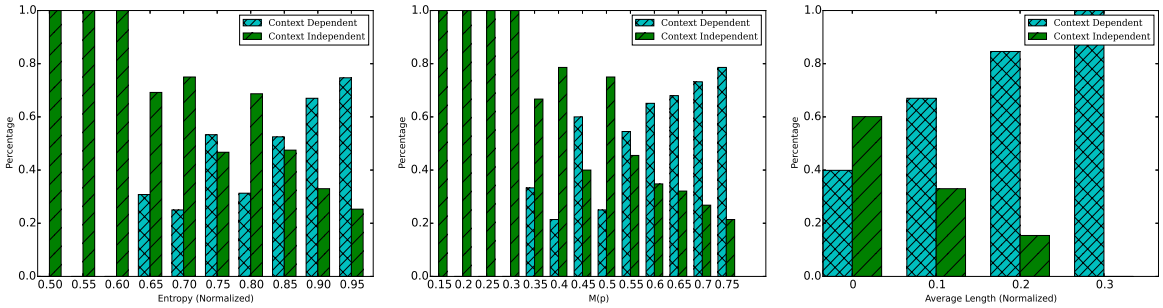
$$E(P) = \sum_{i=1}^{n} -p_i \log_2(p_i). \tag{1}$$

The maximum of the entropy is $\log_2(n)$ which is reached when the distribution is uniform. Then, a large entropy means a word distribution covers many words (i.e., n is big) and is close to a uniform distribution. Therefore, a context dependent message should have a larger entropy on responses than a context independent message (see the comparison in Table 2). We normalize the entropy to $[0, 1]$ by $\frac{E(P)-\min(E)}{\max(E)-\min(E)}$, where $\max(E)$ and $\min(E)$ represent the maximum entropy and the minimum entropy in the data set. Figure 1(a) shows the comparison of the two types of messages on normalized entropy using the Twitter labeled data. In the figure, each value on the x-axis represents an interval with a fixed length 0.05. For example, 0.50 means an interval $[0.5, 0.55)$. Each value on the y-axis represents the percentage of messages in a specific interval. For example, among messages falling in the interval $[0.95, 1)$, nearly 80% are labeled as context dependent and only about 20% are labeled as context independent. From the figure, we can see that entropy is discriminative on the two types of messages: context dependent messages distributes on large entropy areas, while context independent messages tend to have smaller entropy.

M(P): in addition to entropy, another characteristic that might reflect the diversity of responses could be the maximum mass of the word distribution of responses, as in diverse responses, words should be uniformly distributed (stopwords are removed), while in less diverse responses, there may exit dominant words (e.g., "night" in Table 2). Given a word distribution $P = (p_1, p_2, \ldots, p_n)$, we define a characteristic as

$$M(P) = 1 - \max_{1 \leqslant i \leqslant n} p_i \tag{2}$$

Figure 1(b) compares the two types of messages on $M(P)$ using the Twitter labeled data, in which values



(a) Comparison on entropy

(b) Comparison on $M(P)$

(c) Comparison on average length of responses

Figure 1: Comparison of the two types of messages on three characteristics.

on the x-axis and y-axis have the same meaning as those in Figure 1(a). From the figure, we can see that similar to entropy, $M(P)$ is useful on distinguishing the two types of messages. Context dependent messages have larger $M(P)$ than context independent messages.

Average length of responses: finally, we consider the length distribution of responses. Since responses of context dependent messages are more diverse on content, they might be longer than responses of context independent messages. We calculate the average length of responses for each message and normalize it to $[0, 1]$ in the same way as entropy. Figure 1(c) compares the two types of messages on average length of responses using the Twitter labeled data, where values on the x-axis represent intervals with a length 0.1. The result supports our claim and clearly indicates that average length is discriminative on the two types of messages.

We combine the three characteristics using a linear SVM classifier learned with the 1000 labeled messages and take the output of the SVM (a real value) as $\{y_i\}$ in $\mathcal{D}$. By this means, we can create a large scale training data set with only a little human labeling effort. Here, as a reference, we also report the classification accuracy of the three characteristics and the SVM classifier on the 1000 labeled data. Each characteristic corresponds to a threshold tuned on the 1000 labeled data with 5-fold cross validation. If a value of a characteristic of a message is larger than the threshold, then the message will be predicted as context dependent. Table 3 shows the classification accuracy of 5-fold cross validation (average of 5 results), where SVM (com) refers to the SVM classifier. Details of experiment setting will be described in Section 4. From Table 3, we can see that the numbers are consistent with Figure 1(a), 1(b), and 1(c).

Table 3: Classification accuracy on 1000 labeled data

	Weibo	Twitter
Entropy	72.6 %	70.5 %
$M(P)$	72.6 %	69.8 %
Average length of responses	72.8 %	68.5 %
SVM (com)	73.8 %	71.2 %

3.2 Model Learning

We head for learning $g(\cdot)$ using $\mathcal{D}$ constructed in Section 3.1. Note that $g(\cdot)$ only takes a message m as input, and thus can make prediction for any messages in a real chatbot system even though the messages are not in $\mathcal{D}$ and their entropy, M(P), and average length of responses are not available. Our idea is that we first learn a regression model by fitting $\{y_i\}$ in $\mathcal{D}$ through minimizing the sum of squared residuals and then construct $g(\cdot)$ by comparing the output of the regression model with a threshold. We can obtain the threshold by tuning it on a few labeled data (e.g., the 1000 labeled data). The key is how to learn the regression model. We propose using a Recurrent Neural Network (RNN) architecture to embed messages into a continuous vector space and learning a regression model with the embedding of messages using a feed-forward neural network. The RNN model, which is capable of embedding sequences with arbitrary

length, can encode the order of words and the semantics of a message into a vector representation which has been recently proven effective on capturing similarity of short texts (Sordoni et al., 2015a). We take the output vector given by RNN as a feature representation of a message and feed it to a feed-forward neural work. By this means, we can conduct feature learning and model learning in a unified framework and jointly optimize the two components.

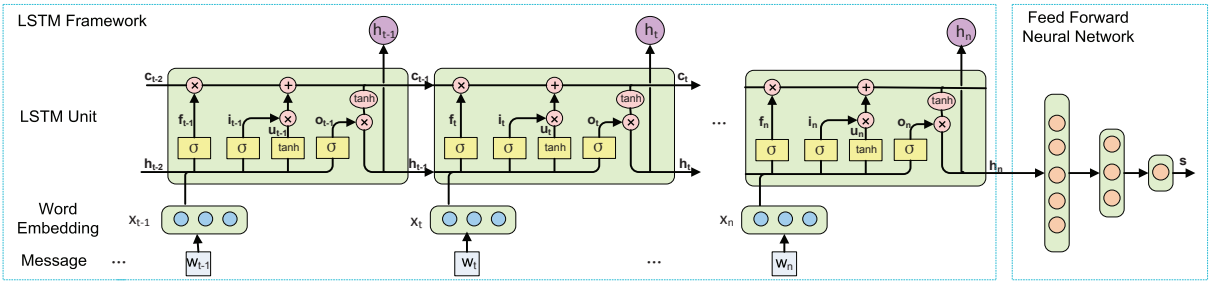


Figure 2: The architecture of our method

Given a message m which consists of n words, the RNN model reads the words one by one, and updates a recurrent state h_t for the t-th word w_t by

$$h_t = f(h_{t-1}, x_t),\ h_0 = 0, \tag{3}$$

where $h_t \in \mathbb{R}^{d_h}$, $x_t \in \mathbb{R}^{d_w}$ is the vector representation of w_t, and f is non-linear transformation. h_t acts as an encoding of the semantics of the word sequence up to position t, and the final output h_n is a representation of message m. Both x_t and h_t are learned in the optimization of the RNN model. We select the Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) as f, since it can model long term dependencies in sequences with affordable complexity. LSTM controls the learning of the representation of a sequence by gates. Specifically, at position t, LSTM controls the information that should be kept from previous states by an input gate i_t, and the information that should be forgotten by a forget gate f_t. After memorizing and forgetting, the information is stored in a memory cell c_t. c_t generates the recurrent state h_t through an output gate o_t. The specific parameterization of LSTM is given by

$$\begin{aligned}
i_t &= \sigma(W^{(i)}x_t + U^{(i)}h_{t-1} + b^{(i)}) \\
f_t &= \sigma(W^{(f)}x_t + U^{(f)}h_{t-1} + b^{(f)}) \\
o_t &= \sigma(W^{(o)}x_t + U^{(o)}h_{t-1} + b^{(o)}) \\
u_t &= \tanh(W^{(u)}x_t + U^{(u)}h_{t-1} + b^{(u)}) \\
c_t &= i_t \otimes u_t + f_t \otimes c_{(t-1)} \\
h_t &= o_t \otimes \tanh(c_t),
\end{aligned}$$

where $\sigma(\cdot)$ is a sigmoid function and $\tanh(\cdot)$ is a hyperbolic tangent function. $W^{(i)}$, $W^{(f)}$, $W^{(o)}$, $W^{(u)}$ $\in \mathbb{R}^{d_h \times d_w}$, $U^{(i)}$, $U^{(f)}$, $U^{(o)}$, $U^{(u)} \in \mathbb{R}^{d_h \times d_h}$, and $b^{(i)}$, $b^{(f)}$, $b^{(o)}$, $b^{(u)} \in \mathbb{R}^{d_h \times 1}$ are parameters. $\otimes$ means element-wise multiplication. After we get the final state h_n, we feed it to a two-layer feed-forward neural network to get an output s which is defined by

$$s = b_2 + W_2\left(\tanh(b_1 + W_1 h_n)\right), \tag{4}$$

where $b_1 \in \mathbb{R}^{d_s \times 1}$, $W_1 \in \mathbb{R}^{d_s \times d_h}$, $W_2 \in \mathbb{R}^{1 \times d_s}$, and $b_2 \in \mathbb{R}$ are parameters. Figure 2 illustrates the architecture of our method.

For each m_i in $\mathcal{D}$, we calculate an s_i using Equation (4) as an estimation of y_i. We then learn the parameters of the LSTM network and the feed-forward network by minimizing the sum of the squared residuals. Formally, our learning approach can be formulated as

$$\arg\min_{s} \sum_{i=1}^{N} (y_i - s_i)^2. \tag{5}$$

After we obtain the parameters, we can calculate an s_m for any message m using Equation (4). We then tune a threshold T with a few labeled messages. The classifier $g(\cdot)$ is given by

$$g(m) = \begin{cases} 1 & \text{if } s_m > T \\ -1 & \text{otherwise} \end{cases} \quad (6)$$

The gradients of the objective function (5) are computed using the back-propagation through time (BPTT) algorithm (Williams and Peng, 1990). We share the code for model learning at `https://github.com/whatsname1991/coling2016`.

4 Experiments

4.1 Experiment Setup

We constructed the conversation data for experiments from Weibo and Twitter. In each of the two social media, two persons can communicate by replying to each other under a post. We crawled sequences of reply with posts and extracted triples like "(context, message, response)" as experimental data. In a triple, "message" is a reply, "context" is the sentence in the previous turn of the message (a reply or a post), and "response" is the sentence in the next turn (reply to the message). Note that in this work, we restrict the context of a message to a single sentence. This is a simplification of context in conversation. In real conversation, context could be more complicated and we leave the discussion of it as future work.

We crawled 5.9 million English triples from Twitter, and 3.1 million Chinese triples from Weibo. The numbers of distinct messages in the Twitter data and in the Weibo data are $92,755$ and $112,175$ respectively. On average, each Twitter message has 63.26 responses (some messages like "hello" can have many different responses) and each Weibo message has 27.52 responses. The average word length of Twitter message is 3.39 and the word average length of Weibo message is 4.65. English sentences were stemmed and stop words were removed, and Chinese sentences were segmented.

We constructed $\mathcal{D} = \{(m_i, y_i)\}_{i=1}^N$ in Section 3.1 in the following way: we first calculated entropy, $M(P)$, and average length of responses for each message using the 5.9 million English triples and 3.1 million Chinese triples. Then from these data, we randomly sampled 1000 English triples and 1000 Chinese triples as validation sets. For each triple in the validation data, we hid the response and recruited human judges to label if the message is context dependent or not. Note that we hid responses when labeling messages because this is more close to the real case. In a real chatbot system, one has to determine if a message is context dependent or not before generating a response. Each judge labeled a message with 1 if it is context dependent, otherwise the judge labeled the message with -1. Each message got three labels and the majority of the labels was taken as the final decision for the message. In the Weibo data, there are 412 positive examples and 588 negative examples. In the Twitter data, the two numbers are 440 and 560, respectively. With the two validation data sets, we learned two SVM classifiers in order to combine the three characteristics as described in Section 3.1. Parameters of SVMs were tuned by 5-fold cross validation. Finally, we assigned a y_i to each m_i in the $112,175$ Twitter messages and $92,755$ Weibo messages by the output of the SVM classifiers, and formed $\mathcal{D}$ for both English data and Chinese data. We trained LSTM models using $\mathcal{D}$.

To evaluate the performance of different models, we crawled another 3000 Chinese context-message pairs and 1000 English context-message pairs from Weibo and Twitter respectively, and followed the same way as the validation data to judge if the messages are context dependent or not. We used these data to simulate real context-message pairs in chatbot systems. In the Weibo data, there are 2715 unique messages and 1983 messages are not in $\mathcal{D}$. The numbers of positive examples and negative examples are 1472 and 1528 respectively. In the Twitter data, the number of unique messages is 875 and 366 messages are not included by $\mathcal{D}$. The numbers of positive and negative examples are 464 and 536 respectively. Note that for messages that are not included by $\mathcal{D}$, their characteristics (i.e., entropy, $M(P)$, and average length of responses) are not available, and we can only use classifiers whose features are extracted from messages (like our LSTM models) to make prediction. This is close to a real situation in chatbots, and we took the two data sets as test sets.

We considered the following methods as baselines:

Length: intuitively, short messages tend to be context dependent (e.g., "why" in Table 2). Therefore, we employed length of a message as a baseline. A message shorter than a threshold will be predicted as a context dependent message.

MDF: given a word, we estimated the number of messages that contain the word and named it "document frequency" (DF). We constructed a list of words associated with DF using $\mathcal{D}$. For a new message, we calculated the minimal DF of words in the message using the list. A context dependent message like "why do you think so" may consist of common words, and thus correspond to a high minimal DF. We considered minimal DF as a baseline. A message with a minimal DF larger than a threshold will be predicted as a context dependent message.

SVM (Length+MDF): we linearly combined Length and MDF by learning an SVM classifier on the validation data.

SVM (classification): we extracted unigrams, bigrams, and frequencies of POS tags as features from a message, and learned a linear SVM classifier on the validation data with these features. POS tags for Chinese data were obtained using Stanford Parser (`http://nlp.stanford.edu/software/lex-parser.shtml`) and POS tags for English data were obtained using TweetNLP (`http://www.cs.cmu.edu/~ark/TweetNLP/`).

SVM (regression): instead of learning a classifier from annotations in the validation data, we fitted $\{y_i\}$ in $\mathcal{D}$ by learning an SVM regression model using the same features as SVM (classification) and made predictions on new messages by a threshold.

All SVM models were learned using SVM-Light (`http://svmlight.joachims.org/`). We employed classification accuracy as an evaluation metric.

4.2 Parameter Tuning

For Length and MDF, the only parameter is a threshold. We tuned the thresholds on the validation data. For all SVM models, we selected the trade-off parameter in SVM from $\{0.01, 0.1, 1, 10, 100\}$ by 5-fold cross validation on the validation data. SVM (regression) also needs a threshold. We tuned it on the validation data. The parameters of LSTM include the dimension of word vectors d_w, the dimension of hidden states d_h, and the dimension of the first layer of the feed-forward network d_s. We set $d_w = d_h = 256$, and $d_s = 100$. Besides these parameters, we also set a dropout rate 0.1 in the learning of the feed-forward network as regularization.

Table 4: Accuracy on two test sets

	Weibo	Twitter
Length	62.6 %	61.3 %
MDF	62.1 %	58.6 %
SVM (Length+MDF)	63.0 %	62.2 %
SVM (classification)	66.8 %	65.4 %
SVM (regression)	64.3 %	68.3 %
LSTM	**75.6 %**	**73.4 %**

Table 5: Comparison between LSTM, SVM (classification), and SVM (regression)

Example	context : Have you heard Taylor Swift's new song? *message: Yep, I have heard it on Saturday night.*
Label	context dependent
SVM (regression)	context independent
SVM (classification)	context independent
LSTM	context dependent

4.3 Quantitative Evaluation

Table 4 reports quantitative evaluation results on the test data. From the results, we can see that our methods outperform baseline methods. The improvement over the best performing baseline methods (i.e., SVM (classification) on Webio and SVM(regression) on Twitter) is statistically significant (sign test, p-value < 0.01).

Length and MDF are characteristics of messages. The results tell us that these characteristics are not so discriminative on the two types of messages. The reason is easy to understand: we may think that context dependent messages tend to be short and consist of common words, but the fact is that short messages composed of common words could be context independent (e.g., "Good night" in Table 2) while long messages like "Yep, I have heard it on Saturday night" (see the example in Table 5) could be context

dependent. Both SVM (classification) and SVM (regression) perform worse than our LSTM model, indicating that shallow features are not effective enough to represent the semantics in short conversation messages. Our method outperforms the baseline methods on both data sets. The results verified our idea on leveraging responses for context dependent message detection, and demonstrates the power of big data and the advantage of LSTM on capturing semantics in short messages.

4.4 Qualitative Evaluation

We use an example to further explain why our method is effective on distinguishing the two types of messages. Table 5 compares LSTM with SVM (classification) and SVM (regression). Both SVM (classification) and SVM (regression) rely on shallow features such as bag of words and pos tags to perform learning. These features, however, are not effective on representing the semantics of short messages. The representation is easily to be biased by some specific words like "Saturday night" in the example. Therefore, both SVM (classification) and SVM (regression) failed on this case. On the other hand, LSTM models term dependencies in sequences with a memorizing-forgetting mechanism. It can capture the semantics in the message "Yep, I have heard it on Saturday night." and identify that it is similar to messages like "Yes, I did" and "Yes, I have". For example, the cosine of the vector of "Yep, I have heard it on Saturday night." and the vector of "Yes, I have" given by LSTM is 0.63. Since messages like "Yes, I did" and "Yes, I have" are common context dependent messages, LSTM can successfully recognize that the message in the example is also context dependent.

5 Conclusion

We propose learning a LSTM network with weak supervision signals estimated from responses of messages to detecting context dependent messages in a conversational environment. Evaluation results show that the proposed method can significantly outperform baseline methods on distinguishing the two types of messages.

Abstract

Identifying *dialogue acts* and *dialogue modes* during tutorial interactions is an extremely crucial sub-step in understanding patterns of effective tutor-tutee interactions. In this work, we develop a novel joint inference method that labels each utterance in a tutoring dialogue session with a dialogue act and a specific mode from a set of pre-defined dialogue acts and modes, respectively. Specifically, we develop our joint model using Markov Logic Networks (MLNs), a framework that combines first-order logic with probabilities, and is thus capable of representing complex, uncertain knowledge. We define first-order formulas in our MLN that encode the inter-dependencies between dialogue modes and more fine-grained dialogue actions. We then use a joint inference to jointly label the modes as well as the dialogue acts in an utterance. We compare our system against a pipeline system based on SVMs on a real-world dataset with tutoring sessions of over 500 students. Our results show that the joint inference system is far more effective than the pipeline system in mode detection, and improves over the performance of the pipeline system by about 6 points in F1 score. The joint inference system also performs much better than the pipeline system in the context of labeling modes that highlight important pedagogical steps in tutoring.

1 Introduction

One-on-one instruction, i.e. tutoring, is one of the most effective forms of instruction. Intelligent Tutoring Systems (ITS) (Rus et al., 2013) have the potential to make effective and affordable "instruction-for-all" a reality since they do not suffer from traditional constraints such as lack of trained and expensive human tutors, physical teaching facilities, etc. However, in order to build effective automated tutoring systems, i.e. tutoring systems the induce student learning gains, we first need to understand what effective human tutors do. Specifically, we would like to identify specific pedagogical steps that promote effective tutoring. For instance, a good tutor may start by building a rapport with the students, followed by helping the student identify the domain of the problem, and so on. The sequence of steps taken by expert human tutors can in turn be used to improve the performance of ITS by re-enacting such effective tutorial strategies that are likely to promote better learning.

Understanding what good tutors do to help students learn has been the subject of much theoretical and empirical research (Chi et al., 2001; Eugenio et al., 2006; Cade et al., 2008; Jeong et al., 2008; Boyer et al., 2010; Lehman et al., 2012). A standard approach to understanding effective tutoring is to characterize tutor-tutee interactions based on the actions tutors and tutees take and then identify patterns of such actions that are associated with effective tutoring. For instance Cade et al. (Cade et al., 2008) used dialogue acts, which are constructs used to describe the intentions behind speakers' utterances, to model tutor-learner dialogue-based interactions. Boyer et al. (Boyer et al., 2010) modeled interactions as a combination of both task actions, which specify fine-grained steps taken by a user such as opening a file, and dialogue acts. However, dialogue acts only identify individual, isolated acts, e.g. asking a question, associated with a particular utterance lacking to characterize the meaning of a sequence of coherent actions, e.g. by the tutor, that might reveal high level constructs such as pedagogical strategies,

Student	I graphed the intercept (0, -27) correctly	Assertion	Calculation	Scaffolding
Tutor	and the y-intercept is (0, -27)	Assertion	Calculation	Scaffolding
Student	the slope is 0	Assertion	Calculation	Scaffolding

Table 1: Example for modes, acts and subacts in a dialogue.

e.g. scaffolding. In this work, we present a novel approach to identify higher-level tutorial constructs called *modes* in tutor-learner dialogue-based interactions. Specifically, dialogue modes are sequences of dialogue acts that map to pedagogical goals such as scaffolding (and sometimes to general dialogue goals such as opening a conversation). An example of the hierarchy of modes, dialogue acts and subacts in utterances is shown in Table 1.

As is often the case in several NLP tasks, a *pipeline* architecture can be naturally adopted to identify dialogue modes. Specifically, we first label acts in each utterance of the dialogue, then, using the labeled acts, we label subacts, and using both the labeled acts and subacts, we finally label the higher level modes. However, as is the case in general with pipeline based architectures, such a system is bound to have a fair amount of *error propagation*, where errors in labeling the acts or subacts affect the performance of mode labeling. Therefore, we propose a novel *joint inference* method for this task where we label modes jointly with dialogue acts and subacts, thereby taking advantage of the inter-dependencies between them. Prior approaches in the ITS research community have largely focused on dialogue act classification (Marineau et al., 2000; Serafin and Di Eugenio, 2004; Moldovan et al., 2011) or on mode labeling given labeled dialogue acts (Cade et al., 2008; Boyer et al., 2010; Rus et al., 2015). To the best of our knowledge, our work is the first joint inference method for this task.

We develop our joint inference system using a modeling language called Markov Logic Networks (MLNs) (Domingos and Lowd, 2009). MLNs are a powerful representation, where uncertain domain-knowledge is encoded as first-order formulas with weights attached to each formula. The weights in an MLN model indicate the uncertainty associated with the formulas. The larger the weight, the more confidence we have in the formula being true. Over the last few years, MLNs have been routinely used for several joint inference tasks in entity resolution (Poon and Domingos, 2008), event extraction (Poon and Vanderwende, 2010; Venugopal et al., 2014) and question answering (Khot et al., 2015). The main advantage of MLNs is that it can represent a large, complex probabilistic model through a highly compact, lifted representation specified through first-order formulas. However, at the same time, the compact representation makes scaling up probabilistic inference and learning a huge challenge in MLNs (Domingos and Lowd, 2009; Poon and Domingos, 2007). More specifically, in our task, the Markov network underlying the MLN turns out to be extremely large with millions of nodes and edges. By systematically exploiting the structure of our MLN model, we scale up MLN learning and inference methods for our task.

We evaluate our joint inference model on a dataset of human annotated dialogue transcripts of 500 students with around 32,000 dialogue utterances. To compare against our approach, we build a baseline, pipeline system using Support Vector Machines where we treat utterances as independent instances and sequentially label dialogue acts, subacts and modes in this dataset. We then compare our joint inference model with the baseline and obtain nearly a 6 point increase in F1-score for mode labeling with both higher recall and higher precision, clearly showing the promise of our joint inference approach.

The rest of this paper is organized as follows. We first present related work and give a brief overview of MLNs. We then present our joint inference model using MLNs and finally conclude with our evaluation.

2 Related Work

Speech-act theory that was developed in in the 1960's (Austin, 1962; Searle, 1969) has been typically used to model speakers' intentions. According to speech-act theory, when we say something, we do something. There are three levels of speech: the locutionary level which is the actual utterance, the illocutionary level which is the intention behind the utterance and perlocutionary level which is the effect of the utterance. Speech acts model the illocutionary level and denote speech acts such as greeting (*Hello*), questioning (*how is the weather?*), etc.

A speech act could be described as the sum of the illocutionary forces carried by an utterance (Moldovan et al., 2011). It is worth mentioning that within one utterance, speech acts can be hierarchical, hence the existence of a division between direct and indirect speech acts, the latter being those by which one says more than what is literally said, in other words, the deeper level of intentional meaning. In the phrase, *Would you mind passing me the salt?*, the direct speech act is the request best described by *Are you willing to do that for me?* while the indirect speech act is the request *I need you to give me the salt*. In a similar way, in the phrase, *Bill and Wendy lost a lot of weight with a diet and daily exercise*. the direct speech act is the actual statement of what happened, i.e., *They achieved "this" by doing "that"*, while the indirect speech act could be the encouraging, *If you do the same, you could lose a lot of weight too*. The present study assumes there is one direct speech act per utterance.

The task of classifying direct speech acts has been well-studied in the general context (Reithinger, 1995; Stolcke et al., 2000; Reithinger and Maier, 1995; Ries, 1999; Moldovan et al., 2011) as well as in the specific context of ITS (Marineau et al., 2000; Serafin and Di Eugenio, 2004; Samei et al., 2014). A related problem of generating the next speech act in a dialogue has also been investigated to some extent (Reithinger, 1995; Bangalore and Stent, 2009). Also, there is work on automatically discovering dialogue acts using data-driven approaches (Moldovan et al., 2011) but it is beyond the scope of this paper to automatically discover the dialogue acts in our tutoring sessions. In the automated speech act classification literature, typically researchers have considered rich feature sets extracted from the utterances such as the actual words (possibly lemmatized or stemmed) and ngrams (sequences of consecutive words) to characterize the type of speech act.

Dialogue modes in tutorial dialogues are sequences of dialogue acts that correspond to general conversational segments of a dialogue, e.g. an Opening mode corresponds to the first phase of the dialogue when the conversational partners greet each other, or to segments associated with pedagogical goals, e.g. a Scaffolding mode would correspond to the tutorial dialogue segment when the student works on something and the tutor scaffolds the learners activity. Compared to speech act classification, mode identification has been far less studied. Based on a manual analysis, Cade et al. (Cade et al., 2008) defined a set of eight mutually exclusive tutorial modes: introduction, lecture, highlighting, modeling, scaffolding, fading, off-topic, and conclusion. An interesting aspect of their analysis is the granularity at which they defined the pedagogically important modes. In their approach, the modes correspond to either the tutor or the student or both focusing on solving a full problem. In our approach, we used a different definition of modes proposed by Morrison et al. (Morrison et al., 2014). In this approach, a tutor or student could switch between proposed modes while working on a particular problem. That is, a particular mode is not associated with one problem solving task but rather with parts of such a problem solving task. Finally, Boyer et al. (Boyer et al., 2010) used acts in conjunction with more specific task actions, e.g., opening a specific file, etc., to discover hidden modes using a HMM. In contrast, we assume a pre-defined set of modes (see next section) that generalize across tutors and identify modes and acts jointly. This is similar to the Conditional Random Fields (CRF) approach proposed by Rus and colleagues (Rus et al., 2015) who used a expert-defined set of modes. It should be noted that Rus and colleagues report a best dialogue mode labeling performance of accuracy=57.18% when they used gold, i.e. human-labeled, dialogue acts as input. The accuracy dropped to 28.77% when automatically labeled dialogue acts were provided as input to the CRF-based dialogue mode labeling system. It should be noted that our results reported here are not exactly comparable to the ones reported by Rus and colleagues as they used a different, albeit related, human-labeled dataset to train and test their system.

3 Background

In this section, we give a brief overview of MLNs and describe the dataset used in this paper.

3.1 Markov Logic Networks

Markov logic networks (MLNs) unify first-order logic with Markov networks (undirected probabilistic graphical models abbreviated as PGMs). Formally, an MLN consists of a set of weighted first-order formulas, $\{(f_i; w_i)\}_{i=1}^{K}$, where f_i is a first-order formula and w_i is a real-valued weight attached to f_i. The weight w_i quantifies the uncertainty in f_i. Higher the weight of a formula, the more belief we have that the formula is true. If the weight w_i is ∞, then it acts as a hard constraint that f_i should always be true, while a weight $-\infty$ specifies the hard constraint that f_i should always be false. MLNs assume Herbrand semantics, i.e., there is a finite number of objects that can be substituted for the variables in the first-order formulas. This set of real-world objects is referred to as the domain. Throughout this paper, we specify constants with capital letters (e.g., A, B, etc.) and variables in the formulas with small letters (e.g., x, y, etc.)

A *ground atom* in the MLN is a first-order predicate where all variables are grounded with constants from the domain. Similarly, a ground formula is an instantiation of a first-order formula, where all variables have been grounded with constants from the domain. Given a domain of interest, MLNs specify a Markov network where a ground atom (a first-order predicate where all variables are grounded with constants) is a binary variable in the network and each ground formula (a first-order formula grounded with constants) is a function over the variables specific to that formula. For example, assume that the domain for the MLN, $\texttt{Smokes}(x) \Rightarrow \texttt{Cancer}(x)$; w, is equal to $\{A, B\}$. Then, $\texttt{Smokes}(A)$ is a ground atom in the MLN which represents a binary random variable in the Markov network. Similarly, $\texttt{Smokes}(A) \Rightarrow \texttt{Cancer}(A)$ represents a function in the Markov network defined over the binary variables corresponding to $\texttt{Smokes}(A)$ and $\texttt{Cancer}(A)$. An assignment (either 0 or 1) to all possible ground atoms in the MLN, $\texttt{Smokes}(A)$, $\texttt{Smokes}(B)$, $\texttt{Cancer}(A)$, $\texttt{Cancer}(B)$, is called a *world*. The MLN describes a *log-linear* model where the probability distribution is defined over the set of possible worlds. Specifically, the probability distribution represented by the MLN is given by,

$$\Pr(\omega) = \frac{1}{Z} \exp\left(\sum_i w_i N_i(\omega)\right) \tag{1}$$

where $N_i(\omega)$ is the number of groundings of the first order formula f_i that evaluate to True given a world ω.

Since MLNs are simply a compact representation of PGMs, all inference tasks in PGMs are also applicable to MLNs. Specifically, the two main inference tasks for MLNs are, 1) Marginal inference, and 2) MAP inference. In marginal inference, given evidence atoms, i.e., ground atoms whose truth value is known/observed, the task is to compute marginal probabilities over other query atoms. For example, say we are given evidence atoms $\texttt{Smokes}(A)$ and $\texttt{Smokes}(B)$, the task is to compute probabilities such as $P(\texttt{Cancer}(A)|\texttt{Smokes}(A), \texttt{Smokes}(B))$. In MAP inference, given evidence, we compute the assignment to the non-evidence atoms such that the probability of that assignment is maximized. For instance, given evidence $\texttt{Smokes}(A)$ and $\texttt{Smokes}(B)$, we need to compute the assignment to $\texttt{Cancer}(A)$, $\texttt{Cancer}(B)$ for which the probability is maximum in the joint distribution. Both marginal inference and MAP inference are computationally intractable and therefore typically approximate algorithms are used for both these tasks.

3.2 Dataset

Our dataset consists of dialogue transcripts of 500 tutoring sessions collected from 500 students working on elementary algebra and physics problems. In all, there are 32,368 individual utterances in these tutorial sessions, where we define an utterance as a single dialogue turn by either the student or the tutor. We selected this data from a sample of sessions obtained from an online, commercial tutoring service. These

sessions are about problem solving in the context of various Algebra and Physics topics. These are student-initiated sessions, mostly in the context of homework help.

We label each utterance with a predefined set of dialogue acts. The dialogue act taxonomy was developed with the assistance of subject matter experts, all experienced tutors and tutor mentors working for an online commercial tutoring service, resulting in a fine-grained 2-level hierarchical taxonomy that includes 17 main act categories. Each main dialog act category consists, in turn, of different subcategories, which we refer to as *subacts*, resulting in an overall taxonomy of 196 distinct dialog act-subact combinations. The size of the dialogue-act and -subact taxonomy is at least one order of magnitude larger than taxonomies proposed and used by others such as Boyer and colleagues (Boyer et al., 2010). It should be noted that the dialog acts were defined and refined to minimize overlap between categories and maximize the coverage of distinct acts.

There were a set of 17 dialogue modes defined by the experts and each utterance was annotated with the act, subact and the dialogue mode for the utterance by humans. The data was manually annotated by a group of tutoring experts who were trained on both the dialogue act taxonomy and set of dialogue modes. When annotating independently, the inter-annotator agreement was 80.91% and kappa statistic was 0.77 for dialogue acts and 64.90% and kappa of 0.63 for dialogue acts and subacts together. These values correspond to very good agreement among the annotators. For modes, the agreement was lower at 55.03% and kappa of 0.47. The list of modes and the number of times they occur in our labeled data set is shown below.

4 MLN Model

Here, we describe our joint inference model for identifying dialogue modes based on MLNs. We first describe the set of first-order formulas of the joint model. We then discuss how we perform joint inference and learning scalably in our model.

4.1 MLN Formulas

The four main predicates in our MLN are: `Act`, `Subact`, `Mode` and `ModeSwitch`. We next describe each of these predicates.

`Act`(s, t, a!) is a predicate that asserts that the dialogue act in the tutorial session corresponding to student s, at time step t, is equal to a. When defining our MLN, we refer to "time" as the utterance number in a dialogue session between the tutor and student. The "!" mark is a special symbol in the MLN language that specifies a hard constraint that for every grounding of s and t, there is exactly one act label. That is, every utterance corresponds to one and only one dialogue act. Similarly, `Subact`(s, t, u!) asserts that the dialogue subact in the tutorial session for student s at time t is equal to u. `Mode`(s, t, m!) asserts that the dialogue mode in the tutorial session for student s at time t is equal to m. Finally, `ModeSwitch`(s, t) asserts that there was a switch in dialogue mode at time t for the tutoring session associated with student s. That is, the mode in the previous time step was different from the mode in the current time step. Since our interest in this task is mode identification, `Mode` is called as a *query* predicate and the inference task is to collectively set a 0/1 truth assignment to all groundings of this predicate. `Act`, `Subact` and `ModeSwitch` are called *hidden* predicates since the truth assignments of their groundings are unknown.

Using the above predicates, we define the following formulas. Unless specified, all variables in the below described formulas are assumed to be universally quantified.

1. The first set of hard formulas specify that each act maps to a specific subset of subacts. This formula encodes the two-level hierarchy that we define in our taxonomy. We specify this by implication formulas of the form,

$$\texttt{Act}(s, t, A) \Leftrightarrow \texttt{Subact}(s, t, U_1) \vee \ldots \texttt{Subact}(s, t, U_k)$$

where $U_1 \ldots U_k$ are possible subacts corresponding to act A.

2. Next, we define hard formulas that encode the rule of mode switching. That is, we specify that mode-switching causes a shift in the dialogue mode using two implications.

$$\texttt{ModeSwitch}(s,t) \wedge \texttt{Mode}(s,t-1,m) \Rightarrow \neg\texttt{Mode}(s,t,m)$$
$$\neg\texttt{ModeSwitch}(s,t) \wedge \texttt{Mode}(s,t-1,m) \Rightarrow \texttt{Mode}(s,t,m)$$

3. The first and last modes of a dialogue are always fixed. We specify this with a conjunctive hard formula,

$$\texttt{Mode}(s,T_0,Opening) \wedge \texttt{Mode}(s,T_k,Closing)$$

where T_0 is the first utterance in the dialogue and T_k is the last utterance in the dialogue.

4. We encode the inter-dependency between modes, acts and subacts with a set of soft formulas. Specifically, we model this interaction by encoding a formula that connects two successive time-steps of a dialogue. The resulting formulation is similar to encoding Hidden Markov Models using MLNs, where we assert that the dialogue mode at time-step t is influenced by the acts, modes and subacts at the previous time-step. Clearly, this is a formula which would not hold true for all possible instantiations. Therefore, we specify a soft formula of the form,

$$\texttt{Mode}(s,t-1,+m_1) \wedge \texttt{Act}(s,t-1,+a) \wedge \texttt{Subact}(s,t-1,+u) \Rightarrow \texttt{Mode}(s,t,+m_2)$$

An important aspect to note about the above soft formula is the "+" sign for variables in the formula. The "+" sign is a special symbol in MLNs that allows us to define multiple weights for a single formula. Recall that in MLNs, generally, all the groundings of a first-order formula share the exact same weight. However, in several practical cases, we need to decrease the bias of the model by introducing more parameters for it. With the use of a "+" sign, we can increase the total number of weights in the MLN and thus induce more complex distributions. Specifically, we can set a different weight for each partially ground formula obtained by grounding all variables in the formula corresponding to the $+$ symbol. For instance, in this case, for each possible grounding of the variables m_1, m_2, u and a in the formula, we will define a distinct weight. This allows us more degrees of freedom to model the data rather than using a single weight for the formula.

5. Next, we define several soft formulas that connect features of the dialogue utterances to `Mode`, `Act`, `Subact` and `ModeSwitch`. Let $\texttt{Feature}_1 \ldots \texttt{Feature}_N$ denote N features extracted from the utterances (we discuss the actual features in the next section), then, we encode these features using soft formulas of the form,

$$\texttt{Feature}_1(s,t,+f_1) \wedge \texttt{Feature}_2(s,t,+f_2) \ldots \texttt{Feature}_N(s,t,+f_N) \Rightarrow \texttt{Mode}(s,t,+m)$$
$$\texttt{Feature}_1(s,t,+f_1) \wedge \texttt{Feature}_2(s,t,+f_2) \ldots \texttt{Feature}_N(s,t,+f_N) \Rightarrow \texttt{ModeSwitch}(s,t)$$
$$\texttt{Feature}_1(s,t,+f_1) \wedge \texttt{Feature}_2(s,t,+f_2) \ldots \texttt{Feature}_N(s,t,+f_N) \Rightarrow \texttt{Act}(s,t,+a)$$
$$\texttt{Feature}_1(s,t,+f_1) \wedge \texttt{Feature}_2(s,t,+f_2) \ldots \texttt{Feature}_N(s,t,+f_N) \Rightarrow \texttt{Subact}(s,t,+u)$$

4.2 Joint Inference

Given the MLN specified in the previous section, the inference task is to jointly compute an assignment to all possible groundings of the query predicate, `Mode`. Specifically, we compute this assignment as a solution to the following optimization problem

$$\max_{\omega'} \sum_{h \in H} P(Q = \omega') \tag{2}$$

where H is the set ground atoms of hidden predicates and Q is the set of ground atoms of query predicates, ω' is an assignment on all atoms in Q. However, Eq. (2) which is an instance of the *marginal-MAP* (MMAP) inference problem involves both summation (summing out the hidden variables) and

maximization, and is well-known to be a very hard problem (Park and Darwiche, 2004). Instead, we approximate the solution to the MMAP problem with a solution to the following *Max a-posteriori* (MAP) inference problem which only involves maximization.

$$\max_{\omega} P(Q \cup H = \omega) \tag{3}$$

where ω is an assignment on all atoms in $Q \cup H$. To obtain an approximate MMAP assignment for only the atoms in Q, we simply project the complete solution obtained from the MAP problem in Eq. (3) on the atoms in Q. Note that even the MAP problem in Eq. (3) is NP-hard. However, several highly efficient off-the-shelf approximate MAP solvers can be used to obtain high-quality approximations. Notable examples include MaxWalkSAT (Kautz et al., 1997), dual-decomposition based solvers (Sontag and Globerson, 2011) and ILP based solvers such as Gurobi (Gurobi., 2013). In our experiments, we use Gurobi, a state-of-the-art ILP solver to compute the MAP solution for the MLN (Sarkhel et al., 2014). However, it turns out that a naive application of approximate MAP solvers to our problem is still infeasible in practice. For instance, suppose we have 500 students' dialogues in our dataset, and each dialogue has on average 100 utterances/time-steps, then, the formula, $\texttt{ModeSwitch}(s, t) \wedge \texttt{Mode}(s, t-1, m) \Rightarrow \neg \texttt{Mode}(s, t, m)$ itself has at least 1 million possible groundings. In other words, grounding the entire MLN and then applying MAP inference on the ground MLN quickly becomes infeasible. However, we notice that our MLN has a decomposable structure, i.e., the ground Markov network obtained by grounding the MLN with a single student's dialogue is independent of the ground Markov network obtained when we ground the MLN with the rest of students' dialogues. This means that we can decompose the MAP problem as,

$$\prod_{k} \max_{\omega_k} P(Q_k \cup H_k = \omega_k) \tag{4}$$

where Q_k and H_k are the query and hidden atoms specific to the dialogues of student the k-th student and ω_k is an assignment to all atoms in $\{Q_k, H_k\}$. Thus, using Eq. (4), we can essentially compute the MAP solution independently for each student dialogue using a standard MAP solver which greatly reduces the computational requirements of the solver and allows us to scale up joint inference over our large dataset of dialogues.

Next, we describe weight-learning for the soft formulas in our MLN. Specifically, we use gradient ascent to compute weights of the soft formulas that maximize the log-likelihood of our dataset. Note that, our model contains hidden variables that are not observed directly, i.e., atoms corresponding to `Act`, `Subact` and `ModeSwitch`. Due to the presence of these hidden variables in our model, the resulting log-likelihood function is no longer convex. Therefore, gradient ascent can get struck in local optima. We reduce the severity of the problem using *random restarts* (Selman et al., 1996). That is, we start gradient ascent from several different initialization points and average all the different weights that gradient ascent converges to when starting from these different initialization points. Note that in each step of gradient ascent, we need to compute the gradient as,

$$\mathbb{E}_w[N_i] - \mathbb{E}_w[N_i'] \tag{5}$$

where $\mathbb{E}_w[N_i]$ is the expected number of groundings of the i-th soft formula that are true given the current set of weights w w.r.t the MLN distribution $P(Q|H)$ and $\mathbb{E}_w[N_i']$ is the expected number of groundings of the i-th soft formula that are true in the dataset w.r.t the MLN distribution $P(Q)$. Both expectations are intractable to compute exactly. Therefore, we approximate these distributions with their respective MAP values. This means that, for each gradient ascent step, we run MAP inference twice and compute the approximate expectations and from the approximate expectations, we compute the approximate gradient direction. We continue updating the weights with the gradient until the weights converge. In order to reduce computation, we compute the weights only for a feasible set of groundings of the "+" variables in the soft formulas. For instance, consider soft formula 4 in the previous section. Here, the number of groundings of the "+" variables is equal to the product of $|Modes| * |Modes| * |Acts| *$

Classifier Type	Model Type	Features	#Classes
Act Classifier	$SVM^{multiclass}$	Unigrams, Bigrams, Number of Tokens, Ending Punctuation, Utterance number	17
Subact Classifier	$SVM^{multiclass}$	All features of Act Classifier, the output acts labeled by Act Classifier	61
Mode Classifier	$SVM^{multiclass}$	All features of Subact Classifier, the output Subacts labeled by Subact Classifier	17
Mode Switch Classifier	SVM	Merged features of Mode classifier for two successive utterances	2

Table 2: SVM Models for Act, Subact, Mode identification and Mode Switch detection.

Metric	Pipeline			Joint Model		
	Precision	Recall	F1	Precision	Recall	F1
Average	0.275	0.28	0.271	0.338	0.341	**0.332**
Weighted-Average	0.32	0.34	0.324	0.375	0.39	**0.378**

Table 3: 5-fold Cross Validation results for Mode labeling.

$|Subacts|$. However, the number of feasible combinations is much lower. That is, several combinations never occur in the training dataset and we assume that for all such cases, the weight is 0 (the likelihood that the formula is true/false is the same). We remove these cases from the set of ground formulas and compute weights only for the remaining set of feasible groundings.

4.3 Learning Feature Based Formulas

Unfortunately, the above weight learning procedure does not work very well to learn weights of the feature-based soft formulas (listed as 5. in the previous section). The number of weights that we need to learn corresponding to the feature-based formulas turns out to be extremely large. Specifically, grounding the "+" variables, we will have at least $O(N * d * |Modes| * |Acts| * |Subacts|)$, where N is the number of features, d is an upper-bound on the number of possible feature-values for a feature. For lexical features of the utterances such as unigrams, bigrams, etc. this number is extremely large. Thus, weight-learning for the MLN that includes the feature-based soft formulas is infeasible in our model. Instead, we utilize the flexibility of MLNs to incorporate the feature-based soft formulas implicitly. Specifically, we remove all the feature-based formulas from the MLN and learn the MLN weights using only the other formulas. We then derive weights for the feature-based formulas through a separate model and add this back into the MLN as described next.

We train an SVM-based pipeline system to label the acts, subacts, modes and mode-switches in sequence. That is, we use $SVM^{multiclass}$ to first label the acts. Using the labeled acts, we label the subacts, and using both the labeled acts and subacts, we label the modes. We detect mode-switches using a binary SVM classifier. The features used in each of these models are shown in Table 2. The SVM-based pipeline system yields confidence values in the form of hyper-plane distances for each dialogue utterance for every mode, act, subact and also whether a mode switch occurred. Specifically, given an utterance t for student s, we will have hyper-plane distances for `Act`(s,t,$+a$), `Subact`(s,t,$+u$), `Mode`(s,t,$+m$) and `ModeSwitch`(s,t) (Note that, these are the atoms in the RHS of the soft formulas specified in 5). We then add to the MLN, a unit clause corresponding to the RHS of each soft formula, with the weight of the unit clause given by the SVM confidence value, which we normalize into the range $[-1, 1]$. Thus, if the SVM classifier is confident that an utterance number t for student s has mode type M, it will output a large confidence value for the type M label, which in turn is encoded into the MLN as the formula `Mode`(s,t,M) with a large weight. This will then make it more likely that the atom `Mode`(s,t,M) will be set as true when computing the MAP solution for the overall joint model.

Type	Pipeline			Joint Model		
	Precision	Recall	F1	Precision	Recall	F1
Act	0.672	0.68	0.65	0.69	0.698	**0.68**
Subact	0.49	0.51	0.48	0.518	0.535	**0.513**

Table 4: 5-fold Cross Validation results for the hidden predicates, Act and Subact (weighted-average F1 scores).

5 Experiments

This section presents the details of our experimental setup and the results obtained. As already mentioned, we compared a pipeline approach with the MLN joint-inference approach.

5.1 Setup

We evaluate the performance of our joint model by comparing it with the SVM based pipeline system which uses the features outlined in Table 2. This system is similar to the one presented in Rus et al. (Rus et al., 2015) who used a related, but not identical dataset, except that Rus et al. use Conditional Random Fields to label the modes, while, here we use SVMs. The performance of Rus et al.'s mode identification system that uses the labels of acts and subacts that were detected using a supervised classifier, is similar to ones we present here.

For our joint model, we use Gurobi, a state-of-the-art ILP solver, to solve the MAP inference problem. That is, we ground the MLN with dialogue data from each student independently and solve the MAP problem for each such partially ground MLN independently using Gurobi. Note that this problem is embarrassingly parallel since each MAP solution can be computed independently of the others. Using this, we could run a single instance of MAP inference over the entire dataset in just a few minutes using a cluster of 5 8-core machines, each with 8GB RAM.

5.2 Results

Table 3 shows a comparison of the F1-scores, precision and recall obtained by running 5-fold cross validation. The scores are reported for simple average of the scores (average over all mode labels) and for the weighted average (average weighted by instances of a particular label). As seen here, the joint method clearly outperforms the pipeline method in every case, in terms of F1-score, precision and recall. The average F1-score we obtained using the joint method was nearly 6 points higher than the average F1-score obtained using the pipeline SVM classifier. Particularly, both precision and recall of mode identification improved over both metrics.

Next, we evaluated statistical significance of our results. Specifically, we ran 5-fold paired t-tests (cf. (Dietterich, 1998)) to determine if our results were significant. Our results showed that our results attained statistical significance at $p \leq 0.05$, i.e., we obtained $t = 3.75$ with $p = 0.009$.

In our next experiment, we evaluated the performance of our model on hidden predicates. Specifically, Table 4 shows a comparison of how well the systems perform in terms of labeling the hidden ground atoms (ground atoms of the `Act` and `Subact` predicates). Since joint inference takes advantage of inter-dependencies between modes, acts and subacts, the accuracy of labeling the hidden variables is also better in the joint model as compared to the pipeline SVM classifier. The improvement in act and subact labeling was slightly smaller than the improvement we got for our main task of mode labeling. However, as shown in Table 4, here again, we observed significant improvements in both precision and recall as compared to the pipeline system.

In our final experiment, we compared results over key pedagogical steps to evaluate the effect of joint inference in these steps. These results are shown in Table 5. The mode names are quite self-explanatory for Rapport Building, Problem Identification and Assessment. Scaffolding is a concept where the tutor scaffolds the learner who is working through the solution by giving hints. Sense Making is the concept of explanations for understanding purposes. Process Negotiation is discussing/confirming the process of how to go about solving the problem. As we see from the results, in most cases, the joint model is significantly

Mode-Label	Pipeline			Joint Model		
	Precision	Recall	F1	Precision	Recall	F1
Rapport Building	0.25	0.5	0.338	0.31	0.53	0.389
Scaffolding	0.2	0.34	0.258	0.22	0.54	0.312
Problem Identification	0.246	0.42	0.31	0.265	0.42	0.325
Assessment	0.06	0.34	0.11	0.28	0.27	0.28
Process Negotiation	0.279	0.47	0.35	0.275	0.56	0.37
Sense Making	0.20	0.21	0.21	0.22	0.32	0.26

Table 5: 5-fold Cross Validation results for modes important in tutoring.

better than the pipeline system. Particularly, in some cases such as Scaffolding, which is an important step that corrects learners when they are going in the wrong direction, there was nearly a 20 percent increase in recall. As such, in almost all modes, we observed improvements in both precision and recall, which clearly illustrates the benefit of our joint model.

6 Conclusion

In this paper, we presented a novel joint inference method to detect modes in human-to-human tutoring. Specifically, modes are high level abstractions of dialogue speech acts, which give us a much deeper understanding of the underlying process by which natural language tutoring occurs. This is an important sub-step in designing Intelligent Tutoring Systems since strategies taken by expert human tutors can be adapted to AI-based tutors. In this work, we exploited inter-dependencies between lower-level dialogue acts and the higher-level modes using joint inference. Specifically, we developed a Markov Logic Network (MLN) to encode the the joint dependencies between dialogue acts, subacts and modes using weighted first-order logic formulas. We then developed a scalable MAP inference strategy for our model by partially grounding the MLN in each inference sub-step instead of pre-grounding the full MLN. We demonstrated the effectiveness of our approach on a real-world dialogue-based tutoring dataset collected from 500 students and annotated by multiple expert tutors. We showed that our MLN-based joint model outperforms a pipeline model that we built using SVMs that detects modes, acts and subacts independently of each other.

Future work includes mode detection without pre-specifying the dialogue acts and modes, i.e., automatically induce the dialogue acts and modes in the dialogue using non-parametric unsupervised machine learning methods. We will also apply joint inference to other complex sub-problems in Intelligent Tutoring Systems such as semantic similarity matching, automatically generate the best subsequent tutoring strategies, and generating hints to a student based on student response. We will also explore utilizing advanced lifted inference methods (Venugopal and Gogate, 2012; Venugopal and Gogate, 2014) in tutoring systems.

This work makes substantial contributions towards discovering effective tutorial strategies using data-driven approaches which in turn will contribute to the development of effective intelligent tutoring systems that could provide affordable, effective, one-on-one instruction to any learner of any age, anytime (24/7), anyhwhere as long as an Internet-connected device is available. The impact of such effective educational technologies will be far-reaching.

Abstract

In this study, we applied a deep LSTM structure to classify dialogue acts (DAs) in open-domain conversations. We found that the word embeddings parameters, dropout regularization, decay rate and number of layers are the parameters that have the largest effect on the final system accuracy. Using the findings of these experiments, we trained a deep LSTM network that outperforms the state-of-the-art on the Switchboard corpus by 3.11%, and MRDA by 2.2%.

1 Introduction

Dialogue Act (DA) classification plays a key role in dialogue interpretation, especially in spontaneous conversation analysis. Dialogue acts are defined as the meaning of each utterance at the illocutionary force level (Austin, 1975). Many applications benefit from the use of automatic dialogue act classification such as dialogue systems, machine translation, Automatic Speech Recognition (ASR), topic identification, and talking avatars (Král and Cerisara, 2012). Due to the complexity of DA classification, most researchers prefer to focus on the task-oriented systems such as restaurant, hotel, or flight, etc. reservation systems.

Almost all standard approaches to classification have been applied in DA classification, from Bayesian Networks (BN) and Hidden Markov Models (HMM) to feed forward Neural Networks, Decision Trees (DT), Support Vector Machines (SVM) and rule-based approaches.

Recently, the advancement of research in deep learning has led to performance upheavals in many Natural Language Processing (NLP) tasks, even leading Manning (2016) to refer to the phenomenon as a neural network "tsunami". One of the main benefits of using deep learning approaches is that they are not as reliant on handcrafted features; instead, they manufacture features automatically from each word (Turian et al., 2010), sentence (Lee and Dernoncourt, 2016; Kim, 2014), or even long texts (Collobert et al., 2011; Mikolov et al., 2013; Pennington et al., 2014). Inspired by the performance of recent studies utilizing deep learning for improving DA classification in domain-independent conversations (Ji et al., 2016; Lee and Dernoncourt, 2016; Kalchbrenner and Blunsom, 2013), we propose a model based on a recurrent neural network, LSTM, that benefits from deep layers of networks and pre-trained word embeddings derived from Wikipedia articles.

2 Related Work

Prior work has defined general sets of DAs for domain-independent dialogues that are commonly used in almost all research on DA classification (Jurafsky et al., 1997; Dhillon et al., 2004). The task of DA classification (sometimes called DA identification) is to attribute one member of a predefined DA to each given utterance. Therefore, DA classification is sometimes treated as short-text classification. Similar to many other traditional text classification methods, five sources of information have been used for DA classification tasks: lexical information, syntax, semantics, prosody, and dialogue history. Among all

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2012–2021, Osaka, Japan, December 11-17 2016.

proposed methods, those which used more sophisticated techniques for extracting lexical information, achieved the best results before deep learning was applied to the problem.

DA classification research started with handcrafting lexical features that yielded high quality results with an accuracy of 75.22% on the 18 DAs in the VERMOBIL dataset (Jekat et al., 1995). In general, Bayesian techniques were the most common approaches for DA classification tasks, which used a mixture of n-gram models together with dialogue history for predicting DAs (Grau et al., 2004; Ivanovic, 2005). In some studies, prosody information was integrated with surface-level lexical information to improve accuracy (Stolcke et al., 2000). Stolcke et al. (2000) reported the best accuracy on the core 42 DAs in the Switchboard corpus as 71%. This result was achieved by applying contextual information with HMM for recognizing temporal patterns in lexical information. Novielli and Strapparava (2013) investigated the sentiment load of each DA. They compared the accuracies of the classification before and after analyzing utterances in the Switchboard corpus by using Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2007) and postulated that affective analysis improved the accuracy.

Recently, approaches based on deep learning methods improved many state-of-the-art techniques in NLP including, DA classification accuracy on open-domain conversations (Kalchbrenner and Blunsom, 2013; Ravuri and Stolcke, 2015; Ji et al., 2016; Lee and Dernoncourt, 2016). Kalchbrenner and Blunsom (2013) used a mixture of Convolutional Neural Networks (CNN) and Recurrent Neural Networks (RNN). CNNs were used to extract local features from each utterance and RNNs were used to create a general view of the whole dialogue. This work improved the state-of-the-art 42-tag DA classification on Switchboard (Stolcke et al., 2000) by 2.9% to reach 73.9% accuracy. Ji et al. (2016) presented a hybrid architecture that merges an RNN language model with a discourse structure that considers relations between two contiguous utterances as a latent variable. This approach improved the result of the state-of-the-art method by about 3% (from 73.9 to 77) when applied on the Switchboard corpus. The best result was achieved when the algorithm was trained to maximize the conditional likelihood. Ji et al. (2016) also investigated the performance of using standard RNN and CNN on DA classification and got the cutting edge results on the MRDA corpus (Ang et al., 2005) using CNN.

3 Our Model

Most deep learning variations were designed and studied in the late 1990s, but their true performance was not revealed until high-speed computers were commercialized and researchers were able to access significant amounts of data. Collobert et al. (2011) used a large amount of unlabeled data to map words to high-dimensional vectors and a Neural Network architecture to generate an internal representation. By adding a CNN architecture Collobert et al. (2011) built the SENNA application that uses representation in language modeling tasks. Their approach outperforms almost all sophisticated traditional NLP applications like part-of-speech-tagging, chunking, named entity recognition, and semantic role labeling without resorting to the use of any handcrafted features or prior knowledge which are usually optimized for each task. In this study, we designed a deep neural network model that benefits from pre-trained word embeddings combined with a variation of the RNN structure for the DA classification task.

For each utterance that contains l number of words, our model convert it into l sequential word vectors. Word vectors can be generated randomly with arbitrary dimensions or being set by a pre-trained word vectors using a variety of word-to-vector techniques (Mikolov et al., 2013; Pennington et al., 2014).

3.1 RNN-based Utterance Representation

Figure 1 illustrates a typical structure of an RNN. As can be seen, information from previous layers, h_{t-1}, is contributed to the succeeding layer's computations that generate h_t. Since almost all tokens, X_i, in a conversation are related to their previous tokens or words, we choose to use an RNN structure.

Given a list of d -dimensional word vectors, $X_1, X_2, ..., X_{t-1}, X_t, ...X_{t+n}$ in a given time step, t, we will have:

$$h_t = \sigma\left(W^{hh}h_{t-1} + W^{hd}X_t\right) \tag{1}$$

$$y_t = softmax\left(W^{(S)}h_t\right) \tag{2}$$

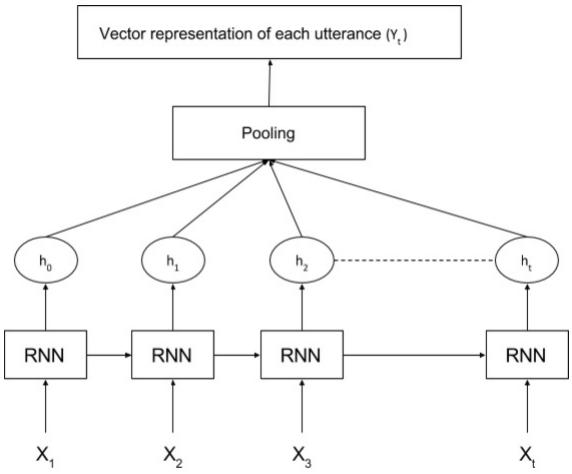

Figure 1: RNN structure for creating a vector-based representation of an utterance from its word.

where $W^{hh}\varepsilon\mathbb{R}^{\mathbb{h}\times\mathbb{h}}$ and $W^{hx}\varepsilon\mathbb{R}^{\mathbb{h}\times d}$ are weight matrices. σ represents logistic sigmoid function, and y_t, $y_t\varepsilon\mathbb{R}^{\mathbb{k}}$, is the class representation of each utterance and k denotes the number of classes for classification task.

In the pooling layer (Figure 1), our model takes all h vectors, $h_{1:t}$, and generate one vector. We can choose from three mechanisms: mean-, max- or last-pooling. Mean-pooling measures the average of all h vectors, max-pooling takes the greatest figure out of each h vector and last-pooling takes the last h vector (i.e., h_t).

Theoretically, RNNs should preserve the memory of previous incidents, but in practice when the gap between relevant information extends, RNNs fail to maintain relevant information. Hochreiter (1991) and Bengio et al. (1994) investigated the main reasons for RNNs' failures in detail. The other problem with RNN is the vanishing and exploding gradient that causes the learning process to be terminated prematurely (Mikolov et al., 2010; Pascanu et al., 2013).

Given the aforementioned problems with RNNs, we use Long Short Term Memory (LSTM), which is a variation of RNNs that is tuned to preserve long-distance dependencies as their default specificity. In DA classification, having the ability to connect related expressions of information that are distant from each other is important, particularly when it comes to classifying utterances as either subjective or objective, which is considered as one of the main sources of error in DA classification (Novielli and Strapparava, 2013). Classifying subjective versus objective texts is one of the major tasks in sentiment analysis in which LSTM-based approaches are shown to achieve high-quality results (Socher et al., 2013). Another reason for using LSTM is that it uses a *forget gate layer* to distill trivial weights, which belong to unimportant words from the cell state (see Eq. 4) . Figure 2 illustrates a standard structure of an LSTM cell.

As can be seen in Figure 2, we can define the LSTM cell at each time step *t* to be a set of vectors in $\mathbb{R}^d$:

$$i_t = \sigma\left(W^{(i)}X_t + U^{(i)}h_{t-1} + b^{(i)}\right) \tag{3}$$

$$f_t = \sigma\left(W^{(f)}X_t + U^{(f)}h_{t-1} + b^{(f)}\right) \tag{4}$$

$$o_t = \sigma\left(W^{(o)}X_t + U^{(o)}h_{t-1} + b^{(o)}\right) \tag{5}$$

$$u_t = \tanh\left(W^{(u)}X_t + U^{(u)}h_{t-1} + b^{(u)}\right) \tag{6}$$

$$c_t = i_t \bigodot u_t + f_{(t)} \bigodot c_{t-1} \tag{7}$$

$$h_t = o_t \bigodot \tanh(c_t) \tag{8}$$

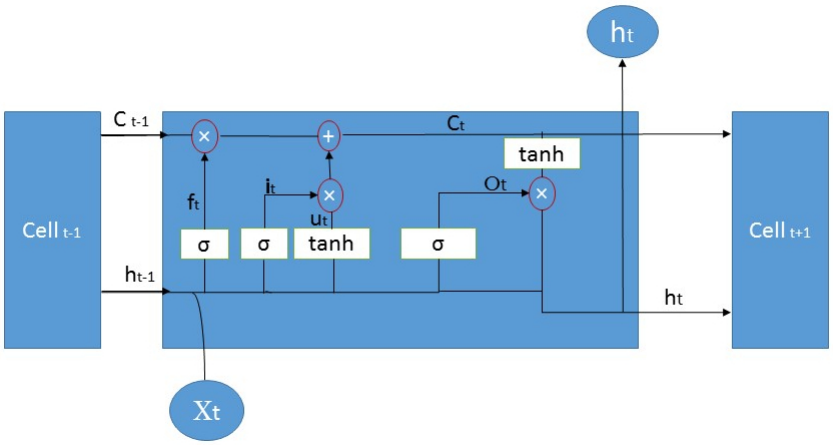

Figure 2: LSTM cell structure and its respective parameters (`http://colah.github.io`).

Where inputs are d dimensional vectors, i_t is the input gate, f_t is the forget gate, o_t is the output gate, c_t is the memory cell, h_t is the hidden state and $\odot$ represents element-wise multiplication.

c_t (Eq. 7) is the key part of LSTMs – it connects chains of cells together with linear interactions. In LSTMs, we have gates in each cell that decide dynamically which signals are allowed to pass through the whole chain. For example, the forget gate f_t (Eq. 4) decides to what extent the previous memory cell should be forgotten, the input gate (Eq. 3) manages the extent to which each cell should be updated, and the output gate manages the exposure of the internal memory state. The hidden layer h_t represents a gated, partial view of its cell state. LSTMs are able to view information over multiple time scales due to the fact that gating variables are assigned different values for each vector element (Tai et al., 2015).

3.2 Stacked LSTM

By arranging some LSTM cells back to back (Figure 2), the hidden layer, h_t, of each cell is considered as input for the subsequent layer in the same time step (Graves et al., 2013; Sutskever et al., 2014). The main reason for stacking LSTM cells is to gain longer dependencies between terms in the input chain of words.

In this study, we used stacked LSTMs with pre-trained word embeddings. Word embedding is distributional representations of words that are used to solve the data sparsity problem (Bengio et al., 2003). We trained word embeddings with 300-dimensional vectors by choosing the window and min-count equal to 5 (Mikolov et al., 2013).

4 Datasets

Since our study focuses on classifying DAs in open-domain conversations, we chose to evaluate our model on Switchboard (SwDA) (Jurafsky et al., 1997) and the five-class version of MRDA (Ang et al., 2005).

- **SwDA:** The Switchboard corpus (Godfrey et al., 1992) contains 1,155 five-minute, spontaneous, open-domain dialogues. Jurafsky et al. (1997) revised and collapsed the original DA tags into 42 DAs, which we use to evaluate our model. SwDA has 19 conversations in its test set.

- **MRDA:** The ICSI Meeting Recorder Dialogue Act corpus was annotated with the DAMSL tagset. This corpus is comprised of recorded multi-party meeting conversations. The MRDA contains 75 one-hour dialogues. There are several variations of the MRDA corpus but MRDA with 5 tags is commonly used in the literature.

  We used the list of files provided by Lee and Dernoncourt (2016) for creating the training, test, and development sets from the MRDA datasets.

5 Experimental Settings

We used the SwDA dataset to tune all hyperparameters including dropout, decay rate, word embeddings and the number of LSTM layers. All conversations in the training set were preprocessed and a randomized selection of one-third of them were utilized as a development set to allow the LSTM parameters to be trained over a reasonable number of epochs. We tuned one parameter value at a time and measured the accuracy on the development set, stopping when the accuracy on the development set did not change for 20 epochs. We used the NN packages provided by Lei et al. (2015) and Barzilay et al. (2016).

5.1 Word Embeddings

We tuned the word embedding parameters $method$, $corpus$ and $dimensionality$, while holding other parameters constant ($dropout = 0.5$, $decayrate = 0.5$ and $layersize = 2$). Specifically, we tested the methods *Word2vec* using the Gensim Word2vec package (Řehůřek and Sojka, 2010) and pretrained *Glove* word embeddings (Pennington et al., 2014). Word2vec embeddings were learned from Google News (Mikolov et al., 2013), and separately, from Wikipedia[1]. The Glove embeddings were pretrained on the 840 billion token Common Crawl corpus.

Method	**Resource**	**Dimension**	**Accuracy (%)**
Word2vec	Wikipedia	75	70.73
Word2vec	Wikipedia	150	71.85
Word2vec	Wikipedia	300	70.77
Word2vec	GoogleNews	75	71.26
Word2vec	GoogleNews	150	71.39
Word2vec	GoogleNews	300	71.32
Glove	CommonCrawl	75	69.28
Glove	CommonCrawl	150	69.71
Glove	CommonCrawl	300	69.40

Table 1: Accuracy using different word embedding techniques, corpora and vector dimensions.

Table 1 illustrates that the best results were consistently achieved by embeddings with 150-dimensions, and of those, Word2vec trained on Wikipedia had the best accuracy. Hence, these settings were used throughout the remainder of the experiments.

5.2 Decay Rate

LSTM uses standard backpropagation to adjust network connection weights (see Eq. 9), where E is the error and W_{ij} is the weight matrix between two nodes, i and j.

$$w_{ij} \leftarrow w_{ij} - \eta \frac{\partial E}{\partial w_{ij}}, \tag{9}$$

where η is the learning rate. To avoid overfitting, a regularization factor is added to Eq. 9 to penalize large changes in w_{ij}.

$$w_{ij} \leftarrow w_{ij} - \eta \frac{\partial E}{\partial w_{ij}} - \eta \lambda w_{ij}. \tag{10}$$

The term $-\eta\lambda w_{ij}$ is the regularization factor and λ is the decay factor that causes w_{ij} decay in scale to its prior measure. We found that changing η does not impact the accuracy so we set $\eta = 1e-3$ and change λ to find the best fit for the data (Table 2).

As can be seen from Table 2, the positive trend of increasing accuracy fails after setting $\lambda = 0.8$. Therefore, we set $\lambda = 0.7$ in our experiments.

[1] https://dumps.wikimedia.org/enwiki/20160421

Accuracy (%)	λ
70.76	0.1
70.79	0.2
70.87	0.3
71.32	0.4
71.85	0.5
71.90	0.6
71.95	0.7
70.95	0.8

Table 2: The impact of changing λ on accuracy.

5.3 Dropout

Most of the recent studies that exploit deep learning approaches use the dropout technique (Hinton et al., 2012). Dropout is a kind of regularization technique that prevents the network from overfitting by discarding some weights. In each training cycle, it is possible that some neurons are co-adapted by randomly assigning zero to their weights. Dropout methods were originally introduced for feed-forward and convolutional neural networks but recently have been applied pervasively in the input embeddings layer of recurrent networks including LSTMs (Zaremba et al., 2014; Pachitariu and Sahani, 2013; Bayer et al., 2013). Bayer et al. (2013) report that standard dropout does not work effectively with RNNs due to noise magnification in the recurrent process which results in diminished learning. Since standard dropout is proven not to work effectively for RNNs, we apply the dropout technique proposed by Zaremba et al. (2014) for regularizing RNNs that is used by most studies in the literature employing LSTM models (Lei et al., 2015; Barzilay et al., 2016; Jaech et al., 2016; Swayamdipta et al., 2016; Lu et al., 2016). Zaremba et al. (2014) postulate that their approach reduces overfitting on a variety of tasks, including language modeling, speech recognition, image caption generation, and machine translation. We experimented with dropout probability settings in the range between 0.0 and 0.5.

Accuracy (%)	Dropout probability
71.95	0.5
72.01	0.4
72.05	0.3
72.15	0.2
72.55	0.1
73.29	0.0

Table 3: Impact of changing dropout on accuracy.

As can be seen in Table 3, any dropout at all hurt the accuracy. Hence, the value was set at 0.0 – dropout was not used in later tuning or in the final model.

5.4 Number of LSTM Layers

Finally, we tuned the number of layers. If you utilize only two layers, the model does not detect relevant tokens that are distant from each other. Conversely, if you use too many LSTM layers, the model will be prone to overfitting. We tested values in the range of 2 to 15. Table 4 illustrates our settings' performance on the development set – the accuracy increases up to a 10 LSTM cells before dropping significantly at 15.

5.5 Other Parameters

In addition to the aforementioned parameters, we investigated the impact of changing $L2\text{-}reg$, $pooling$, and $activation$ and finally set them to $1e-5$, $last\ pooling$, and $tanh$ respectively. These settings were

Accuracy (%)	No. of layers
73.29	2
73.61	5
73.92	10
72.90	15

Table 4: Impact of LSTM layers on accuracy.

consistent with previous findings in the literature and we did not observe significant improvements by changing these values.

6 Results and Discussion

In previous sections, we found the best setting for our model, with which we gained the best accuracy on the SwDA development set. In this section, we report our results on the SwDA and MRDA test set.

Model	Accuracy (%)
Our RNN Model	**80.1**
HMM (Stolcke et al., 2000)	71.0
CNN (Lee and Dernoncourt, 2016)	73.1
RCNN (Kalchbrenner and Blunsom, 2013)	73.9
DRLM-joint training (Ji et al., 2016)	74.0
DRLM-conditional training (Ji et al., 2016)	77.0
Tf-idf (baseline)	47.3
Inter-annotator agreement	84.0

Table 5: SwDA dialogue act tagging accuracies.

Table 5 shows the results achieved by our model in comparison with previous works. As a baseline, we consider the accuracy obtained from a Naive Bayes classifier using *tf-idf* bigrams as features (Naive Bayes outperformed other classifiers including SVM and Random Forest). Our model improved results over the state-of-the-art methods and the baseline by 3.11% and 32.85%, respectively.

We also applied our model to classify dialogue acts in the MRDA with 5 dialogue acts. To do so, we used the same settings as described above for classifying dialogue acts in SwDA (Table 5). Table 6 shows our results on the MRDA corpus.

Model	Accuracy (%)
Our RNN Model	**86.8**
CNN (Lee and Dernoncourt, 2016)	84.6
Graphical Model (Ji and Bilmes, 2006)	81.3
Naive Bayes (Lendvai and Geertzen, 2007)	82.0
Tf-idf (baseline)	74.6

Table 6: MRDA dialogue act tagging accuracies.

We calculate the baseline as before, by using *tf-idf* bigram features. The Random Forest classifier achieved the best result in comparison to other classifiers such as Naive Bayes and SVM. Our results in Table 6 show that our model outperformed the state-of-the-art method by 2.2%. It should be emphasized that our model achieved this result without being tuned on an MRDA development set.

7 Conclusion

In this study, we used a deep recurrent neural network for classifying dialogue acts. We showed that our model improved over the state-of-the-art in classifying dialogue act in open-domain conversational text.

We ran several experiments to realize the effects of setting each hyperparameter on the final results. We found that dropout regularization should be applied to LSTM-based structures (even for LSTM-adapted dropout methods that have been proven to have a positive impact on some datasets) cautiously to ensure that it does not have a negative impact on the accuracy of the system.

Abstract

An interactive Question Answering (QA) system frequently encounters non-sentential (incomplete) questions. These non-sentential questions may not make sense to the system when a user asks them without the context of conversation. The system thus needs to take into account the conversation context to process the incomplete question. In this work, we present a recurrent neural network (RNN) based encoder decoder network that can generate a complete (intended) question, given an incomplete question and conversation context. RNN encoder decoder networks have been show to work well when trained on a parallel corpus with millions of sentences, however it is extremely hard to obtain conversation data of this magnitude. We therefore propose to decompose the original problem into two separate simplified problems where each problem focuses on an abstraction. Specifically, we train a semantic sequence model to learn semantic patterns, and a syntactic sequence model to learn linguistic patterns. We further combine syntactic and semantic sequence models to generate an ensemble model. Our model achieves a BLEU score of 30.15 as compared to 18.54 using a standard RNN encoder decoder model.

1 Introduction

Question Answering (QA) systems (Green Jr et al., 1961; Winograd, 1971; Woods and Kaplan, 1977; Hickl et al., 2006; Gobeill et al., 2009) enable a user to obtain precise information. A natural extension is an interactive and dialogue based QA system that allows a user to ask follow up or related questions. Interactive QA system however comes with its unique set of challenges. Users ask a follow up or related question by being as terse as possible, and they implicitly refer to concepts and entities in the past conversation. Table 1 depicts a few instances of follow up questions users may ask in an ongoing conversation.

Incomplete questions are a subset of non-sentential utterances (NSU) (Fernández, 2006). NSUs are incomplete utterances which make complete sense when seen in conjunction with the utterances in conversation. Table 1 illustrates some examples of NSU questions ($Q2$) a user might ask the system given a previous question ($Q1$) and an answer ($A1$). $R1$ refers to the intended complete question. Note that (a) and (c) need the previous question $Q1$, (b) needs previous answer $A1$, whereas (d) needs both $Q1$ and $A1$ to generate $R1$. The system thus either needs to restrict how users interact (Carbonell, 1983), or needs to handle the NSU questions by considering the conversation context. Restricting how users interact with a QA system is not natural, and thus can make the system hard to use. In this work, we focus on using the incomplete question and the conversation context to generate the resolved (intended) question. In the rest of the paper, we refer to this problem as NSU question resolution.

NSU resolution is an active area of research. One set of work deals with classifying NSU (Fernández et al., 2005). Another set of work proposes a rule or grammar based approach to resolve NSU (Carbonell, 1983; Dalrymple et al., 1991). Recently, a statistical based approach has been proposed for resolving NSU question (Raghu et al., 2015). However, this approach only focuses on the simpler problem of

resolving NSU based on previous questions, and thus will not be able to handle examples given in Table 1(b) and 1(d), where previous answer or a combination of previous question and answer is needed.

Recently, recurrent neural network (RNN) based encoder decoder networks have been applied successfully to the task of statistical machine translation (Cho et al., 2014; Bahdanau et al., 2014; Sutskever et al., 2014). RNN encoder decoder, also known as sequence to sequence learning, maps a variable length input sequence to a variable length output sequence. In this work, we approach the problem of NSU question resolution as sequence to sequence learning. We generate the input sequence by concatenating NSU question, previous question and answer. RNN encoder decoder is then used to learn a mapping of this input sequence to the resolved question.

RNN encoder decoder models have been successfully trained on huge parallel corpus of millions of sentences (Bahdanau et al., 2014; Cho et al., 2014; Sutskever et al., 2014). However, it is extremely hard to obtain conversation data of this magnitude. We have access to only 7220 conversations containing NSU questions, which were collected using Amazon Mechanical Turk (Raghu et al., 2015).

As we have a small dataset, we propose to decompose the original problem into two separate simplified problems where each problem uses an abstraction. These abstractions help the model training to focus on learning a specific aspect of the problem. Specifically, we train a syntactic sequence model to learn linguistic patterns, and a semantic sequence model to learn semantic patterns. We combine these two different models to generate an ensemble model, which can capture both linguistic and semantic patterns in NSU question conversations.

Our main contributions in this work are as follows:

1. We present a novel approach to handle non-sentential questions using the framework of sequence to sequence learning. Our approach is completely data driven, and can generate complete questions from a non-sentential question, given previous question and answer.

2. We propose a method to decompose the original NSU question resolution problem into two separate simplified abstractions that focus on learning a specific aspect of the problem. One such abstraction is semantic patterns in conversation data, that we learn with the help of a semantic sequence model.

3. We present a syntactic sequence model that focuses solely on learning linguistic patterns in conversations. Finally, we combine the semantic and syntactic sequence models to generate an ensemble model. Our ensemble model achieves a BLEU score of 30.15 as compared to 18.54 using a standard RNN encoder decoder.

Rest of this paper is organized as follows. We discuss related work in Section 2. Background needed to understand RNN encoder decoder model is discussed in Section 3. We present syntactic and semantic sequence models in Section 4 and Section 5 respectively. Finally, we discuss experiment settings and results in Section 6 and conclude in Section 7.

2 Related Work

NSUs were studied and classified into various classes by Ferna'ndez and Ginzburg (2002). One thread of work has focused on identifying and classifying NSUs into classes (Fernández et al., 2005; Rovira, 2006). Another thread of work has focused on resolving NSUs into complete intended utterances by building domain specific rules or grammar (Dalrymple et al., 1991; Carbonell, 1983). Writing rules or grammar is hard, extremely time consuming and may suffer with low recall. Therefore, we focus on a data driven and statistical approach.

Raghu et al. (2015) is the only work we know of that uses a statistical and data-driven model to resolve NSU questions. However their model cannot handle cases where previous answer or a combination of previous question and answer is needed to resolve a NSU question. For example, their approach cannot handle examples given in Table 1(b) and 1(d). Our approach does not have any such restrictions.

Sequence to sequence learning (Sutskever et al., 2014; Bahdanau et al., 2014; Cho et al., 2014) has been applied to a myriad applications. Some of the successful applications include statistical machine translation, speech translation (Duong et al., 2016), translating videos to sentences (Venugopalan et al., 2015), image captioning (Karpathy and Fei-Fei, 2015; Jia et al., 2015). Sequence to sequence learning has also been applied in modeling conversations (Li et al., 2016; Serban et al., 2016).

To the best of our knowledge, ours is the first work that approaches NSU question resolution as a sequence to sequence learning problem. Ours is also the first work that decomposes the original sequence to sequence learning problem, into separate simplified problems where each problem focuses on an abstraction.

3 Sequence to Sequence Learning

In this section, we discuss the framework of RNN encoder decoder model. This is followed by discussion on why it can be hard to train a RNN encoder decoder model using a small dataset. We finally formulate NSU question resolution as a sequence to sequence learning problem.

3.1 Background and Model Size

Sequence to sequence learning framework uses a recurrent neural network (RNN) to encode a variable-length input sequence to a fixed length vector, and then uses another RNN to decode the vector into a variable-length target sequence (Cho et al., 2014).

The model takes a source sentence (x) as input. Each sentence is a sequence of words, and each word is encoded using a one-hot encoding:

$$x = (x_1, x_2, \cdots, x_{t_x}), x_i \in \Re^{|V|}$$

The model outputs a target sentence (y), which is a sequence of words:

$$y = (y_1, y_2, \cdots, y_{t_y}), y_i \in \Re^{|V|}$$

where t_x and t_y respectively denote length of sequence x and y, and $|V|$ denotes the vocabulary size, and t_x need not be same as t_y. Note that compared to a neural machine translation model, we do not need a separate vocabulary for source and target, as source and target are in the same language (English).

RNN encoder first computes its forward state which are fixed length vectors $\vec{h}_i$:

$$\vec{h}_i = \begin{cases} (1 - \vec{z}_i) \circ \vec{h}_{i-1} + \vec{z}_i \circ \underline{\vec{h}_i} & \text{if i} > 0 \\ 0 & \text{if } i = 0 \end{cases}$$

where

$$\underline{\vec{h}_i} = tanh(\vec{W}\overline{E}x_i + \vec{U}[\vec{r}_i \circ \vec{h}_{i-1}])$$
$$\vec{z}_i = \sigma(\vec{W}_z\overline{E}x_+\vec{U}_z\vec{h}_{i-1})$$
$$\vec{r}_i = \sigma(\vec{W}_r\overline{E}x_+\vec{U}_r\vec{h}_{i-1})$$

$\overline{E} \in \Re^{m \times |V|}$ is the word embedding matrix. $\vec{W}, \vec{W}_z, \vec{W}_r \in \Re^{n \times m}$, $\vec{U}, \vec{U}_z, \vec{U}_r \in \Re^{n \times n}$ are weight matrices. m and n are word embedding dimensionality and number of hidden units respectively. σ is the logistic sigmoid function, $\circ$ is element wise multiplication.

RNN decoder is then initialized by a context vector $\vec{c}$. Typically a context vector is some combination of RNN Encoder's forward state vectors $\vec{h}_i$. Cho et al. (2014) and Sutskever et al. (2014) assign the context vector as $\vec{h}_{t_x}$, whereas Bahdanau et al. (2014) assign the context vector as a combination of RNN encoder hidden states ($\vec{h}_1, \vec{h}_2 \cdots \vec{h}_{t_x}$). The context vector c is then used to output sequence words.

Table 2 shows model size used by various RNN encoder decoder implementations. As $n \ll |V|$ and $m \ll |V|$, we can see that $\overline{E}$ dominates over other parameters $\vec{W}, \vec{W}_z, \vec{W}_r, \vec{U}, \vec{U}_z, \vec{U}_r$. This is usually not a problem when training data is large (of order of million sentences). However, for a small dataset, training a model with so many parameters does not work. We observed the same in our experiments.

We can reduce the vocabulary size, by replacing words that occur below a minimum frequency threshold with a special unknown symbol (UNK). This however, discards lots of useful information.

We present two new models: syntactic sequence (Section 4) and semantic sequence (Section 5) which can preserve and learn linguistic and semantic patterns respectively, while keeping the vocabulary size small.

Table 2: Model size for RNN Decoder. n is hidden layer size, m is word embedding size

3.2 Modeling NSU question resolution as sequence to sequence learning

We cast the problem of NSU question resolution as sequence to sequence learning. We concatenate the non-sentential question ($Q2$) and context ($Q1$, $A1$) to generate the source sequence. We use a special end of utterance symbol (END) to create the input sequence. This source sequence is then used to generate the resolved question ($R1$). For example, Table 3 depicts parallel corpus transformation for Table 1(c).

Source	what is greece 's national sport ? END football END flower ?
Target	what is greece 's national flower ?

Table 3: Parallel corpus formulation of Table 1(c)

Figure 1 depicts how RNN encoder decoder works. RNN encoder first processes the entire input sequence ($Q1$, $A1$, $Q2$) to a single fixed dimension vector (context vector $\vec{c}$). This vector is then used to initialize the RNN decoder. RNN decoder then samples output sequence by conditioning on previous sampled word, and the context vector.

4 Syntactic Sequence Model

We discussed in Section 3.1 that the parameters of RNN encoder decoder model are dominated by the size of vocabulary $|V|$. Even for a small dataset (1000s of sentences), $|V|$ may be of the order of 10,000. Thus for a small dataset, a RNN encoder decoder model has too many parameters to train it well.

We can reduce the vocabulary size by replacing out of vocabulary (OOV) with a special unknown symbol (UNK). However, we lose information by restricting vocabulary in this manner. In some cases, we just end up training the model to reproduce previous question $Q1$. For example, Table 1(c) is transformed such that $R1$ is exactly identical to $Q1$. Important information is lost that last OOV word (sport) in $Q1$ should be replaced by the OOV (flower) in $Q2$ to generate the complete question $R1$.

```
Q1: what is UNK 's national UNK ?
A1: UNK
Q2: UNK ?
R1: what is UNK 's national UNK ?
```

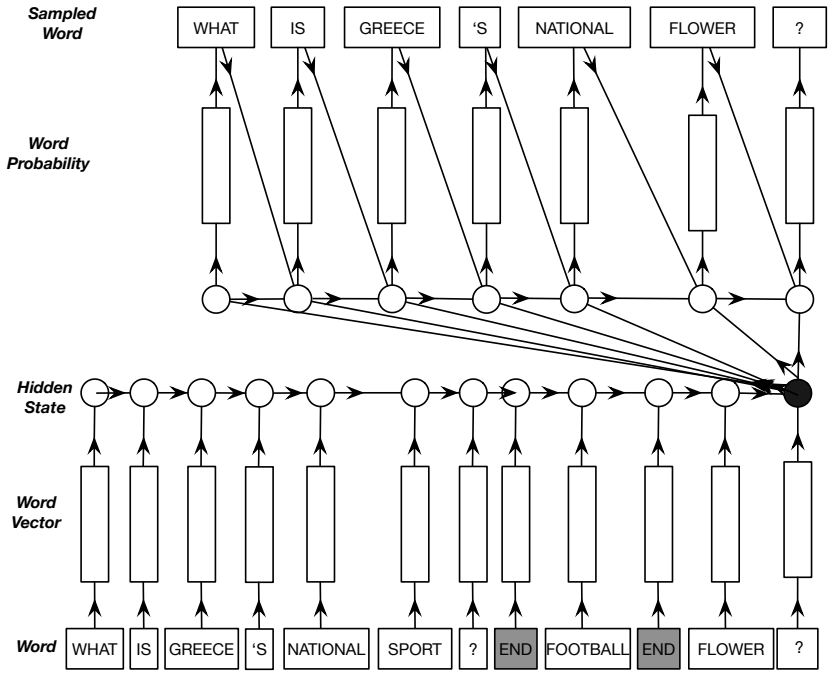

Figure 1: RNN based Encoder decoder for NSU question resolution

We can preserve linguistic structure by assigning a unique symbol to each OOV word. However, this does not help in reducing the vocabulary size. We can thus restrict assigning a new symbol only within a conversation($Q1, Q2, R1$) and reuse the symbols across conversations. Hence, it makes sense to assign symbols based on number of unknowns and its position in a single conversation. Table 4 (a) depicts how new symbols are assigned for the conversation in Table 1(c). Table 4(b) similarly shows how new symbols are assigned for the conversation in Table 1(b). Note how symbols(UNK1, UNK2, UNK3, UNK4) are shared across these two conversations. This allows the model to preserve (and learn) linguistic structure across different conversations.

(a)

Q1	what is UNK1 's national UNK2 ?	greece	UNK1
A1	UNK3	sport	UNK2
Q2	UNK4 ?	football	UNK3
R1	what is UNK1 's national UNK4 ?	flower	UNK4

(b)

Q1	what UNK1 has a UNK2 UNK3 name ?	animal	UNK1
A1	UNK4	7	UNK2
Q2	and how fast can it run ?	lettered	UNK3
R1	how fast can a UNK4 run ?	cheetah	UNK4

Table 4: Syntactic sequence training data for Table 1(c) and Table 1(b). Note how new symbols are assigned for each conversation, but shared across conversations.

Syntactic sequence model uses NSU question ($Q2$), conversation context ($Q1, A1$) and a symbol map, to generate the resolved question ($R1$). This symbol map helps in two important ways: it helps preserve the linguistic structure, and at the time of prediction it helps replace unknown symbol with the original word. We can also compare syntactic sequence model to a standard RNN encoder decoder model, where vocabulary is restricted and all OOV words are replaced with a single UNK. A standard RNN encoder decoder model will end up having UNK symbols as output. However, it is not possible to determine which word does this symbol correspond to, as there will be typically many UNK words in an input sequence. Syntactic sequence model addresses this problem by having a symbol map for the current conversation.

Syntactic sequence model however focuses solely on the position of OOV word in the sequence to assign a new unknown symbol and completely discards similarity between OOV words. In the next section (Section 5), we introduce a semantic sequence model that directly addresses this issue. Semantic sequence model focuses on learning semantic patterns from conversations.

5 Semantic Sequence Model

Syntactic sequence model focuses on learning linguistic patterns in conversations. However, it completely ignores the similarity of OOV words. This can lead to two different input sequences($Q1, A1, Q2$) to appear completely identical, even when they resolve to a different question $R1$. For example, Table 5 depicts two different input sequences with different $R1$, that look completely identical after assigning new unknown symbols based solely on position. Syntactic sequence model discards the information that OOV words 'Greece' and 'India' are similar, and 'flower' and 'sport' are similar (as compared to other tokens).

(a)

Q1	What is Greece 's national sport ?
A1	football
Q2	flower ?
R1	What is Greece 's national flower ?

Q1	What is UNK1 's national UNK2 ?
A1	UNK3
Q2	UNK4 ?
R1	What is UNK1 's national UNK4 ?

Greece	UNK1
sport	UNK2
football	UNK3
flower	UNK4

(b)

Q1	What is Greece 's national sport ?
A1	football
Q2	India ?
R1	What is India 's national sport ?

Q1	What is UNK1 's national UNK2 ?
A1	UNK3
Q2	UNK4 ?
R1	What is UNK4 's national UNK2 ?

Greece	UNK1
sport	UNK2
football	UNK3
India	UNK4

Table 5: Syntactic sequence input and output for two conversations with same $Q1$ but different $Q2$. Note how this model ends up assigning the same input sequence to (a) and (b)

We thus need a model that can exploit the similarity between OOV words and learn a higher level of abstraction. We can assign each OOV word a category number, based on a pre-learnt word category assignment. Each OOV word can then be assigned a new symbol based upon its word category index.

Semantic sequence model assigns a new symbol to each OOV word, based on the word category index. We learn the word category assignments by using a k-means algorithm (MacQueen and others, 1967), where pre-trained word vectors (Mikolov et al., 2013) are used as features.

Assigning new unknown symbols based on word similarity helps the model to focus on a powerful abstraction. The model learns that if a word of a particular category appears in a conversation, output will have words of a specific category. For example, Table 6 demonstrates how the model is trained to retain same output structure even with different NSU question ($Q2$). This is helpful as model can correctly be trained to preserve output structure at the level of word category, even with variations in input sequence.

Semantic sequence model takes as input a NSU question $Q2$, conversation context ($Q1, A1$) and a cluster symbol map. As compared to syntactic sequence model, we can have multiple OOV words assigned to the same cluster symbol token. We can replace the cluster symbol token (such as CL3) by replacing it with $Q2$ OOV word that was assigned to this cluster. We replace it with $Q2$ OOV word, as there is a greater chance that words in $Q2$ will appear in resolved utterance. For example, in Table 6(a), we can replace CL3 with flower.

(a)

Q1	What is CL1 's national CL3 ?
A1	CL3
Q2	CL3 ?
R1	What is CL1 's national CL3 ?

Greece	CL1
sport, football, flower	CL3

(b)

Q1	What is CL1 's national CL3 ?
A1	CL3
Q2	CL1 ?
R1	What is CL1 's national CL3 ?

Greece, India	CL1
sport, football	CL3

6 Experiments and Results

6.1 Dataset

We evaluate our models on NSU question conversation data which was collected using Amazon Mechanical Turk (Raghu et al., 2015). NSU question conversation data has 7220 conversations. Each conversation consists of a previous question ($Q1$), previous answer ($A1$), NSU question ($Q2$), and a

resolved question ($R1$). Table 1 highlights a few examples from the dataset. This dataset however has many spelling mistakes, that were fixed manually using a spell checker. 6820 conversations were used for training and the remaining 400 were used as a validation set. We further lower case and then tokenize the text. RNN encoder decoder needs a parallel corpus of an input and output sequence for training. Input sequence is generated by concatenating question ($Q1$), answer ($A1$) and NSU question ($Q2$) with a special end of utterance symbol (END). We use resolved question ($R1$) as the output sequence. Table 3 lists a sample input and output sequence. There are a total of 12,603 word types, 134K words in input sequence text and 65K words in output sequence text.

6.2 Training and Model details

For all experiments, Bidirectional RNN encoder decoder with attention mechanism (Bahdanau et al., 2014) is used. Gated Recurrent unit (GRU) (Cho et al., 2014) is used as the hidden unit for RNN. We used Adam (Kingma and Ba, 2014) as the optimization algorithm with a learning rate of 0.005 and mini-batch size of 128. Although GRU does not suffer from the vanishing gradient problem, it can still suffer from exploding gradient (Graves, 2013; Pascanu et al., 2013). Thus, a hard constraint on norm of the gradient was enforced by scaling it when norm exceeds a threshold.

Word embedding matrix was initialized using pre-trained word vectors (Mikolov et al., 2013). We use an open source Theano (Theano Development Team, 2016) based implementation[1] for training all our models. Word embedding size m, hidden unit size n and regularization parameters are treated as hyper-parameters. We train with different configurations based on a combination of these hyper-parameters and select the model that gives the best BLEU score on held out set of 400 conversations.

6.3 Evaluation Metric

One possible method to evaluate our models is to manually compare the generated output sequence to gold standard (collected from a held out set). However, this method is slow, human intensive and prone to errors. We wanted a method that could automatically assign a score to the generated output sequence based on how similar it is to the gold standard. BLEU (Papineni et al., 2002) is a popular metric for evaluating statistical machine translation systems and fits our needs well. A corpus level BLEU score (based on average of four grams) on a held out dataset of 400 was computed to evaluate all our models. We use the standard evaluation script [2] used by machine translation community.

Experiment	V	**BLEU4**
All-Vocab	12,603	8.24
Freq-10	1519	17.76
Freq-20	808	**18.54**
semantic-seq-20	818	21.20
syntactic-seq-20	823	29.11
ensemble-20	823	**30.15**

Table 7: BLEU score on a held out set of 400. V refers to vocabulary size

6.4 Experiments

Section 3.1 highlighted that RNN encoder decoder model parameters are dominated by the size of vocabulary $|V|$, which can make the model difficult to train on a small dataset. To evaluate the effect of a large vocabulary on a small dataset, standard RNN encoder decoder is trained. We obtain low BLEU score for this model which has 12,603 words in vocabulary (All-Vocab). For further experiments, size of vocabulary is reduced by selecting only words that occur above a minimum threshold. All the remaining out of vocabulary words (OOV) are marked as UNK. We found that restricting vocabulary further leads to a drop in BLEU score as we generate many UNK words in the output sequence. Thus, we consider this standard RNN encoder decoder model with reduced vocabulary of 808 words as our baseline model for comparison with semantic and syntactic sequence models.

[1] https://github.com/nyu-dl/dl4mt-tutorial/tree/master/session2

[2] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

To train semantic sequence model, first all words (12,603) in original vocabulary are assigned clusters using k-means algorithm. Pre-trained word vectors (Mikolov et al., 2013) are used as word features. We use default parameters of scikit-learn (Pedregosa et al., 2011) with $k = 8$ clusters to assign the word clusters. We experimented with different cluster size, and found $k = 8$ to give the best results. Words with no word vectors are assigned a new UNK cluster, and words that are numbers are assigned a new NUM cluster. We thus have a total of 10 word clusters. Semantic sequence model shows improvement over the baseline.

Syntactic sequence model is trained by replacing OOV words in input sequence with unique UNK symbols based on its position, as described in Section 4. Maximum length of sequence symbol map for a conversation was found to be 15. Syntactic sequence model achieves significant gain in BLEU score over the baseline. We summarize all the results in Table 7.

We finally combine the best semantic and syntactic model to create an ensemble model. Ensemble model picks the output sequence which has maximum keywords overlap with NSU question $Q2$. The intuition behind this criteria is that keywords that appear in Q2 are likely to occur in the resolved question, and therefor a higher overlap of a candidate resolution with Q2 is likely to lead to a better resolution. Table 8 highlights model output for the same input sequence as generated by the best syntactic sequence and semantic sequence model. Ensemble model picks up the better among the two candidate resolutions.

7 Conclusion

In this work we approach non-sentential question resolution in conversations as a sequence to sequence learning problem. Sequence to sequence learning models have been shown to work well when trained on a parallel corpus with millions of sentences. However, dataset of this magnitude is extremely hard to get for NSU question conversations.

We thus propose to decompose the original problem of NSU question resolution into two separate simplified problems. Each of these simpler problems focuses on an abstraction. Specifically we train a semantic sequence model that learns semantic patterns in conversations, and a syntactic sequence model that learns linguistic patterns in conversations. We finally combine the syntactic and semantic sequence model to generate an ensemble model. Our ensemble model achieves a BLEU score of 30.15 when compared to 18.54 on a standard RNN encoder decoder model with same vocabulary size.

As future work we wish to explore learning much simpler abstractions such as entity and concepts. Ensemble model is created using simple rules that pick the output sequence which has maximum overlap with NSU question. One can learn a statistical ensemble model too that uses other richer features from the simpler abstract models.

Abstract

Natural language generation (NLG) is an important component of question answering(QA) systems which has a significant impact on system quality. Most tranditional QA systems based on templates or rules tend to generate rigid and stylised responses without the natural variation of human language. Furthermore, such methods need an amount of work to generate the templates or rules. To address this problem, we propose a Context-Aware LSTM model for NLG. The model is completely driven by data without manual designed templates or rules. In addition, the context information, including the question to be answered, semantic values to be addressed in the response, and the dialogue act type during interaction, are well approached in the neural network model, which enables the model to produce variant and informative responses. The quantitative evaluation and human evaluation show that CA-LSTM obtains state-of-the-art performance.

1 Introduction

Natural language generation (NLG), the task of generating natural language from a knowledge base or a logical form representation, is an important component of dialogue or question answering system. NLG can be treated as a single-turn dialogue generation. Traditional approaches to NLG problem are mostly rule-based or template-based (Bateman and Henschel, 1999; Busemann and Horacek, 2002). However, these methods tend to generate rigid and stylised language without the natural variation of human language. In addition, they need a heavy workload to design the templates or rules.

Recently due to the growth of artificial neural networks and the increase of labeled data available on the Internet, data-driven approaches are developed to attack the NLG problem (Ritter et al., 2011; Shang et al., 2015). Shang et al. (2015) and Serban et al. (2015) apply the RNN-based general encoder-decoder framework to the open-domain dialogue response generation task. Although their model can generate the relevant and variant responses according to the input text in a statistical manner, the quality and content of responses depend on the quality and quantum of the training corpus. Wen et al. (2015) propose a task-oriented NLG model that can generate the responses providing the correct answers given the dialogue act (for instance, confirm or request some information), including the answer information. However the context information, such as the input question and dialogue act, is ignored. Yin et al. (2016) propose a neural network model that can generate answers to simple factoid questions based on a knowledge base. But a large error rate is observed due to the complex architecture introduced.

In this paper, we deal with the NLG problem in this setting: given a question, the corresponding dialogue act, and the semantic slots to be addressed in the response, how to generate a natural language response in a dialogue. We present a statistical task-oriented NLG model based on a Context-Aware Long Short-term Memory network (CA-LSTM), which adopts the general encoder-decoder framework to incorporate the question information, semantic slot values, and dialogue act type to generate correct answers. The major departures from prior work lie in:

- We design a context-aware generation framework for NLG. The framework incorporates the embedding of question and dialogue act type, and semantic values to be satisfied in the generated

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2032–2041, Osaka, Japan, December 11-17 2016.

response.

- We propose an attention mechanism that attends the key information in question conditioned on the current decoding state of the decoder. Thus the question embedding is dynamically changed over the decoding states.

- We propose to encode dialogue act type embedding to enable the model to generate variant answers in response to different act types. In this way, the response quality is substantially improved for particular act types.

2 Related Work

Traditional NLG methods divide the task into three phases: text planning, sentence planning, and surface realization (Walker et al., 2002), which can be solved by rules or templates in traditional approach (Mirkovic and Cavedon, 2011). The quality of language generated by rule-based or template-based methods mostly depends on the handcrafted rules or templates. Even if they can ensure the adequacy, fluency and readability of the language, the need of writing and maintaining the rules or templates is a large burden to these methods. Furthermore, the rule-based or template-based methods tend to generate rigid and nonvariant responses. To address the problem, Oh and Rudnicky(2000) propose a statistical approach which can learn from data to generate variant language using a class-based n-gram language model. However, due to the limits of the model and the lack of semantically-annotated corpora, the statistical approach cannot ensure the adequacy and readability of the generated language. Thus the statistical approach has not yet been employed widely compared to the rule-based or template-based methods.

Recently due to the maturity of artificial neural networks and the rich annotated data available on the Internet, data-driven statistical approaches are developed to address the NLG problem. These methods can be divided into two categories according to the corpus type, one is open-domain chat-based NLG, the other is task-oriented NLG for solving specific tasks.

2.1 Open-domain Chat-based NLG

Chat-based NLG aims to generate relevant and coherent responses in either single-turn or multi-turn dialogues. Shang et al.(2015) propose a Neural Responding Machine (NRM), a neural network-based chatbot NLG for Short-Text Conversation, which is trained on a large amount of one-round conversation data collected from a microblogging service. NRM takes the general encoder-decoder framework: NRM encodes the input text to the latent representation and then decodes the encoded information to generate responses. Rather than the traditional NLG task which includes text planning, sentence planning, and surface realization phases, NRM formalizes the NLG task as a general decoding process based on the encoded latent representation of the input text. Serban et al. (2015) propose a hierarchical recurrent encoder-decoder neural network to the open domain dialogue. In addition to the input text, the hierarchical model encodes the context information to generate the response.

Data-driven statistical approaches have also been studied for the text planning phase. In the text planning phase, NLG chooses the proper information of every sentence to be presented to users. The generation models mentioned above are trained by predicting the system response in a given conversational context using the maximum-likelihood estimation (MLE) objective so that they tend to generate nonsense responses such as "I dont know". To address this problem, Li et al. (2016) applies deep reinforcement learning to model long-term reward in chatbot dialogue which can plan the information in the response and avoid generating the nonsense responses in the dialogue.

2.2 Task-oriented NLG for Specific Domain

The statistical methods mentioned above are designed for open-domain chatbots, which emphasize on generating relevant and fluent responses according to the input text. While these methods are not suitable for task-solving scenarios (for instance, dialogue systems for restaurant and hotel reservation), which aims at providing correct answers to the input questions, because the responses of these methods are generated from the training data, which can not contain correct answers to any questions. Wen et al.

(2015) propose a statistical NLG based on a semantically controlled Long Short-term Memory (SC-LSTM) recurrent network which partially solves this problem. In the sentence planning phase, SC-LSTM generates the answers containing the slot tokens according to the dialogue act and slot-value pairs; in the surface realization phase, SC-LSTM replaces the slot tokens with the correct answers to the input questions. However, SC-LSTM generates responses with given answers information (the dialogue act and slot-value pairs) regardless of the input questions and generated answers. A Neural Generative Question Answering (GENQA), which can generate answers to simple factoid questions based on a knowledge base, addresses the task-oriented NLG problem further (Yin et al., 2016). However after unifying understanding of question, generation of answer, and retrieval of relevant facts in a knowledge-base into an end-to-end framework, GENQA introduces more errors in answers.

3 The Context-Aware LSTM Model (CA-LSTM)

3.1 Overview

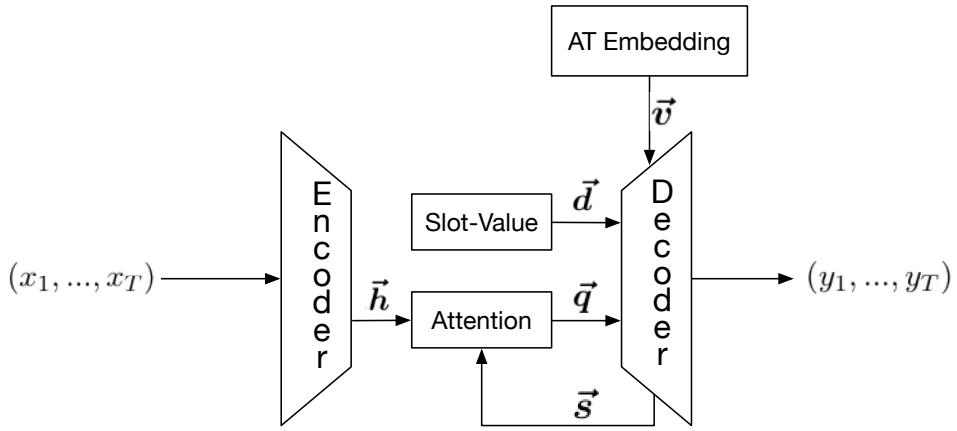

Figure 1: The general framework and dataflow of CA-LSTM. $\vec{h}$ is the hidden representation of the input question $(x_1, ..., x_T)$, $\vec{q}$ is the question vector generated by attention on $\vec{h}$ and the state of decoder $\vec{s}$, $(y_1, ..., y_T)$ is the output answer decoded with the question vector $\vec{q}$, the slot-value vector $\vec{d}$ and the dialogue act type (AT) embedding $\vec{v}$.

The Context-Aware LSTM (CA-LSTM) is built on the general encoder-decoder framework for sequence-to-sequence learning (Sutskever et al., 2014), as shown in Figure 1. Let $\boldsymbol{X} = (x_1, ..., x_T)$ and $\boldsymbol{Y} = (y_1, ..., y_T)$ denote the input question and output response respectively. The encoder converts the question sequence $\boldsymbol{X}$ to the hidden representation of the question sequence $\boldsymbol{h} = (h_1, ..., h_T)$. Then the hidden vector $\boldsymbol{h}$ is converted to the high dimensional question vector $\boldsymbol{q}$ after being attended with the current state of decoder. Finally, with the input of the question vector $\boldsymbol{q}$, the slot-value vector $\boldsymbol{d}$ and the embedding vector $\boldsymbol{v}$ of dialogue act type, the decoder generates the answer sequence $\boldsymbol{Y}$. Specifically, the slot-value vector $\boldsymbol{d}$[1] is a one-hot representation of the slot-value pairs which can regularize the generation process and ensure the information adequacy of answers as suggested by (Wen et al., 2015). By providing to the decoder the context information, including question vector and the act type embedding vector, CA-LSTM can generate context-aware responses which are related to the input question and dialogue acts.

The encoder and decoder are both based on Long Short-term Memory for its ability of modeling sequences of arbitrary lengths (Hochreiter and Schmidhuber, 1997). The procedure of generating variant responses has two components: the forward generator and the backward reranker, which share the same CA-LSTM network structure but with different parameters. To make use of the context information, the generator handles sequences in the forward direction and the reranker in the backward direction. The CA-LSTM network is introduced in Section 3.1 3.5 and the reranker is discussed in Section 3.6.

[1]The slot values are a set of values that must be satisfied in the response to be a correct answer, such as the price and type of requested restaurants.

3.2 Context-aware Decoding

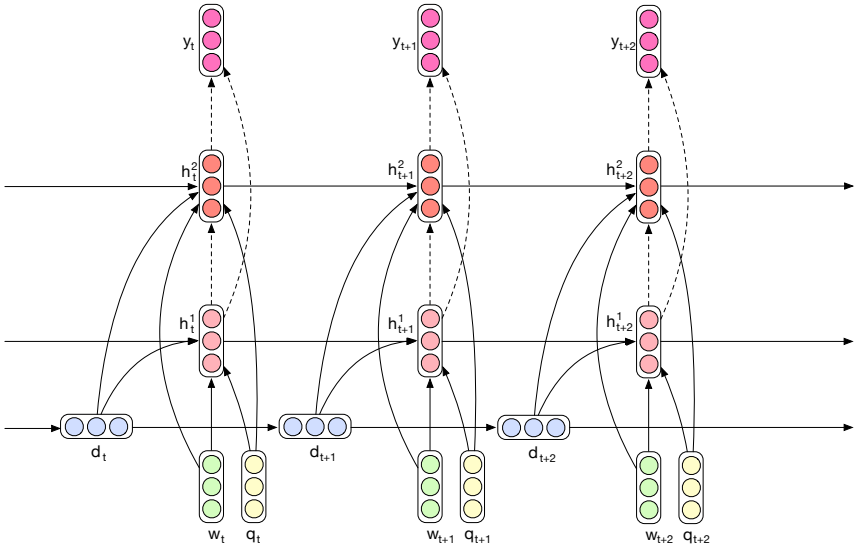

Figure 2: The graphical model of the decoder. w_t is the word embedding of the input token, q_t and d_t is the question vector and slot-value vector respectively, h_t^1 and h_t^2 are the hidden layer representations, and y_t is the probability distribution of the next token.

The decoder is based on the RNN language model (RNNLM), which takes the word embedding w_t of a token as the input at every time step t and outputs the probability distribution y_t of the next token w_{t+1} conditioned on the hidden layer representations h_t^1 and h_t^2. In addition to using the traditional LSTM cell in the RNNLM, we add the question vector $\boldsymbol{q}$ and the slot-value vector $\boldsymbol{d}$ in the network, as shown in Figure 2.

Deep neural networks can improve the network performance by learning multiple levels of feature abstraction. In order to learn more rich features, we adopt a two-layer Stacked-LSTM in the model, which has been proved effective in speech recognition (Graves et al., 2013) and other tasks. We apply the dropout operation on the dashed connections to prevent co-adaptation and overfitting, as shown in Figure 2. The Stacked-LSTM network is defined as follows,

$$i_t^n = \sigma(W_{wi}^n w_t + W_{hi}^n h_{t-1}^n + W_{hhi}^n h_t^{n-1} + W_{qi}^n q_t + b_i^n) \quad (1)$$

$$f_t^n = \sigma(W_{wf}^n w_t + W_{hf}^n h_{t-1}^n + W_{hhf}^n h_t^{n-1} + W_{qf}^n q_t + b_f^n) \quad (2)$$

$$o_t^n = \sigma(W_{wo}^n w_t + W_{ho}^n h_{t-1}^n + W_{hho}^n h_t^{n-1} + W_{qo}^n q_t + b_o^n) \quad (3)$$

$$\hat{c}_t^n = tanh(W_{wc}^n w_t + W_{hc}^n h_{t-1}^n + W_{hhc}^n h_t^{n-1} + W_{qc}^n q_t + b_c^n) \quad (4)$$

$$c_t^n = f_t^n \odot c_{t-1}^n + i_t^n \odot \hat{c}_t^n + tanh(W_{dc}^n d_t) \quad (5)$$

$$h_t^n = o_t^n \odot tanh(c_t^n) \quad (6)$$

where n and t denote the n^{th} layer in space and the t step in time respectively, σ is the sigmoid function, i_t^n, f_t^n, $o_t^n \in [0,1]^n$ are respectively the input gate, forget gate and output gate , $\hat{c}_t^n$ is the candidate cell value and c_t^n is the true cell value, and h_t^n is the hidden layer vector at time step t and layer n, all of which have the same dimension as the hidden layer vector. q_t is the question embedding vector and d_t is the slot-value vectors which will be described soon later.

Recalling that the task-oriented NLG aims at providing correct answers in responses, we thus use the slot-value vector $\boldsymbol{d}$ as the sentence planning cell to regularize the generation process and ensure the information adequacy of responses. The $\boldsymbol{d}$ vector stores a set of slot values that must be satisfied for the generated response to be qualified as a correct answer. The sentence planning cell is defined by the following equations,

$$r_t = \sigma(W_{wr} w_t + \sum_n \alpha_n W_{hr}^n h_{t-1}^n) \quad (7)$$

$$d_t = r_t \odot d_{t-1} \tag{8}$$

where $r_t \in [0,1]^d$ is the reading gate, d_0 is the initial one-hot slot-value vector by setting the corresponding bit to 1 and d_t is the slot-value vector at time step t which updates at every time step with the reading gate r_t. d_t influences the cell value c_t of the traditional LSTM cell by adding a nonlinear transformation $tanh(W_{dc}d_t)$ as shown in Equation 5.

Finally, the output probability distribution y_t of the next token w_{t+1} is computed as follows, and the next token w_{t+1} is generated by sampling from the distribution y_t.

$$w_{t+1} \sim y_t = P(w_{t+1} \mid w_t, w_{t-1}, , w_0, q_t, d_t) = softmax(\sum_n W_{ho}^n h_t^n) \tag{9}$$

3.3 Attention-based Encoding

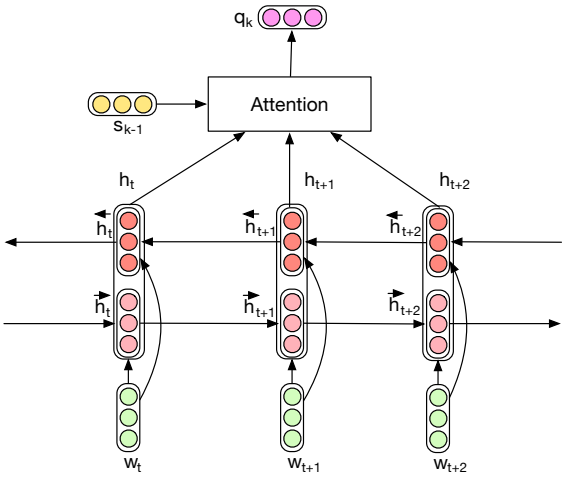

Figure 3: The graphical model of the encoder. h_t is the hidden layer representation of the input question at time step t for encoder, s_{k-1} is the state of the decoder at time step $k-1$ for decoder, q_k is the question vector at time step k for decoder generated by attention of $\boldsymbol{h}$ and the state of decoder s_{k-1}.

The encoder is built on Long Short-term Memory network. To model the question sequence with both of the preceeding and following contexts, we apply a Bidirectional-LSTM architecture (Graves et al., 2005) to the encoder as shown in Figure 3. The $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$ are the two directional hidden representations which are computed by iterating the forward layer from $t = 1$ to T and the backward layer from $t = T$ to 1 respectively. By concatenating the $\overrightarrow{h}_t$ and $\overleftarrow{h}_t$, we obtain the hidden representation of the question sequence $h_t = [\overrightarrow{h}_t ; \overleftarrow{h}_t]$.

Although we can feed the hidden layer representation h_T at time step T to the decoder as the question vector q_k, this method has its shortcomings: the question is processed at one time instead of being dynamically attended as the decoder proceeds. To address this problem, the attention mechanism (Bahdanau et al., 2014) is applied to generate question vector according to the hidden layer representation $\boldsymbol{h}$ and the state of the decoder s_{k-1}, which is computed as follows,

$$q_k = \sum_{t=1}^{T} \alpha_{kt} h_t \tag{10}$$

$$\alpha_{kt} = \frac{exp(e_{kt})}{\sum_{j=1}^{T} exp(e_{kj})} \tag{11}$$

$$e_{kt} = v_a^T tanh(W_a s_{k-1} + U_a h_t) \tag{12}$$

$$s_{k-1} = [h_{k-1}^1; h_{k-1}^2] \tag{13}$$

where α_{kt} is the weight of every hidden layer representation h_t of the question sequence, and s_{k-1} is the state of the decoder by concatenating h_{k-1}^1 and h_{k-1}^2 of the decoder. By weighted average of the hidden

layer representation $\boldsymbol{h}$, the decoder can obtain the critical information of the question sequence when generating the next token.

3.4 Act Type Embedding

Dialogue act consists of two parts: the act type that denotes the goal of the response to be generated, such as confirm and recommend, and the slot values which should be satisfied in the response, such as the price range or area of a requested restaurant. The act type information can be very useful to generate the response, however, it has not been fully exploited by SC-LSTM. In order to make the best use of the act type information, we embed the act type to an n-dimentional vector v_d which is randomly initialized and subsequently learned through the iterative training. By concatenating the act type embedding vector v_d and the word vector w_t and feeding them to the network, the act type information is able to influence the generation process at a global level. The computation of input gate, forget gate, output gate, candidate cell and reading gate of the network are updated by the following equations,

$$i_t^n = \sigma(W_{wi}^n[w_t; v_d] + W_{hi}^n h_{t-1}^n + W_{hhi}^n h_t^{n-1} + W_{qi}^n q_t + b_i^n) \quad (14)$$

$$f_t^n = \sigma(W_{wf}^n[w_t; v_d] + W_{hf}^n h_{t-1}^n + W_{hhf}^n h_t^{n-1} + W_{qf}^n q_t + b_f^n) \quad (15)$$

$$o_t^n = \sigma(W_{wo}^n[w_t; v_d] + W_{ho}^n h_{t-1}^n + W_{hho}^n h_t^{n-1} + W_{qo}^n q_t + b_o^n) \quad (16)$$

$$\hat{c}_t^n = tanh(W_{wc}^n[w_t; v_d] + W_{hc}^n h_{t-1}^n + W_{hhc}^n h_t^{n-1} + W_{qc}^n q_t + b_c^n) \quad (17)$$

$$r_t = \sigma(W_{wr}[w_t; v_d] + \sum_n \alpha_n W_{hr}^n h_{t-1}^n). \quad (18)$$

3.5 Training

The objective function is based on the cross entropy error between the predicted token distribution y_t and the gold distribution p_t in the training corpus. And to regularize the slot-value vector d_t, the cost function is modified to the following equation as suggested by (Wen et al., 2015),

$$F(\theta) = \sum_t p_t^\top log(y_t) + \parallel d_T \parallel + \sum_{t=0}^{T-1} \eta \xi^{\|d_{t+1} - d_t\|} \quad (19)$$

where d_T is the slot-value vector at the last time step T , and η and ξ are constants set to 10^4 and 100, respectively. To minimize $\parallel d_T \parallel$ is used to encourage the responses to provide adequate required slots. And the last term $\sum_{t=0}^{T-1} \eta \xi^{\|d_{t+1} - d_t\|}$ discourages the reading gate from turning off more than one bit of slot-value vector in a single time step. The parameters of CA-LSTM network are randomly initialized except for the word embeddings which are initialized by pre-trained 300-dimension word vectors (Pennington et al., 2014). The trade-off weights α are set to 0.5 as mentioned in Section 3.2 and 3.4. The dimension of hidden layer and act type embedding are set to 80 and 20 respectively. The decoder takes the two hidden layer Stacked-LSTM network with a 50% dropout rate. The network is trained with back propagation through time (Werbos, 1990) by treating each user question and system response turn as a mini-batch. AdaDelta (Zeiler, 2012) is applied to optimise the parameters, and the word embeddings are fine tuned through the iterative training. The forward generator and backward reranker are based on the same CA-LSTM network while the parameters are independent.

3.6 Reranking

In the decoding phase, the decoder generates a candidate set of response sequences by randomly sampling the probability distribution of next token. In the reranking phase, the candidate set is reranked by the sentence $score$. As a result, the top-n responses of the candidate set are chosen as the output responses. By combining the cost $F_f(\theta)$ of the forward generator as defined in Eq. (19), the cost $F_b(\theta)$ of the backward reranker (also in Eq. (19)) and the penalty of the error slot, the $score$ is defined as follows,

$$score = -(F_f(\theta) + F_b(\theta) + \lambda \frac{p+q}{N}) \quad (20)$$

where p, q are the number of missing and redundant slots respectively, N is the number of slots required, and λ is set to 100000 to penalize the response with wrong answers.

act types	inform, inform only match inform no match, confirm, hello select, request, reqmore, goodbye
slot names	name, type, *pricerange, postcode price, phone, address, *area, *near *food, *goodformeal, ***kids-allowed**

SC-LSTM	0.731
CA-LSTM	0.775
CA-LSTM+att	0.783
CA-LSTM+att+emb	**0.790**

Table 2: BLEU-4 score of the top 5 responses.

4 Experiments

4.1 Dataset Description

To evaluate the performance of CA-LSTM, we adopt the SF Restaurant dataset as used in (Wen et al., 2015), which is a corpus of a spoken dialogue system providing information about restaurants in San Francisco. It has around 5000 user question and system response turns sampled from about 1000 dialogues. The act types and slot-value pairs are labeled in the dataset. The details about the dialogue act are provided in Table 1. The training, validation and testing set are partitioned in the ratio of 3:1:1. And upsampling w.r.t act type is applied to make the corpus more uniform similar to (Wen et al., 2015).

4.2 Implementation Details

We use Theano (Bergstra et al., 2010) to implement the proposed model. For each dialogue act and input question, we generate 20 responses and select the top 5 responses as the output after reranking. The BLEU-4 metric (Papineni et al., 2002) implemented by NLTK (Bird, 2006) is used for quantitative evaluation. And the references set of the BLEU-4 metric are built by grouping the references of the same dialogue acts after delexicalising the responses and lexicalizing them by the correct values. Since the performance of CA-LSTM depends on initialisation, the results shown below are averaged over 5 randomly initialised CA-LSTM and the corpus are partitioned after random shuffle as well.

4.3 Quantitative Evaluation

We compare our proposed model with several baselines including: the handcrafted generator (hdc), k-nearest neighbour (kNN), class-based LMs (classlm) as proposed by Oh and Rudnicky (2000), the 2-hidder-layer semantically conditioned LSTM network (SC-LSTM) proposed by Wen et al. (2015). For our own method, we experiment with several settings: the basic setting (denoted by CA-LSTM), the Context-Aware LSTM with attention (CA-LSTM+att) which encodes the question vector with an attention mechanism, and the Context-Aware LSTM with attention and act type embeddings (CA-LSTM+att+emb). The result is shown in Table 2. As we can see, the performances of our methods have been greatly improved compared to the baselines shown in the first block (hdc,kNN,classlm and SC-LSTM). By combining more context information (attention and act type embeddings), the performance of CA-LSTM is further improved correspondingly. And the Context-Aware LSTM with attention and act type embeddings (CA-LSTM+att+emb) obtains the best overall performance.

4.4 Human Evaluation

Method	Informativeness	Naturalness
classlm	2.28	2.32
SC-LSTM	2.62	2.63
CA-LSTM	**2.78**	**2.74**

Table 3: Human evaluation for the quality of top 5 responses on two metrics (rating out of 3).

Pref.%	classlm	SC-LSTM	CA-LSTM
classlm	-	16.9	15.7
SC-LSTM	83.1	-	25.3
CA-LSTM	**84.3**	**74.7**	-

Table 4: Pairwise preference among the three systems.

We recruit 10 judges for human evaluation experiments. For each task, the three systems(classlm, SC-LSTM and CA-LSTM with attention and act type embeddings which is denoted by CA-LSTM for simplicity) are used to generate 5 responses. Judges are asked to score each of them in terms of informativeness and naturalness (rating scale is 1,2,3), and also asked to state a preference between any two of them. The informativeness is defined as whether the response provides all the information contained in the DA and the naturalness is defined as whether the response could plausibly have been produced by a human as proposed by Wen et al.(2015). We test 200 DAs and 1000 responses per system in total. The result of human evaluation for the quality of response is shown in Table 3. As can be seen, CA-LSTM outperforms the baseline methods in both metrics of informativeness and naturalness significantly ($p < 0.05$, Student's t-test). Besides, CA-LSTM is preferred by judges as shown in Table 4 where CA-LSTM is much more perferred than SC-LSTM.

4.5 Case Study

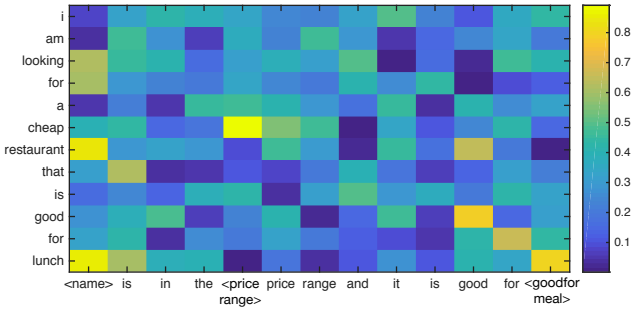

Figure 4: Attention matrix visualization

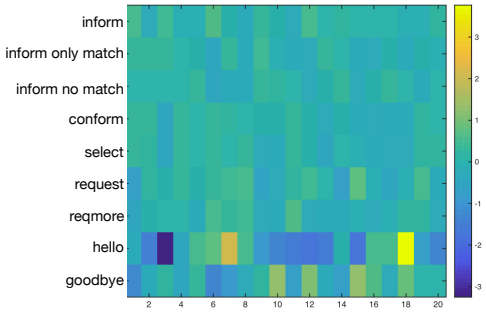

Figure 5: AT embedding visualization

Figure 4 visualizes the attention matrix for a pair of input question and output response. As can be seen, the weights of keywords in the question are strengthened when the decoder generates the relevant tokens, for example the weights of "restaurant", "lunch", "looking", "for" are augmented when the decoder generates the slot token "<name>".

Figure 5 visualizes the learned AT embeddings. The x-axis indicates the dimension index of AT embeddings and the color indicates the value of the corresponding dimension. The similar act types have similar AT embeddings such as "inform" and "inform only match", "request" and "reqmore", while dissimilar act types have different AT embeddings such as "hello" and "goodbye".

CA-LSTM can generate more coherent responses than SC-LSTM for particular act types such as "inform no match". Quantitative evaluation shows that CA-LSTM achieves 0.858 BLEU-4 score compared to 0.772 of SC-LSTM for the act type of "inform no match". For this act type, CA-LSTM can generate negation responses, such as " there is no basque restaurant that allows child -s. ", while SC-LSTM tends to ignore the negation information and generates responses like " there are basque restaurant -s that allow kid -s .".

5 Conclusion and Future Work

In this paper, we have proposed a statistical task-oriented NLG model based on a Context-Aware Long Short-term Memory (CA-LSTM) recurrent network. The network can learn from unaligned data without any heuristics, and it can generate variant responses and provide correct answers in response to the input information. Both quantitative evaluation and human evaluation show that CA-LSTM obtains the state-of-the-art performance. We also reveal the influence of the attention mechanism and act type embeddings with case studies. As future work, we would explore the NLG task in different domains and scenarios which need to consider more context information in the generation process.

Abstract

This work proposes a new confidence measure for evaluating text-to-speech alignment systems outputs, which is a key component for many applications, such as semi-automatic corpus anonymization, lips syncing, film dubbing, corpus preparation for speech synthesis and speech recognition acoustic models training. This confidence measure exploits deep neural networks that are trained on large corpora without direct supervision. It is evaluated on an open-source spontaneous speech corpus and outperforms a confidence score derived from a state-of-the-art text-to-speech aligner. We further show that this confidence measure can be used to fine-tune the output of this aligner and improve the quality of the resulting alignment.

1 Introduction

This work focuses on the text-to-speech alignment (T2SA) task, which consists in temporally aligning a given speech sound file with its known text transcription. The standard objective quality metric is the expected alignment error, measured in seconds and defined as $\mathcal{L} = E[|\hat{t} - t|]$, where t is the gold timestamp of a word boundary, and $\hat{t}$ the corresponding timestamp estimated by the aligner (Keshet et al., 2005).

Text-to-speech alignment is an important task for many applications, including: (i) Lip-syncing in cartoons production and film dubbing; (ii) Anonymization of audio corpus; (iii) Pre-processing of audio corpora for training new speech recognition systems; (iv) Indexing audio-visual corpora for browsing and querying; (v) Sampling sounds for speech synthesis; (vi) Second-language learning.

We propose in this work a novel confidence measure for detecting erroneous word boundaries at the output of an existing T2SA system. Accurately detecting misplaced word boundaries is crucial to reduce post-processing costs in every previous application. For instance, only the most reliable segments may be chosen for acoustic model training and speech synthesis, and manual corrections may be limited to the less reliable boundaries for lip syncing and corpus anonymization.

The proposed confidence measure is computed by a deep neural network (DNN) that is trained on a large corpus without any manually annotated word boundaries. We show on a gold corpus of French spontaneous speech that the proposed model is able to detect correct boundaries with a significantly better accuracy than the acoustic models used in the T2SA system, thanks to the acoustic features automatically captured by the deep neural model on the large unlabelled corpus. We further show that the proposed confidence measure may be used to post-process the T2SA output and improve its precision.

2 Related works

Every text-to-speech aligner faces three main challenges: (i) Handling imperfect transcriptions; (ii) Supporting noisy acoustic conditions; (iii) Finding the globally optimal alignment on long (up to a few hours) audio files. Many solutions have been proposed to address these issues. For instance, "anchor-based" approaches (Moreno et al., 1998; de Jong et al., 2006; Hazen, 2006) automatically infer high-confidence words timestamps at regular intervals in a long audio file in order to enable regular batch

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2042–2050, Osaka, Japan, December 11-17 2016.

alignment between two successive anchors. The issue of aligning highly imperfect text to speech may be addressed with standard acoustic adaptation (Zhao et al., 2005), or by performing recognition at the phoneme level only with monophthongs and fricatives, which appear to be more robust to noise than other phonemes (Haubold and Kender, 2007). Complementary, better phonetization models of unknown words may also be used (Bigi, 2013). More generally, various models have been proposed for phoneme alignment, such as discriminative shallow large-margin alignment models in (Keshet et al., 2005), non-neural unsupervised acoustic models in (Milde, 2014) and in (Lanchantin et al., 2015), where two DNNs are used respectively for acoustic modelling for speech transcription and for segmenting the speech file into speech and non-speech segments. A remarkable HMM-based architecture is also proposed in (Brognaux and Drugman, 2016), where the acoustic models are trained solely on the target corpus to align. The authors of (Yuan et al., 2013) demonstrate the importance of producing high-precision temporal limits with dedicated models, and propose in (Stolcke et al., 2014) a neural network to fine-tune the alignment. We follow this line of work, but rather focus on estimating the actual quality of the proposed boundaries with a confidence measure. A confidence measure is proposed in the aligner ALISA (Stan et al., 2016), but its role is to filter-out wrongly recognized sentences. Conversely, few publications address the problem of detecting reliable temporal boundaries after T2SA. (Paulo and Oliveira, 2004) proposes a confidence measure that is based on a synthetic speech signal, while (Keshet et al., 2005) discriminatively trains base functions that define an alignment confidence measure, but which is not evaluated per se: thanks to the decomposability property of the base functions, this measure is rather used with a dynamic programming algorithm to output a final alignment. Our work is, to the best of our knowledge, the first proposal to use the modelling potential of deep networks to compute successful confidence measures of text-to-speech alignment outputs.

3 Proposed model

3.1 Model description

The proposed model is shown in Figure 1. Two models, respectively called the *Boundary inspector* and the *Boundary selector*, are built to compute a confidence measure that any candidate word boundary is correct or not. Both the *Boundary inspector* and *selector* take as input an acoustic window of ± 0.05s around the candidate word boundary, plus two categorical inputs representing the left and right phonemes. They can thus be viewed as acoustic models that are specialized in identifying boundaries between two segments, as opposed to classical acoustic models that are designed to discriminate between phonemes that may generate a given segment.

The *Boundary inspector* is a standard feed-forward deep network with two output neurons, which encodes the probability that the central input frame [1] t is a true word boundary. It thus focuses on a single frame, the middle one, and makes a decision about it. It is completed with another model, the *Boundary selector*, which rather considers simultaneously all possible candidate frames in the interval $t \pm 5$, and decides which one is the most likely to be the target word boundary. Because we know that consecutive frames are more correlated than distant frames, we use a recurrent LSTM model to capture correlation between frames. Because no privileged direction is assumed, we use a bi-directional LSTM. The output of this LSTM is then merged with the contextual phonetic information in a feedforward network with 11 outputs: one for each input frame. Both models are finally combined with a deep feedforward network called *Aggregator*, which is trained separately on another corpus.

3.2 Training

Our choice to use a Deep Neural Network (DNN) is motivated by the potential of deep networks to infer complex hierarchical features from data that would have been difficult to design by hand. But this is only possible on large training corpora, while only our small gold corpus is manually annotated with temporal boundaries. We thus have to rely on one of the common deep learning "tricks" for building a large enough training corpus, such as transfer learning, the use of auxiliary tasks or data augmentation. In this

[1] A frame is a time-segment of 10ms length encoded into an acoustic vector of dimension 39 composed of 12 MFCC (Mel-Feature Cepstral Coefficients) plus their derivative and acceleration.

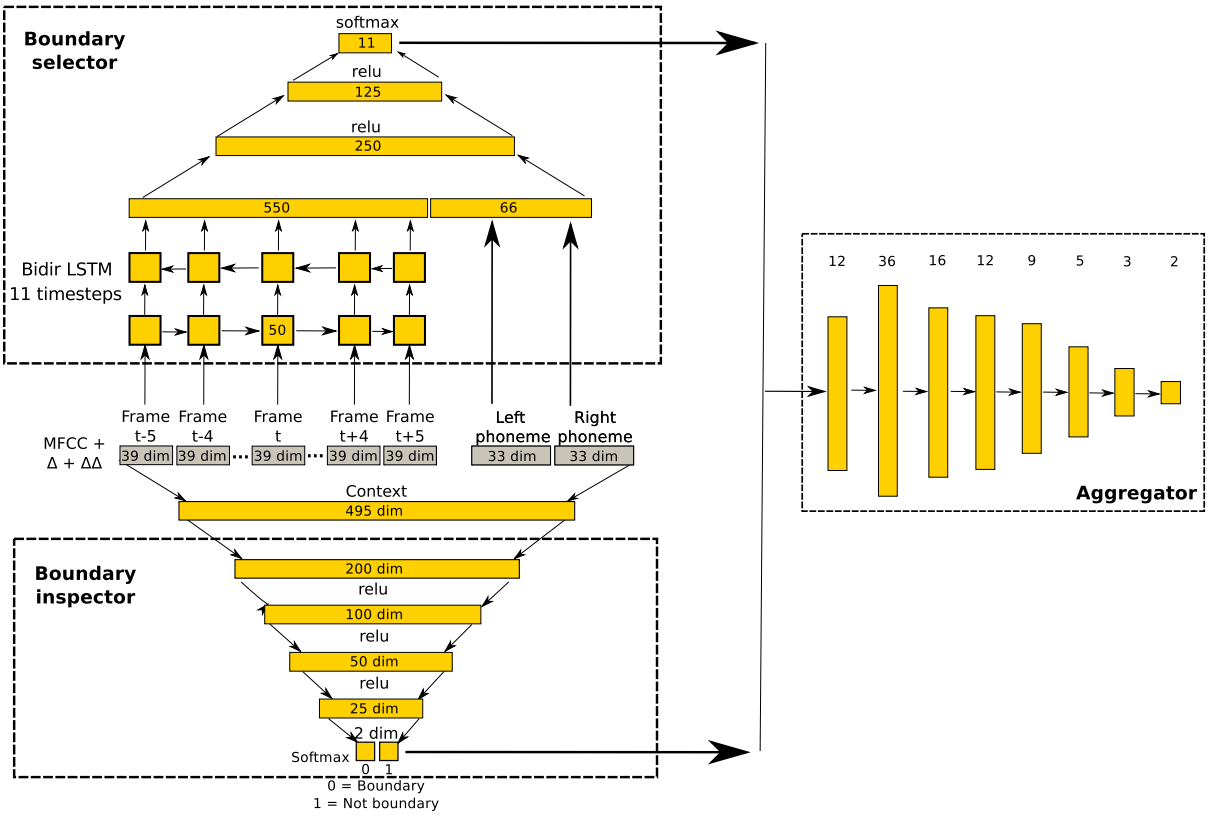

Figure 1: Proposed model. The input vector is composed of 11 frames plus 2 phonemes, shown in the center. Below, the *Boundary inspector* detects whether the middle frame t is a true word boundary or not. Above, the *Boundary selector* is composed of a bi-directional LSTM with 11 timesteps (only 5 are shown) plus 3 feed-forward layers that select the most likely word boundary frame in the input segment. Both models outputs are fed into the *Aggregator* model, on the right, which outputs a confidence probability that frame t is a word boundary.

work, we have decided to combine two state-of-the-art French text-to-speech aligners, ASTALI (Fohr et al., 2015) and JTrans (Cerisara et al., 2009) [2] in order to align part of the open-source ORFEO corpus, composed of 3 million words of French spontaneous speech manually transcribed and available at `http://www.projet-orfeo.fr`.

We then compare both ASTALI and JTrans alignments on this corpus and consider that any word boundary that has the same timestamp in both alignments, within a tolerance of ± 0.02s, is correct[3]. This procedure allows us to automatically build a large training corpus of positive examples which is then completed with 3 times more negative instances obtained by randomly sampling frames that are distant from any ASTALI and JTrans word boundary by at least 0.04s, leading to a training corpus of 377662 examples, which is used to train both the *Boundary inspector* and *selector*.

The same process is used on another set of files from the ORFEO corpus to create a second training corpus of 105406 examples, on which both model output probabilities are computed and used to train the *Aggregator*. During the training of each model, 20% of the training corpus is further reserved to compute a validation loss.

The evolution of the training and validation loss for the three models is shown in Figure 2. These curves suggest that overfitting is not a major issue at this stage. The hyper-parameters of the DNN, including the number and size of the layers, have been set-up empirically with a few trials and errors

[2] JTrans is available on github `https://github.com/synalp/jtrans` and ASTALI is released by its authors

[3] The exact timestamp chosen for this positive temporal limit is the average of the timestamps proposed by JTrans and ASTALI. The tolerance of 0.02s is standard in the phoneme alignment literature (Hosom, 2009).

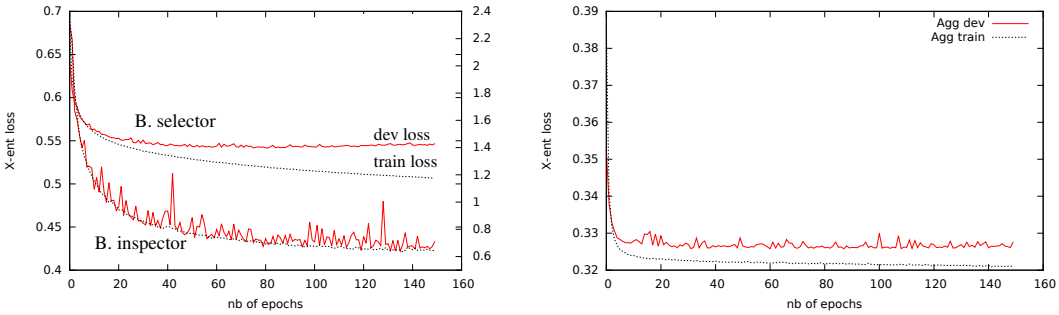

Figure 2: Loss curves during training of the models.

on the training and validation corpus. In particular, we have not used any automatic hyper-parameter tuning strategy. This search of an appropriate model topology has mainly been driven by our motivation to design an architecture that is deep enough to model rich transformations and at the same time that limits the number of parameters to prevent overfitting. Note however that we have only tried a few alternative hyperparameters and thus that the proposed topology is certainly not optimal. The DNN has been implemented with Keras (Chollet, 2015) and trained on these positive and negative instances with the ADAM stochastic gradient descent for 150 epochs.

3.3 Test

The proposed system is evaluated on a gold corpus that is composed of 10988 words extracted from the original ORFEO corpus, and for which 16264 word boundaries, obtained with ASTALI, have been manually corrected. There is no overlapping between this gold corpus and the previous corpora.

At test time, JTrans is run on the test corpus to compute candidate temporal limits of words.

An example of inputs/outputs is shown in Figure 3. Let t be a temporal word boundary[4] given by JTrans, with h_l and h_r respectively the left and right phonemes that are separated by t. For instance, in Figure 3, $t = 186$, h_l =õ and h_r =s.

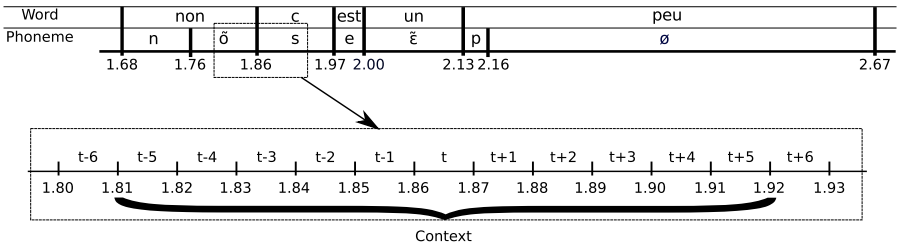

Figure 3: Example of a segmented sentence with its context for the fragment: “no, that’s a bit [...]”

The *Boundary inspector* and *selector* are run on the temporal limits proposed by JTrans and their output probabilities are then passed to the *Aggregator*, which finally returns, for each JTrans temporal limit t, the probability that t is correct or not.

4 Evaluation

4.1 Confidence measure evaluation

Similarly to most other confidence measures in the literature (Yu et al., 2011), we evaluate the proposed confidence measure as a detector of correct vs. erroneous examples. We evaluate next its performances with a Detection Error Tradeoff (DET) curve, which is easier to interpret than the ROC curve (Martin et al., 1997).

[4]Time variables such as t represent an integer number of frames since the start of the audio file. Hence, $t + 2$ is the second frame after the JTrans limit t.

We compare our proposed model first with a baseline confidence measure derived from the acoustic Hidden Markov Models (HMM) used in the text-to-speech alignment process. Let $(w_i)_{1\leq i\leq N}$ be the sequence of words in the transcription. For ease of notation, we assume here without loss of generality that every word is modelled with a single-state Hidden Markov Model (HMM); in fact, every word is actually composed of a sequence of phonemes, and every phoneme is modelled by an HMM with 3 emitting states. However, this hierarchy of models would lead to excessively long equations, and we prefer to simplify the presentation of this baseline.

For a given possible alignment, let the random variable $Q_t = i$ with $1 \leq i \leq N$ represents the index of the word aligned with frame t. By definition, in the context of text-to-speech alignment, a confidence measure for the transition $(Q_t = i, Q_{t+1} = i + 1)$ is given by the posterior probability:

$$P(Q_t = i, Q_{t+1} = i + 1|X, \lambda)$$

where λ represents the parameters of the acoustic models used in JTrans, and $X = (X_t)_{1\leq t\leq T}$ represents all observed acoustic frames.

For our baseline confidence measure, we rely on the acoustic models used in the JTrans system. These acoustic models are Hidden Markov Models, and it is thus well known that the previous posterior can be computed with the forward-backward algorithm:

$$P(Q_t = i, Q_{t+1} = i + 1|X, \lambda) = \frac{\alpha_i(t)a_{i,i+1}\beta_{i+1}(t + 1)b_{i+1}(X_{t+1})}{\sum_{k=1}^{N}\sum_{l=1}^{N}\alpha_k(t)a_{k,l}\beta_l(t + 1)b_l(X_{t+1})}$$

where $b_i(X_t)$ is the observation likelihood of frame X_t in state i. $b_i(X_t)$ is modeled in JTrans by a Gaussian Mixture Model. $a_{i,j} = P(Q_{t+1} = j|Q_t = i)$ is the prior transition probability between words i and j, which is irrelevant in the context of text-to-speech alignment, where we just set $a_{i,i} = \frac{1}{2}$ and $a_{i,i+1} = \frac{1}{2}$. α and β are respectively the matrices of forward and backward probabilities, which can be computed recursively:

$$\alpha_j(t) = \left[\sum_{i=1}^{N}\alpha_i(t - 1)a_{ij}\right] b_j(X_t)$$

$$\beta_i(t) = \sum_{j=1}^{N} a_{ij}b_j(X_{t+1})\beta_j(t + 1)$$

We first evaluate the quality of the DNN as a detector of correct limits, assuming that any JTrans output boundary is a correct limit when its distance to the corresponding gold limit is smaller than 0.02s, as done during training. The corresponding DET curve is shown in Figure 4.

In the DET plot, the closer the curve is to the bottom-left origin, the better it is. We can observe that the proposed confidence measure is a better detector of true boundaries than the acoustic baseline for all possible detection thresholds. The first row in Table 1 also shows the Equal Error Rate (EER), which is the intersection between the $y = x$ diagonal and the DET. With 36% of equal errors, the proposed confidence measure is significantly better than random and it is the first efficient confidence measure for word boundaries based on acoustic information that we are aware of.

While the EER is a good summary of the DET curve, it can only be computed assuming knowledge of the true labels. The next rows in Table 1 thus show standard detection performances at another operating point, the median, which corresponds to the threshold that tags half of the corpus as positive, and half as negative. The proposed model is then compared with a second baseline, called *JTrans/ASTALI agreement*, which tags every JTrans boundary as positive when it lies within the ± 0.02s interval around the corresponding ASTALI limit. This baseline has already been used to automatically annotate the training corpora of the DNN models (see Section 3.2), except that for training, all boundaries tagged as negative are removed, while they are used here to compute the detection metrics in Table 1.

The acoustic baseline confidence measure is not significantly better than random, which confirms for text-to-speech alignment what has already been reported in the literature for speech recognition, i.e., that

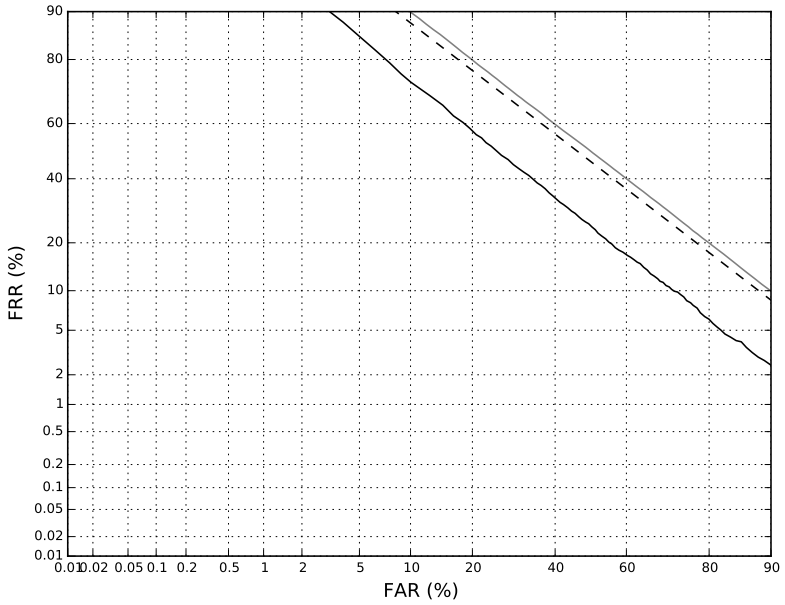

Figure 4: Detection Error Tradeoff curves for detecting word boundaries. The X-axis is the False Accept Rate, while the Y-axis is the False Reject Rate. Three curves are shown, from the worst (top-right corner) to the best (bottom-left corner): random baseline detector (straight grey line), baseline (dash) and our proposed DNN (plain line).

	Acoustic baseline	Proposed model	JTrans / ASTALI agreement
Equal Error Rate (EER)	48%	**36%**	
Precision (median)	43%	52%	60%
Recall (median)	53%	69%	45%
F1 (median)	48%	**60%**	51%

Table 1: Detection performances at fixed operating points of the proposed DNN and two baselines: an acoustic baseline, which computes the posterior of each boundary given JTrans' acoustic models, and a deterministic baseline that tags a boundary as correct when JTrans and ASTALI give close timestamps.

confidence measures based solely on acoustic observation likelihoods usually fail to reliably detect correct words (Willett et al., 1998). This is why state-of-the-art confidence measures for speech recognition mainly exploit other types of features, in particular language-model features (Seigel, 2013). However, language-model information is irrelevant in text-to-speech alignment applications, which makes the task of detecting reliable word boundaries especially challenging. With an F1 of 60%, the performances obtained with our proposed DNN-based confidence measure are thus encouraging, because:

- Our DNN only exploits the same information as speech acoustic models, i.e., acoustic observations and phoneme identities;
- It is trained without manual supervision, only exploiting agreement between two automatic T2SA systems.
- Despite the relatively weak precision of 60% for annotating positive labels in the DNNs' training corpus, the DNN is able to learn relevant acoustic information and provide the first working confidence measure for detecting true word boundaries.

The JTrans/ASTALI agreement baseline has a low recall of 45%. Although this low recall penalizes

its performances as a confidence measure, we can note that the recall is actually not crucial when this JTrans/ASTALI agreement approach is used to automatically annotate training examples for the proposed deep models, because all negative limits are discarded, as explained in Section 3.2. In fact, it may even be preferable to tune this automatic annotation method so that its precision is further increased, at the expense of an even lower recall, so that the positive examples that are kept have a higher likelihood of being correct. However, the JTrans/ASTALI agreement baseline may not easily be tuned in order to increase its precision above 60%. An interesting future work would then be to replace this agreement process with another detector, like the proposed DNN itself, for which the operating point can be tuned, and eventually iteratively retrain the DNN in a self-training fashion on larger corpora, without the need to rely on two different aligners.

4.2 Enhanced aligner evaluation

We propose next a simple post-processing module that enhances the precision of the original T2SA system. This fine-tuning algorithm basically detects suspicious JTrans temporal limits and replaces them by temporal limits with a higher confidence measure in their neighbourhood. It proceeds as follows:

Algorithm 1: Simple fine-tuning of JTrans' output alignment

- For every JTrans output word boundary t:
  - For every distance $d \in 1, 2, 3, 4, 5, \cdots, D$ up to a *maximum distance* D:
    - Compute both DNN output probabilities at distance d from t: $P(t-d)$ and $P(t+d)$
    - Pick the best of both frames $\hat{t} = \arg\max_{t' \in t-d, t+d} P(t')$
    - If the new frame is better than the original JTrans frame $P(\hat{t}) > P(t)$ and better than a minimum confidence threshold $P(\hat{t}) > \delta$, then move the word boundary to $\hat{t}$ and continue with the next boundary t.

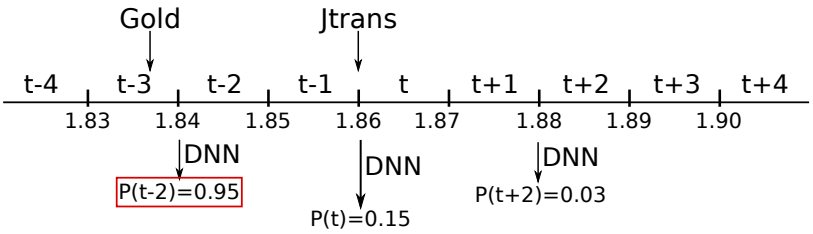

Figure 5: Fine-tuning example. The Jtrans initial limit is 1.86s. The DNN output probability is computed for frames (185,187) first, and then for frames (184,188). The best output is obtained for 1.84s.

Figure 6 plots the original (top horizontal dashed line) and resulting alignment error for various D and δ. Although the global impact of our fine-tuning algorithm is small, it is positive for all D and δ. Because our fine-tuning algorithm just looks for the most confident limits in a neighbourhood of the original JTrans boundary, the iterative application of the confidence measure onto more and more distant frames increases the probability of misclassification. Furthermore, whenever it moves a word boundary, the resulting impact on the previous or following words should be handled, for instance with a Viterbi algorithm. So this experiment is merely a proof of concept that confirms the possibility to post-process a text-to-speech aligner output with the proposed confidence measure; the main focus of this work is rather confidence measure evaluation, which may benefit to many other applications, as discussed in the introduction. These results are thus encouraging to further pursue efforts into investigating weakly supervised deep neural networks for fine-tuning existing text-to-speech aligners.

5 CONCLUSIONS AND FUTURE WORKS

We develop a weakly supervised approach that exploits two existing text-to-speech aligners to automatically annotate a corpus for training a deep neural network-based confidence measure without direct

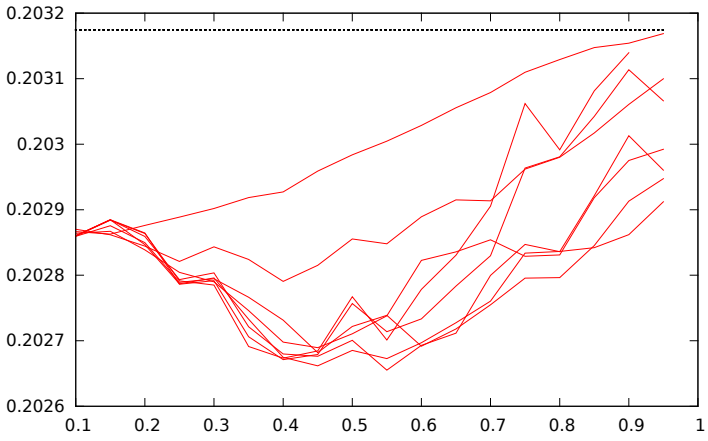

Figure 6: Average alignment error (Y-axis, in seconds) for various maximum distance D (from ± 1 to ± 8 frames), as a function of the minimum confidence threshold (X-axis). The top dashed horizontal line is the original JTrans alignment error.

supervision. We propose two different types of neural networks for this task and combine them within a single model. For now, all three components of the proposed model are trained independently, but we plan to train them jointly in a future work to further improve the resulting model. Experimental results show that the proposed confidence measure outperforms a baseline acoustic confidence measure derived from the original text-to-speech aligner. We further show that it outperforms another baseline, which results from a voting ensemble of both original text-to-speech aligners. This is, to the best of our knowledge, the first good performances ever reported for confidence measure detection of true word boundaries. The performances reached are also interesting because the deep models only exploit acoustic information, which has been shown to be otherwise unsuccessful for confidence estimation in the context of speech recognition, and because these models are trained without manual supervision. These results open the way to further improvements in automatic annotation of unlabelled corpora for text-to-speech alignment, for instance by iteratively re-labelling the training corpus with the proposed model setup in high-precision mode and retraining new confidence models. We further apply the trained confidence measure with a simple corrective algorithm that fine-tunes the output timestamps given by the original text-to-speech aligner. This experiment shows encouraging results for improving text-to-speech alignments thanks to the proposed confidence measure. Possible ways to improve these results include designing a better exploration strategy for fine-tuning the initial alignment, as well as investigating other DNN topologies.

The complete source code as well as links to all datasets is available at `https://github.com/cerisara/speechAlignConfidence`.

Abstract

In many applications such as personal digital assistants, there is a constant need for new domains to increase the system's coverage of user queries. A conventional approach is to learn a separate model every time a new domain is introduced. This approach is slow, inefficient, and a bottleneck for scaling to a large number of domains. In this paper, we introduce a framework that allows us to have a single model that can handle all domains: including unknown domains that may be created in the future as long as they are covered in the master schema. The key idea is to remove the need for distinguishing domains by explicitly predicting the schema of queries. Given permitted schema of a query, we perform constrained decoding on a lattice of slot sequences allowed under the schema. The proposed model achieves competitive and often superior performance over the conventional model trained separately per domain.

1 Introduction

Recently, there has been much investment on the personal digital assistant (PDA) technology in industry (Sarikaya, 2015). Apple's Siri, Google Now, Microsoft's Cortana, and Amazon's Alexa are some examples of personal digital assistants. Spoken language understanding is an important component of these examples that allows natural communication between the user and the agent (Tur, 2006; El-Kahky et al., 2014; Kim et al., 2015a; Kim et al., 2016b). PDAs support a number of scenarios including creating reminders, setting up alarms, note taking, scheduling meetings, finding and consuming entertainment (i.e. movie, music, games), finding places of interest and getting driving directions to them. The number of domains supported by these systems constantly increases, and whether there is a method that allows us to easily scale to a larger number of domains is an unsolved problem (Kim et al., 2015d; Kim et al., 2016a).

The main reason behind the need for additional domains is that we require a new set of schema (i.e., query topics), composed of intents, and slots for processing user queries in a new category. For example, a query in the TAXI domain is processed according to domain-specific schema that is different from those in the HOTEL domain. This in turn requires collecting and annotating new data, which is time consuming and expensive. Once the data is prepared, we also need to build a new system (i.e., models) for this specific domain. In particular, slot modeling is one of the most demanding components of the system in terms of costs in annotation and computation.

In this paper, we introduce a new approach that entirely removes the costs traditionally associated with enlarging the set of supported domains while significantly improving performance. This approach uses a single model to handle all domains: including unknown domains that may be created in the future using a combination of intents and slots in the master schema. The key idea is to remove the need for distinguishing domains by explicitly predicting topics/schema of queries. Thus we obviate the need and directly predict the schema from queries by multi-label classification (either with an RNN or with binary

logistic regressions). Given permitted schema of a query, we perform constrained decoding on a lattice of slot sequences allowed under the schema.

In experiments on slot tagging 17 Cortana personal digital assistant domains, we observe that our single model outperforms each of the 17 models trained separately on different domains. This is because our model is able to leverage the data in all domains by reusing the same slots. It can be viewed as a form of domain adaptation, although "domainless adaptation" may be a more accurate description since we remove the need for distinguishing domains!

2 Background

2.1 Domain Adaptation

The goal of domain adaptation is to jointly leverage multiple sources of data (i.e., domains) in attempt to improve performance on any particular domain. There is a rich body of work in domain adaptation for natural language processing. A notable example is the feature augmentation method of Daumé III (2009), who propose partitioning the model parameters to those that handle common patterns and those that handle domain-specific patterns. This way, the model is forced to learn from all domains yet preserve domain-specific knowledge.

Another domain adaptation technique used in natural language processing utilizes unlabeled data in source and target distributions to find shared patterns (Blitzer et al., 2006; Blitzer et al., 2011). This is achieved by finding a shared subspace between the two domains through singular value decomposition (SVD). Unlike the feature augmentation method of Daumé III (2009), however, it does not leverage labeled data in the target domain.

This work is rather different from the conventional works in domain adaptation in that we remove the need to distinguish domains: we have a single model that can handle arbitrary (including unknown) domains. Among other benefits, this approach removes the error propagation due to domain misclassification. Most domain adaptation methods require that we know the data's domain at test time (e.g., the feature augmentation method). But in practice, the domain needs to be predicted separately by a domain classifier whose error propagates to later stages of processing such as intent detection and slot tagging.

2.2 Constrained Decoding

In a later section, we perform constrained decoding on a lattice of possible label sequences. This technique was originally proposed for transfer learning by Täckström et al. (2013). Suppose we have sequences that are only partially labeled. That is, for each token x_j in sequence $x_1 \dots x_n$ we have a set of allowed label types $\mathcal{Y}(x_j)$. Täckström et al. (2013) define a constrained lattice $\mathcal{Y}(x, \tilde{y}) = \mathcal{Y}(x_1, \tilde{y}_1) \times \dots \times \mathcal{Y}(x_n, \tilde{y}_n)$ where at each position j a set of allowed label types is given as:

$$\mathcal{Y}(x_j, \tilde{y}_j) = \begin{cases} \{\tilde{y}_j\} & \text{if } \tilde{y}_j \text{ is given} \\ \mathcal{Y}(x_j) & \text{otherwise} \end{cases}$$

We compute the most likely sequence in the lattice for a given observation sequence x under model θ as:

$$y^* = \arg\max_{y \in \mathcal{Y}(x, \tilde{y})} p_\theta(y|x)$$

3 Methods

In this section, we describe our domainless prediction framework. It consists of two stages:

1. Given a query, we perform *multi-label classification* to predict a set of allowed schema for the query.
2. Given the predicted schema, we perform *constrained decoding* on the lattice of valid slot sequences.

Since this framework does not involve domain prediction at all, given a query in an unknown domain we can still use the same model to infer its slot sequence, as long as the new domain is composed of existing slots and intents. In cases where the new domain needs an a new intent or slot, the underlying generic models have to updated with the updated schema.

3.1 Schema Prediction

The first stage produces a set of label types that serve as constraints in the second stage. To this end, we use Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) (Figure 1). The LSTM processes the given query to produce a fixed-size vector where the input at each time step is the word embedding corresponding to the word used at the time. We initialize these word embeddings with GloVe vectors (Pennington et al., 2014). Then the network maps the query vector to a distribution over schema types.

In more detail, we first map each word of the utterance into d-dimensional vector space using an embedding matrix of size V by d (which is trained along with other parameters in the network), where V is the size of the vocabulary. Then we map the sequence of the word vectors, $\{x_1, \dots x_T\}$, to LSTM outputs $\{h_1, \dots h_T\}$ where we take the last output to be a d-dimensional summary vector of the utterance $s = h_T$. We then use parameters $W \in \mathbb{R}^{k \times d}$ and $b \in \mathbb{R}^k$ where k is the number of slot types and compute

$$\hat{y} = \text{softmax}\left(Ws + b\right)$$

Thus $\hat{y}_i \in [0, 1]$ is the probability of slot i for the given utterance. To train the model, we minimize the sum of squared errors $||\hat{y} - y||$ (we could certainly use other metrics such as the KL divergence, but we did not pursue this direction).

At test time, we need to perform multi-label classification with the predicted probabilities of slot types $\hat{y} \in [0, 1]^k$. We achieve this by thresholding. But rather than using 0.5 as the threshold, we use the *minimum* probability of a ground-truth schema type from the training data. This results in predictions that are very high in recall at the expense of some precision. This trade-off is suitable in our setting, since these labels are only constraints in the second stage: while missing true labels causes the second stage to fail, over-predicting labels does not.

Since the minimum probabilities of ground-truth schema types are observed in the training data, we can train an separate model (SVM) to predict the threshold value for unseen inputs. In summary, given a test utterance, we first use the LSTM network to compute a distribution of slot types $\hat{y}$, next use the trained regressor to predict a suitable value of threshold, and take labels that have probabilities higher than the threshold. Figure 1 illustrates the process.

3.2 Constrained Decoding

In sequence learning, given a sample query $x_1 \dots x_n$, the decoding problem is to find the most likely tag sequence among all the possible sequences, $y_1 \dots y_n$:

$$f(x_1 \dots x_n) = \arg\max_{y_1 \dots y_n} p(x_1 \dots x_n, y_1 \dots y_n)$$

Here, given constraints $\tilde{y}$ from the first stage, we can simply define a constrained lattice *lattice* $\mathcal{Y}(x, \tilde{y}) = \mathcal{Y}(x_1, \tilde{y}) \times \dots \times \mathcal{Y}(x_n, \tilde{y})$ by pruning all tags not licensed by the constraints, as shown in Figure 2. Then, to find the most likely tag sequence which does not violate the given constrained lattice, we perform the decoding in the constrained lattice:

$$f(x_1 \dots x_n, \tilde{y}) = \arg\max_{\mathcal{Y}(x, \tilde{y})} p(x_1 \dots x_n, y_1 \dots y_n)$$

In experiments, we train a single sequence labeling model (CRF) on all domains, but at test time apply this constrained decoding with slot types predicted by the model in Section 3.1.

3.3 Relation to the Union Method

One of the most naive baselines in domain adaptation is to simply train a single model on the union of all data in different domains; at test time, the model predicts labels for any input regardless of which domain it comes from. Since our approach uses all data as well, it can be seen as a variation on this naive method.

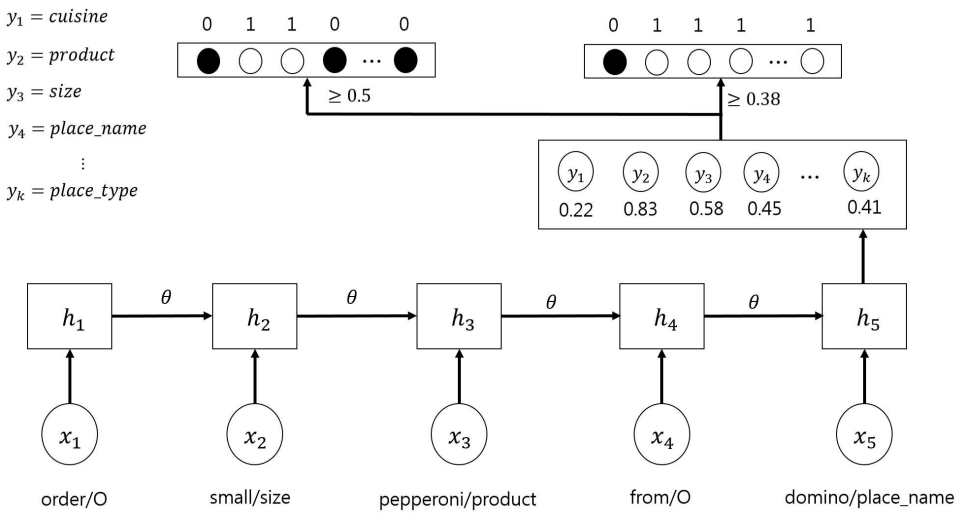

Figure 1: Illustration of schema prediction. In given a query, "order small pepperoni from domino", the word "small", "pepperoni" and "domino" is tagged as *size*, *product* and *place_name*, respectively. Therefore, LSTM multi-label classification model should predict a set of slots a query would be tagged with. When we fix a threshold for final result to 0.5, we can get two permitted labels, *product* and *size*. Whereas, we select different threshold corresponding to each query such as 0.38 in this example, we can obtain four permitted labels, *product*, *size*, *place_name* and *place_type*.

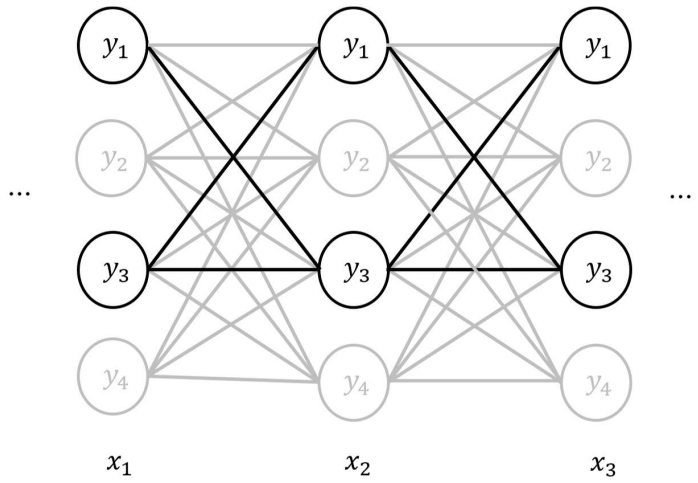

Figure 2: Constrained Lattice: Disabling nodes and transition while decoding the lattice to honor given constraints of domain schema.

The naive method also implicitly makes a decision on the domain of a query when the model predicts domain-specific labels. But it is well-known that this approach typically, unlike ours, yields poor performance. We conjecture that the reason for poor performance is the following. In the union method, the model must perform the *segmentation* as well as labeling of slots, which involves predicting labels in the BIO format (B: begin, I: inside, O: outside) (Ramshaw and Marcus, 1999). In comparison, our method only predicts possible labels and delegates inference to constrained decoding. Thus it can potentially

make more efficient use of labeled data.

4 Experiments

In this section, we turn to experimental findings to provide empirical support for our proposed methods.

4.1 Setting

	# of labels	# of shared label	#train	#test	#dev	#vocab	Description

Table 1: Data sets used in the experiments. For each domain, the number of unique slots, the number of examples in the training, development, and test sets, input vocabulary size of the training set, and short description about domain.

To test the effectiveness of the proposed approach, we apply it to a suite of 17 Cortana personal assistant domains for slot (label) tagging tasks, where the goal is to find the correct semantic tags of the words in a given user utterance. For example, a user could say "reserve a table at joeys grill for thursday at seven pm for five people". Then the goal is to tag "joeys grill" with `restaurant`, "thursday" with `date`, "seven pm" with `time`, and "five" with `number_people`. The data statistics and short descriptions about the 17 domains are shown in Table 1. As the table indicates, the domains have very different granularity and diverse semantics. The total numbers of training, test and development queries across domains are 2964K, 217K and 153K, respectively. Note that we keep domain-specific slots such as `alarm_state`, but there are enough shared labels across domains. To be specific, we have shared 62 labels among 131 labels. In ALARM domain, there are 6 shared slots among 8 slots.

4.2 Results

In all our experiments, we follow same setting as in (Kim et al., 2015b; Kim et al., 2015c). We trained Conditional Random Fields (CRFs)(Lafferty et al., 2001) and used n-gram features up to $n = 3$, regular expression, lexicon features, and Brown Clusters (Brown et al., 1992). With these features, we compare the following methods for slot tagging[1]:

- *In-domain*: Train a domain-specific model using the domain-specific data covering the slots supported in that domain.
- *Binary*: Train a binary classifier for each slot type, assuming prediction for each slot type is independent of one another. Then combine the classification result with the slots needed for a given schema. For each binary slot tagger targeting a specific slot type, the labeled data is programatically

[1]For parameter estimation, we used L-BFGS (Liu and Nocedal, 1989) with 100 as the maximum number of iterations and 1.0 for the L2 regularization parameter.

Table 2: F1 scores for models which can handle all domains.

mapped to create a new labeled data set, where only the target label is kept while all the other labels are mapped `other` label.

- *Post*: Train a single model with all domain data, take the one-best parse of the tagger and filter-out slots outside the a given schema.

- *Const*: Train a single model with all domain data and then perform constrained decoding using a given schema.

To evaluate performance of the constrained decoding approach without schema prediction, we compare the performance among possible models, which can handle all domains in Table 2. Here, a schema is given from a pre-trained domain classifier with an average accuracy of 97%.

We consider *In-domain* as a plausible upper bound of the performance, yielding 90.93% of F1 on average. Second, *Binary* has the lowest performance of 75.67%. When we train a binary classifier for each slot type, the other slots that provide valuable contextual information are ignored. This leads to the degradation in tagging accuracy. Third, *Post* improves F1 scores across domains, resulting in 85.31% F1 on average. Note that this technique does not handle ambiguities and data distribution mismatches due to combining multiple domain specific data with different data sizes. Finally, *Const(CRF)* leads to consistent gains across all domains, achieving 90.38%, which almost matches the *In-domain* performance. *Const(CRF)* performs better than *Binary* because *Const(CRF)* constrains the best path search to the target domain schema. It does not consider the schema elements that are outside of the target domain schema. By doing so, it addresses the training data distribution issue as well as overlap on various schema elements.

Also, we performed experiments with LSTM for slot tagging by masking scores of predicted class labels from predicted schema. LSTM is one of the most popular deep learning techniques for sequence tagging (Bahdanau et al., 2014; Dyer et al., 2015), but we observe that the LSTM results (*Const(LSTM)*) on our dataset are very similar to that of CRFs (*Const(CRF)*, as shown in Table 2. In the following experiments, we mostly focus on the *Const* version of CRFs for simplicity.

The main results of constrained decoding with different schema prediction methods are shown in Table 3. *Bin* approach trains k binary logistic regression classifier for each slot type. Each binary classifier

Table 3: F1 scores for *Const* with various schema prediction methods across 17 personal assistant domains.

determines if a query has a specific slot or not, while *Mult* approaches use a single LSTM to predict a set of allowed schema for a query. Subscript Fix denotes that a fixed threshold (0.5) is used to make a decision of positive versus negative label, and Min denotes that the threshold is set to be the minimum of positive label thresholds, which hence gives the maximum recall rate. *GoldQ* denotes the decoding was constrained by true schema for a query and and *PredD* denotes the decoding was constrained by a predicted domain. Here *In-domain* also uses domain classifier.

In the preliminary experiments, we observed that there are significant performance improvements when performing constrained decoding given a gold standard schema of a query *(GoldQ)*. However, it is very difficult to get similar performance by the predicted schema. The main reason is because it does not guarantee recall. As you can see, all methods based on schema prediction except for $\textit{Mult}_{Min}$, fail to achieve any improvement compared to *In-domain* and *PredD*. So, we use the minimum probability of a ground-truth schema type per query to increase recall. Using predicted minimum boundary $\textit{Mult}_{Min}$ finally boost up performance up to 93.55%, huge relative error reduction of 33% over *In-domain* approach.

Unlike previous experiments, the experiments shown in Table 4 assume that the true domain and its schema are given. So, there are no domain classification error. $\textit{MULT}_{Min}$ removes the predicted schema elements that are outside of the true domain schema. *In-domain* yields 92.53% F1 score. $\textit{MULT}_{Min}$ boosts the performance to 93.99%.

To further compare multi-classification approach to binary approach, we show performance for multi-class labeling task in Table 5. Unlike slot tagging performance, $\textit{Mult}_{Fix}$ has the highest F1 score because of its precision. $\textit{Mult}_{Min}$ has high recall at the slight expense of precision. However, binary logistic regression (Bin_{Min}) fails to keep reasonable precision. This is because logistic regression models are over-fitted to each label, minimum boundary is very low and thus it causes a lot false positives.

For the last scenario shown in Table 6, we assume that we do not have training data for the test domains. The amount of test data is about 2k. The $\textit{Mult}_{Min}$ performs reasonably well, yielding 96.48% on average. Interestingly, for the *Bus* domain, we can get almost perfect tagging performance of 99.5%. Note that all tags in *Bus* and *Ferry* domains are fully covered by our single model, but the *ShopElectric*

5 Conclusion

In this paper, we proposed a solution for scaling domains and experiences potentially to a large number of use cases by reusing existing data labeled for different domains and applications. The single slot tagging coupled with schema prediction and constrained decoding achieves competitive and often superior performance over the conventional model trained in per domain fashion. This approach enables creation of new virtual domains through any combination of slot types covered in the single slot tagger schema, reducing the need to collect and annotate the same slot types multiple times for different domains.

Sub-Word Similarity based Search for Embeddings: Inducing Rare-Word Embeddings for Word Similarity Tasks and Language Modelling

Abstract

Training good word embeddings requires large amounts of data. Out-of-vocabulary words will still be encountered at test-time, leaving these words without embeddings. To overcome this lack of embeddings for rare words, existing methods leverage morphological features to generate embeddings. While the existing methods use computationally-intensive rule-based (Soricut and Och, 2015) or tool-based (Botha and Blunsom, 2014) morphological analysis to generate embeddings, our system applies a computationally-simpler sub-word search on words that have existing embeddings. Embeddings of the sub-word search results are then combined using string similarity functions to generate rare word embeddings. We augmented pre-trained word embeddings with these novel embeddings and evaluated on a rare word similarity task, obtaining up to 3 times improvement in correlation over the original set of embeddings. Applying our technique to embeddings trained on larger datasets led to on-par performance with the existing state-of-the-art for this task. Additionally, while analysing augmented embeddings in a log-bilinear language model, we observed up to 50% reduction in rare word perplexity in comparison to other more complex language models.

1 Introduction

Word embeddings have been successfully applied to many NLP tasks (Collobert and Weston, 2008; Collobert, 2011; Socher et al., 2011; Socher et al., 2012; Hermann and Blunsom, 2014; Bengio and Heigold, 2014; Yang et al., 2015), and these systems often achieved state-of-the-art performance. This success has been ascribed to embeddings' ability to capture regularities traditionally represented in core NLP features. Most of these embeddings were trained on large amounts of data, allowing them to have good coverage of the relevant vocabularies. However, embeddings often still cannot satisfactorily represent *rare words*, i.e. words with few occurrences in training data.

To generate useful embeddings for words too rare for standard methods to handle, Luong et al. (2013) and Botha and Blunsom (2014) leveraged the segmentation tool, Morfessor (Creutz and Lagus, 2005), while Cotterell et al. (2016) used morphological lexica to generate rare-word embeddings. In general, these methods added resource-based knowledge to their systems in order to form word vector representations, showing impressive performance gains over methods which did not address the rare words problem.

In contrast, Soricut and Och (2015) applied an automatic method to induce morphological rules and transformations as vectors in the same embedding space. More specifically, they exploited automatically-learned prefix- and suffix-based rules using the frequency of such transformations in the data and induced a morphological relationship-based word graph. Then, they searched over this graph for rules that best infer the morphology of the rare words. The embeddings were then estimated using these rare-word explaining rules. In this method, creating and tuning this morphological graph could lead to a high initial cost.

Rare Word + Google News	2951	173	100

Table 2: This table reports various statistics of a few language word similarity datasets used in our experiments. The last column shows the coverage of our method in percentage.

In order to overcome this cost and still be able to automatically induce rare word representations, we propose a sub-word similarity-based search. This technique maps a rare word to a set of its morphologically-similar words and combines the embeddings of these similar words to generate the rare word's representation (further discussed in Section 2). These generated embeddings can then be combined with existing word embeddings to be applied in various tasks.

In Section 3, we evaluate our embeddings on word similarity tasks. For further evaluation, in Section 4, we instantiate a log-bilinear language model (Mnih and Hinton, 2007) with our word embeddings and analyse their perplexity performance on rare words over various language modelling corpora. Finally, we summarise our findings in Section 5.

2 Rare-Word Embeddings

Rare words form a large part of a language's vocabulary. This is illustrated in Table 1, which reports the vocabulary size and number of rare words (RW) with zero (out-of-vocabulary words) or one training set occurrence for our corpora. As shown in this table, rare words constitute 10%-50% of the vocabulary. Further, it is widely known that in English, roughly half of all tokens in a given corpus occur only once. Thus, it is essential to handle rare words properly to obtain good performance.

In the context of word embeddings-related tasks, training good word embeddings can incur huge computational costs (Al-Rfou et al., 2013). So, in this work, we focus on augmenting readily available embeddings rather than creating new ones from scratch. To increase the availability of resources for many languages, Al-Rfou et al. (2013) released[1] pre-trained word embeddings for more than one hundred languages. These pre-trained word embeddings, namely *Polyglot*, were constructed by applying the method outlined in Bengio et al. (2009) on Wikipedia text, which vary in size from millions of tokens to a few billion tokens.

Among other available pre-trained word embeddings, Google released `word2vec` (Mikolov et al., 2013)-based embeddings[2] trained on their English News dataset (about 100 billion tokens). In our experiments, we applied both of these embeddings sets to jump start generating the rare word embeddings for different languages.

2.1 Inducing Rare-Word Embeddings

Statistics about the various language modelling corpora and word similarity tasks that we used in our experiments are shown in Table 1 and Table 2. In these tables, along with the vocabulary size and number of rare words, we also report the number of words for which the embeddings were not found (ENF = Embedding Not Found) in the pre-trained embedding sets. For most of the language and pre-trained embedding pairs, number of ENFs formed a large share of the vocabulary for word similarity tasks and of rare-word set size for language modelling tasks. Hence, we estimated the missing word embeddings before using them in our tasks.

We first provide a high level description of the steps of our method to induce the word embeddings for these missing rare words, followed by detailed description of each step. For a given set of pre-trained embeddings with a finite vocabulary V_E applied to a task with vocabulary V_T and a finite set of given rare words $RW = \{w | w \notin V_E \& \ w \in V_T\}$, we apply the following steps:

[1] `https://sites.google.com/site/rmyeid/projects/polyglot`
[2] `https://code.google.com/archive/p/word2vec/`

1. Map every word $w \in V_E$ to its sub-word features
2. Index $w \in V_T$ using its sub-word features
3. Search the index for matches of $w' \in RW$
4. For every $w' \in RW$, combine matched words' embeddings to generate its embedding

Step 1: Map words to sub-words
Although a word may be rare, substrings of that word are, in general, less rare. Hence, we start by breaking down each word $w \in V$ into its constituent N-sized sub-word units: $D_N(w)$. For example, given the sub-word size $N = 3$:

$$D_N(language) = \{lan, ang, ngu, gua, uag, age\}$$

In our experiments, we worked with value of $N = 3$. However, it remains to be seen how using differently sized sub-word units or even morphemes affects the performance of this method. Note that our procedure does not formally require that sub-word units be of equal length, so linguistically-sensible morphemes may be used if the resource is available for that language.

Step 2: Index word using its sub-words
Pre-trained sets of embeddings can cover large numbers of words already (for example, *Polyglot* embeddings have 100K words in their vocabulary). So, performing substring searches and comparisons can become quite computationally expensive. To speed up the search for sub-word units, we create an inverted index on words. For each $w \in V$, we treat $D_N(w)$ as a document and feed it into a search engine-based indexer. In this work, we used Lucene[3] (McCandless et al., 2010) to index the words.

Step 3: Search for matches of a rare word
Next, we break down the rare word $w' \notin V$ into its sub-word units ($D_N(w')$) and search for $D_N(w')$ using the index. We restrict the search results set to the top K results, denoted by $R^K(w')$. $R^K(w')$ contains the words having similar sub-word units as w', hence, containing words which are sub-word similar to w'. In our experiments, we fixed $K = 10$.

Step 4: Generating rare-word embeddings
To estimate the word embedding of $w' \in RW$, we compute the weighted average of embeddings (v) of the rare-word matches. For this weighted average, we employ a string similarity function S, such that

$$v_{w'} = \sum_{w:D_N(w) \in R^K(w')} S(w', w) \times v_w$$

The above method particularly hinges on the third step, where we utilise sub-word similarity of morphologically similar words to search for rare word alternatives, leading to embedding combination in the fourth step. Hence, we refer to the above technique as **S**ub-**Word** **S**imilarity based **S**earch (**SWordSS**: pronounced swordz). The SWordSS embeddings ($\{v_{w'} : w' \in RW\}$) are used along with $\{v_w : w \in V\}$ to perform rare word-related tasks.

In the fourth step, we apply different string similarity functions (S), described in the list below, to average different embeddings of matches from the third step. These different similarity functions help provide a more morphologically-sensible scoring of matches and eventually are used to weight the inputs of the final rare word embeddings.

- Jaccard Index, Jaccard (1912) computes the size of the character intersection over the size of the character union. Therefore, order of characters is not considered by this metric. Frequent characters such as vowels lead to uninteresting intersections, and short words could possibly suffer from an unfair floor.

[3] `https://lucene.apache.org/`

- Jaro similarity, Jaro (1989) considers the number of matching characters in corresponding positions and the number of transpositions detected. So, order of characters does matter for this metric. Insertions and deletions are treated similarly, and the frequency and length effects from Jaccard could also affect this metric.

- Most frequent K Characters similarity, Seker et al. (2014) considers the counts of the top K characters in each string. Thus, if the "root morphemes" are long enough to create nontrivial count statistics, this metric may, too, favor a more linguistic similarity, but as before, shorter strings could have unwanted effects.

- Subsequence Kernels, Lodhi et al. (2002) create automatically-generated features based on sequences of characters within the strings to be compared. Therefore, those sequences that do not cross morpheme boundaries could be especially helpful for estimating morphological similarity.

- Tversky coefficient, Tversky (1977) breaks down the union in the Jaccard index, allowing different weights for the denominator intersection, those characters that only appear in the first string, and those characters that only appear in the second string. These metaparameters allow the metric some flexibility that the others do not.

In our experiments on rare word-related tasks, we mostly observed that using SWordSS led to high coverage rates, also presented in Table 1 and Table 2. We note that whenever words w' resulted in zero matches in our experiments, they were either removed completely (in case of word similarity tasks) or substituted with random vectors (in case of language modelling tasks, Section 4).

3 Word Similarity Task

To test the efficacy of SWordSS embeddings, we evaluated them on two standard word similarity tasks. In such tasks, the correlation between the human annotator ratings of word pairs and the scores generated using embeddings was calculated. A good set of embeddings would achieve a high correlation.

Specifically, we evaluated the SWordSS embeddings on Luong et al. (2013)'s English Rare Words dataset with 2034 word pairs (Luong2034) and also evaluated these embeddings on a German word similarity task (Gurevych, 2005) with 65 word pairs (Gur65).

3.1 Experimental Setup

For the German word similarity task, we used only *Polyglot* word embeddings, which are 64-dimensional vectors. For English along with *Polyglot* word embeddings, we used the Google News word2vec embeddings, which are 300-dimensional vectors.

As a baseline, we used the existing pre-trained word embeddings, which are compared to their augmented SWordSS versions. While augmenting the pre-trained set with the SWordSS embeddings, we also explored various string similarity functions to be used in the fourth step (Section 2.1), namely, Jaccard Index (SWordSS$_{ji}$), Jaro similarity (SWordSS$_{jaro}$), Most Frequent K Characters similarity (SWordSS$_{mfk}$), Subsequence Kernels (SWordSS$_{ssk}$) and Tversky Coefficient (SWordSS$_{tc}$).

To evaluate the effect of these string similarity functions, we also implemented a constant similarity function ($S(w, w') = 1$, where w and w' are words) used in the fourth step, denoting the corresponding embeddings by SWordSS$_1$. Finally, we also compared the SWordSS embeddings to SO2015 (Soricut and Och, 2015), which also applies morphological analysis to generate missing word embeddings quite similar to SWordSS embeddings.

3.2 Results

Using SWordSS embeddings definitely increased the correlation with humans in comparison to the original on the Gur65 task (shown in Table 3), though the different string similarity functions except the constant function (SWordSS$_1$) led to correlations in a very close range, showing that particularly for German, different similarity functions behave very similarly. Henceforth, we only report the best correlation coefficient after applying these functions.

Word Vectors	Gur65
Polyglot	28.5
Polyglot+SWordSS$_{ji}$	37.5
Polyglot+SWordSS$_{jaro}$	37.1
Polyglot+SWordSS$_{mfk}$	37.2
Polyglot+SWordSS$_{ssk}$	36.9
Polyglot+SWordSS$_{tc}$	**37.6**
Polyglot+SWordSS$_{1}$	35.8

Table 3: Spearman's rank correlation (%) based evaluation of various string similarity functions used to generate augmented word vectors for the German word similarity task (Gur65)

Task	Luong2034	
Word Vectors	*Polyglot*	*Google News*
SO2015 w/o morph	-	44.7
SO2015 w/ morph	-	**52.0**
w/o SWordSS	9.7	45.3
w/ SWordSS$_{1}$	28.9	51.3
w/ SWordSS$_{sim}$	30.4	51.4

Table 4: Spearman's rank correlation (%) based evaluation of techniques with and without morphological features used to generate representations for the word similarity task.

Next, we compared SWordSS versions of *Polyglot* embeddings and Google News Embeddings on the Luong2034 task. When the SWordSS versions were compared to the original (labelled w/o SWordSS) it led to a higher correlation, as shown in Table 4. However, for each set of embeddings, the difference between SWordSS$_1$ and SWordSS$_{sim}$ remained small. The correlations for the SWordSS version of *Polyglot* were still lower than the correlation rates reported by SO2015. This was due to the difference in initial quality of embeddings used by each method. As *Polyglot* embeddings trained on a lesser amount of data than SO2015, they were easily outperformed.

In Table 4, we addressed this lower performance issue by replicating our experiment using Google News `word2vec` embeddings to jump start the SWordSS versions for the Luong2034 task. Using these embeddings, trained on a larger dataset than used by *Polyglot*, led to SWordSS versions having on-par results with the SO2015 results for the Luong2034 task.

Overall the SWordSS technique was able to drastically improve pre-trained embeddings performance on the above word similarity tasks. Even though SWordSS-augmented Google News embeddings did not significantly outperform SO2015, this method provides a simpler sub-word search based alternative to the graph search over morphological relationships performed by SO2015. Furthermore, by applying sub-word search in the third step as shown in Section 2.1, SWordSS overcomes the need for creating and tuning the graph of morphological relationships as required by SO2015.

4 Word Embeddings in Language Models

Training language models (LMs) using an expanded vocabulary (having more word types than contained in the training corpus) requires assigning probabilities to words which are not present in the training set. Traditionally, these rare words are assigned a default value of probability in conventional N-gram and long short term memory (LSTM)-based reccurrent neural network LMs (Sundermeyer et al., 2012). This is usually not beneficial for spoken term detection and automatic speech recognition systems made for low resourced languages, since presence of rare words in speech queries is high (Logan et al., 1996; Logan et al., 2005).

To avoid this misrepresentation of rare words, we apply SWordSS embeddings in a language modelling framework. Specifically, a log-bilinear language model (LBL) (Mnih and Hinton, 2007). In our experiments, when the SWordSS embeddings were used to initialise an LSTM's input layer, the system obtained the same perplexity values as the LSTM initialised with random embeddings. This observation suggests that the LBL framework is better suited than LSTMs for this naïve way of initialising neural language models with SWordSS embeddings and improving perplexity on rare words.

LBL predicts the next word vector $p \in \mathbb{R}^d$, given a context of $n-1$ words, as a transformed sum of context word vectors $q_j \in \mathbb{R}^d$, as:

$$p = \sum_{j=1}^{n-1} q_j C j$$

where $C_j \in \mathbb{R}^{d \times d}$ are position-specific transformation matrices. p is compared with the next word w's representation r_w. This comparison is performed using the vector dot product and then is used in a

softmax function to obtain the probability of the next word as follows:

$$p(w_i|w_{i-n+1}^{i-1}) = \frac{\exp(p \cdot r_w + b_w)}{\sum_{v \in V} \exp(p \cdot r_v + b_v)}$$

where b is the bias term encoding the prior probability of word type w.

First, Q the collection of context word vectors (q_j) and R the collection next word representations (r_w) are initialised with the pre-trained word embeddings. Thereafter, we train the LBL using stochastic gradient descent.

Previously, extensions to class based and factor based formulations have provided impressive improvements over regular N-gram LMs for morphological languages (Botha and Blunsom, 2014). But, these LMs do not provide straightforward ways of incorporating pre-trained word embeddings, so we use the original LBL because of the ease with which it incorporates pre-trained embeddings in its formulation.

4.1 Data

To evaluate the SWordSS embeddings for language modelling, we used the Europarl-v7 corpus of German (de) language as processed by Botha and Blunsom (2014). We also performed language modelling experiments with the SWordSS embeddings on Tagalog (tl), Turkish (tr) and Vietnamese (vi) corpora, which include transcriptions of phone conversations collected under the IARPA Babel Program language collection releases babel106b-v0.2f, babel105-v0.5 and babel107b-v0.7 respectively.

The German corpus was processed to have no out-of-vocabulary words (OOVs), however, it still had a lot of low frequency words (see Table 2). Contrastingly, the Babel corpora have OOVs as well as other low frequency words.

The Babel corpora were provided with training and development sets. We divided the existing development set into two halves to use one as the test set and the other half as the new development set. The statistics on these corpora are summarised in Table 5.

Statistics	de	tl	tr	vi
Train	1000K	585K	239K	985K
Dev	74K	30K	5K	65K
Test	73K	31K	6K	60K
Voc Size	37K	22K	25K	6K

Table 5: Statistical summary of corpora used for the language modelling experiments. Information corresponding to a language is presented in a column.

In Tables 1 & 2, we had shown that even though a lot of rare-word embeddings are missing from the pre-trained set, SWordSS was able to generate and obtain high coverage rates for such words, giving this method added benefit in the context of rare words.

4.2 Experimental Setup

Before evaluating the SWordSS embeddings for predicting rare words, we used all the OOVs to expand the corresponding vocabulary. SWordSS embeddings for all the words in the expanded vocabulary were used to initialise LBL framework as described in Section 4. A bigram version of this LBL (LBL2$_{SWordSS}$) was further trained on language corpora before being evaluated.

We compare our LBL2$_{SWordSS}$ model with the conventional Modified-Kneser-Ney five-gram LM (MKN5) (Kneser and Ney, 1995; Chen and Goodman, 1996) and also with the bigram (LBL2) based log-bilinear LM. As a more powerful baseline, we also trained an LSTM based RNN LM to compare with LBL2$_{SWordSS}$. Moreover, we compare the LBL2$_{SWordSS}$, with a character aware language model (Kim et al., 2015), denoted as CCNN-LSTM. The CCNN-LSTMs were chosen for comparison because of their ability to use character-based features to implicitly handle OOVs and rare words. For training each of these LMs, we used the expanded vocabulary as used by LBL2$_{SWordSS}$. In training neural network-based language models, we restricted the number of parameters to have a similar number of parameters as LBL2$_{SWordSS}$.

4.3 Perplexity Experiments

We compare the language models described in Section 4.2 using perplexity values calculated on test sets of different languages, shown in the Table 6.

Language Model	German		Tagalog		Turkish		Vietnamese	
	PPL	RW1PPL	PPL	RW1PPL	PPL	RW1PPL	PPL	RW1PPL
MKN5	364.2	559K	162.6	420K	478.9	139K	120.8	174K
LBL2	391.1	404K	171.4	204K	649	**94K**	137.6	**100K**
LSTM[4]	323.1	596K	134.7	343K	489.8	110K	**102.1**	457K
CCNN-LSTM	**315.7**	636K	**117.4**	354K	**408.7**	168K	182.7	516K
LBL2$_{SWordSS}$	369.4	**260K**	167.2	**167K**	513.2	110K	136.4	143K
#PAR	4.7 M		2.9 M		3.2 M		0.8 M	

Table 6: Perplexities on test set (PPL), RW1 perplexities (RW1PPL) in thousands and number of parameters (#PAR) for LBL and LSTM LMs in millions, presented on four language corpora

As shown in Table 6, LBL2$_{SWordSS}$ was able to outperform the conventional LBL2 comfortably on all the corpora except Vietnamese. For Vietnamese, LBL2$_{SWordSS}$ and LBL2 performed comparably. Due to SWordSS' low coverage of Vietnamese vocabulary, initialising LBL2 with SWordSS embedding led to only a marginal performance gain.

Overall in terms of test set perplexity, CCNN-LSTM outperformed LBL2$_{SWordSS}$ comfortably on most language corpora. However, on Vietnamese (in which characters represent meaning units rather than sounds) CCNN-LSTM suffered and the LSTM outperformed the other language models. In comparison to LSTM and CCNN-LSTM, LBL2$_{SWordSS}$'s lower performance on test data was expected as the former are more non-linearly complex language models.

However, for tasks like spoken term detection, having low perplexities on most frequent set of words is not good enough and hence, we compare LMs on the perplexity of a rare-word based test set. To perform this comparison, we computed perplexity only on rare words (RW1PPL), i.e. with training-set frequency of one, present in the test set. As shown in Table 6, we observe that LBL2$_{SWordSS}$ performed better than the LSTM-based LMs across various languages in terms of RW1PPL.

We note that CCNN-LSTM model cannot include SWordSS embeddings easily. Hence, they are not directly comparable to LBL2$_{SWordSS}$, as the latter has more information at its disposal.

4.4 Performance on OOVs and Rare Words

To further compare the performance of the aforementioned language models on rare words, we analyse perplexities of such words (RWPPL) in the test set as a variation of the frequency classes of these words in the training set. This variation is displayed in Figure 1.

For OOVs (rare words with zero training-set frequency), LBL2$_{SWordSS}$ outperformed the other language models built with similar number of parameters, on the Tagalog and Turkish corpora. In these cases, LBL2$_{SWordSS}$ reduced rare-word perplexities by a factor of two over the character-feature rich CCNN-LSTM, whose design allows it to implicitly handle rare words.

Even for rare words with training set frequency up to one, LBL2$_{SWordSS}$ reduced perplexity up to a factor of 2.5 times with respect to CCNN-LSTM, on the German, Tagalog and Turkish corpora. Interestingly on these particular language corpora, Figure 1 shows that LBL also performed better than both the LSTM-based LMs in modelling OOV and rare words of frequency up to ten.

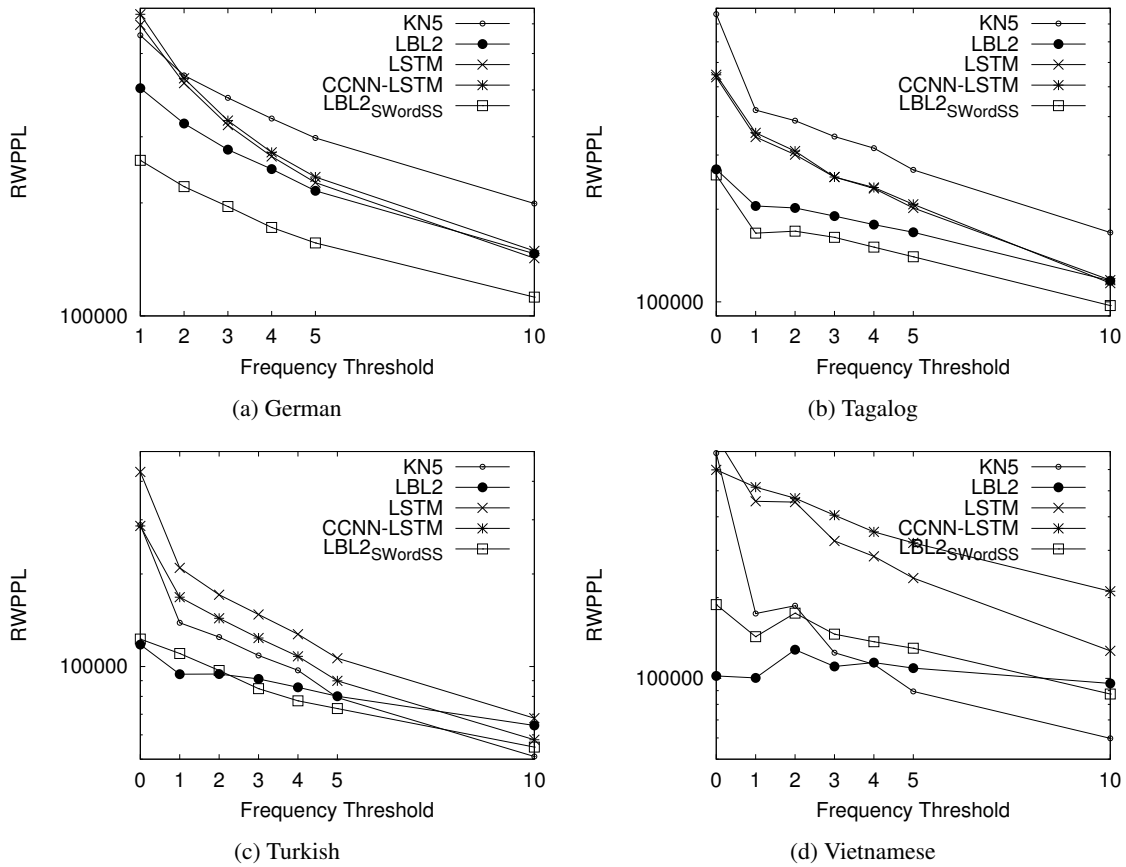
For Vietnamese, LBL alone was able to improve OOV and RW1 words over the other LMs. We attribute this to lower coverage of Vietnamese rare words by SWordSS than for other languages. Instead adding SWordSS embeddings harmed the prediction of OOV and RW1 words.

These perplexity improvements stared to wane when higher frequency words were included into the rare word set, across the different languages. Nevertheless, for languages with rich morphology, initialising LBL with SWordSS embeddings reduced perplexities on rare words.

5 Conclusion

In this paper, we introduced SWordSS, a novel sub-word similarity based search for generating rare word embeddings. It leverages the sub-word similarity in morphologically rich languages to search for close

[4]when initialised with SWordSS embeddings it obtained the same perplexity values



(a) German (b) Tagalog

(c) Turkish (d) Vietnamese

Figure 1: Variation of rare-word perplexity versus threshold on frequency of training-set words on German, Tagalog, Turkish and Vietnamese corpora

matches of a rare word, and then combines these close matches to estimate the embedding of a rare word.

Even though SWordSS is an unsupervised approach like Soricut and Och (2015), it differs from latter in the way it utilises the morphological information. The latter automatically induces morphological rules and transformations to build a morphological word graph. This graph is then tuned and used to induce embedding of a rare word. Instead, SWordSS replaces the overhead of induction of rules and creation of graph by searching a sub-word inverted index to find rare-word matches and combining their embeddings to estimate rare-word embedding.

To test the SWordSS technique, we augmented pre-trained embeddings and then evaluated them on word similarity tasks. The augmented embeddings outperformed the initial set of embeddings drastically. However, it lagged behind the state-of-the-art performance of Soricut and Och (2015). But, by employing embeddings trained on larger corpora, SWordSS was able to perform comparably on a rare-word task.

We also investigated the effects of using SWordSS augmented embeddings for modelling rare words. To perform this experiment, we trained LBL$_{SWordSS}$ LM and compared it with language models like the character aware LM, LSTM-based RNN LM restricted to similar size. On almost all datasets, the character aware LM outperformed the other LMs with respect to perplexity on complete test sets. But on rare words, SWordSS showed up to 50 % reduced perplexity values in comparison to other LMs. Hence, SWordSS embeddings contributed substantially in modelling rare-word tasks.

In future work, we plan to incorporate SWordSS embeddings into more complex LMs than LBL and further analyse the different string similarity functions used in SWordSS's formulation.

Acknowledgments

We would like to thank anonymous reviewers for their comments, which helped improve this paper. We are also immensely grateful to Rose Hoberman for her comments on an earlier version of this manuscript.

Abstract

We introduce the task of detecting cross-lingual marketing blunders, which occur if a trade name resembles an inappropriate or negatively connotated word in a target language. To this end, we suggest a formal task definition and a semi-automatic method based the propagation of pragmatic labels from Wiktionary across sense-disambiguated translations. Our final tool assists users by providing clues for problematic names in any language, which we simulate in two experiments on detecting previously occurred marketing blunders and identifying relevant clues for established international brands. We conclude the paper with a suggested research roadmap for this new task. To initiate further research, we publish our online demo along with the source code and data at http://uby.ukp.informatik.tu-darmstadt.de/blunder/.

1 Introduction

Large companies increasingly advertise and sell their products in international markets. Developing a marketing campaign for a new country requires tremendous translation efforts in order to bridge language and cultural boundaries. A particular problem often occurs if an established product, brand, or company name is introduced to a new, foreign market without being adapted to local habits and language use. This may yield offensive, embarrassing, or (at best) funny results causing excessive remedial cost and maybe even the withdrawal of a product from the new market. Such a *marketing blunder* can have multiple different reasons. A commercial for a men's fragrance showing a man with his dog failed, for instance, in Islamic countries where dogs are considered unclean. Dalgic and Heijblom (1996) distinguish possible reasons, including political, ethical, and legal issues, different traditions, inappropriate language, etc.

In this work, we focus on *cross-lingual marketing blunders*, which are a result of using inappropriate or negatively connotated expressions or translations for naming a company, brand, or product. One example for this is using the word *mist*, which usually describes fabulous, enigmatic, lightweight, or mystic things in English. A British car manufacturer, for example, chose the word to advertise their *Silver Mist* model. In German, the false friend *Mist* means, however, dung or manure, and it is a frequently used slang expression to describe a futile, cheap, or broken thing, nonsense, or an annoying, tedious situation. This pejorative meaning has caused the car manufacturer to rename its product (Room, 1982; Felser, 2010). A more recent example is the announcement of the 7th edition of a smartphone in Asia. The company's original English slogan "This is 7" has been changed for the Hong Kong market, as the pronunciation of the numeral seven (jyutping: *cat1*) is very similar to a vulgar expression for the male genitals (*cat6*), which would cause funny reactions when combined with "This is" on a product's advertisement poster.[1]

Spotting a marketing blunder can be very time-consuming and expensive for companies, especially if they do not operate local branches in all their target countries. With the emergence of the world wide web, a myriad of start-ups and small companies is struggling with this issue when planning an international online shop. They face two major problems:

(1) The absence of large-scale resources yielding *clues* for potential marketing blunders. Since many blunders are caused by false friends used in colloquial speech, multilingual dictionaries covering the

[1] See for example http://qz.com/777628/ (September 9, 2016)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2071–2081, Osaka, Japan, December 11-17 2016.

standard language are of limited help. Although there are specialized monolingual slang dictionaries such as the *McGraw-Hill's American Slang Dictionary* (Spears, 2007) for the U.S., it is very challenging to keep these dictionaries up-to-date and to provide them for a large number of languages.

(2) The absence of tools that assist the process of identifying the *relevant clues* from these resources. Obviously, not every word that exists in a target language is problematic for marketing a product. The English word *fog* is, for instance, a false friend of the Hungarian *fog* (English: *tooth*). Neither meaning has a negative connotation per se that would impede the use of *fog* in a successful marketing campaign within those countries. A tool assisting the detection of marketing blunders thus needs to separate relevant clues from irrelevant ones in order to reduce the manual effort.

In the present paper, we propose a novel method and tool for assisting copywriters and sales promoters with the detection of cross-lingual marketing blunders. Our method is primarily based on disambiguated translations and pragmatic labels extracted from Wiktionary (`http://www.wiktionary.org`), for which we create a large inter-lingual index and a retrieval process. We evaluate our approach in two experiments: (1) detecting previously occurred marketing blunders and (2) finding evidence for potential blunders in established brand names. The detection of cross-lingual marketing blunders is a new task in natural language processing and, to the best of our knowledge, there are yet no existing tools that assist copywriters in avoiding such blunders. This is why we aim at introducing a formal task definition, a first, freely available dataset, and a novel knowledge-based method to initiate further research in this direction. Based on our results and error analysis, we lay out a research agenda for this new task. Apart from detecting marketing blunders in trade names, we believe that this research strand is enabling for many other tasks, including the identification of problematic product slogans, acronyms (e.g., of scientific proposals), and names of persons, institutions, and projects that should not be misinterpreted in foreign languages.

2 Related Work

Marketing blunders are yet mostly discussed in management and marketing research. Ricks (2006) reports a large number of previously occurred blunders in international business, including a separate chapter on product and company names. Knight (1995) and Dalgic and Heijblom (1996) discuss a few number of cases in detail. These works aim at finding new management strategies for inter-cultural marketing (cf. Jallat and Kimmel, 2002), rather than providing actual assistance and tools for copywriters.

In another strand of research, linguists have studied the properties of the language used in advertising, including teasers, slogans, and names. Cook (1992) and Janich (2013) give comprehensive introductions to the linguistic analysis of marketing language. While these works are mostly concerned with the question of how positive connotations and rhetorical figures enhance the value of a product, they also touch on the issues of cross-cultural and cross-lingual marketing communication. However, none of these works describes specific properties or methods to detect potential naming blunders. In addition to that, there are dictionaries on slang and pejorative expressions like the ones by Spears (2007) or Küpper (1984), as well as specialized dictionaries on trade names, such as Room (1982). Slang dictionaries are limited in their up-to-dateness (as indicated by the old publication years), word coverage, and range of available languages. Specialized name dictionaries are generally of little use for this task, as it is often the essence of a marketing campaign to create new, previously unused product or brand names.

In natural language processing, there are previous works which address the automatic generation and retrieval of slogans and creative names. Veale (2011) presents a search engine for creative text retrieval, which assists copywriters to find metaphors and unusual word combinations. Özbal and Strapparava (2012) describe an automatic approach to generate neologisms that can be used as product names or slogans. Both works are focused on the English language and on the identification or generation of *good* names, whereas our work aims at the detection of *problematic* names without focusing on a particular language or target market. Our task is similar to automatically distinguishing cognates and false friends. Inkpen et al. (2005) use orthographic similarity metrics for this task including Soundex, which we also propose for our method. Follow-up works by Mitkov et al. (2007), Gomes and Lopes (2011), Beinborn et al. (2013), and Ciobanu and Dinu (2014) propose different edit distance, machine translation, and seman-

tic similarity methods for identifying cognates. While false friends play a crucial role for the detection of marketing blunders, the existing approaches cannot be used directly, because they are specific for a certain language pair and do not make any assumptions on the (negative) connotations of a trade name. Kondrak and Dorr (2004) adapt orthographic and phonetic similarity methods to find confusable drug names. Unlike our tool which retrieves pragmatically marked sense descriptions, their work is limited to identifying similar forms.

The recognition of words and phrases associated with opinions and emotions is the goal of sentiment analysis. There have been multiple attempts to construct large sentiment lexicons, such as SentiWordNet (Esuli and Sebastiani, 2006). Banea et al. (2008) propose a bootstrapping approach to induce such lexicons from a small, manually defined seed list. Our approach is similar, since we propagate pragmatic information based on lexical relations. However, we do not require a seed list and we consider relations across many languages. While monolingual resources are not suitable for our task at all, the existing multilingual sentiment lexicons are severely limited in size. The NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2013) is among the largest and available in about 40 languages, but since it has been automatically translated, it does not distinguish word senses and lacks slang and dialects. In recent work, Vo and Zhang (2016) propose a neural network architecture to build sentiment lexicons relying on emoticons as distant supervision signals. Although they currently publish only English and Arabic lexicons, such (almost) unsupervised methods are promising for building multilingual lexicons.

3 Task Formalization

Let T denote a product, brand, or company name. Our goal is to develop a method $\mathcal{M}$ retrieving a set of clues $C = \mathcal{M}(T)$ for a given T, which can be used by copywriters to decide whether T should be accepted or rejected as a name. We consider each clue $c = (w, \ell, d) \in C$ as a tuple of a word form w of language ℓ and a textual description d, which paraphrases the (potentially problematic) meaning of w in ℓ. While T is not specific to any language, a copywriter is typically only fluent in a few number of languages, which is why d must be in a language spoken by the end user (hereafter *output language*). For the example $T =$ "Silver Mist", a method could return the following clues:

#	form w	language ℓ	description d
1	Silber	German (deu)	A shiny gray color.
2	mist	English (eng)	A layer of fine droplets or particles.
3	Mist	German (deu)	Manure; animal excrement.
4	miist	Seri (sei)	An animal of the family Felidae.
5	miste	Danish (dan)	To lose something.
6	silver mine	English (eng)	A mine for silver ore.

The first clue refers to the German translation of *silver*, which has the similar word form *Silber*. The second and third clues address the word *mist* with its meanings in English and German. The fourth and fifth clues refer to similar word forms of *mist* in Danish and Seri (an isolated language spoken in Mexico). The last clue addresses a multi-word expression which has a similar form to the entire name T. When deciding if T should be rejected as a name, only the third and fifth clues are helpful, since the specified meanings are negatively connotated and thus do not enhance the value of a product with such a name. We say a clue c is *relevant* for T if it should be considered in the decision of accepting or rejecting the name. Note that there might be good reasons for a copywriter to ignore the fact that *Mist* has a negatively connotated meaning in German. In section 5, we discuss such cases.

The primary objective of a method $\mathcal{M}$ is to return relevant clues for as many names as possible and thus obtain a high recall. While this is obviously important for maximizing the usefulness of the method, a secondary objective is to retrieve *only* relevant clues and thus obtain a high precision. The rationale behind this is to minimize the amount of information that needs to be manually checked by humans.

4 Proposed Method

Our solution is based on the following considerations:

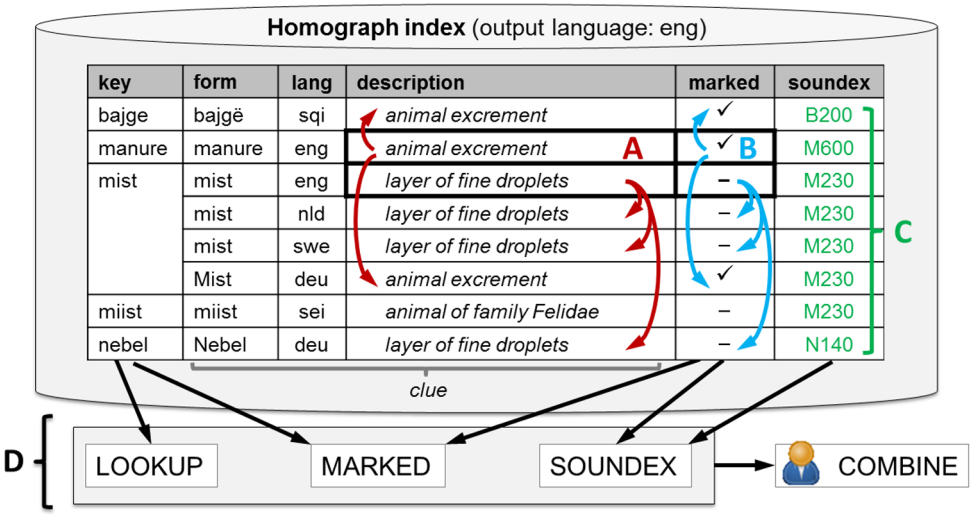

Figure 1: Running example of our method showing sense definition (A) and pragmatic label propagation (B), Soundex representation (C), and the practical usage scenario based on different query methods (D)

(1) The input name T can be of any language. Approaches using *monolingual* corpora or knowledge bases are therefore of little help or yield a tool that can only be used for a single target market. Instead, we aim at covering many languages and markets.
(2) The description of a clue should be limited to a few predefined output languages understood by the copywriters using the system.
(3) A solution must deal with non-standard language varieties, such as slang and dialects, to detect vulgarities, negative connotations, etc.
(4) Crowdsourcing platforms might prove helpful, but do not return instant feedback, require to divulge T before its official announcement, and are highly biased towards certain languages (cf. Pavlick et al., 2014).
(5) We lack training data for the marketing blunder task, which is why we do not consider data-driven or machine-learning approaches yet. Large annotated multilingual datasets including non-standard language will be necessary to learn a generalizing model (cf. section 7).

We propose using data from Wiktionary, which is particularly suitable for this task, since it contains lexicon entries and translations in many languages and a broad diversity of technical domains, colloquial language, slang, and dialects (cf. Meyer and Gurevych, 2012). As the users of our tool, we assume copywriters speaking English and German, which is a realistic example for central European marketing agencies. Our method is, however, not limited to these two output languages.

In the remaining section, we describe our family of methods $\mathcal{M}(T)$, which first segment the input name T into a sequence of k tokens $T = t_1 t_2 \dots t_k$. The methods then create the set Q of all token n-grams in T and retrieve clues for each $q \in Q$ from a huge inter-lingual index. We create this so-called *homograph index* by extracting and propagating sense definitions, translations, and pragmatic labels from Wiktionary.[2] The four steps of this approach are explained below and summarized in figure 1. We use the running example $T =$ "Silver Mist", for which our methods retrieve clues from the homograph index for each token n-gram $q \in Q = \{$*Silver*, *Mist*, *Silver␣Mist*$\}$.

Step A: Propagating sense definitions. The example of the *Silver Mist* car suggests that a large share of cross-lingual marketing blunders is due to false friends (i.e., two words with the same pronunciation or written form, but different meanings). This is why we first create a *homograph index* of words sharing the same word form. Each index entry consists of a normalized word form (the *key*) that points to one or multiple clues (i.e., triples of word form w, language ℓ, and textual description d).

Initially, the homograph index contains only clues extracted from all Wiktionary word senses of the

[2]We use the DKPro JWKTL software to extract this information: `https://dkpro.github.io/dkpro-jwktl/`

output languages (e.g., English and German). We create the key by converting the lemma of the Wiktionary word sense to lower case and removing special characters and diacritics. As the textual description d of the corresponding clues, we use the senses' definitions. In a subsequent step, we extend the homograph index by adding all translations of these word senses. We apply the same normalization technique for the translated word form to obtain the key. The key *han* thus points to clues in eleven languages, including the lemma forms *Han* (e.g., English), *han* (Turkish), *hän* (Finnish), *hăn* (Frisian), *hån* (Swedish), and *hắn* (Vietnamese). This multilingual homograph index already enables queries in any language for which translations are encoded in Wiktionary. In order to determine the clues for the translated word forms, we propagate the sense definition from the output language to the translation language. This is possible, because each Wiktionary translation is associated with a specific word sense. This way, copywriters can decide to accept or reject a name using a proper sense description instead of a bare word translation, which is especially necessary for polysemous words: Showing only the English word *arm* as a translation of the Polish *broń* would not be helpful, as it remains unclear if the potentially unwanted weapon sense or the unproblematic body part sense of *arm* is meant. In figure 1 (A), we show the homograph index creation for the two English output language lemmas *manure* and *mist*. We add the translations of the corresponding Wiktionary word senses as new index entries, and we propagate the sense description from the thick-framed cells to the foreign language entries.

Our final homograph index consists of 1.3 million normalized word forms referring to about 3.0 million clues covering 2,022 languages.[3] Using this index, we can define our first method for retrieving clues, which we call LOOKUP. Given the input name T and the set of all token n-grams Q, the LOOKUP method normalizes each $q \in Q$ using the same technique as for index keys and then looks up every normalized q in our index. For $T =$ "Silver Mist", LOOKUP returns 48 clues from six languages.

Step B: Propagating pragmatic labels. An important goal of our approach is separating relevant from irrelevant clues. The Dutch and Swedish forms of *mist* are, for instance, cognates of the English word form and thus carry the same, unproblematic meaning. Likewise, false friends without any negative connotation, such as the English and Hungarian *fog* discussed above, yield irrelevant clues that should be ignored. In a dictionary, the corresponding entries for these words are usually *unmarked* – i.e., they are not associated with a particular language variety, but considered standard language. As opposed to that, the German *Mist* is marked as "umgangssprachlich" ("slang") and as "verärgerte Äußerung" ("annoyed utterance") in Wiktionary, which are good indicators to avoid using *Mist* in a product name. We call these markings *pragmatic labels* (Wiegand et al., 2010). For our purposes, we are interested in sociological labels (the diastratic variety) that mark jargon used by a certain culture, social group, or social class (e.g., *army slang*, *argot*, *children's language*), register and style labels (the diaphasic variety) that mark word senses used in certain communicative situations (e.g., *colloquial*, *informal*, *slang*), and evaluative labels (the diaevaluative variety) that mark offensive words and words with a certain connotation (e.g., *pejorative*, *rude*, *derogatory*). Note that this goes beyond sentiment lexicons, which typically focus on the diaevaluative variety. In Wiktionary, pragmatic labels are specified at the beginning of a sense definition, usually enclosed in parentheses, typed in italics, or separated by a colon. We extract all the labels used for the word senses of the output languages. Of the 2,440 distinct labels used at least three times, we manually select 245 labels that belong to one of the three label categories and we enrich our homograph index by storing whether a word sense is marked by one of these labels. In a subsequent step, we propagate the labels from the output languages to the other languages by following the translation links. The underlying assumption is that a pragmatic label of a word sense in one language is conserved in another language, given that the translation is correct. Figure 1 (B) shows an example for English: The output language word sense of *manure* is marked as slang. We propagate this marking to the equivalent German word sense *Mist* and the Albanian (sqi) word sense *bajgë*. About 63,000 clues of the homograph index are marked by at least one of the 245 pragmatic labels. Based on this, we define a second method called MARKED, which looks up each normalized token n-gram of Q in the homograph index (equivalent to LOOKUP), but returns only clues marked by a pragmatic label.

[3] But note the long tail: 1,015 languages have only one clue.

Step C: Similar word form representations. Marketing blunders are of course not limited to forms with the exact same written form. Choosing the word forms *misd*, *misth*, or *miist* could, for instance, cause similar reactions in German-speaking markets as their pronunciation is highly similar to *Mist*. This is why we propose a third method SOUNDEX, which queries the homograph index for marked word forms starting with the same three letters and having the same *Soundex* representation (Russell, 1918) as the queried token n-gram (but not being identical to it). Soundex is an algorithm that returns a pseudo-phonetic representation of a given English word, which consists of the word's initial letter followed by at least three digits denoting groups of similar consonants. The main idea of the algorithm is that two words with similar pronunciations return similar Soundex representations: The Soundex representation of both *mist* and *miist* is M230, but M62352 for *marketing*. Although the Soundex algorithm is designed for the English language, we apply it to any token n-gram and leave the development of a language-independent pseudo-phonetic model to future research. To allow for faster queries, we precompute the Soundex representations for all clues of our homograph index as shown in figure 1 (C). When using the SOUNDEX method, we can then create a Soundex representation for each token n-gram $q \in Q$ and retrieve all marked clues that have the same Soundex representation in a simple homograph index lookup.

Step D: Practical, semi-automatic usage scenario. We combine the three methods by first querying the homograph index using MARKED. If this search does not yield relevant clues, we query the index using SOUNDEX and, analogously, we query the index using the LOOKUP method if there are still no relevant clues. We thus define the method COMBINE as the sequential application of MARKED, SOUNDEX and LOOKUP, see figure 1 (D). The rationale behind this is to simulate a practical usage situation of our approach: Since only a fraction of the entries are marked by pragmatic labels, we first present those to a user (MARKED). If she or he finds evidence for a marketing blunder, no further lookup is required for the given name. Otherwise, the user can check for marked forms with a similar form representation (SOUNDEX) and only turn towards reading all entries (LOOKUP) if there are still no relevant clues.

5 Evaluation

To evaluate our approach, we conduct two experiments: (1) We measure the performance of our four methods using a newly created dataset of previously occurred cross-lingual marketing blunders. (2) We apply our method to a large dataset of international brand names to check for potential blunders.

Marketing blunder dataset. As a novel evaluation dataset for this task, we extract the marketing blunder examples discussed by Ricks (2006, § 3) and provided on the homepage of the British consultancy *Commisceo Global*.[4] We omit examples that are not related to a name or whose name or translation is not explicitly provided. Ricks notes, for instance, that a U.S. food manufacturer wrongly translated the name of their mascot "Jolly Green Giant" into Arabic as "intimidating green ogre", but does not provide the exact Arabic form, which would be required to properly simulate the tool-assisted detection of this blunder. For each blunder in this dataset, we store the problematic name T, a remark on the vendor or type of product, and a short textual explanation of the blunder. In addition to that, we manually group the blunders into the following four categories:

- *vulgar:* names containing vulgar, rude, or offensive expressions,
- *sexual:* names with sexual innuendos,
- *negative:* names with negative connotations or suggesting negative properties,
- *intent:* names containing an expression with a different, unrelated meaning in a certain language causing astonishment and distraction among potential customers.

The fruit drink *Pavian* is an example for the *intent* group since *Pavian* means *baboon* in German, which caused distraction among customers, although the word is not negatively connotated. Our initial dataset consists of 44 cross-lingual marketing blunders, which we make publicly available for other researchers.

Experiment 1. We apply our four methods to each problematic name of this novel marketing blunder dataset. In total, our methods returned 1,494 clues. In order to judge a clue relevant or irrelevant, we

	MARKED	SOUNDEX	LOOKUP	COMBINE
Detected marketing blunders:	18 / 44	18 / 44	28 / 44	34 / 44
intent	0 / 3	0 / 3	3 / 3	3 / 3
negative	3 / 15	8 / 15	10 / 15	14 / 15
sexual	7 / 14	4 / 14	7 / 14	8 / 14
vulgar	8 / 12	6 / 12	8 / 12	9 / 12
Retrieved clues:	105 / 151	85 / 247	341 / 1202	229 / 517
Precision P:	.70	.34	.28	.44
Recall R:	.41	.41	.64	.77
F_1 score:	.52	.37	.39	.56
F_2 score:	.45	.39	.51	.67

Table 1: Evaluation results for our marketing blunder dataset

ask two human raters to annotate this set of retrieved clues. The raters agree on 95 % of the judgments yielding an inter-rater agreement of $\kappa = .87$ (using Cohen's kappa). Based on this agreement, we consider the annotations reliable (cf. Artstein and Poesio, 2008). For obtaining a gold standard, we ask an additional adjudicator to decide on the 76 ties.

Table 1 summarizes the evaluation results. We report the number of detected blunders over the total number of blunders both for the whole dataset and separately for each blunder category. The table additionally provides the total number of relevant and retrieved clues as well as the precision, recall, F_1 and F_2 scores. We define the precision P as the ratio of relevant clues to the total number of retrieved clues (i.e., a method is more precise if it returns more relevant clues) and recall R as the proportion of detected marketing blunders in the dataset (i.e., a method has a higher recall if it is able to detect more marketing blunders). The F_1 and F_2 scores follow the standard definitions of being the (weighted) harmonic mean between precision and recall. In accordance with our task's primary objective (see section 3), the F_2 score prefers high recall over high precision.

The basic LOOKUP method yields a recall of .64 indicating that our homograph index is able to effectively detect cross-lingual marketing blunders. As the low precision indicates, there are, however, a large number of irrelevant clues that are retrieved by this simple index lookup. As opposed to that, we find a high precision for the MARKED method, as the index entries marked with pragmatic labels yield relevant clues in over 70 % of the cases. The MARKED method is, however, not suitable to detect marketing blunders of the categories *intent* and *negative*, which causes a low recall. It should be noted that it is not surprising to find the recall of MARKED lower than that of LOOKUP, because the former returns a subset of the latter. This is different for SOUNDEX, which facilitates the detection of marketing blunders that remain unseen by the other methods. We find that our semi-automatic usage simulation COMBINE yields the most reasonable trade-off between precision and recall, since it achieves the highest recall of the three methods and a higher precision than LOOKUP and SOUNDEX. With this method, we are able to detect 34 of the 44 cross-lingual marketing blunders ($R = .77$) and we achieve the highest F_1 and F_2 scores. For the corresponding marketing campaigns, the copywriters would have to examine a total of 517 clues (on average 12 per blunder); 229 of them are relevant (on average 5 per blunder; $P = .44$).

Experiment 2. In our second experiment, we aim at finding potential marketing blunders in existing names on a larger scale. To this end, we use all 998 brand names of the BrandPitt corpus (Özbal et al., 2012) and retrieve clues using our tool. It is important to note that this corpus mostly contains top-tier international brands, such as *Pizza Hut*, *Jaguar*, and *IKEA*, whose names are established for many years and thought over by leading marketing agencies. Initially, we therefore did not expect to find many relevant clues. Our tool returns a total of 756 clues using MARKED, 3,549 using SOUNDEX, and 17,270 using LOOKUP. Given the high number of brand names and clues, we focus on the clues returned by MARKED (i.e., the first step of our simulation) and ask two human raters to judge them relevant or irrelevant for deciding whether or not to use a name for a particular region in the world. The raters find

154 (rater 1) and 192 (rater 2) of the 756 clues to be relevant. This corresponds to returning relevant clues for 70 (rater 1) and 88 (rater 2) of the 215 names for which MARKED returned at least one clue. The raters agree in 90 % of the cases ($\kappa = .72$).

Finding this many relevant clues is surprising, which is why we carefully checked the annotated data. We indeed find very helpful clues, which – in our opinion – should at least be known to the corresponding marketing agencies. The name of the animation studio *Pixar* means, for example, to urinate in the Catalan language. The name of the Norwegian confectionery *NERO* and the German software producer *Nero* means *brainiac* in Finnish, which is marked derogatory in some contexts, and the related form *ñero* is a rough equivalent of *thug* or *gangsta* in Colombia. The name of the Russian car manufacturer *Lada* has a related form *låda* in Swedish meaning *box*, including a pejorative meaning for unattractive houses and cars. Though being differently pronounced, the relationship could still be problematic in written communication (e.g., a poster with barely visible ring diacritic). In the Darfur and Chad language Fur, *martìn* is a vulgar form for the buttocks, which the raters consider relevant for the *Aston Martin* car brand. The popular coffee bar name *Thanks a Latte* might be less suitable for the German market, where *Latte* is a colloquial word for erected penis. The name of the *Coco Pops* cereals might prove problematic in French markets, where *coco* means cocaine. Though being relevant, many of these clues are of course not problematic, since the brand names are already well-established. However, we consider our tool helpful for new names, which lack this brand strength. Another important finding from this experiment is that there are often relevant clues for which a more salient word sense exists that prevents misinterpretation. The related forms *cocó* and *cocô* mean, for instance, *shit* in Portugal and Brazil, respectively, which we consider highly relevant for the *Coco Pops* example. Since there is, however, also the frequent form *coco* in both languages meaning coconut, it is unlikely that the product name is misinterpreted.

6 Discussion and Error Analysis

MARKED works well for detecting the blunder categories *vulgar* and *sexual*, whereas LOOKUP predominantly retrieves clues for the *intent* and *negative* categories. Since we designed SOUNDEX to only return marked entries, it is likewise less suitable for *negative* and *intent*. For *negative* blunders, additional knowledge from sentiment lexicons could be helpful to recognize relevant clues containing a negative connotation. In order to do so, we require either language-independent sentiment analysis tools or a sense-disambiguated notion of sentiment for Wiktionary word senses, which can be used for propagating sentiment information across languages. Existing lexicons, such as the NRC Word-Emotion Association Lexicon (Mohammad and Turney, 2013), provide a good starting point.

Blunders of the *intent* category are much harder and most likely require copywriters to read all clues returned by LOOKUP. Semantic relatedness measures might prove useful for identifying false friends with highly different meanings. Especially in the BrandPitt dataset, we note, however, that there are some names using pragmatically marked or ambiguous words intentionally. The *Get Lost Magazine*, for instance, includes the English phrase *get lost* which raises negative associations of rudely being asked to leave. Since the magazine is about adventure traveling, the copywriters use this name on purpose to create an interesting name with multiple interpretations. This illustrates why we consider it important to model marketing blunder detection as a semi-automatic task leaving the final decision to humans.

None of our current methods is able to detect blunders whose text contains a problematic word as a substring. The product name *FARTFULL*, for instance, needs to be split into *fart* and *full*, before an index lookup can yield relevant clues. The large number of substring combinations would, however, yield a huge number of irrelevant clues if all combinations are queried. The English words *fartherer* or *penny-farthing* contain, for instance, the substring *fart*, but do not lead to a vulgar interpretation right away. A similar problem occurs for inflected word forms (e.g., *Vicks*). Relying on automatic lemmatization or morphological analysis is problematic, since such tools are usually language-specific. For our task, they would need to cover essentially any language. Trimming suffixes of different lengths might be a solution, but would not work for highly agglutinative languages.

The use of Soundex representations for identifying similar forms works well in some cases, for example for finding the Finnish *hullu* (IPA: [ˈhulːu]) meaning insane, which has a similar pronunciation as

the American streaming service *Hulu* ([huˈlu]). For the Japanese *creap*, SOUNDEX retrieves the English *creep* (annoying person) and the French *crevé* (extremely fatigued). While the former is relevant for detecting this blunder, the latter might have a somewhat similar pronunciation in English (e.g., [kɹiːv]), but definitely not in French ([kʁə.ve]). The same is true for *Lada* and the Swedish *Låda* ([ˈloː.da]). Such problems are due to Soundex being designed for English. Since Wiktionary also contains pronunciation information, a future method could lookup index entries with similar or equal IPA representation, given that they are available at a large-scale and for a large number of languages. Recently, Deri and Knight (2016) introduced a new grapheme-to-phoneme model for almost any language, which we consider highly relevant for indexing language-independent pseudo-phonetic representations.

Ricks (2006) also notes the English form *crap* as a blunder cause for *creap*, since it has a similar spelling. None of our methods, however, returns *crap* as a clue for this name. An obvious solution would be the use of string similarity metrics, such as Levenshtein's edit distance. We indeed tried this metric, but found that it returns a huge number of irrelevant clues. We therefore suggest to develop a modified edit distance metric for this task, which, for example, puts more weight on editing letters with similar shape. Finally, our tool cannot retrieve clues for potential marketing blunders across different scripts. For the *Bardak* machines, a method would have to transliterate the Latin spelling to the Cyrillic бардак in order to find the problematic meaning of a whorehouse. Future work should incorporate state-of-the-art transliteration systems for as many language pairs as possible.

7 Future Research Demands and Dissemination

Along with this paper, we publish our newly compiled marketing blunder dataset, homograph index, and annotations. In addition to that, we provide a web interface which implements the three steps of our COMBINE method. It allows retrieving clues for arbitrary names. Besides product, brand, and company names, our tool can retrieve clues for acronyms (e.g., of proposals) and person or organization names, which might cause misinterpretations in foreign languages.[5]

With these materials, our Wiktionary-based method and the detailed error analysis, we lay the foundation for the new natural language processing task of detecting marketing blunders. This task raises a number of important research challenges:

- Finding good names is a creative process, for which copywriters intentionally deviate from known patterns. This makes it hard to model the overall detection task with standard pattern recognition algorithms.
- Our task formulation is based on the notion of clues, which explain *why* a name is considered problematic. As opposed to that, many current tasks use a classification setup (e.g., a binary classification into *problematic* and *unproblematic*), which only indicates *if* there is a problem.
- Evaluating a name is highly subjective, as there might be intended ambiguity, jokes and language games, varying association and brand strength, etc. We therefore introduce marketing blunder detection as a semi-automatic task, which are typically very difficult to evaluate.
- Detecting marketing blunders makes most sense if *all* languages are considered, which is especially challenging for poorly documented languages. The necessity to limit the number of output languages raises another interesting challenge of separating object and meta language.

There is a large variety of future projects around this task. First and foremost, we require larger datasets for developing and evaluating our methods. While Wiktionary is continually updated by its community, future versions will yield improved coverage. For supporting additional output languages beyond English and German, it is necessary to scrape other language versions and associate the pragmatic label system with the existing index in a one-time effort. Further knowledge bases and corpora of colloquial language (e.g., from Twitter) may prove useful for background knowledge. For evaluation data, it will be interesting to cooperate with marketing researchers and copywriters. Previously occurred marketing blunders might be collected in a crowdsourcing effort. The second important strand of research will be better blunder detection methods for retrieving relevant clues. The most important issues to solve are

[5] https://github.com/UKPLab/coling2016-marketing-blunders

the intelligent segmentation of names containing problematic words, the automatic transliteration and phonetic representation of the index entries, and the integration of multilingual sentiment lexicons and analysis methods.

8 Conclusion

In this paper, we introduced the task of detecting cross-lingual marketing blunders. In addition to a formal task definition, we proposed a knowledge-based method, which propagates pragmatic labels to translated word senses from Wiktionary. Our final tool assists copywriters who design new names and accept or reject a suggested name based on a number of clues returned by the automatic method. We evaluated our work in two experiments. On a newly created dataset of previously occurred marketing blunders, we were able to detect 78 % of the problematic names. Our second experiment identified between 150 and 200 relevant clues for a large collection of top-tier international brand names.

We find that Wiktionary is well-suited for this task, as it contains many languages and a large number of pragmatic labels allowing us to process non-standard language varieties, such as slang. These language varieties are often absent from newswire corpora and expert-build dictionaries and therefore remain underresearched in our community.

We put a special focus on the error analysis and learned that follow-up work needs to find better tools and methods for computing language- and script-agnostic orthographic and phonetic similarity, for interpreting negative connotations that appear as substrings, and for language-independent sentiment and morphological analysis. To establish the new marketing blunder detection task, we finally discussed its main challenges and demands in order to suggest a research agenda to the scientific community. In future work, it will be especially interesting to cooperate with marketing agencies, in order to study how copywriters use a blunder detection tool for yet unknown product, brand, or company names.

Abstract

We present Ambient Search, an open source system for displaying and retrieving relevant documents in real time for speech input. The system works ambiently, that is, it unobstructively listens to speech streams in the background, identifies keywords and keyphrases for query construction and continuously serves relevant documents from its index. Query terms are ranked with Word2Vec and TF-IDF and are continuously updated to allow for ongoing querying of a document collection. The retrieved documents, in our case Wikipedia articles, are visualized in real time in a browser interface. Our evaluation shows that Ambient Search compares favorably to another implicit information retrieval system on speech streams. Furthermore, we extrinsically evaluate multiword keyphrase generation, showing positive impact for manual transcriptions.

1 Introduction

Recent advancements in Automated Speech Recognition (ASR) and Natural Language Understanding (NLU) have proliferated the use of personal assistants like Siri[1] or Google Now[2], with which people interact naturally with their voice. However, the activation of such systems has to be specifically triggered and they are targeted to an (ever–growing) set of anticipated question types and commands.

When taking part in a conversation or listening to a lecture, people may want to look up helpful information or check facts. Manually checking this information or interacting with a personal assistant would hamper the flow of the discussion, respectively distract from the lecture. In the following, we present *Ambient Search*, a system that ambiently researches relevant information, in the form of proposing relevant documents to users in conversations or users who passively listen to spoken language. In contrast to other personal assistants, our system is not specifically triggered, it unobtrusively listens to speech streams in the background and implicitly queries an index of documents. We see the following utility in our approach: The assistant stays in the background and does not disturb the user. Access to the displayed snippets is on demand and the user can access the information in context without the need to formulate a specific query.

On the other hand, these advantages are fundamentally based on how well the system is able to retrieve relevant documents, as the system's utility diminishes when proposing a lot of irrelevant documents. In this paper, we also evaluate how well the system is able to retrieve relevant Wikipedia articles in spite of average speech recognition word error rates (WER) of 15.6% on TED talks and show that it finds more relevant articles compared to another implicit information retrieval system on speech streams.

The next section discusses related research, while we give an overview and technical details of our approach in Section 3. We evaluate keyword recognition and retrieval relevance in Section 4, and conclude in Section 5.

2 Related Work

The Remembrance Agent (Rhodes and Starner, 1996) is an early prototype of a continuously running automated information retrieval system, which was implemented as a plugin for the text editor Emacs[3]. Given a collection of the user's accumulated email, Usenet news articles, papers, saved HTML files and other text notes, it attempts to find those documents that are most relevant to the user's current context. Rhodes and Maes (2000) defined the term *just-in-time information retrieval agents* as "a class of software agents that proactively present information based on a person's context in an easily accessible and non-instrusive manner". A person's context can be a very broad term in this regard. E.g. Jimminy (Rhodes, 1997) represents a multimodal extension of the Remembrance Agent. Dumais et al. (2004) introduced an implicit query (IQ) system, which serves as a background system when writing emails. It also uses Term Frequency – Inverse Document Frequency (TF-IDF) scores for keyword extraction, like the Remembrance Agent.

Other systems cover a user's explicit information needs, e.g. Ada and Grace are virtual museum guides (Traum et al., 2012), that can suggest exhibitions and answer questions. The Mindmeld[4] commercial assistant can listen to conversations between people to improve the retrieval results by fusing the users location information with from transcripts extracted keywords. The FAME interactive space (Metze et al., 2005) is a multi-modal system that interacts with humans in multiple communication modes in order to suggest additional information to them. Although FAME supports speech recognition and voice commands, it only listens to conversations for a longer period of time when it guesses a conversation's topic and can suggest documents with explicit commands. Another class of systems try to record the content of a conversation or speech stream and visualize it using a network of terms: E.g. SemanticTalk (Biemann et al., 2004) iteratively builds a structure similar to a mind map and can also visualize conversation trails with respect to background documents.

The most similar approach to *Ambient Search* was presented by Habibi and Popescu-Belis (2015), extending earlier work of an Automatic Content Linking Device (ACLD) (Popescu-Belis et al., 2000). It uses an LDA topic model for the extraction of keywords and the formulation of topically separated search queries. The extracted set of keywords as well as the ultimately returned set of document recommendations fulfill a trade-off between topical coverage and topical diversity.

Because this system can be considered a state-of-the-art system of implicit information retrieval in speech streams, we compare our approach to this one in the evaluation in Section 4, alongside a TF-IDF-based baseline. A major difference to Habibi and Popescu-Belis (2015), that operates on complete speech transcriptions only, is that our implementation is also able to retrieve relevant documents in real time, e.g. process live speech input.

3 Our Approach to Ambient Search

Our approach is based on five major processing steps, as depicted in Figure 1. These steps are carried out in real-time and in a streaming fashion, i.e. we make use of a new transcription hypothesis as soon as it is available.

At first, the speech signal is streamed into an ASR system (1). It emits the partial sentence hypothesis and also predicts sentence boundaries. Once a full sentence has been hypothesized, new keywords and keyphrases are extracted in the current sentence, if available (2). These terms are then ranked (3) and merged with the ones from previous sentences. A query is then composed, which is submitted to a precomputed index of documents (4).

Eventually, the returned documents are also aggregated (5a), i.e. previously found documents decay their score over time and newer documents are sorted into a list of n best documents. This list is thus sorted by topical relevance of the documents and by time, with newer documents having precedence. Finally, the n best relevant documents are presented to the user (5b) and updated as soon as changes become available. Alongside the n best documents, a time line of previously suggested articles is also maintained and displayed. The next subsections provide further details on the individual major processing steps.

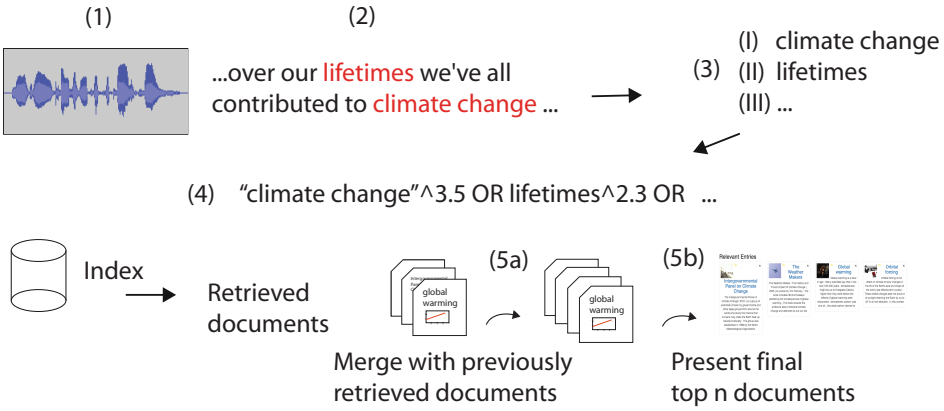

Figure 1: Processing steps of *Ambient search*

3.1 Speech Decoding

We use the popular Kaldi (Povey et al., 2011) open-source speech recognition framework and acoustic models based on the TED-LIUM corpus (Rousseau et al., 2014). We make use of online speech recognition, i.e. models that transcribe speech in real-time and emit partial transcription hypothesis, as opposed to offline models that operate on already recorded and complete utterances. The models were built using the standard recipe for online acoustic models based on a DNN-HMM acoustic model and i-vectors. We also make use of the TED-LIUM 4-gram language model (LM) from Cantab Research (Williams et al., 2015). The vocabulary of the speech recognizer is determined by its phoneme dictionary[5] and is confined to about 150k words. The online speech recognizer achieved an average WER of 15.6% on TED talks that we selected for the evaluation in Section 4.

We make use of kaldi-gstreamer-server[6], which wraps a Kaldi online model into a streaming server that can be accessed with websockets. This provides a bi-directional communication channel, where audio is streamed to the server application and partial and full sentence hypothesis and boundaries are simultaneously returned as JSON objects.

3.2 Keyphrase Extraction

A keyphrase, as opposed to a single keyword, can consist of one or more keywords that refer to one concept. We first precompute a DRUID (Riedl and Biemann, 2015) dictionary on a recent Wikipedia dump with scores for single adjectives or nouns and noun phrases. The restriction to only use adjectives and nouns is a common one in keyword detection, c.f. (Liu et al., 2010). DRUID is a state-of-the-art unsupervised measure for multiword expressions using distributional semantics. Intuitively, DRUID finds multiword expressions by combining an uniqueness measure for phrases with a measure for their incompleteness. Uniqueness in this context is based on the assumption that multiword expressions (MWEs) can often be substituted by a single word without considerably changing the meaning of a sentence.

The uniqueness measure uq(t) is computed with a distributional thesaurus, as the ratio of all similar unigrams of a term t divided by the number of n-grams similar to t. The incompleteness (ic) measure serves to punish incomplete terms in that it counts the number of times that the same words appear next to a term. The final DRUID measure for any term t is the subtraction of the incompleteness measure from the uniqueness measure: $DRUID(t) = uq(t) - ic(t)$. This helps to rank incomplete multiwords lower than their complete counterparts, e.g. 'red blood' is ranked lower than 'red blood cell'.

DRUID is implemented as a JoBimText (Biemann and Riedl, 2013) component, which can be down-

[5]The Kaldi TEDLIUM recipe uses CMUDICT (`http://www.speech.cs.cmu.edu/cgi-bin/cmudict`) plus a few automatically generated entries

[6]`https://github.com/alumae/kaldi-gstreamer-server`

loaded from the JoBimText project website[7] alongside precomputed dictionaries for English.

3.3 Term Ranking

We first precompute IDF and Word2Vec (Mikolov et al., 2013) lookup tables for all unique words in the Simple English Wikipedia and for all multiword terms in our DRUID dictionary. Word2Vec (CBOW) is our source of semantic similarity. We train it on stemmed text and treat multiwords as found with DRUID as opaque units. The final word embedding lookup table maps (in our case stemmed) word and phrase ids into a 100 dimensional continuous vector space. The model exploits the distributional properties of raw text for semantic similarity and the distance between embeddings can be used as a word and phrase similarity measure.

Using the lookup tables, we build a term ranking measure as follows. We extract all keyphrases from the last 10 sentences with a DRUID score of $\geq c$ and filter all stop words and any word that is not an adjective or noun, as determined by an off-the-shelf part of speech (POS)-tagger[8]. The cutoff constant c can be used to tune the amount of generated multiword candidates, with useful values ranging from 0.3 to 0.7 (see also Section 4). All multiwords and any single word remaining after filtering is proposed as a candidate. We then compute the average Word2Vec vector over all candidate terms. Finally, we score each candidate term according to the cosine distance of each term word vector to the average term word vector of the last 10 sentences and multiply this with the TF-IDF score of the given term:

$$tr(term_k, trans) = d_{cos}\left(w2v(term_k), \frac{1}{|terms|}\sum_{i=1}^{|terms|} w2v(term_i)\right) \cdot TFIDF(term_k, trans)$$

where tr is the term ranking function that ranks a $term_k$ out of the set of all candidate $terms$ to a given transcript $trans$. $w2v$ yields the embedding of the given term, TFIDF yields the TFIDF score of the given term and transcript (IDF computed on the background Wikipedia corpus) and d_{cos} is the standard cosine similarity.

This ranking measure tr can be interpreted as a combination of the distance to the core topic (Word2Vec) and the general importance of the term for the text window (TF-IDF). We use the measure to extract up to 10 highest ranked candidate keywords and keyphrases in the text window. For the first third of Alice Bows Larkin's TED talk on climate change[9], the system would rank the terms as: "climate change", future, emissions, "negative impacts", potential, profound, workplaces, behaviors, gas.

3.4 Index Queries

We use Elastic Search[10] and stream2es[11] to build an index of the Simple English Wikipedia[12]. We index all articles, including special pages and disambiguation pages and use a query filter to obtain only regular articles when querying the index. We build an OR query where at least 25% of the query terms should match (by setting the "minimum_should_match" parameter), also assigning the scores obtained in the last section to the individual terms in the query.

With the example ranking from the previous section the query would be:

```
"climate change"^23.111 future^13.537 emissions^9.431 "negative impacts"^3.120
   potential^2.985 profound^2.679 workplaces^2.562 behaviors^2.368 gas^1.925
```

It would return the following Wikipedia articles (ranked by Elastic Search in that order):

[7] http://jobimtext.org/components/druid/

[8] The POS tagger we use is from the spacy library (http://spacy.io)

[9] https://www.ted.com/talks/alice_bows_larkin_we_re_too_late_to_prevent_climate_change_here_s_how_we_adapt

[10] https://www.elastic.co/

[11] https://github.com/elastic/stream2es

[12] https://simple.wikipedia.org

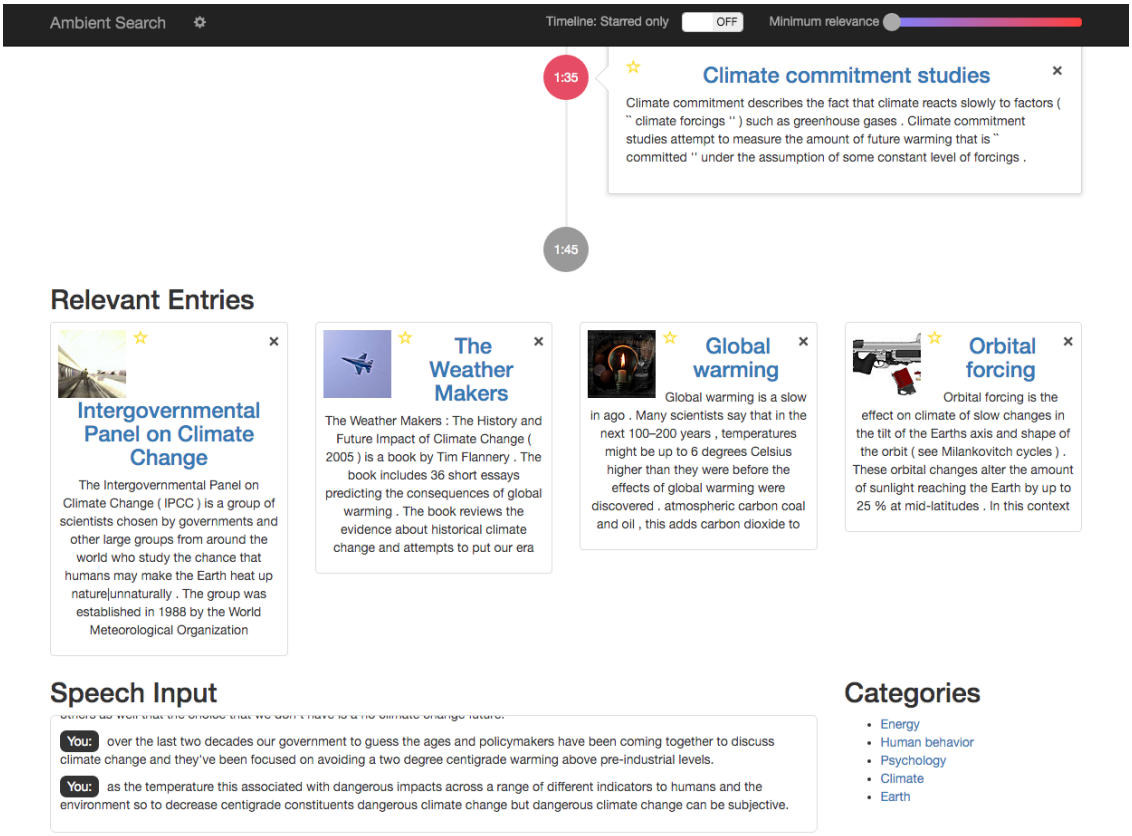

Figure 2: Screenshot of the system after listening to the first minutes of the TED talk "We're too late to prevent climate change - here is how we adapt" by Alice Bows Larkin [9]

```
"Intergovernmental Panel on Climate Change", "Global warming", "Climate change", "
    Global dimming", "The Weather Makers", "Greenhouse effect", "United Kingdom
    Climate Change Programme", "Ocean acidification", ...
```

This process is repeated for every new sentence and the scores of older retrieved documents decay (are multiplied with $d = 0.9$), to allow newer documents to rank higher.

3.5 Visual Presentation

Figure 2 gives a visual impression of our system, after it had been listening for a few minutes to Alice Bows Larkin's TED talk on climate change. We show excerpts of up to four relevant Wikipedia documents to the user. Clicking on such a document opens up a modal view to read the Wikipedia article. Articles are either retrieved online or using an offline version of the Simple English Wikipedia using XOWA[13]. Articles can be starred, to quickly retrieve them later and also removed, to signal the system that the article was irrelevant. When newer and more relevant articles are retrieved, older articles move into a timeline, which is constructed above the currently retrieved articles. The newest articles are at the bottom of the page and the page keeps automatically scrolling to the end, like a terminal, if the user does not scroll up. In the timeline, the relevance of a document is also visually displayed with different coloring of an element's circular anchor. The user can also regulate the threshold for minimum document relevance.

3.6 Implementation Details

We encapsulate the processing steps outlined in Section 3 into the following Python programs:

[13] https://gnosygnu.github.io/xowa/

(1) A *Kaldi client program*, that either uses the system's microphone or an audio file, streaming it in real time to obtain partial and full transcription hypothesis. (2) A *relevant event generator program*, that searches for new keywords and keyphrases and queries the elastic search index to obtain relevant documents. (3) The *Ambient Search server*, which sends out appropriate events to the browser view, to display the current top n relevant documents and to move older documents into a timeline.

We make use of message passing to communicate inputs and results of the individual programs using a redis-server[14]. Word2Vec and TF-IDF vectors are computed with the Gensim (Řehůřek and Sojka, 2010) package, while DRUID is precomputed as a list with JoBimText[15]. The Ambient Search web page is using HTML5/JS and Bootstrap[16] and connects to an ambient server instance running on the Python micro-framework Flask[17]. The web page is updated using Server Sent Events (SSE) or Long Polling as a browser fallback. This enables a reversed information channel, where the server pushes descriptions of new relevant documents to the browser client as it becomes available.

4 Evaluation

We base our evaluation on 30 fragments of 10 recent TED talks, which we downloaded as mp3 files from the TED.com website. These talks are not part of the TED-LIUM training dataset. In the following, we evaluate the proposed keywords and keyphrases, as well as the proposed documents from the in real-time transcribed audio file.

4.1 Keyphrase and Document Retrieval

We had two annotators manually pick terms (keywords and keyphrases) that are central to the topic of the talk and those that would cover a user's potential additional information needs. What should be included as a term can be very subjective, the inter-annotator agreement is $\kappa = 0.45$, with one annotator choosing 292 terms in total and the other 580. The overlapping set which we use in our evaluation consists of 206 terms and 460 other terms were chosen by only one of the annotators.

Finally, we also measure directly how relevant the retrieved documents are: We focus on an evaluation of the top-ranked documents returned by our ambient IR system for a particular TED talk fragment, since only top documents are suggested to the user of *Ambient Search*. The Normalized Discounted Cumulative Gain (NDCG) measure (Järvelin and Kekäläinen, 2002) is a popular choice to evaluate search engines and also takes into account the ranking of the proposed documents.

We evaluate on the top-5 returned documents of the complete system. We had two annotators that used the standard relevance scale from 0-3, where 0 means irrelevant and 3 very relevant. NDCG directly measures how relevant the returned documents are. While the effort is considerably higher, since different system outputs have to be judged, NDCG measures the end-to-end performance of the system. For computing NDCG, we pool all judgments across systems, obtaining an average of 27.7 relevance judgments per fragment, following standard practices for IR evaluations (Clarke et al., 2012). We use the standard NDCG measure with $k = 5$:

$$NDCG_k = \frac{DCG_k}{IDCG_k}$$

$$DCG_k = (rel_1 + \sum_{i=2}^{k} \frac{rel_i}{log_2 i})$$

where rel_i is a documents average relevance score in respect to the speech input. The Ideal Discounted Cumulative Gain (IDCG) assumes the best ranking of all possible relevant documents found in the set of all pooled judgements of a given transcript. The DCG on this optimal ranking, with respect to the set of documents retrieved by all systems for a particular transcript, is then used to compute IDCG.

4.2 Results

Keyword/keyphrase extraction method	Mean Recall (Std. Dev. in %)	Mean Precision (Std. Dev. in %)	Mean NDCG (Std. Dev. in %)
(1) TF-IDF baseline no MWEs, no filtering	26.97% (16.74%)	24.33% (15.42%)	0.188 (20.0%)
(2) TF-IDF baseline no MWEs, stopword filtering	39.24% (15.36%)	34.33% (10.86%)	0.387 (27.8%)
(3) TF-IDF baseline no MWEs, full filtering	40.91% (13.55%)	36.42% (10.99%)	0.426 (27.8%)
(4) TF-IDF baseline with MWEs (c=0.3), full filtering	43.22% (18.22%)	37.09% (16.61%)	0.392 (27.4%)
(5) Habibi and PB original implementation	36.68% (15.37%)	32.00% % (11.66%)	0.427 (28.0%)
(6) Habibi and PB our prep., without MWEs	43.76% (16.78%)	39.24% % (12.75%)	0.465 (24.1%)
(7) Our proposed method with MWEs (c=0.3)	**48.52% (21.55%)**	41.89 % (15.82%)	0.453 (25.7%)
(8) Our proposed method with MWEs (c=0.5)	48.08% (17.63%)	**42.42 % (13.20%)**	0.469 (26.9%)
(9) Our proposed method with MWEs (c=0.7)	48.48% (19.15%)	**42.42 % (13.45%)**	0.471 (26.1%)
(10) Our proposed method without MWEs	44.87% (17.24%)	40.08% (14.03%)	**0.481 (26.8%)**

Table 1: Comparison of TF-IDF baseline keyword and keyphrase extraction methods, the proposed LDA based keyword extraction method by Habibi and Popescu-Belis (2015) and our proposed method based on DRUID, Word2vec and TF-IDF. The comparison is based on the same Kaldi transcriptions and the same training resources (Simple English Wikipedia from May 2016).

Keyword/keyphrase extraction method	Mean Recall (Std. Dev. in %)	Mean Precision (Std. Dev. in %)	Mean NDCG (Std. Dev. in %)
(11) Habibi and PB our prep., without MWEs	43.99% (15.26%)	39.33 % (12.63%)	0.476 (21.7%)
(12) Our proposed method with MWEs (c=0.3)	51.75% (20.43%)	45.67 % (16.47%)	0.518 (24.8%)
(13) Our proposed method with MWEs (c=0.5)	52.19% (19.09%)	46.19 % (15.27%)	0.574 (22.1%)
(14) Our proposed method with MWEs (c=0.7)	**52.68% (17.20%)**	**46.85 % (14.76%)**	**0.602 (22.1%)**
(15) Our proposed method without MWEs	47.81% (17.28%)	43.52 % (16.09%)	0.578 (25.2%)

Table 2: Comparison of the proposed LDA based keyword extraction method by Habibi and Popescu-Belis (2015) and our proposed method based on DRUID, Word2vec and TF-IDF on manual TED talk transcripts.

In Table 1, we show a comparison of different methods for automatic keyword extraction on TED talk transcriptions (as produced by kaldi-gstreamer-server / the Kaldi online model). All methods use the same resources, i.e. they are all pretrained on the same Simple English Wikipedia dump from May 2016. However, our proposed method and the TF-IDF baseline can also produce terms that are DRUID multiwords, whereas the original implementation of Habibi and Popescu-Belis (2015) can only produce single keywords. All methods where allowed to produce maximally 10 words in the keyword evaluation – partially covered keyphrases where also counted as a hit for the direct keyword evaluation and a multiword term was counted as multiple words. In the NDCG evaluation, we allow each system to produce an equal number of 10 terms.

For the TF-IDF baselines (1-4), preprocessing is the most important performance factor, with the best results obtained by filtering stop words and any words that are not adjectives and nouns. However, while DRUID multiwords help to gain much better keyword recognition scores, it did not achieve a better

NDCG score on speech transcripts. We also saw good results using the method proposed by Habibi and Popescu-Belis (2015), with the diversity constraint (λ) set to the default value of 0.75, which was the optimal value in the domain of meeting transcripts. However, we noticed that the publicly available Matlab implementation of this method[18] only removed stopwords as part of its preprocessing (5). When we use our preprocessing as input (6), we can improve both keyword and NDCG evaluation scores significantly.

Our proposed methods (7-9) with enabled multiword keyphrases seem to better represent the content of fragments, as shown by the keyword judgements. Again, DRUID further improved keyword recognition scores, but it did not achieve a better NDCG score on speech transcripts. The best NDCG score using speech transcripts was obtained with our proposed method *without* using multiwords (10). We experimented with different values of c: 0.3, 0.5 and 0.7, which all lowered NDCG scores. On average, this translates to 2.16, 1.56 and 0.53 multiword terms per query respectively. The numbers are slightly lower if we use manual transcripts (1.9, 1.4 , 0.5).

We also evaluated our methods on manual transcriptions (11-15), see Table 2. Here the picture is different, as using DRUID can improve NDCG scores. However, only the highest cutoff factor of 0.7 (producing the smallest number of multiword candidates) yielded the best performance, suggesting that the number of added multiword candidates is an important parameter in the query generation. The scores on manual transcriptions can also be understood as the theoretically best possible scores for each method, assuming a perfect speech transcription system. If we compare them, we find that imperfect transcriptions have a high impact on system performance for all methods, as NDCGs are considerably higher with manual transcripts. If we correlate WER with our method in (10), we only observe a weak negative correlation of -0.193. If we use multiword terms the negative correlation is higher with a coefficient of -0.293. The comparison system from Habibi and Popescu-Belis in (6) has the lowest negative correlation of -0.118 and it does not seem to gain as much in the NDCG evaluation on perfect transcriptions as our system.

4.3 Error Analysis

If we look at fragments individually and compare our method (10) to Habibi and Popescu-Belis (2015), we find that in 15 transcription fragments their system has a higher NDCG score and in 14 our system scores higher, with one equal score. On average, in cases where our system scored higher, WER was 14.8%, and where it scored lower WER was 16.8%. For example, for all 3 fragments of the talk "Kids Science" by Cesar Harada[19], where the accent of the speaker deteriorates WER to 33.4%, our system returns much more irrelevant documents. Our average NDCG for the talk is 0.180, while Habibi and Popescu-Belis' system scores 0.454. Among the articles found by our system are "National School Lunch Program", "Arctic Ocean", "Fresh water", "Water", "Coal preparation plant", "Coal mining", "Plant" with most of the articles being irrelevant to the talk.

Word errors and resulting erroneous search terms are responsible for most irrelevant documents, e.g. "in coal power plant" appears in the transcript instead of "nuclear power plant". On the other hand, in this example Habibi and Popescu-Belis' system finds better matching articles, like "Microscope", "Light Microscope", "Mangrove" , "Fresh water", "River delta", "Fishing" which can be attributed to finding the keyword "microscope" and otherwise picking simpler keywords like "ocean", "sea", "fishing" and "river", which our system entirely misses. This changes when we run the systems on the manually transcribed texts, as e.g. our system with enabled multiword terms (9) then finds "nuclear power plant", which helps to retrieve very relevant documents ("Nuclear reaction", "Nuclear chemistry", "Nuclear power plants").

Moreover, if we enable the use of multiword terms in our method with c=0.7, we observe that NDCG was improved by the keyphrase enabled method in 9 cases, but also decreased in 11, with the other 10 transcripts remaining unchanged. If WER is poor, the keyphrase enabled methods do not seem to contribute to improving NDCG performance and tend to lower it. E.g. in the 5 transcripts with the

[18] https://github.com/idiap/DocRec

[19] http://www.ted.com/talks/cesar_harada_how_i_teach_kids_to_love_science

highest WER (19.8-40.9%, average: 26.4%), 3 scores are lowered and 2 unchanged. If we group all cases where the NDCG performance drops, we observe an average WER of 16.9% vs. 12.3% for the cases where they help to improve the NDCG score (average of all transcripts is 15.6%). This further suggests that a query generation with multiword terms helps more in cases where word error rates are low.

Interestingly, in 5 out of 30 transcripts, no multiword terms are found with c=0.7 but NDCG values were still slightly lower in all cases compared to our single word method. While the set of terms in all queries were nearly unchanged, their ranking was affected. This might be attributed to how we build IDF and Word2Vec models: multiwords are opaque units in the models. This can change the dense vectors and IDF values for the constituents of multiwords compared to training on single words and thus affect ranking scores. However, in some of the automatic transcriptions, only constituents of the correct multiwords can be found because of transcription errors, so that our method has to rank the constituent instead of the full multiword.

5 Conclusion

We presented *Ambient Search*, an approach that can show and retrieve relevant documents for speech streams. Our current prototype uses Wikipedia pages, as this provides a large document collection for testing purposes with an universal coverage of different topics.

Our method compares favorably over previous methods of topic discovery and keyword extraction in speech transcriptions. We explored the use of multiword terms as keyphrases, alongside single word terms. Our proposed extraction method using Word2Vec (CBOW) embeddings and TF-IDF is fairly simple to implement and can also be adapted quickly to other languages as it does not need any labelled training data. The only barrier of entry can be the availability of a speech recognition system in the target language.

We have started first efforts to build open source speech recognition models for German in (Radeck-Arneth et al., 2015) and have plans to support this language in future prototypes of *Ambient Search*. These speech models target distant speech recognition and could help to apply Ambient Search to more challenging situations in the future, e.g. distant conversational speech.

We also plan to evaluate a more dynamic approach to query generation, where the number of terms is dynamically chosen and not simply capped at a maximum number of term candidates after ranking. As the proposed use of multiword terms seems to be somewhat dependent on the quality of the transcription, it might also make sense to include likelihood information of the speech recognition system. Our evaluation on manual transcriptions also suggests that there is quite a large headroom for our system to benefit from any future reductions in WER of the online speech recognition component.

For actual live deployment and usage in discussions, lectures or business meetings, confidential information can be present in the speech streams. A privacy aspect has already been addressed by *Ambient Search*: the speech recognition is not carried out "in the cloud" and can be deployed on one's own infrastructure. Similarly, an offline version of the Simple English Wikipedia and a corresponding search index is used to retrieve and find articles. It can be entirely circumvented that personal information is ever transmitted through the internet – a vital aspect for the acceptance of such an application.

We have published the source code of *Ambient Search* under a permissive license on Github[20], along with all pretrained models, a demonstration video, evaluation files and scripts that are necessary to repeat and reproduce the results presented in this paper.

Acknowledgments

This work was partly supported by the Bundesministerium für Bildung und Forschung (BMBF), Germany, within the Dialog+ project within the program KMU-innovativ. We also want to thank Alexander Hendrich for contributing to improve the HTML5/JS display client and Michelle Sandbrink for helping out with the relevance judgements of the retrieved documents.

Abstract

In gender classification, labeled data is often limited while unlabeled data is ample. This motivates semi-supervised learning for gender classification to improve the performance by exploring the knowledge in both labeled and unlabeled data. In this paper, we propose a semi-supervised approach to gender classification by leveraging textual features and a specific kind of indirect links among the users which we call "s*ame-interest*" links. Specifically, we propose a factor graph, namely Textual and Social Factor Graph (TSFG), to model both the textual and the "*same-interest*" link information. Empirical studies demonstrate the effectiveness of the proposed approach to semi-supervised gender classification.

1 Introduction

Gender classification is a fundamental task with regard to infer user's gender from the user-generated data. Recently, this task is getting increasingly more attention in some prevailing research fields, such as social network analysis and natural language processing. Applications developed from gender classification have enormous commercial value in personalization, marketing and judicial investigation (Mukherjee and Liu, 2010; Burger *et al.*, 2001; Volkova *et al.*, 2013).

In social media, conventional methods handle gender classification as a supervised learning problem over the past decade (Corney *et al.*, 2002; Ciot *et al.*, 2013). In supervised learning approaches, both user-generated textual and user social link features are verified to be effective for gender classification. For instance, in Figure 1, it is easy to infer *User* ***c*** to be a *female* through analyzing her saying "*I'm gonna be a* ***mom****!!* " Meanwhile, it is also possible to infer *User* ***c*** is more likely to be a *female* through analyzing her social link since she follows a cosmetic-selling *User* "***Dior***".

Although supervised methods have achieved remarkable success for gender classification, their good performances always depend on a large amount of labeled data, which often need expensive labor costs and long production time. How to learn a classification model with low dependence on the large-scale labeled data becomes an important and challenging problem in gender classification.

In this paper, we propose a semi-supervised learning approach to alleviate the above problem in supervised gender classification. Instead of using a large scale of labeled data, we exploit a small scale of labeled data and large amount of unlabeled data to train the model. Our semi-supervised approach employs both user-generated textual knowledge and user social link information. The basic motivation of our approach lies in the observation that social link information might be helpful to infer user gender. Specifically, we focus on the "*following*" link and think that two users who follow the same particular user could have the same gender. For instance, in Figure 1, *User* ***b***, *User* ***c*** and *User* ***d*** follow the same user named ***Dior*** and they are thought to be indirectly linked. Once *User* ***b*** and *User* ***c*** are correctly classified to be *female* with textual features, *User* ***d*** is more likely to be *female* since she is indirectly linked to *User* ***b*** and *User* ***c***.

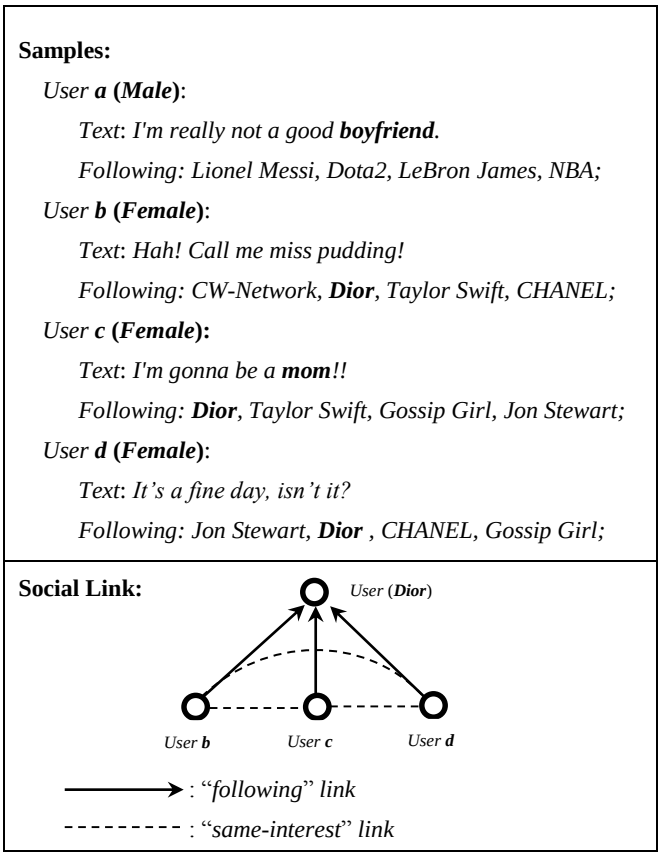

Figure 1: An example of Text and concerns in social media

Specifically, we propose a factor graph, namely Textual and Social Factor Graph (TSFG), to model both the textual and user social link information. Here, a social link between two users happens when the two users follow the same user. For instance, in Figure 1, *User **b*** and *User **c*** both follow the user named ***Dior***. These two users are thought to be linked with an indirect link, called "*same-interest*" link. In our TSFG approach, both the textual features and social links are modeled as various factor functions and the learning task aims to maximize the joint probability of all these factor functions. Empirical evaluation demonstrates the effectiveness of our TSFG approach to capture the inherent user social link. To the best of our knowledge, this work is the first attempt to incorporate both the textual and social information in semi-supervised gender classification.

The remainder of this paper is organized as follows. Section 2 overviews related work on gender classification. Section 3 introduces data collection and analysis. Section 4 describes our TSFG approach to gender classification. Section 5 presents the experimental results. Finally, Section 6 gives the conclusion and future work.

2 Related Work

In the last decade, gender classification has been studied in two main aspects: supervised learning and semi-supervised learning.

As for supervised learning, gender classification has been extensively studied in several textual styles, such as Blog (Nowson and Oberlander, 2006; Peersman *et al.*, 2011; Gianfortoni *et al.*, 2011), E-mail (Mohanmad *et al.*, 2011), YouTube (Filippova, 2012) and Micro-blog (Rao *et al.*, 2010; Liu et al., 2013). These studies mainly focus on employing various kinds of textual features such as character, word, POS features and their *n*-gram features to train the classifier. More recently, some studies focus on some specific application scenarios on supervised gender classification, such as multi-lingual gender classification (Ciot *et al.*, 2013; Alowibdi *et al.*, 2013) and interactive gender classification (Li *et al.*, 2015).

As for semi-supervised learning, gender classification has been studied with much less previous studies. Ikeda *et al.* (2008) propose a semi-supervised approach to gender classification in blog. Their

main idea is to utilize a sub-classifier to measure the relative similarity between two blogs so as to capture the classification knowledge in the unlabeled data. More recently, Burger *et al.* (2011) mention the importance of using unlabeled data and directly apply a self-training approach to perform semi-supervised learning for gender classification. Wang *et al.* (2015) employ both non-interactive and interactive texts as two different views in their co-training approach for semi-supervised gender classification.

Unlike the studies above, our study focuses on both textual features and social links for semi-supervised gender classification.

3 Data Collection and Analysis

The data is collected from Sina Micro-blog[2], the most famous Micro-blogging platform in China. In this platform, local users publish short messages and are allowed to follow other users to listen to their messages. From the website, we crawl each user's homepage which contains the user information (e.g. Name, gender, and, verified type), messages and following users. The data collection process starts from some randomly selected users, and then iteratively gets the data of their followers and followings. We remove some unsuitable users that meet one of the following two conditions: (1) verified organizational users that are verified as organization; (2) the non-active users that have less than 50 followers or 50 followings.

In total, we obtain about 10000 user homepages, from which we randomly select a balanced data set containing 1000 male and 1000 female users. Let $Fo(u_i)$ denotes the set of u_i 's all "following" users; F_{male} denotes the set of all male users' "following" users; F_{female} denotes the set of all female users' "following" users. F_{male} and F_{female} can be calculated as following:

$$F_{male} = \bigcup_{u_i \in S_{male}} Fo(u_i) \tag{1}$$

$$F_{male} = \bigcup_{u_i \in S_{female}} Fo(u_i) \tag{2}$$

Where S_{male} and S_{female} denote the sets of male and female users respectively.

Table 1 shows the statistics about the numbers of "following" users of all male and female users. From this table, we can see that there are many users who are only followed by male users or female users. Specifically, in our data set, 143389 users are followed by only male users and 119504 users are followed by only female users. Thus, these gender-sensitive followings are good clues to infer each user's gender.

	#of "*following*" users
$\lvert F_{male} \rvert$	162116
$\lvert F_{female} \rvert$	138231
$\lvert F_{male} \cap F_{female} \rvert$	18727
$\lvert F_{male} \rvert - \lvert F_{male} \cap F_{female} \rvert$	143389
$\lvert F_{female} \rvert - \lvert F_{male} \cap F_{female} \rvert$	119504

Table 1: Statistics of the following users

4 Textual and Social Factor Graph Model

A factor graph consists of two layers of nodes, i.e., variable nodes and factor nodes, with links between them. The joint distribution over the whole set of variables can be factorized as a product of all factors.

[2] http://weibo.com/

4.1 Model Definition

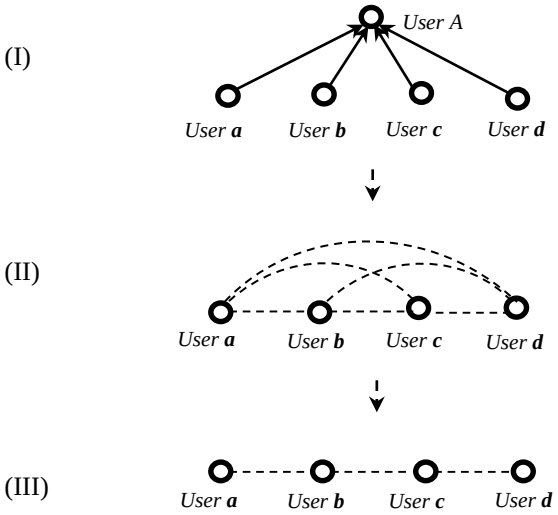

Figure 2: An example for illustrating the user links where

(I) shows the "following" links among all users;
(II) shows the "same-interest" links among the four users;
(III) shows the simplified four "same-interest" links among the four users.

Formally, let $G=(V,E)$ represent an instance network, where V denotes a set of the involved users in our data set. $E \subset V \times V$ is a set of relationships between users. Specifically, if a user u_i and a user u_j have the same following (i.e., the same-interest link), there is an edge $e_{ij}, e_{ij} \in E$, linking the two users u_i and u_j.

The "following" link: If a user u_i follows another user u_j, there is a "following" link between u_i and u_j. For instance, Figure 2(I) shows an example where four users, namely *User a*, *User b*, *User c*, and *User d*, are in our data set and each of them follows *User A*. Thus there are four "following" links among these five users.

The "same-interest" link: If a user u_i and a user u_j follows the same user, there is a "same-interest" link between u_i and u_j. For instance, Figure 2(II) shows six "same-interest" links among the four users, i.e., *User a*, *User b*, *User c*, and *User d*. The "same-interest" links derived from "following" links as showed in Figure 2(I).

Suppose that there are N users who have the same interest, the number of the same-interest links is C_N^2. However, when N is large, the number of the links is too large, which might make our factor graph model difficult to learn. Therefore, we simplify the link model by deleting $C_N^2-(N-1)$ links, only reserving a link line containing N-1 links, as shown in Figure 2(III).

We model the above network with a factor graph and our objective is to infer the gender categories of instances by learning the following joint distribution:

$$P(Y|G)=\prod_i \prod_k f(X_i,y_i) h_k(y_i,H(y_i)) \tag{3}$$

Where two kinds of factor functions are used.

1) Textual feature factor function: $f(X_i,y_i)$ denotes the traditional textual feature factor functions associated with each text representation of the user u_i, i.e., X_i. The textual feature factor function is instantiated as follows:

$$f(X_i,y_i)=\frac{1}{Z_1}\exp\left(\sum_j \alpha_j \Phi(x_{ij},y_i)\right) \tag{4}$$

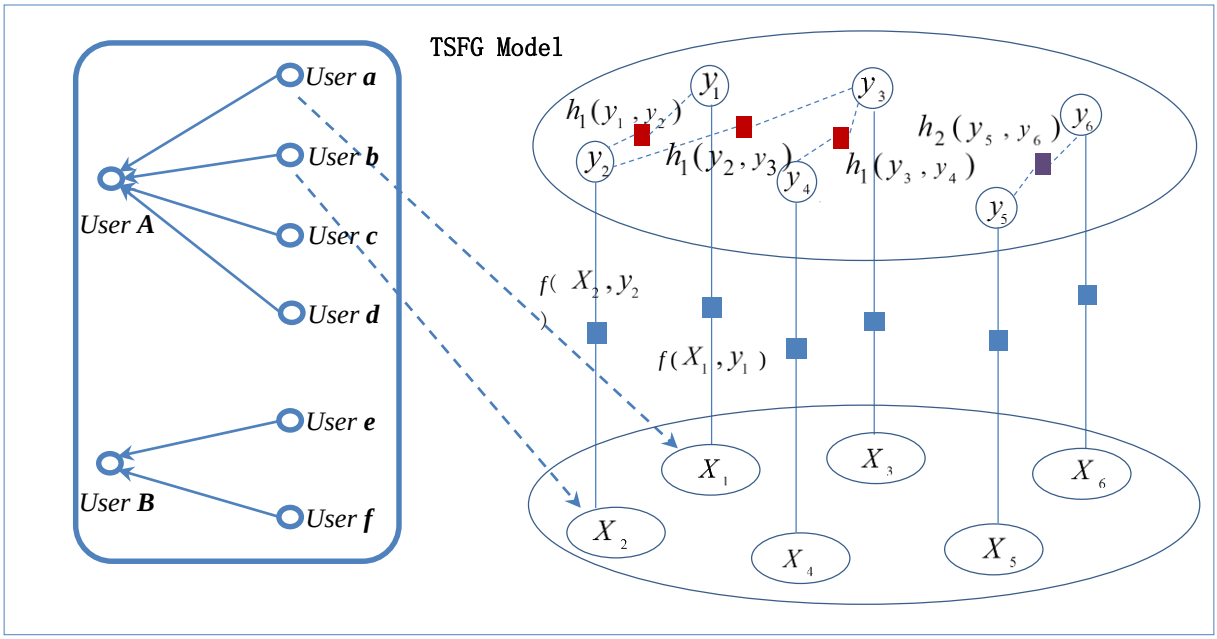

Figure 3: An example of TSFG where six instances are involved:

User ***a****, User* ***b****, User* ***c****, User* ***d****, User* ***e****, and User* ***f****.*

Note: each instance is represented as X_i . $f(\cdot)$ represents a factor function for modeling textual features. $h(\cdot)$ represents a factor function for modeling the "*same-interest*" link between two instances.

Where $\Phi(x_{ij}, y_i)$ is a feature function and x_{ij} represents a textual feature, i.e., a word feature in this study.

2) Social link factor function: $h_k(y_i, H(y_i))$ denotes the "same-interest" relationship among the users who follow the same user $u_k, u_k \in F_{male} \bigcup F_{female}$. $H(y_i)$ is the label set of the users linked to y_i. The social link factor function is instantiated as follows:

$$h_k(y_i, H(y_i)) = \frac{1}{Z_2} \exp\left\{ \sum_{y_i^l \in H(y_i)} \beta_{ikl} \left(y_i - y_i^l \right)^2 \right\} \tag{5}$$

Where β_{ikl} is the weight of the function, representing the degree if influence of the two instances y_i and y_i^l.

Figure 3 gives an example of our textual and social factor graph (TSFG) where six users, i.e., *User* ***a****, User* ***b****, User* ***c****, User* ***d****, User* ***e****,* and *User* ***f****,* are involved.

4.2 Model Learning

Learning the DFG model is to estimate the best parameter configuration $\theta = (\{\alpha\}, \{\beta\})$ to maximize the log-likelihood objective function $L(\theta) = \log P_\theta(Y|G)$, i.e.,

$$\theta^* = \arg\max L(\theta) \tag{6}$$

In this study, we employ the gradient decent method to optimize the objective function. For example, we can write the gradient of each α_j with regard to the objective function:

$$\frac{\partial L(\theta)}{\partial \alpha_j} = E\left[\Phi(x_{ij}, y_i)\right] - E_{P_{\alpha_j}(Y|G)}\left[\Phi(x_{ij}, y_i)\right] \tag{7}$$

Where $E\left[\Phi(x_{ij}, y_i)\right]$ is the expectation of feature function $\Phi(x_{ij}, y_i)$ given the data distribution. $E_{P_{\alpha_j}(Y|G)}\left[\Phi(x_{ij}, y_i)\right]$ is the expectation of feature function $\Phi(x_{ij}, y_i)$ under the distribution $P_{\alpha_j}(Y|G)$

given by the estimated model. Figure 4 illustrates the detailed algorithm for learning the parameter α. Note that LBP denotes the Loopy Belief Propagation (LBP) algorithm which is applied to approximately infer the marginal distribution in a factor graph (Frey and MacKay, 1998). A similar gradient can be derived for the other parameters.

Input: Learning rate η

Output: Estimated parameters α

Initialize $\alpha \leftarrow 0$

Repeat

1) Calculate $E\left[\Phi\left(x_{ij}, y_i\right)\right]$ using LBP
2) Calculate $E_{P_{\alpha_{ij}}(Y|G)}\left[\Phi\left(x_{ij}, y_i\right)\right]$ using LBP
3) Calculate the gradient of α according to Eq. (7)
4) Update parameter α with the learning rate η

$$\alpha_{\text{new}} = \alpha_{\text{old}} + \eta \frac{L(\alpha)}{\alpha}$$

Until *Convergence*

Figure 4: The learning algorithm for TSFG model

It is worth noting that we need to perform the LBP process twice for each iteration: One is to estimate the original distribution of unlabeled instances which are denoted as $y_i = ?$ and the other is to estimate the marginal distribution over all pairs. In this way, the algorithm essentially leverage both the labeled data and unlabeled data to optimize the complete network.

4.3 Model Prediction

With the learned parameter configuration θ, the prediction task is to find a Y^{T*} which optimizes the objective function, i.e.,

$$Y^{T*} = \arg\max P\left(Y^T \middle| Y^{L+U}, G, \theta\right) \tag{8}$$

Where Y^{T*} are the labels of the instances in the testing data and Y^{L+U} are the labels (or estimated labels) of the instances in the labeled and unlabeled data.

Again, we utilize LBP to calculate the marginal probability of each instance $P\left(y_i \middle| Y^{L+U}, G, \theta\right)$ and predict the label with the largest marginal probability. For all instances in the test data, the prediction indicated above is performed iteratively until converge.

5 Experimentation

We have systematically evaluated our TSFG approach to semi-supervised gender classification.

5.1 Experimental Settings

Data Setting: The data set contains 2000 users, as described in Section 3. From this data set, we select 200 users as initial labeled data, 1400 users as unlabeled data, and the remaining 400 users as the test data.

Features: Three types of textual features, including bag-of-words, f-measure, and POS pattern features, are adopted in our experiments. These features yield the state-of-the-art performance in gender classification (Mukherjee and Liu, 2010). To get word and POS features, we use the toolkit ICTCLAS[3] to perform word segmentation and POS tagging on the Chinese text.

[3] http://www.ictclas.org/ictclas_download.aspx

Classification Algorithm: For supervised learning, various of classification algorithms are available. As suggested by Li *et al.* (2015), we apply maximum entropy (ME) for supervised gender classification. Specifically, the ME algorithm is implemented with the Mallet Toolkit[4]. For semi-supervised learning, we implement our TSFG approach, together with some baselines.

Evaluation Measurement: The performances are evaluated using the standard *precision*, *recall*, and *F-score* in each gender category. For overall evaluation, we use macro-average *F-score* over both gender categories, which is denoted as F_{macro}.

Significance test: *T*-test is used to evaluate the significance of the performance difference between two approaches (Yang and Liu, 1999).

5.2 Experimental Results

For thorough comparison, several gender classification approaches are implemented including:

- **Baseline(Textual)**: employing ME classifier and textual features with only initial labeled data (without any unlabeled data).
- **Baseline(Textual+Social)**: employing ME classifier and both textual and social features with only initial labeled data (without any unlabeled data). Social features are extracted by considering each user ID of the followers of a user as a word.
- **Self-training(Textual)**: employing ME classifier and textual features with both labeled data and unlabeled data using self-training.
- **Self-training(Textual+Social)**: employing ME classifier and both textual and social features with both labeled data and unlabeled data using self-training.
- **Co-training(Textual)**: employing ME classifier and textual features with both labeled data and unlabeled data using co-training. We implement the co-training algorithm by randomly splitting the feature space into two disjoint feature subspaces as two views (Nigam and Ghani, 2000).
- **Co-training(Textual+Social)**: employing ME classifier and both textual and social features with both labeled data and unlabeled data using co-training. We implement the co-training algorithm by randomly splitting the feature space into two disjoint feature subspaces as two views (Nigam and Ghani, 2000).
- **TSFG:** our approach as described in Section 4.

	Male			*Female*			*Total*
Approach	*Precision*	*Recall*	*F-score*	*Precision*	*Recall*	*F-score*	F_{macro}
Baseline(Textual)	0.760	0.650	0.700	0.694	0.795	0.741	0.721
Baseline(Textual+Social)	0.800	0.700	0.747	0.733	0.825	0.776	0.762
Self-Training(Textual)	0.714	0.710	0.711	0.711	0.715	0.713	0.712
Self-Training(Textual+Social)	0.754	0.735	0.744	0.741	0.760	0.751	0.747
Co-Training(Textual)	0.725	0.700	0.712	0.710	0.735	0.722	0.717
Co-Training(Textual+Social)	0.784	**0.745**	0.764	0.757	0.795	0.776	0.770
TSFG	**0.961**	0.735	**0.833**	**0.785**	**0.970**	**0.868**	**0.851**

Table 2: Performance comparison of different approaches to semi-supervised gender classification

Table 2 shows the performance comparison of different approaches to gender classification. From this table, we can see that:

(1) Social BOW features are helpful in both supervised and semi-supervised learning approaches.
(2) Self-training fails to exploit unlabeled data to improve the performance and it performs even worse than the baseline approaches.

[4] http://mallet.cs.umass.edu/

(3) Co-training is effective for semi-supervised gender classification when both textual and social features are employed. This result indicates that the use of social features in semi-supervised gender classification in co-training is beneficial, although the improvement is rather limited, about 1%.

(4) Our approach TSFG performs best among all semi-supervised learning approaches. Moreover, the improvement over the two baselines is remarkable, 13% higher than Baseline(Textual) and 8.9% higher than Baseline(Textual+Social). Significance test shows that our approach significantly outperforms co-training (p-value<0.01)

Figure 5 shows the performances of our approach and the two baseline approaches when varying the sizes of the initial labeled data. From this figure, we can see that social features are always helpful for gender classification and Baseline(Textual+Social) consistently outperforms Baseline(Textual). Our approach fails to take effect when the size of the initial labeled data is too small (10 labeled instances in each category). When the size of the initial data is larger than 20 instances in each category, our TSFG approaches consistently performs much better than the two baseline approaches. Significance test shows that our TSFG approach significantly outperforms both Baseline(Textual) and Baseline(Textual+Social) when the size of the initial labeled instance is larger than 20 in each gender category (p-value<0.01).

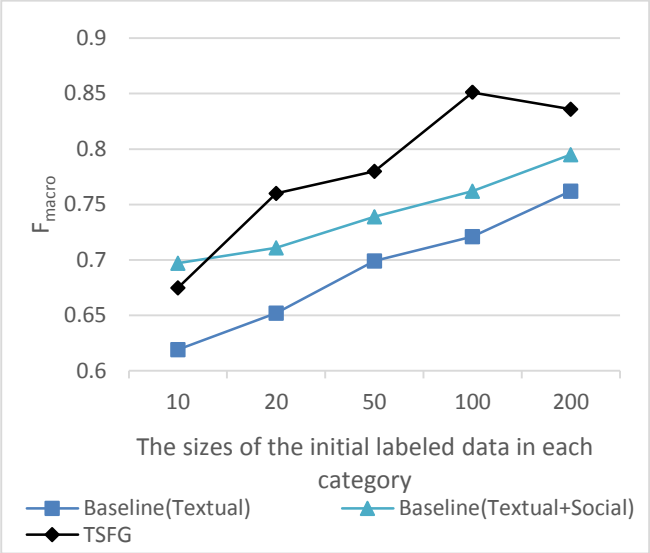

Figure 5: The performances of our approach and the two baseline approaches when varying the sizes of the initial labeled data.

6 Conclusion

In this paper, we propose a novel approach to semi-supervised gender classification in social media. In our approach, we first define a social link named "*same-interest*" link which models an indirect link between two users who follow the same user. Then, we propose a factor graph-based approach, namely Textual and Social Factor Graph (TSFG), where both the textual features and "*same-interest*" social links are modeled as various factor functions. Finally, we employ the graph to leverage both the labeled data and unlabeled data to optimize the complete network. Empirical studies show that our TSFG approach successfully exploits unlabeled data to improve the performance, remarkably outperforming other semi-supervised learning approaches.

In our future work, we would like to improve our semi-supervised learning approach by leveraging some other kinds of link information. Furthermore, we will apply our TSFG approach to some other NLP tasks where both textual and social features are available, such as user age prediction (Rosenthal and McKeown, 2011) and user occupation classification (Preotiuc-Pietro *et al.*, 2015).

Abstract

The lack of a sufficient amount of data tailored for a task is a well-recognized problem for many statistical NLP methods. In this paper, we explore whether data sparsity can be successfully tackled when classifying language proficiency levels in the domain of learner-written output texts. We aim at overcoming data sparsity by incorporating knowledge in the trained model from another domain consisting of input texts written by teaching professionals for learners. We compare different domain adaptation techniques and find that a weighted combination of the two types of data performs best, which can even rival systems based on considerably larger amounts of in-domain data. Moreover, we show that normalizing errors in learners' texts can substantially improve classification when in-domain data with annotated proficiency levels is not available.

1 Introduction

Data sparsity is a recognized problem in many machine learning based NLP approaches since the creation of data specifically collected and annotated for a certain task or language is time-consuming and costly. Previous attempts to overcome data sparsity include transferring knowledge between different types of data through the application of models from languages and tasks where sufficient data exists to the ones where data is unavailable or sparse (Daumé III and Marcu, 2006). A common case of such a transfer learning scenario is *domain adaptation*, where training and test data belong to different domains (e.g. text genres) referred to as *source domain* and *target domain* respectively.

In our experiments, we aim at exploring the plausibility of domain adaptation as a strategy for overcoming data sparsity in the context of foreign and second language (L2) learning. More specifically, we operationalize *domain* as the type of text involved in the language learning process: on the one hand, texts from coursebooks intended for L2 learners (referred to as *L2 input texts* in this paper), and on the other hand, essays created by learners (*L2 output texts*). Our goal is to predict L2 language development stages in terms of linguistic complexity in the latter category, i.e. learner-produced texts. These stages are commonly referred to as *proficiency levels* in second language acquisition and language testing. Levels range from 'absolute beginner' to 'advanced language user' with increasing linguistic complexity as learners progress with the levels. A scale of such levels, very influential both in Europe and outside, is the CEFR – Common European Framework of Reference for Languages (Council of Europe, 2001).

In previous work, NLP methods have been successfully applied to both assessing proficiency levels in L2 input texts collected from coursebooks and output texts written by learners (see section 2). However, the two text types have always been considered separately, while we argue that there is a shared linguistic content between the two that can be used for knowledge transfer. Specifically, the output of learners is a subset of the linguistic input that they are able to understand (Barrot, 2015). Thus, incorporating knowledge from coursebook texts representing L2 input may improve the classification of proficiency levels in L2 output text. Decreasing the need for a large amount of L2 output data is particularly appealing since acquiring this type of text poses a number of challenges including copyright issues, anonymization of sensitive information, and often even digitizing hand-written material (Megyesi et al.,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2101–2111, Osaka, Japan, December 11-17 2016.

2016; Mendes et al., 2016; Volodina et al., 2016). Since an increasing amount of people learn foreign languages worldwide either out of necessity or as a personal interest, systems targeting the needs of this user group are especially valuable. Within this context, the automatic assessment of proficiency levels in learner-produced texts would be a powerful tool for increasing both learners' autonomy and teaching professionals' efficiency.

Research Questions In particular, this paper aims at answering the following research questions: (i) Can we overcome the lack of a sufficient amount of learner output data by incorporating knowledge from L2 input texts when performing proficiency level classification? (ii) What kind of domain adaptation technique performs best in this context? (iii) Does normalizing errors in L2 learner output benefit proficiency level classification in a domain adaptation setting?

The motivation behind error normalization is that learner output typically contains errors which may influence the performance of automatic taggers and parsers and thus, classification performance. Therefore, error normalization may allow for a more precise calculation of feature values and a more successful transfer from and to a non error-prone domain. The amount and type of errors, i.e. degree of incorrectness, however, is not explicitly considered as an indicator of proficiency for L2 learner output in our experiments in order to keep comparability with coursebook texts. Unlike linguistic complexity, incorrectness is not a relevant aspect for L2 input texts as these are authored by teaching professionals and are supposed to be relatively error-free examples of language use.

Our target language of choice is Swedish, a language considerably less resource-rich than English and for which a CEFR-level classification model of L2 learners' writing is not available yet, despite the clear need for breaking down CEFR descriptors into linguistic constituents that characterize proficiency levels for each individual language (Little, 2011; North, 2007).

Main Findings We find that, in the absence of annotated learner-written data, using a classification model trained only on coursebook texts is a viable alternative if learner errors are normalized. Furthermore, if a small amount of learner output data is available and it is combined with L2 input texts, it can even outperform a model trained only on the few in-domain instances, resulting in a prediction quality matching that of in-domain state-of-the-art systems for other languages. In a domain adaptation setting, normalizing learner errors proved to yield a substantial improvement for features based on token, character and sentence counts as well as for features based on the CEFR-level distribution of tokens.

2 Text Categorization in the Language Learning Context

The automated evaluation of learner output is primarily a text classification task which aims at determining the quality of writing and assigning an appropriate label from a given set, for example a score or grade on the continuum between pass-fail (*essay scoring*) or a level indicating learning progress (*proficiency level classification*). In a L2 learning scenario, a longer piece of learner-written text is a popular means to assess learners' proficiency level. The human assessment of learner output, however, is both time-consuming and prone to subjectivity. Different linguistic dimensions need to be taken into consideration usually requiring several iterations of re-reading and different factors may influence the decision, such as negative attitude to a learner, hunger, bad mood, and boredom. Therefore, the number of initiatives to complement (or even replace) human assessment with a more objective and more efficient supervised machine learning system has been increasing the past years, with essay grading (Burstein and Chodorow, 2010) as an important application field.

2.1 Automatic Essay Scoring

Automatic essay scoring (AES) has been an active research area since 1990s, targeting mostly English (Burstein and Chodorow, 2010; Miltsakaki and Kukich, 2004; Page, 2003). Recently, with the availability of annotated learner corpora for other languages, automatic essay grading has expanded to cover also other languages, e.g. German (Zesch et al., 2015) and Swedish (Östling et al., 2013), to name just a few.

In its nature, AES has mostly relied on machine learning approaches, exploring both supervised (Yannakoudakis et al., 2011) and unsupervised methods (Chen et al., 2010) with different degrees of success.

Östling et al. (2013) have looked at Swedish upper secondary school essays, i.e. first language learner essays, and automatically assessed them in terms of a four-point scale of performance grades with an accuracy of 62%. The authors found that this result exceeded the agreement rate between two human assessors which was as low as 45.8% which might indicate that human-like performance is a rather uncertain goal. Linguistic parameters that have over time been presumed to be strong predictors of writing quality have varied from shallow ones like text and word length (Page, 2003; Östling et al., 2013) to more sophisticated features using Latent Semantic Analysis (Landauer et al., 2003), cosine similarity (Attali and Burstein, 2006), discourse structure and stylistic features (Attali and Burstein, 2006).

2.2 Proficiency Level Classification

A closely related task to AES is classifying texts into L2 proficiency levels which consists of predicting at which language learning stage a text can be produced or understood by a L2 learner, rather than assigning a grade within a pass-fail range. The CEFR, the scale of proficiency levels adopted in our experiments, contains guidelines for the standardization of language teaching and assessment across languages and countries (Council of Europe, 2001). It provides a common metalanguage to talk about objectives, assessment, (Little, 2011), and it defines language competences at six proficiency levels (A1, A2, B1, B2, C1, C2) where A1 is the beginner level. Since the publication of the CEFR guidelines in 2001, several countries have adopted the system, but its practical application has proven to be rather non-straightforward since the descriptions of the competences at each level remain vague (Little, 2011; North, 2007).

The past few years have seen an increasing interest in the CEFR-level classification of both L2 input and output texts. In the case of coursebook texts such a classification has also been referred to as *L2 readability* and it has been investigated for, among others, French (François and Fairon, 2012), Portuguese (Branco et al., 2014), Chinese (Sung et al., 2015), Swedish (Pilán et al., 2015), and English (Xia et al., 2016).

Apart from L2 input texts, CEFR-level annotated L2 learner corpora are also available for a number of languages including but not limited to English (Nicholls, 2003), Estonian (Vajjala and Lõo, 2014) and German (Hancke and Meurers, 2013). Moreover, MERLIN (Wisniewski et al., 2013) is a trilingual learner corpus comprised of written productions of L2 learners of Czech, German, and Italian also linked to CEFR levels. Despite the availability of annotated corpora for several languages, the number of projects targeting the automatic CEFR-level classification of learner essays has remained rather limited. Previously reported results for this task in terms of accuracy include 61% for German (Hancke and Meurers, 2013) and 79% for Estonian (Vajjala and Lõo, 2014).

2.3 Domain Adaptation for Tasks Related to L2 Learning

While there is a lot of previous work on domain adaptation in general, relatively few approaches exist in the field of assessing learner output texts. Previous applications of domain adaptation to learner essays focused on exploring the transfer of models between different writing tasks that prompted students to produce the essays, e.g. expressing an opinion on a topic vs. summarizing a news article (Zesch et al., 2015; Phandi et al., 2015). Zesch et al. (2015) explore which features are transferable from one essay grading task to another task based on a different prompt. They find that by excluding some highly domain-specific features, the transfer loss can be reduced significantly without noticeable differences in overall performance.

A popular domain adaptation approach is EASYADAPT (Daumé III, 2007) that augments the original feature space with source- and target-specific versions. Phandi et al. (2015) successfully applied EASYADAPT for automatic essay scoring and Xia et al. (2016) for the CEFR-level classification of L2 input texts with native language texts as source domain.

3 Datasets

For our experiments, we use L2 Swedish data including learners' output, i.e. error-prone essays written by learners, as well as L2 input data for learners, i.e. relatively error-free texts written by experts for

		CEFR Levels				
		A2	**B1**	**B2**	**C1**	**Total**
Learner Output	**Texts**	83	75	74	88	**320**
	Tokens	18,349	29,814	32,691	60,095	**140,949**
Expert Input	**Texts**	157	258	288	115	**818**
	Tokens	37,168	79,124	101,297	71,723	**289,312**

Table 1: Overview of CEFR-level annotated Swedish datasets.

L2 learners primarily intended as reading material. Both types of data are manually labeled for CEFR levels and automatically annotated across different linguistic dimensions including lemmatization, part-of-speech (POS) tagging, and dependency parsing using the Sparv (previously known as 'Korp') pipeline (Borin et al., 2012).

3.1 L2 Output Texts

Our source of output texts is SweLL (Volodina et al., 2016), a corpus consisting of L2 Swedish learner essays on a variety of topics, manually linked to CEFR levels. The essays also contain meta-information on learners' mother tongue(s), age, gender, education level, the exam setting, and, in certain cases, topic and genre. The distribution of essays per level is given in Table 1.

The corpus includes some essays at A1 and C2 levels, but these classes were too under-represented to be included in our experiments. As for A1 level, this may depend on learners' limited ability to write due to the lack of familiarity with many linguistic constructs. In fact, the CEFR contains no descriptor for writing essays and reports at A1 level (Council of Europe, 2001, 62). C2 is lacking since courses at this level are not provided, and it is in general characterized as a near-native language competence.

Since SweLL consists of learner-produced texts, it is likely that it contains some errors which, however, have not been annotated or normalized yet in the resource. The number of non-lemmatized tokens in the resource (i.e. tokens that could not be assigned baseforms during automatic annotation), which could indicate spelling errors or creative compounding at more advanced levels is higher at lower proficiency levels, but their amount always remains within a range of 5% and 8%.

3.2 L2 Input Texts

Our L2 input texts were collected from COCTAILL, a corpus of coursebooks used for teaching CEFR-based courses of L2 Swedish (Volodina et al., 2014). The coursebooks are divided into lessons (book chapters), each of which is labeled for the CEFR level it is aimed at. Each lesson contains a variety of elements including reading texts, exercises, lists, etc. Out of these only the texts intended for reading have been included in our dataset, whose CEFR level was derived from the level of the lesson they occurred in. Table 1 gives an overview of the distribution of these texts per level. For the same reasons as in section 3.1, C2 was not included in this dataset and A1 level has been omitted to keep the classes consistent between the two datasets.

4 Feature Set

We use the feature set presented in Pilán et al. (2015) designed for modeling linguistic complexity in input texts for L2 Swedish learners. These features rely on morpho-syntactic tags, information about the CEFR level of tokens, and aspects inspired by L2 Swedish curricula. Five sub-group of features can be distinguished in this set: length-based, (weakly) lexical, morphological, syntactic, and semantic features. The detailed list of features is presented in Table 2.

Count-based features rely on the number of characters and tokens (*tkn*), extra-long words being tokens longer than 13 characters. LIX (Läsbarhetsindex) is a traditional Swedish readability formula corresponding to the sum of the average number of words per sentence in the text and the percentage of

Count	Lexical	Syntactic	Morphological	
Sentence length	A1 lemma IS	Avg DepArc length	Modal V to V	Verb IS
Avg token length	A2 lemma IS	DepArc Len > 5	Particle IS	V variation
Extra-long token	B1 lemma IS	Max length DepArc	3SG pronoun IS	Function W IS
Nr characters	B2 lemma IS	Right DepArc Ratio	Punctuation IS	Lex tkn to non-lex tkn
LIX	C1 lemma IS	Left DepArc Ratio	Subjunction IS	Lex tkn to Nr tkn
Bilog TTR	C2 lemma IS	Modifier variation	PR to N	Neuter N IS

			N IS	Nominal ratio
			N variation	N to V

Table 2: Feature set.

tokens longer than six characters (Björnsson, 1968). Rather than a simple type-token ratio (TTR), we use a bi-logarithmic and a square root equivalent following Vajjala and Meurers (2012).

Lexical features incorporate information from the KELLY list (Volodina and Kokkinakis, 2012), a frequency-based word list compiled using a corpus of web texts (thus completely independent of our datasets), which also provides a suggested CEFR level per each lemma based on frequency bands. For some feature values, *incidence scores* (IS) are computed, in other words, instead of absolute counts, normalized values per 1000 tokens are considered to reduce the influence of sentence length. Lexical complexity is modeled with a set of weakly lexicalized features, i.e. we do not use word forms or lemmas themselves as features, but the IS of their corresponding CEFR levels instead. This aspect is especially important considering the limited size of our learner essay data. *Difficult* tokens are those that belong to levels above the overall CEFR level of the text. Moreover, we consider the IS of tokens not present in KELLY (OOV IS), the IS of tokens for which the lemmatizer could not identify a corresponding lemma (No lemma IS), as well as average KELLY log frequencies.

Morphological features include not only IS but also variational scores, i.e. the ratio of a category to the ratio of lexical tokens: nouns (N), verbs (V), adjectives (ADJ) and adverbs (ADV). The IS of all lexical categories as well as the IS of punctuation, particles, sub- and conjunctions (SJ, CJ) are taken into consideration. Nominal ratio (Hultman and Westman, 1977) is another readability formula proposed for Swedish that corresponds to the ratio of nominal categories, i.e. nouns, prepositions (PP) and participles to the ratio of verbal categories, namely pronouns (PR) adverbs, and verbs. Relative structures consist of relative adverbs, determiners, pronouns and possessives. Some features are inspired by L2 teaching material (Fasth and Kannermark, 1997) and they are based on fine-grained inflectional information such as the IS of neuter gender nouns and the ratio of different verb forms to all verbs.

Syntactic features are based, among others, on the length (depth) and the direction of dependency arcs (DepArc). Within this feature group, we consider also relative clauses as well as pre- and post-modifiers, which include, for example, adjectives and prepositional phrases respectively.

Semantic features build on information from the SALDO lexicon (Borin et al., 2013). We use the average number of senses per token and the average number of noun senses per nouns.

5 Experimental Setup

For all experiments, we use SVMs as implemented in WEKA (Hall et al., 2009) and the feature set presented in detail in section 4. Results are obtained using 10-fold cross-validation. We report the F_1 score, i.e. the harmonic mean of precision and recall, as well as quadratic weighted kappa (κ^2), a distance-based scoring function taking into consideration also the degree of misclassifications.

Experimental setup	Data used	# Training inst.	# Informing inst.
MAJORITY	D_T	288	320
IN-DOMAIN	D_T	288	320
SOURCE-ONLY	D_S	818	818
EASYADAPT	D_S with augmented features	818	1138
+FEATURE	D_T with D_S prediction as feature	288	1138
COMBINED	D_S + 60% of D_T	1010	1010
WEIGHTED	D_S ($w = 1$) + 60% of D_T ($w = 10$)	1010	1010
WEIGHTED-INSTSEL	Correctly classified D_S ($w = 1$) + 60% of D_T ($w = 10$)	505	1138

Table 3: Domain adaptation experimental setups.

5.1 Domain Adaptation

In a domain adaptation scenario, data from a source domain (D_S) is used to predict labels in a different, target domain (D_T). To overcome data sparsity, especially relevant for our learner essay data, we experiment with improving CEFR level classification by transferring information from our D_S consisting of L2 coursebook texts to D_T consisting of Swedish L2 learners' essays.

As baselines, we employ both assigning the most frequent label in the dataset (MAJORITY) and an IN-DOMAIN setup using only the learner essays in a cross-validation setup. We compare these to different domain adaptation scenarios inspired mostly by Daumé III and Marcu (2006) and Pan and Yang (2010) which differ in the type and the amount of data used as detailed in Table 3. We report the number of instances employed at the moment of training as well as the amount of instances from which information has been incorporated in some form in the final models.

In the **SOURCE-ONLY** setup, a model trained on all available source domain instances, i.e. coursebook texts, was applied directly to the target domain instances consisting of learner essays. **EASYADAPT** (Daumé III, 2007) is a feature augmentation approach which consists of triplicating the feature space by including three versions of each feature in the augmented equivalent: a general, a source-specific and a target-specific version. In more formal terms, to each feature vector x, the mapping function $\phi^S(x) = \langle x, x, 0\rangle$ is applied in the source domain and $\phi^T(x) = \langle x, 0, x\rangle$ in the target domain, 0 being a zero vector of length $|x|$. In **+FEATURE** we first train a model trained on the L2 input texts. Then, the CEFR label predicted by this system is incorporated as an additional feature for each essay instance and a new model is trained on the essays with this extra dimension. For **COMBINED** and **WEIGHTED** the training data includes not only D_S instances, but also 60% of D_T. In the WEIGHTED setup, an increased importance is given to D_T instances during training through the assignment of a higher weight (w). Finally, to obtain **WEIGHTED-INSTSEL**, we first train a model on the available D_T data and use that to classify D_S instances. Then those D_S instances that the essay-only model correctly classified are combined with 60% D_T, the latter ones receiving a weight of 10. Compared to WEIGHTED, in this setup we discard D_S instances that might be misleading when making predictions on D_T, due to differences in the underlying distributions in the two domains. A similar approach is presented in Jiang and Zhai (2007).

5.2 Error Normalization

Besides using learners' output texts in their original form, we investigate also the effects of error normalization on the domain-adapted strategies. By correcting errors we aim at bringing learners' texts closer to the standard language present in the coursebooks. Making the texts belonging to these two different domains more similar to each other may improve the domain-adapted classification performance. Moreover, since the annotation tools used were originally designed for dealing with standard Swedish, error normalization leads to a more reliable tagging and parsing, and hence to more precise feature values in the corrected learner output texts.

Previous error-normalization approaches include, among others, finite state transducers (Antonsen, 2012) and a number of, mostly hybrid, systems created within the CoNLL Shared Task on grammatical error correction for L2 English (Ng et al., 2014).

	ORIGINAL		ERROR-NORMALIZED	
	F_1	κ^2	F_1	κ^2
MAJORITY	.120	.000	.120	.000
IN-DOMAIN	.721	.886	.720	.872
SOURCE-ONLY	.438	.713	.620	.807
EASYADAPT	.503	.681	.533	.741
+FEATURE	.709	.879	**.802**	.864
COMBINED	.733	.863	.726	.885
WEIGHTED	**.747**	**.890**	.779	**.915**
WEIGHTED-INSTSEL	.733	.873	.795	.914

Table 4: Domain adaptation results with and without error normalization.

We use LanguageTool[1] (Naber, 2003), an open-source rule-based proof-reading program available for multiple languages which detects not only spelling, but also some grammatical errors (e.g. inconsistent gender use in inflected forms). We propose a two-step algorithm consisting of first obtaining correction candidates from LanguageTool and then ranking these candidates based on a word co-occurrence measure. As a first step, we identify errors in the learner essays and a list of one or more LanguageTool correction suggestions, as well as the *context*, i.e. the surrounding tokens for the error within the same sentence. When more than one correction candidate is available, as an additional step, we make a selection based on *Lexicographers' Mutual Information* (LMI) scores (Kilgarriff et al., 2004). Here we assume a positive correlation between a correction candidate co-occurring with a context word and being the correct version of the word intended by the learner. We check LMI scores for each LanguageTool correction candidate paired with the lemma of each available noun, verb, and adjective in the context based on a pre-compiled list of LMI scores. We create this list using a Korp API (Borin et al., 2012) providing LMI scores computed based on a customizable set of corpora. We use a variety of modern Swedish corpora totaling to more than 209 million tokens for our list of LMI scores. Only scores for noun-verb and noun-adjective combinations have been included with a threshold of LMI ≥ 50. When available, we select the correction candidate maximizing the sum of all LMI scores for the context words. In the absence of LMI scores for the pairs of correction candidates and context words, the most frequent word form in Swedish Wikipedia texts is chosen as a fallback.

Once correction candidates are ranked, each erroneous token identified by LanguageTool is replaced in the essays by the top ranked correction candidate. The normalized texts are then annotated again and feature values are re-computed.

6 Results and Discussion

Table 4 presents the results of our domain adaptation experiments first without error normalization (*original*) and then with corrected errors (*error-normalized*). In the case of the non-normalized essays, the in-domain baseline obtained using only the small amount of learner output texts in a cross-validation setup is .721 F_1 and .886 κ^2. Compared to this, transferring a model based on coursebook texts directly (SOURCE-ONLY) results in a considerable performance drop (-.283 F_1 and -.173 κ^2). When using the essays in their original, noisy form, the best performing domain adaptation setup is the weighted combination of L2 input and output texts, which outperforms even the in-domain baseline both in terms of F_1 and κ^2.

The obtained domain-adaptation results are comparable to state-of-the-art in-domain systems for other languages, like the system for Estonian described in Vajjala and Lõo (2014) with an F_1 of .78, or the one for German (Hancke, 2013) with .71 F_1 for a feature selected model distinguishing 5 classes. It is worth

Morphological	.538	.743	.297	.403	.291	.419
Semantic	.299	.198	.087	.000	.087	.000

Table 5: Performance of individual feature groups.

noting, however, that both of these systems required a considerably (about three times) larger annotated in-domain corpus. This shows that additional coursebook data can benefit the classification of language proficiency levels in learner output texts, especially if only a small amount of annotated in-domain data is available.

Error Normalization Our error-normalization method corrects in total 5,080 errors in the essays which amounts to 3.6% of all tokens in the data. In absence of error-annotated Swedish resources, we manually evaluate the method by inspecting 120 normalized items out of which we find 83 correct, corresponding to 69% accuracy. Out of the normalized tokens, about 87% are categorized as spelling errors by LanguageTool. Moreover, the choice of correction candidate is based on LMI scores in 24% of all cases.

Since our feature set does not target learner errors specifically (to be able to maintain comparability when applied to coursebook text), we do not expect error normalization to influence classification results with IN-DOMAIN. Our experiment results in Table 4 show, in fact, that correcting learner errors does not have any statistically significant effect in the IN-DOMAIN setup, but it does improve performance to a great extent for most domain-adapted cases. This latter would support the hypothesis that correcting spelling and grammatical errors increases the similarity between the target and the source domain. The gain is especially large (+.182 F_1) in the case of the SOURCEONLY setup, which does not rely on annotated essays. EASYADAPT, which has been successfully used in an AES task previously (Phandi et al., 2015), is outperformed by most other domain adaptation methods in our case, independently from error normalization.

In terms of F_1, +FEATURE using the predictions of a classifier trained on the L2 input texts performs best (.802 F_1), however, the degree of misclassifications indicated by κ^2 is smallest with WEIGHTED (.915), as in the case of the essays without error normalization. After error correction, WEIGHTED-INSTSEL achieves approximately the same quality of performance for all measures as the aforementioned two best performing models WEIGHTED and +FEATURE. These all improve over the IN-DOMAIN baseline by about .07 F_1 and .03 κ^2.

These results show that the knowledge transfer from L2 input texts can be substantially boosted by normalizing errors in the learner-produced texts.

Contribution of Feature Groups In the next step, we investigate the contribution of individual feature groups to the classification performance both in- and cross-domain with the SOURCE-ONLY setup which does not presuppose the availability of annotated in-domain data. Results for our ablation test are shown in Table 5.

The most predictive features in- and cross-domain on both the original and on the normalized essays are lexical features measuring the proportion of tokens per CEFR level in the texts. Morphological features also preserve their strong predictive power when transferred between L2 input and output texts. The informativeness of syntactic and count features is very low in the cross-domain setting with the original essays, but the latter category transfers much better after error-normalizing L2 output texts. A

potential explanation could be that error normalization includes also corrections of capitalization and whitespaces which might contribute to an improved detection of sentence boundaries, a central element in most of these features. Lexical features also benefit from error correction, presumably due to a more precise estimation of the CEFR-level distribution of tokens.

Direction of Misclassifications Finally, to investigate whether the transferred coursebook model predicts learner-written texts to be of higher or lower proficiency levels compared to the available annotations, we perform regression using SMO and the SOURCEONLY setup, transforming CEFR levels into numeric values. We use the normalized essays for this purpose since the automatic annotation is presumably more precise in these texts compared to their original version. Predictions within a distance of 0.5 from the numeric value representing the actual CEFR level are considered sufficiently close for being considered correct, thus the amount of errors is computed based only on cases exceeding this margin. The regression model produces .800 correlation and 1.120 RMSE (root mean squared error). We find that 64% of the erroneous predictions consider essays to be of a lower level than they actually are. This could be a data-driven confirmation of the pedagogical observation that learners' output texts are typically of a lower linguistic complexity compared to the L2 input texts written for them within the same CEFR level.

7 Conclusions

In this work we investigated the benefits of using texts from language learning coursebooks to classify proficiency levels in learner-written texts, since the latter type of data is especially costly to collect. Moreover, our experiments provide useful insights into how some simple domain adaptation techniques compare to each other for this task. Training only on source domain data did not yield a successfully transferable model between the L2 input and output texts if errors were not normalized in the learner-produced essays. With such a normalization, however, using only coursebook texts as training data produced a result rather close to what learning only from a small amount of essays did. Joining domains was useful, especially when weighted target domain instances were added to all, or a subset of the coursebook data, and learner errors were normalized. We showed that, with these two steps, it is possible to outperform a model based only on a limited amount of in-domain data. Furthermore, our results are competitive even compared to systems for other languages that make use of a considerably larger amount of in-domain data.

In the future, it would be informative to repeat the experiments for other languages, where we expect similar results. Additional domain adaptation techniques could also be explored for this task, for example, the identification of shared priors and kernel transformations. Alternatives to the current error normalization could be investigated in order to identify a broader range of incorrect tokens more precisely. More reliable error correction methods may yield further improvement to transferring classification models between these domains.

User Classification with Multiple Textual Perspectives

Dong Zhang, Shoushan Li*, Hongling Wang, Guodong Zhou

Abstract

Textual information is of critical importance for automatic user classification in social media. However, most previous studies model textual features in a single perspective while the text in a user homepage typically possesses different styles of text, such as *original message* and *comment from others*. In this paper, we propose a novel approach, namely ensemble LSTM, to user classification by incorporating multiple textual perspectives. Specifically, our approach first learns a LSTM representation with a LSTM recurrent neural network and then presents a joint learning method to integrating all naturally-divided textual perspectives. Empirical studies on two basic user classification tasks, i.e., gender classification and age classification, demonstrate the effectiveness of the proposed approach to user classification with multiple textual perspectives.

1 Introduction

User attribute classification, also namely user classification for short, is a task which aims to leverage user-generated content to automatically predict user's attributes, such as gender (Wang et al., 2015), age (Rao et al., 2010; Sap et al., 2014) and location (Cheng et al., 2010). Recently, the growth of online social networks provides the opportunity to perform user classification in a broader context (Bollen et al., 2011; Sadilek et al., 2012; Lampos and Cristianini, 2010; Zamal et al., 2012). Basically, user classification is a fundamental task not only in sociolinguistic studies, but also in many real applications, such as recommender systems, and online advertising (O'Connor et al., 2010; Preotiuc-Pietro et al, 2015).

Text style	***User A*** ***Gender: female***	***User B*** ***Gender: male***
Original Message	"*Just bought the lipstick, look beautiful?*"	"*The first day, hard work.*"
Retweeted Message	"*Seaweed mask, it is so remarkably efficient.*"	"*Love her, take her to see the sea.*"
Comment from others	*"Sister, you're so pretty!"*	"*Go to see my latest message*"
Comment to others	"*Thanks.*"	*"Sister, you're so pretty!"*

Table 1: Some examples of different text styles in two users' homepages in a social media

Currently, machine learning approaches have dominated the research on user classification where statistic classifiers are learned with labeled data and various kinds of features, such as textual features,

* Corresponding author

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2112–2121, Osaka, Japan, December 11-17 2016.

behavior features, and social connection features (Preotiuc et al., 2015, Lampos et al., 2016). Among these features, textual features are most popular and they are good clues to infer the user attributes (Zhu et al., 2015; Li et al., 2015). For example, in Table 1, User A publishes a text "*Just bought the lipstick, look beautiful*?" which could be used to infer the user to be a *female* since *females* are more likely to buy a lipstick.

However, user-generated text sometimes possesses different styles, especially in social media. For instance, in Table 1, a homepage in a social media contains at least four kinds of text, namely *Original Message*, *Retweeted Message*, *Comment From Others*, and *Comment To Others*. Almost all previous studies do not distinguish these different styles of text, which might hurt the classification performance. For instance, in Table 1, User A has a *Comment From Others* "*Sister, you're so pretty!*" and User B has the same text but belongs to a different text style, i.e., *Comment To Others*. When the classifier do not carefully differentiate these text styles but merely mix all textual information together, using the sample of User A as training data is more likely to classify User B to be the same gender due to the same text "*Sister, you're so pretty!*". Obviously, this is a wrong prediction because User B is a *male* and the word "sister" is used to call someone else. Therefore, a better way to leverage textual knowledge in social media should be able to distinguish different styles of text.

In this paper, we address the above challenge by proposing a novel approach called ensemble LSTM recurrent neural network. Specifically, we first consider the features from each style of text as a separate textual perspective. Then, we train a Long Short-Term Memory (LSTM) network for each textual perspective respectively. Third, we add a merge layer to combine all LSTM representations by joint learning so as to fuse all textual knowledge. Empirical studies demonstrate that our approach performs much better than many strong baseline approaches.

Note that the motivation of employing LSTM as our single-perspective learning approach is that LSTM equips with a special gating mechanism that controls access to memory cells and it is powerful and effective at capturing long-term dependencies (Bengio et al., 1994). This advantage is helpful for modeling text and thus this approach has been successfully applied to a variety of NLP tasks, such as machine translation (Bahdanau et al., 2015), sentiment analysis (Tang et al., 2015), and sequence labeling (Chen et al., 2015).

The remainder of this paper is organized as follows. Section 2 overviews related work on user classification. Section 3 introduces data collection. Section 4 proposes our multi-perspective ensemble LSTM approach with multiple textual perspectives for user classification. Section 5 evaluates our approach with a benchmark dataset. Finally, Section 6 gives the conclusion and future work.

2 Related Work

Over the last decade, many previous studies have been devoted to the research on user classification with multiple attributes, such as user gender and user age.

User gender classification has been extensively studied in several domains, such as Blog (Peersman et al., 2011; Gianfortoni et al., 2011), E-mail (Mohanmad et al., 2011), YouTube (Filippova, 2012) and Micro-blog (Liu et al., 2013). More recently, some studies focus on some specific application scenarios on gender classification, such as multi-lingual gender classification (Ciot et al., 2013; Alowibdi et al., 2013), inferring gender by crowd (Nguyen et al., 2014) and interactive gender classification (Li et al., 2015).

User age classification has been studied in two main domains, i.e., blog (Burger and Hender son, 2006) and social media (Machinnon and Warren, 2006). In the blog domain, Schler et al. (2006) focus on textual features extracted from the blog text, such as word context features and POS stylistic features. Burger and Henderson (2006) explore some social features, such as location, time, and friend features, related to blogger age. Other studies, such as Rosenthal and McKeown (2011) and Goswami et al. (2009) explore both the textual and social features in automatic age classification. In the social media domain, Mackinnon and Warren (2006) explore some kind of social features, i.e., the relationship between users to predict a user's age and country of residence in a social network. Peersman et al. (2011) apply a text categorization approach to age classification with textual features only, i.e., word unigrams and bigrams. More recently, Marquardt et al. (2014) propose a multi-label classification approach to predict both the gender and age of authors from texts. Specifically, besides the word features, they also adopt some sentiment and emotion features in their approach.

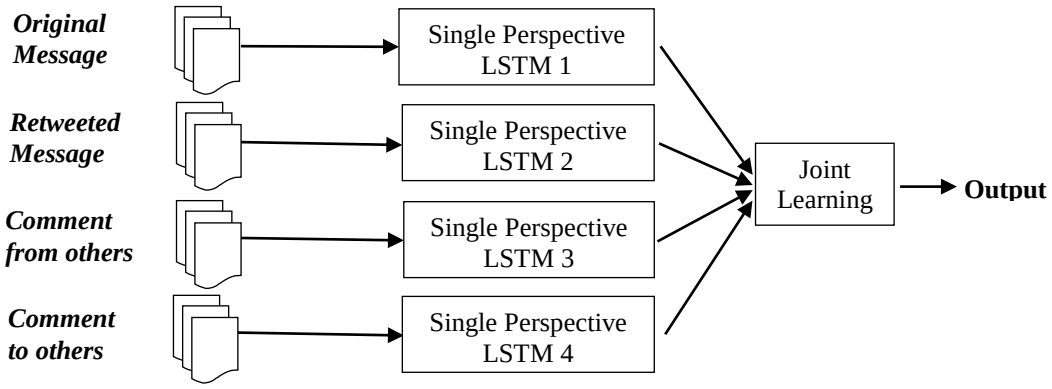

Figure 1: The framework of multi-perspective ensemble LSTM neural network

Some other user attributes, such as user location (Cheng et al., 2010), political orientation (Rao et al., 2010) and user occupational class prediction (Preotiuc-Pietro et al, 2015) are also popularly studied in recent years. Unlike all previous studies, this paper employs a deep learning approach to user classification and different styles of textual features are treated separately.

3 Data Collection

Our data are collected from Sina Micro-blog[1], a famous Micro-blogging platform in China. From the website, we crawl each user's homepage which contains user information (e.g., *name*, *age*, *gender*, *verified type*), and their posted messages. The data collection process starts from some randomly selected users, and iteratively gets the data of both their user attributes including gender and age. Different styles of text in each user's homepage are collected and they are:

1) ***Original message***: the messsages which are originally published by the user;
2) ***Retweeted message***: the messages which are retweeted by the user;
3) ***Comment from others***: the comments which are written by other users;
4) ***Comment to others***: the comments which are written by the user.

For gender classification, we randomly select 3000 *male* and 3000 *female* users for our empirical study and for age classification, we randomly focus on two age categories: *80s* (birthday between 1980 and 1989), *90s* (birthday between 1990 and 1999), each of which contains 3000 samples.

Table 2 shows the statistics about the average number of messages each user possessed in his/her homepage. From this table, we can see that each style of text has a decent number of messages or comments where *original message* and *comment to others* have more messages or comments than the other two styles.

	Gender		Age	
	Male	*Female*	*80s*	*90s*
Original message	148	158	154	153
Retweeted message	84	95	86	90
Comment from others	140	189	175	189
Comment to others	83	121	105	128

Table 2: Statistics about the average number of messages each user processed in his/her homepage

4 Our Approach

We treat the four styles of text as four textual perspectives for user classification and learn a multi-perspective ensemble LSTM recurrent neural network to make full use of all these perspectives. In general, our approach consists of two main components: (1) learning a new representation via a single-

[1] http://weibo.com/

perspective LSTM recurrent neural network of one type of user perspective. (2) employing a merge layer via joint learning to combine four different types of user perspectives. Figure 1 shows the framework overview of our approach and the two main components, i.e., single-perspective LSTM and multi-perspective ensemble LSTM via joint learning, will be discussed in detail.

4.1 Single perspective LSTM

In this study, we apply the implementation used by (Graves, 2013). The LSTM units at each time step t are defined to be a collection of vectors in $\mathbb{R}^d$: an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t and a hidden state h_t.

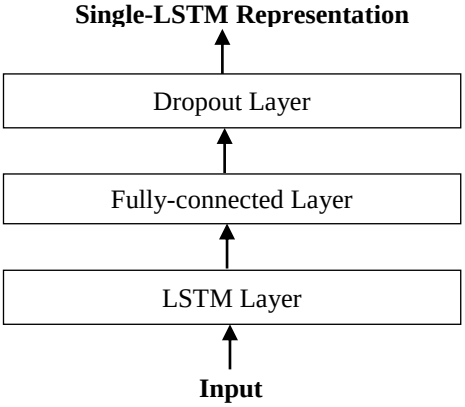

Figure 2: The framework of single perspective LSTM

Figure 2 illustrates the model architecture of our single-perspective LSTM where only one single LSTM layer is used. The input contains the representation of one type of textual perspective. According to the transition mode above, the input propagates through LSTM layer, Fully-connected layer and Dropout layer. The computing functions are given as following:

$$h^* = \phi\left(\omega^T h + b\right) \tag{1}$$

$$g = h^* \cdot D(p) \tag{2}$$

Where ϕ is the non-linear activation function, employed "*relu*" in our model and h is the output from LSTM layer. D denotes the dropout operator and p denotes a tune-able hyperparameter (the probability of retaining a hidden unit in the network).

4.2 Multi-perspective Ensemble LSTM via Joint Learning

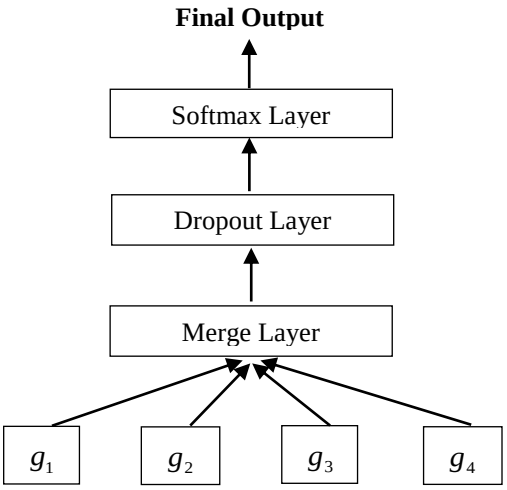

Figure 3: The framework of our multi-perspective ensemble LSTM approach

In order to distinguish the four types of textual perspectives and make full use of them legitimately, we propose a multi-perspective ensemble LSTM via joint learning to incorporate classification knowledge in *original message*, *retweeted message*, *comment from others* and *comment to others* separately. Figure 3 shows the framework of our multi-perspective ensemble LSTM approach where g_1, g_2, g_3 and g_4 are four LSTM representations learned from four single-perspective LSTM neural networks with four styles of textual perspectives.

The merge layer is designed to combine four types of user representation with a standard concatenation operation, i.e.:

$$g^* = [g_1; g_2; g_3; g_4] \tag{3}$$

Finally, a softmax output layer is used for classification. The model's prediction $label_{pred}$ is the class whose probability is maximal, specifically:

$$label_{pred} = \arg\max_i P(Y = i | x, W, U, V) \tag{4}$$

In our joint learning, the training objective is the penalized cross-entropy error, i.e.:

$$J = -\sum_{i=1}^{n_c} t_i \log y_i + \lambda \sum_{i=1}^{m} \left(\sum_{\varepsilon \in \omega} \left\| W_i^{\varepsilon} \right\|_F^2 + \sum_{\varepsilon \in \mu} \left\| U_i^{\varepsilon} \right\|_F^2 + \sum_{\varepsilon \in \nu} \left\| V_i^{\varepsilon} \right\|_F^2 \right) \tag{5}$$

Where $t \in \mathbb{R}^{n_c}$ is the one-hot represented ground truth and $y \in \mathbb{R}^{n_c}$ is the estimated probability for each class by softmax. (n_c is the number of target classes; m is the number of textual perspectives). In addition, W, U and V represent the corresponding weight matrices connecting them to the gates. $\| \cdot \|_F$ denotes the Frobenius norm of a matrix. $\omega = \{i, f, o, c\}$, $\mu = \{i, f, o, c\}$ and $\nu = \{i, f, o\}$ are the set of different gates (for W 's, U 's and V 's, respectively). λ is a hyperparameter that specifies the magnitude of penalty on weights.

To train our ensemble LSTM, we use Stochastic Gradient Descent with mini-batches. The set of parameters to learn is the set $\theta = \{W, U, V\}$ in each single LSTM RNN of user perspective. The gradients $\partial J / \partial \theta$ are achieved through the back propagation algorithm (a special case of the chain-rule of derivation). Specifically, in terms of W_i^{ε}, the update equation is given by:

$$W_i^{\varepsilon} := W_i^{\varepsilon} + \frac{\partial J}{\partial g^*} \cdot \frac{\partial g^*}{\partial g_i} \cdot \frac{\partial g_i}{\partial h_i^*} \cdot \frac{\partial h_i^*}{\partial h_i} \cdot \frac{\partial h_i}{\partial W_i^{\varepsilon}} \tag{6}$$

Where $\frac{\partial h_i}{\partial W_i^{\varepsilon}}$ in LSTM unit will be computed via back propagation though time (BPTT). In the same spirit, U_i^{ε} and V_i^{ε} could be obtained as following:

$$U_i^{\varepsilon} := U_i^{\varepsilon} + \frac{\partial J}{\partial g^*} \cdot \frac{\partial g^*}{\partial g_i} \cdot \frac{\partial g_i}{\partial h_i^*} \cdot \frac{\partial h_i^*}{\partial h_i} \cdot \frac{\partial h_i}{\partial U_i^{\varepsilon}} \tag{7}$$

$$V_i^{\varepsilon} := V_i^{\varepsilon} + \frac{\partial J}{\partial g^*} \cdot \frac{\partial g^*}{\partial g_i} \cdot \frac{\partial g_i}{\partial h_i^*} \cdot \frac{\partial h_i^*}{\partial h_i} \cdot \frac{\partial h_i}{\partial V_i^{\varepsilon}} \tag{8}$$

5 Experiments

In this section, we empirically evaluate the performance of our approach to user classification in social media.

5.1 Experimental Settings

Dataset: (1) **Gender classification**: the dataset contains 3000 *male* and 3000 *female* users and each user has four styles of text: *original message*, *retweeted message*, *comment from others* and *comment to others*. We randomly select 4200 (70%) users as training data, 600 (10%) users as development data and use the remaining 1200 (20%) users as test data. (2) **Age classification**: the data set contains 3000 *80s* (between 1980 and 1989) users and *90s* (between 1990 and 1999) users and each user has four

Parameter and Description	Value
Size of total unigram features	30000
Dimension of the LSTM layer output	128
Dimension of the fully-connected layer output	64
Dropout rate	0.5
Epochs of iteration	10

Table 3: Parameters setting in LSTM RNN

	ME	CNN	Parallel CNN	LSTM
Original message	0.843	0.843	0.849	0.863
Retweeted message	0.784	0.793	0.788	0.791
Comment from others	0.825	0.798	0.818	0.823
Comment to others	0.736	0.743	0.754	0.776
Average	*0.797*	*0.794*	*0.802*	***0.813***

Table 4: Performance comparison of different approaches with single textual perspective (**Gender Classification**)

styles of text: *original message*, *retweeted message*, *comment from others* and *comment to others*. We randomly select 4200 (70%) users as training data, 600 (10%) users as development data and use the remaining 1200 (20%) users as test data.

Representations: Each message text is treated as a bag-of-features and transformed into binary vectors encoding the presence or absence of each feature. The features include word unigrams, and two kinds of complex features, i.e., F-measure and POS sequence pattern features, which yield the state-of-the-art performance in user classification (Mukherjee and Liu, 2010).

Classification algorithms: (1) The maximum entropy (ME) classifier implemented with the public tool, Mallet Toolkits[2]. (2) The random forest classifier and adaboost classifier implemented with the public tool, scikit-learn[3]. (3) The CNN classifier implemented with the help of the tool Keras[4]. (4) The LSTM classifier implemented with the help of the tool Keras.

Parameters Setting: (1) The most important parameter of RF and ABC is *estimators*, which is set 500 via fine-tuning. (2) The parameters of LSTM are set as shown in Table 3.

Evaluation Measurement: The performance is evaluated using the standard accuracy measurement.

5.2 Experimental Results

Experimental Results on Single Textual Perspective

For thorough comparison, four approaches with single perspective are implemented:

- **ME**: the maximum entropy classifier with all the parameters default.
- **CNN**: the basic bow-CNN is proposed in (Johnson and Zhang, 2014).
- **Parallel CNN**: the extension of bow-CNN, which has two or more convolution layers in parallel to learn multiple types of embedding of small text regions, proposed in (Johnson and Zhang, 2014).
- **LSTM**: the single perspective LSTM introduced in Section 4.1.

Table 4 shows the performance comparison of four approaches to gender classification. From this table, we can see that the text style of *original message* performs best among all four styles of text no matter what classification approach is used. On average, CNN and Parallel CNN performs better than ME. Among the four approaches, LSTM perform best. Significance test shows that our LSTM approach significantly outperforms the other four approaches (p-value<0.05).

Table 5 shows the performance comparison of four approaches to age classification. From the table, we can see that the text style of *original message* performs best among all four styles of text no matter

what classification approach is used. Similar to the results in gender classification, LSTM still perform best in age classification. Significance test shows that our LSTM approach significantly outperforms the other three approaches (p-value<0.05).

Experimental Results on Multiple Textual Perspectives

For thorough comparison, several ensemble learning approaches with multiple perspectives are implemented:

- **RandomForest**: a popular ensemble learning approach proposed by Strobl et al. (2007). In our implementation, we train multiple decision tree classifiers and employ random forest algorithm to combine them.
- **Adaboost**: a popular ensemble learning approach proposed by (Zhu et al., 2009). In our implementation, we mixture the data of all perspective and use each word feature to form a weak classifier and then combine all feature classifier with adaboost algorithm.
- **Voting LSTM**: we first use each single textual perspective to train a LSTM classifier and then use the voting rule (Kuncheva and Rodriguez, 2014) to combine the obtained label outputs from all single-perspective LSTM classifiers.
- **Weighted_Sum LSTM**: we first use each single textual perspective to train a LSTM classifier and then use weighted sum rule (Marler and Arora, 2010) to combine the obtained probability outputs from all single-perspective LSTM classifiers.
- **Ensemble LSTM (Our approach)**: our joint learning approach as introduced in Section 4.2.

Table 6 shows the performance comparison of all approaches to gender classification when multiple textual perspectives are used. From this table, we can see that, using multiple textual perspectives does not always outperform the best performed approach with a single textual perspective. For instance, when RandomForest and Adaboost are used, the performance of using multiple textual perspective are 0.791 and 0.803 respectively, which are worse than that of using the *Original message* perspective with LSTM classifier, i.e., 0.863. Our ensemble LSTM approach performs best and it performs much better than both the best-performed single perspective LSTM (as shown in Table 4) and other strong ensemble strategies with multiple textual perspectives, such as Voting LSTM and Weighted_Sum LSTM. Significance test shows that our ensemble LSTM approach significantly outperforms other approaches when multiple textual perspectives are used (p-value<0.05).

Table 7 shows the performance comparison of all approaches to age classification when multiple textual perspectives are used. From this table, we can see that our ensemble LSTM approach performs best and it is also performs better than other strong ensemble strategies with multiple textual perspectives, such as Voting LSTM and Weighted_Sum LSTM. Significance test shows that our ensemble LSTM approach significantly outperforms other approaches when multiple textual perspectives are used (p-value<0.05).

5.3 Effectiveness Analysis and Case Study

In order to further illustrate the superiority of our approach, we give a case study as following. Table 8 shows the selected features sorted by the feature selection method of information gain (IG) (Li et al., 2009) when the task of gender classification is considered. We extract the features from the *original message* text and the *retweeted message* text separately.

This table shows the top-10 IG features from the *original message* text and their ranks in the *retweeted message* text. N denotes the sequence number of the feature in the selected features. $|F_f|$ denotes the feature frequency in all samples of female. $|F_m|$ denotes the feature frequency in all samples of male. For instance, the sequence number of emoticon "rabbit" in *original message* is the first, the feature frequency in all samples of female is 5871, and the feature frequency in all samples of male is 1872. It is observed that this feature is usually used by a woman. From the table, we can see that many '*good*' features in *original message*, such as *emoticon [rabbit]*, *亲亲* (*kiss*) and *讨厌* (*hate*), are not ranked top in *retweeted message*. If we merely merge all styles of text, some '*good*' features in one textual perspective would not be as effective as in the scenario when they are separately treated.

Feature	Original message			Retweeted message		
	N	$\|F_f\|$	$\|F_m\|$	N	$\|F_f\|$	$\|F_m\|$
表情符-兔子 (emoticon [rabbit])	1	5871	1872	154	1553	960
亲亲 (kiss)	2	3700	978	104	1186	606
闺蜜 (ladybro)	3	588	103	1	1186	313
NBA	4	53	467	10	120	500
足球 (football)	5	169	1144	5	328	1561
球队 (team)	6	31	378	3	135	810
讨厌 (hate)	7	1854	773	797	1470	943
进球 (goal)	8	23	296	6	96	607
委屈 (grievance)	9	2358	802	--	--	--
男神 (dream guy)	10	1163	331	26	843	334

Table 8: The top-10 IG features from the *original message* text and their ranks in the *retweeted message* text

6 Conclusion

In this study, we propose a novel approach, namely ensemble LSTM, to user classification, which jointly learns textual features from different textual perspectives. Our contributions lie in two main aspects: First, the proposed LSTM approach with a single textual perspective performs much better than traditional approaches, such as ME and CNN, for user classification. Second, the proposed ensemble LSTM approach significantly outperforms both the approaches which use only one single textual perspective and several other ensemble approaches.

In our future work, we attempt to apply bidirectional LSTM in user classification to utilize both the bi-directional contexts. Moreover, in addition to the textual features, we would like to merge social features to further improve performance. What's more, we will apply our proposed multi-perspective ensemble LSTM model in some other tasks of user classification, such as user occupation classification and so on.

Abstract

We extend classic review mining work by building a binary classifier that predicts whether a review of a documentary film was written by an expert or a layman with 90.70% accuracy (F1 score), and compare the characteristics of the predicted classes. A variety of standard lexical and syntactic features was used for this supervised learning task. Our results suggest that experts write comparatively lengthier and more detailed reviews that feature more complex grammar and a higher diversity in their vocabulary. Layman reviews are more subjective and contextualized in peoples' everyday lives. Our error analysis shows that laymen are about twice as likely to be mistaken as experts than vice versa. We argue that the type of author might be a useful new feature for improving the accuracy of predicting the rating, helpfulness and authenticity of reviews. Finally, the outcomes of this work might help researchers and practitioners in the field of impact assessment to gain a more fine-grained understanding of the perception of different types of media consumers and reviewers of a topic, genre or information product.

1 Introduction

Product reviews help customers to make purchase decisions, and producers to improve and develop goods (Hu & Liu, 2004; Kim et al., 2006; Mudambi & Schuff, 2010). Scalable NLP-based solutions have been developed to support various aspects of these decision-making processes:

(1) Describing, understanding and anticipating product ratings can help manufacturers to comprehend a market. Ranking reviews and reviewers further aids this step. The rating values per review are typically user-generated, ordinal variables, often on a 5-point scale (Jiang & Diesner, 2016; Pang & Lee, 2005).

(2) Identifying the trustworthiness or authenticity of reviews can assist in separating authentic from fudged reviews (Jindal & Liu, 2007; Jindal et al., 2010; Wu et al., 2010). Predicting this feature is more challenging than the previously mentioned ones as authenticity values are not explicitly provided by reviewers or readers, but need to be inferred from the content of reviews and related metadata.

(3) Predicting whether a review was written by an expert or a layman helps to differentiate the impact of the electronic word-of-mouth on the e-marketplace. McAuley and Leskovec (2013) studied the change of reviewers' expertise over time in order to improve personal recommender systems. Knowing the type of reviewer can also assist with asserting the credibility of reviewers (Basuroy et al., 2003; Flanagin & Metzger, 2013; Liu et al., 2008).

Besides commercially motivated analyses of product reviews, assessing the impact of information products such as books, films and other works of art on individuals, groups and society is another domain where knowing the type of author can be beneficial. In the context of impact assessment, *expert critics* (short experts in this paper) can be conceptualized as people with high standards of integrity and an extrinsic motivation for this task, such as writing reviews as part of their jobs as journalists. *Laymen reviewers* can be considered as ordinary customer who are intrinsically motivated to voluntarily provide this type of user-generated content based on their personal experience and points of view (Amblee & Bui, 2007; Chattoo & Das, 2014; Napoli, 2014; Rezapour & Diesner, 2017). We acknowledge the possibility that laymen might write expert-level reviews and vice versa.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2122–2132, Osaka, Japan, December 11-17 2016.

Creators and funders of works of art can use the knowledge about the type of writer to evaluate the impact of information products on the public, e.g. in terms of knowledge diffusion, framing, and sentiment. To provide some better understanding of this process, in this paper, we develop a binary classifier that predicts whether a review of a documentary film was authored by an expert or a layman. We focus on the domain of issue-focused documentaries to complement work based on feature films and box-office blockbusters. Our work also complements prior knowledge gained from studies that predict reviewer expertise based on personal ratings (Amblee & Bui, 2007; Flanagin & Metzger, 2013; Plucker et al., 2009), and/or the online behaviour of reviewers (Liu et al., 2008). We hypothesize that the type of reviewer can be inferred from characteristics of the text data, and address the following research question: Do different text patterns exist in reviews authored by experts versus laymen? If so, what features are unique to each group?

To the best of our knowledge, our study is the first one to apply machine-learning methods to computationally detect the type of author based on the content of reviews. We achieve an overall prediction accuracy of about 90.70% (F-measure), and explain the characteristics of each predicted class (expert versus layman).

The remainder of this paper is organized as follows. We review related work in section 2. Our corpus is described in section 3, and the methods in section 4. In the results section (5), we identify characteristics of each type of author and provide an error analysis. Finally, conclusions and future work are discussed in section 6.

2 Related Work

Nelson (1970, 1974) divides products into "search goods," i.e., tangible objects like cars, and "experience goods," i.e., intangible objects like films. While it might be possible to objectively evaluate search goods, e.g. in terms of their form, function and behaviour, rating experience goods, which are the subject of this study, may involve more personal perspectives, opinions, emotions and subjective judgment (Liu et al., 2008).

The majority of prior NLP-based solutions to commercially inspired review mining tasks can be divided into three groups: First, studies that predict the rating of products and the helpfulness of reviews (Ghose & Ipeirotis, 2011; Kim et al., 2006; Liu et al., 2008; Mudambi & Schuff, 2010; Yang et al., 2015; Zhang et al., 2015). These two tasks are fairly straightforward because user-generated ground-truth data on these features is available. Second, work that identifies the sentiment or opinion entailed in reviews. Knowledge about this feature might also help to explain or predict the former two features. This task requires the labelling of reviews with (values for) sentiment or opinion categories. Building such predictors is typically approached by using deterministic (look-up dictionaries) and/or probabilistic NLP techniques (de Albornoz et al., 2011; Pang & Lee, 2005; Turney, 2002). Third, work that focuses on summarizing the content or the gist of reviews to reduce the complexity of large text corpora (Hu & Liu, 2004; Li et al., 2010; Zhuang et al., 2006).

Studying reviewer expertise, which is the focus of this paper, is a minor branch in current review mining research. In prior work, this problem has mainly been approached by a) using empirical statistical investigations, such as counting average rating scores of experts versus novices, or correlating rating values with product consumption, b) conducting content analysis of reviews (de Jong & Burgers, 2013; Mackiewicz, 2009), and c) computational identifying the level of reviewers' expertise. As an example for the last type, Liu and colleagues (2008) used "reviewer expertise" as one of three variables for identifying the helpfulness of movie reviews. The authors operationalized expertise as frequent and highly positive-rated reviews per author and per pre-defined film genre. Their other two features were writing style and review timeliness. Combining all three features in a non-linear regression resulted in a helpfulness prediction accuracy of 71.2% (F-measure). The isolated contribution of the expertise feature was 51.8% (F-measure). In another study, which also falls into the last category, McAuley and Leskovec (2013) showed that users become more experienced in developing their taste for experience goods (tested for the product categories of beer, wine, fine foods and movies) with over-time exposure to these products. The authors found that the accuracy for predicting item ratings increases when users had higher levels of experience or expertise.

Our work differs from prior studies in that we focus on predicting reviewer expertise as a binary variable based on text-based features of reviews of issue-focused documentaries. The primary goal of

this study is to detect indicative text features that can differentiate reviews written by experts from laymen.

3 Data

We collected a dataset that contained ground-truth or gold-standard data, i.e., expert versus layman reviews, for 20 documentaries. The films were selected based on their coverage of main social justice issues (as defined by philanthropic funders), including environmental issues, politics, public health, gender and ethnicity (Diesner et al., 2016). Table 1 shows the list of selected films, their abbreviation used in this paper, and the number of reviews per category.

Based on our reading of reviews on several popular film-rating sites, such as Rotten Tomatoes, Metacritic, Amazon and YouTube, we assume that layman reviews are mainly provided voluntarily. For these reviews, the full texts are provided on these websites. However, for expert reviews, only snippets and a link to the original source (e.g., major newspapers) are typically displayed. Due to copyright regulations and the terms of service for these pages, we could not access expert reviews from these review sites. Alternatively, we used LexisNexis Academic to collect comments written by professional critics that were published in newspapers and other sources. For these searches, the queries contained the film's title, name(s) of the director and/ or producer, and the keyword "review". The latter two items mainly served as disambiguators. For laymen reviews, we collected customer reviews from Amazon after obtaining Amazon's permission for this procedure. Even though reviews per author type were collected from a different platform (customer reviews from Amazon, expert reviews from LexisNexis Academic), we argue that the source does not determine or predict the type of author for the following reason: Many of these platforms list both types of reviews side by side, on the same platform. In other words, expert reviews from sources like Rotten Tomatoes are not written by Rotten Tomatoes, but come from the same sources that we used for our study – e.g., major newspapers.

The data collection involved some challenges. First, manual inspection of each article from LexisNexis was unavoidable as many texts were (soft) duplicates or poor fits, e.g., comments on multiple films with the target film being only briefly mentioned. We manually eliminated duplicates,

false positives and poor fits. In the end, 33.53% of the downloaded reviews were judged as valid data points for this study. The resulting number of valid instances per class is also shown in Table 1.

Second, the number of laymen reviews exceeds that of expert reviews. Therefore, for learning, we used the smaller set (i.e., expert reviews) as the defining upper bound for the number of instances considered per class, and randomly sampled an equally-sized number of reviews from the larger set.

4 Method

4.1 Features

Our features selection is guided by prior work that have shown that different aspects of writing style are useful indicators of review helpfulness and reviewer expertise. Based on this prior work, we chose three types of features (discussed in detail below): length features, lexical features and syntactic features.

The content of all considered reviews (N=1446; 723 per class) was pre-processed via stop word removal, stemming, and converting capitalization to lower case[1] for most lexical features except for sentiment analysis. We tested the impact of each routine on feature construction and prediction performance (F-measure), and selected the abovementioned techniques as they contributed most strongly to prediction performance.

4.1.1 Length Features

The length of both reviews and sentences per reviews were considered (Review length, Average sentence length) and computed by using the Stanford Parser (De Marneffe et al., 2006).

4.1.2 Lexical Features

As word choice may also characterize or correlate with each type of reviewer, we leveraged the top 250 unigrams according to the TF*IDF metric (unigram) as shown in Equation 1.

$$weight(w, C_f) = tf(w, C_f) \times idf(w) = c(w, C_f) \times \log\left(1 + \frac{N}{df(w)}\right) \quad (1)$$

$$weight(w, d) = tf(w, d) \times idf(w) = c(w, d) \times idf(w) \quad (2)$$

In this equation, C_f represents the corpus of all reviews per film, *w* is any term in C_f, c(w, C_f) is the number of occurences of *w* in C_f, *N* is the total number of reviews in the collection of a film, and *df(w)* is the number of reviews within the corresponded collection in which *w* appears.

Equation 2 calculates the TF*IDF per unigram per review, where d is the content per review.

We also used the informativeness per review as a feature (Equation 4) (Weaver & Shannon, 1949) by calculating information entropy. This metric is based on the average amount of information that each w carries per review as well as in the whole corpus per film, respectively (see Equation 3). The calculation is determined by the *w*'s normalized weight in review d and corpus C. As we focus more on the amount of information carried by w in corpus, the ratio parameter λ was set to 0.3 after experimenting with various values.

$$p(w) = \lambda \times \frac{weight(w, d)}{\sum_{w' \in d} weight(w', d)} + (1 - \lambda) \times \frac{weight(w, C_f)}{\sum_{w' \in C} weight(w', C_f)} \quad (3)$$

$$H(d) = \sum_{w \in d} [-p(w) \log_2 p(w)] \quad (4)$$

In addition, the emotionality of reviews has been shown to correlate with formal (more neutral) versus informal (more emotional) writing styles (Hu & Liu, 2004; Jiang & Diesner, 2016; Kim et al., 2006). To calculate emotionality, we reused the previously built, evaluated and widely used MPQA Subjectivity Lexicon (Wilson et al., 2005). Using this external lexical resources, we identified sentiment-loaded terms, summed them up per text, and normalized the sum of the number of sentiment words per valence type by text length (Sentiment%).

[1] Implemented by using an open-source package:

TR	Definition	Examples
Addition	Provide similar or further information	and, also, or, further
Introduction	Illustrate an argument with a detailed instance	for example, such as
Emphasis	Underline an argument	Even, very especially
Concession	Counter a previous argument	but, however, although
Causality	Describe cause and effect	because, since
Condition	Explain a precondition	if, unless
Order	Sequentially order	before, after
Summary	Conclusion	in a word

Table 2: Selected transition relationships

Syntax	Usage
Aux	Identify clause with non-main verb
Auxpass	Identify passive voice of clause with non-main verb
Csubj	Identify subject clause
Csubjpass	Identify passive voice of subject clause
Dobj	Identify direct object of clause
Iobj	Identify indirect object of clause
Nsubj	Identify nominal subject in clause
Nsubjpass	Identify passive nominal subject in passive clause
Mark	Identify finite clause that subordinate to another clause

Table 3: Selected syntax dependencies

Finally, we considered transition words and phrases to capture text cohesion, i.e., how ideas within a review relate to each other. We also leveraged an external lexical resource for this feature (Campbell et al.). Table 2 shows the list of main transition relationships (TR) used in this paper. We counted the number of transitions per review and normalized the value by review length (Transition%). We also calculated the ratio of each type of TR to capture individual preferences among TR per text (see Equation 5), where t is any transition term that appears in the review d and belongs to the i^{th} type of TR. N_{t_d} notes total number of transition terms in d.

$$Ratio(TR_i, d) = \frac{\sum_{t \in TR_i} tf(t,d)}{N_{t\_d}} \quad (5)$$

4.1.3 Syntax Features

The Stanford POS tagger was used to assign a single best fitting grammatical function (part of speech or POS) to every token. Per review, we calculated: 1) POS diversity, i.e., the number of unique POS tags, and normalized the value by total 36, which is the total number of POS tags considered by the tagger (Marcus et al., 1993), and 2) the prevalence of content bearing terms (see Equation 6), where tag is any POS tag that belongs to the i^{th} type of content words $Content\_W$ in review d. N_{tag_d} represents the total number of POS tags appeared in d. For each type of content words, we considered a set of POS tags shown as below:

- Nouns (i.e., NN, NNS, NNP & NNPS)
- Verbs (i.e., VB, VBD, VBG, VBN, VBP & VBZ)
- Adjectives (i.e., JJ, JJR & JJS)
- Adverbs (i.e., RB, RBR & RBS)

$$Ratio(Content\_W_i, d) = \frac{\sum_{tag \in Content\_W_i} count(tag,d)}{N_{tag\_d}} \quad (6)$$

Beyond the token level syntax features, we further used the Stanford NLP Parser to take the grammatical functions of words on the sentence level into account. Similar to our approach for using POS tags, for each review, we calculated: 1) syntax label diversity, where we normalized the number of unique syntax dependencies which appear in each review by the total number of dependency relations (N=48) given in the Stanford parser (De Marneffe et al., 2006), and 2) the ratio of each selected syntax dependency (see Table 3) to all dependencies occurring per review; using the Stanford typed dependencies for this task (De Marneffe & Manning, 2008).

4.2 Learning and Evaluation

After experimenting with various learning algorithms and observing SVM outperforming Naïve Bayes, we decided to present results based on training an SVM with a radial kernel. The classifier was implemented using the R package e1071 (Dimitriadou et al., 2011).

$$F1 = \frac{2 \times Precision \times Recall}{Precision + Recall} \quad \begin{cases} Precision = \frac{TP}{TP+FP} \\ Recall = \frac{TP}{TP+FN} \end{cases} \qquad (7)$$

In order to assess the performance of our features, we conducted a 10-fold cross validation, where we used all reviews (expert and non-expert) for 18 films for training, and documents from the remaining 2 films for testing. To create comparatively similarly sized folds, we sorted films by decreasing numbers of reviews, and iteratively combined the two films from each end into one fold. This non-standard way of partitioning the data was chosen to enable result interpretation and error analysis not only on the class label basis, but to also be able to see if certain films, e.g. on certain topics or from different release dates, impact predictability.

We evaluate the performance of the proposed approach using the standard metrics of precision, recall and the F1 score (see Equation 7). Since we code the class labels with 0 for experts and 1 for laymen, TP (i.e., true positives) represents the number of layman reviews that are correctly predicted while FP (i.e., false positives) is the number of reviews that are mistakenly predicted as layman reviews. TN (i.e., true negatives) and FN (i.e., false negatives) are defined in the same way, but for expert reviews.

5 Results and Analysis

5.1 Experimental Results

The overall prediction accuracy of our classifier is 90.70% (F1 score) (Table 4). While F1 values are fairly similar across evaluation metrics and films, recall is lower than precision and has a larger standard deviation (7.52%).

In general, high performance correlates with higher numbers of training instances, but not vice versa (Table 4). This concern is moderate as the Pearson correlation coefficient for F1 and the number of instances per fold is -0.65.

Also, precision (94.02%) is higher than recall (87.90%) on average (Table 4), which indicates that $\frac{TP}{TP+FP} > \frac{TP}{TP+FN} \stackrel{\text{def}}{=} FP < FN$ (Equation 7). Since we have the same number of training instances for each class (i.e., $TP + FN = TN + FP$), we can infer that $FP < FN \stackrel{\text{def}}{=} TN > TP$. The results suggest that overall, expert reviews are more accurately predictable than layman reviews. With a further comparison of the standard deviation between precision (4.59%) and recall (7.52%), this finding suggests that expert reviews show lower in-group variability than layman comments. This might be due to professional norms and standards.

The isolated contribution of each feature to prediction accuracy is shown in Table 5 (sorted by decreasing contribution), and the actual values per feature per class are provided in Table 6.

The syntax features have the highest isolated impact, which indicates that out of the considered features, grammar use contributes the most for distinguishing the considered two groups. Looking into POS diversity and parser label diversity as shown in Table 6, expert reviews (0.61 for POS diversity; 0.57 for syntax labels diversity) feature more complex syntax than layman reviews (0.44 for POS

Fold No.	Documentary	Precision	Recall	F1	# Instances

Length	Review length	69.63%	74.82%	71.79%
	Avg sentence length	79.29%	64.85%	71.12%

Table 5: Isolated contribution per feature (highest value per column in bold)

diversity; 0.37 for syntax labels diversity). However, this feature may correlate with review length, which is considerably higher for experts (362 words) than for laymen (107 words). Also, experts use more nouns than laymen, while laymen use more verbs and adjectives.

The choice of salient words (unigrams) has a strong impact on recall, while text informativeness (entropy) and transition words rather contribute to precision. Given the aforementioned definition of precision and recall, this result hints at some uniformity or consistency of word choice in laymen reviews, and at higher vocabulary diversity as well as more coherent structure in expert reviews. Sentiment is the weakest contributor to the prediction.

Further analyzing the differences between both groups (Table 6), we find that experts, in comparison to laymen, write longer reviews and longer sentences, use more complex syntax, provide more new information (i.e., expert reviews have higher entropy values than layman reviews), have a higher diversity in their vocabulary, and use fewer emotional words. Some of these features might correlate with review length, but overall, these findings might be explainable by a professional text production style that reflects established norms and rules of journalistic writing. Based on our data, short reviews are the strongest defining feature for non-expert reviews. Layman reviews are also more opinionated and emphasize points made more strongly (i.e., high and fluctuating Sentiment%).

In addition to these quantitative analyses, we conducted a qualitative analysis by reading through the top 20 unigrams (based on TF*IDF) for each film to better understand difference in content and writing between experts and laymen. Table 7 provides an illustrative example for two randomly selected films, and we refer to this example in the following discussion of descriptive features per category. Overall, we find that experts frequently refer to 1) people involved in making and producing films ("director"; "morgan," "spurlock"), 2) film titles ("inside," "job"), 3) cinematographic concepts ("moore" as *Michael Moore style*), and 4) awards and festivals. Also, experts connect issues addressed in films to current affairs and higher level topics ("obesity"), and provide details or background information (e.g., "hubbard"; who frequently appeared in expert reviews of INJO, represents *Glenn Hubbard;* an economist who previously worked for the federal government). Expert reviews entail specific concepts ("obesity") and formalities ("Mr."), while laymen use more casual terms ("fat"; "bad"). Laymen reviews represent substantial engagement with the topic of a film ("eat"; "diet"), contextualize issues in peoples' regular lives ("people"; "day"; "money"; "job"; "school"; "healthy"), and contain more subjective terms ("good"; "bad").

Feature	Expert (AVG±STD)	Layman (AVG±STD)

Table 6: Values and variance of features per class

5.2 Error Analysis

The confusion matrix (Table 8) shows that our classifier predicts expert reviews with higher accuracy (93.36%) than laymen reviews (86.17%). More importantly, laymen are more likely to be mistaken for experts (13.83%) than

SPSZM	Expert	size, spurlock, mcdonald, super, film, year, days, director, big, moore, month, obesity, company, million, morgan, day, people, festival, burger, american
	Layman	mcdonalds, people, spurlock, movie, film, diet, mcdonald, eat, day, fat, make, school, healthy, bad, time, eating, good, watch, body, experiment
INJO	Expert	ferguson, inside, film, job, charles, crisis, director, men, mr, company, financial, global, banks, documentary, bankers, economic, end, hubbard, street, crash
	Layman	film, movie, wall, people, government, street, job, money, documentary, banks, great, financial, crisis, inside, world, watch, good, american, loans, made

Table 7: Top 20 Unigrams for Case Study

vice versa (6.64%). Looking into laymen reviews labeled as expert reviews, we find that these texts are long, detailed, and contain subject matter expertise. Expert reviews that got misclassified as laymen reports were typically short. These findings further substantiate our previously made point that some laymen write expert-level reviews, and vice versa.

To analyze our prediction errors more in depth, we selected a random sample (N=62) of misclassified reviews from both classes. We removed the class labels from these documents and asked two independent human annotators to code the texts as expert or layman reviews. Their inter-coder agreement was 45.2%, which suggests that categorizing these cases is also hard for humans.

We further discussed the label assignments with our two human coders. Trends emerging from their observations and our discussion are summarized in Table 9, where we synthesize the humans' feedback into a high or low value per identified feature and class. The features and values that the humans identified strongly overlap with those considered for supervised learning, e.g., level of detail (high for experts), subject matter expertise (high for experts), emotionality (high for laymen), and formal (experts) versus informal (laymen) writing styles. Beyond that, the close reading analysis also revealed additional features, e.g., differences in the usage of personal pronouns ("I" for laymen) and comparatives and superlatives (high for laymen), which can be used in future work, e.g. as new features. Overall, the majority of cases where both the classifier and the humans were incorrect are short expert reviews.

		Prediction	
		Expert	Layman
Truth	Expert	93.36%	6.64%
	Layman	13.83%	86.17%

Table 8: Error analysis

6 Discussion, Conclusions and Limitations

We have developed a binary classifier that predicts whether a review was authored by an expert or a layman with an accuracy of (90.70% (F-measure). Our work is novel with respect to its goal, focus, and potential applications. While prior work has focused on predicting commercially motivated

Features identified by human coders	**Expert**	**Layman**
Deep analysis including identification of different opinions about a given topic	High	Low
Technical details, e.g. running time, and screenings references, such as film festivals and award nominations	High	Low
Movie jargon, subject matter expertise about film-making ("guerrilla filmmaking style")	High	Low
Words and short phrases with strong emotions ("I strongly recommend this film to any ocean lover")	Low	High
Comparatives and superlatives ("Charles Ferguson made the best documentary")	Low	High
Personal pronouns used as self-reference to reviewer ("I")	Low	High
Questions to convey disbelief ("What about the effort to find the person, or people who did do it?")	Low	High
Casual, informal style ("In the second doc").	Low	High
Words with all letters in upper case ("Watch this film NOW").	Low	High
Smaller variability in vocabulary (e.g., duplicated words/phrases)	Low	High
Grammatical errors, sloppiness	Low	High

Table 9: Manually identified features and values

features, e.g. the rating, helpfulness, and sentiment of reviews, we aim to predict the type of author. We believe that this work enhances our understanding of the impact of issue-focused media, in our case documentary films, on different types of users.

Our results suggest that experts write comparatively lengthier and more detailed reviews with more complex grammar, higher entropy, and lower emotionality. Laymen are less object (noun) and more action (verb) oriented, and engage more emotionally with the content of a film. The relevance of these features was empirically demonstrated, and then manually verified and extended by human judges.

The generalizability of our findings is limited by several choices we made: First, we worked with data from two particular sources, i.e., expert reviews published mainly in major newspapers and retrieved from LexisNexis Academic, and laymen reviews collected from Amazon. Although our data come from different platforms, we argue that the considered text features are not a function of the type of source, but of the way in which experts versus laymen express their impressions of a film. Second, the first choice furthermore entails the assumption that user-generated reviews on Amazon are authored by laymen, while professional writers author expert reviews. We have shown that this assumption does not always hold: For the case of erroneous predictions, laymen are about twice as likely to be identified as experts than vice versa. Third, we also tried to use additional sources of reviews, but were constrained by the terms of service for these sites (e.g., Metacritic, Rotten Tomatoes). Fourth, since our primary goal is feature selection and analysis, we report results based on only one learning algorithm, namely SVM. In the future, we plan to explore the contribution of our binary classifier as a feature for predicting review ratings, helpfulness and authenticity. We will also test if prediction accuracy can be further increased by adding features that were detected by our human annotators during the error analysis process, namely the consideration of personal pronouns, comparatives and superlatives.

Finally, even though it is peripheral to the NLP work presented in this paper, looking at our results from a social or media impact assessment perspective, we find that laymen do engage with the content of a film, and contextualize issues raised in documentaries in their personal lives. These effects indicate public awareness and impact on information consumers. Our work might help researchers and practitioners in the field of impact assessment to understand how different groups of stakeholders reflect on a topic or a work of art (Barrett & Leddy, 2008; Chattoo & Das, 2014; Clark & Abrash, 2011; Diesner et al., 2014; Green & Patel, 2013; John & James, 2011; Napoli, 2014).

Acknowledgement

Abstract

Representing structured events as vectors in continuous space offers a new way for defining dense features for natural language processing (NLP) applications. Prior work has proposed effective methods to learn event representations that can capture syntactic and semantic information over text corpus, demonstrating their effectiveness for downstream tasks such as event-driven stock prediction. On the other hand, events extracted from raw texts do not contain background knowledge on entities and relations that they are mentioned. To address this issue, this paper proposes to leverage extra information from knowledge graph, which provides ground truth such as attributes and properties of entities and encodes valuable relations between entities. Specifically, we propose a joint model to combine knowledge graph information into the objective function of an event embedding learning model. Experiments on event similarity and stock market prediction show that our model is more capable of obtaining better event embeddings and making more accurate prediction on stock market volatilities.

1 Introduction

Text mining techniques have been used to perform event-driven stock prediction (Ding et al., 2015). The main idea is to learn distributed representations of structured events (i.e. event embeddings) from text, and use them as the basis to generate textual features for predicting price movements in stock markets. Here the definition of *events* follows the open information extraction literature (Fader et al., 2011; Yates et al., 2007), which has seen applications in semantic parsing (Berant et al., 2013), information retrieval (Sun et al., 2015) and text mining (Ding et al., 2014). Formally, an event is defined as a tuple (A, P, O), where A represents the agent, P represents the predicate and O represents the object. For example, "Microsoft profit rises 11 percent" can be represented as the event tuple (A ="Microsoft profit", P ="rises", O ="11 percent"). In addition, the main advantages of *event embeddings* include (1) they can capture both the syntactic and the semantic information among events and (2) they can be used to alleviate the sparsity of discrete events compared with one-hot feature vectors. The learning principle is that events are syntactically or semantically similar should have similar vectors.

The *event embedding* method of Ding et al. (2015) is based on *word embeddings* of the agent, predicate and object of an event. Neural tensor networks are used to combine the embeddings of the three components into embedding vectors of events. For training, one component of gold-standard event is randomly flipped to synthesize negative examples. This form of event embedding method suffers from some limitations. First, the obtained event embeddings cannot capture the relationship between two syntactically or semantically similar events if they do not have similar word vectors. On the other hand, two events with similar word embeddings, such as "Steve Jobs quits Apple" and "John leaves Starbucks" may have similar embeddings despite that they are quite unrelated. One important reason for the problem is the lack of background knowledge in training event embeddings. In particular, if it is known that "Steve Jobs" is the CEO of "Apple", and "John" is likely to be a customer at "Starbucks", the two events can have very different embeddings according to their semantic differences.

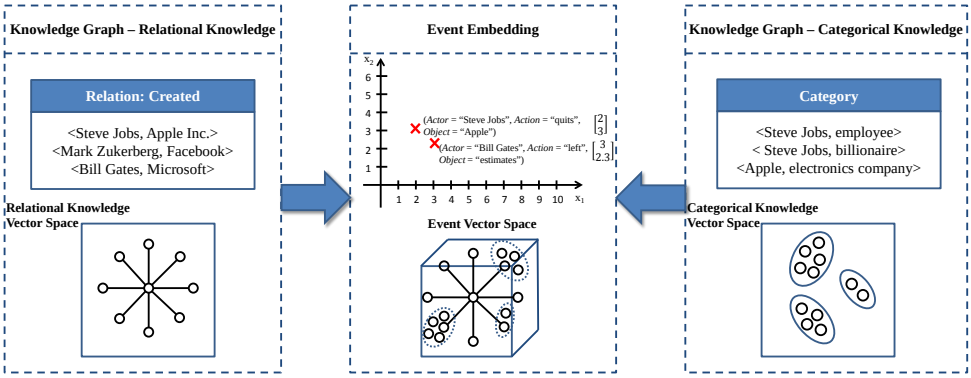

Figure 1: Incorporating knowledge graph into the learning process for event embeddings.

We propose to incorporate the external information from knowledge graphs, such as Freebase (Bollacker et al., 2008) and YAGO (Suchanek et al., 2007), into the learning process to generate better event representations. A knowledge graph stores complex structured and unstructured knowledge, and usually contains a set of vertices representing *entities* and a set of edges corresponding to the *relations* between entities. It commonly contains two forms of knowledge: *categorical knowledge* and *relational knowledge*. While categorical knowledge encodes the attributes and properties of certain entities, such as "programmer", "employee" for the person Mark Zuckerberg, relational knowledge encodes the relationship between entities, such as hasEconomicGrowth, isCEOof, etc. Both categorical knowledge and relational knowledge are useful for improving event embeddings. More specifically, categorical knowledge can be used for correlating entities with similar attributes, and relational knowledge can be used to differentiate event pairs with similar word embeddings.

We propose a novel framework for leveraging both categorical knowledge and relational knowledge in knowledge graphs for better event representations. As shown in Figure 1, we propose a coherent model to jointly embed knowledge graph and events into the same vector space, which consists of three components: the events model, the knowledge model, and the joint model. A neural tensor network is used to learn baseline event embeddings, and we define a corresponding loss function to incorporate knowledge graph information, by following recent work on multi-relation models (Socher et al., 2013).

Large-scale experiments on a YAGO corpus show that incorporating knowledge graph brings promising improvements to event embeddings. With better embeddings, we achieve better performance on stock prediction compared to the state-of-the-art methods.

2 Related Work

Stock Market Prediction There has been a line of work predicting stock markets using text information from daily news (Lavrenko et al., 2000; Schumaker and Chen, 2009; Xie et al., 2013; Peng and Jiang, 2015; Li et al., 2016). Pioneering work extracts different types of textual features from news documents, such as bags-of-words, noun phrases, named entities and structured events. Ding et al. (2014) show that structured events from open information extraction (Yates et al., 2007; Fader et al., 2011) can achieve better performance compared to conventional features, as they can capture structured relations. However, one disadvantage of structured representations of events is that they lead to increased sparsity, which potentially limits the predictive power. Ding et al. (2015) propose to address this issue by representing structured events using event embeddings, which are dense vectors. This paper proposes to leverage ground truth from knowledge graph to enhance event embeddings.

Knowledge Graph Embedding Recently, several methods have been explored to represent and encode knowledge graph (Bordes et al., 2013; Bordes et al., 2014; Chang et al., 2013; Ji et al., 2015; Lin et al., 2015) in distributed vectors. In this line of work, each entity is represented as a d-dimensional vector and each relation between two entities is modeled by using a matrix or a tensor. Most existing methods learn knowledge embeddings by minimizing a global loss function over all the entities and relations in

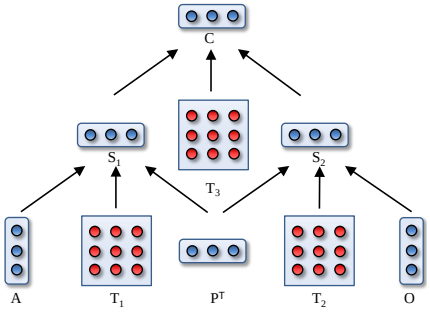

Figure 2: Baseline event-embedding model.

a knowledge graph. Entity vectors can encode global information over the knowledge graph, and hence are useful for knowledge graph completion (Socher et al., 2013). In this paper, we encode entity vectors into the learning process for event embeddings, so that information of knowledge graphs can be used for event-driven text mining and other tasks. Socher et al. (2013) has shown that previous work (Bordes et al., 2011; Jenatton et al., 2012; Bordes et al., 2012; Sutskever et al., 2009; Collobert and Weston, 2008) are special cases of their model, which is based on a neural tensor network. We follow Socher et al. (2013) and use tensors to represent relations in knowledge graph embeddings.

Our work is also related to prior research on joint embedding of words and knowledge graphs (Xu et al., 2014; Wang et al., 2014; Tian et al., 2016; Yang et al., 2014). Such work focuses on injecting semantic knowledge into distributed word representations, thus enhancing their information content. The resulting embeddings of words and phrases have been shown useful for improving NLP tasks, such as question answering and topic prediction. In comparison, our work integrates knowledge into vector representations of events, which was shown more useful than words for certain text mining tasks.

3 Knowledge-Driven Event Representations

We begin by introducing the baseline event embedding learning model, which serves as the basis of proposed framework. Then, we show how to model knowledge graph information. Subsequently, we describe the proposed joint model by integrating knowledge into the original objective function to help learn high-quality event representations. At the end of this section, we introduce the training process of the proposed framework in details.

3.1 Event Embedding

The goal of event embedding is to learn low-dimension dense vector representations for event tuples $E = (A, P, O)$, where P is the action or predicate, A is the actor or subject and O is the object on which the action is performed. We take the neural tensor network model of Ding et al. (2015) as the basis of our proposed framework. The architecture of neural tensor network for learning event embeddings is shown in Figure 2, where the bilinear tensors are used to explicitly model the relationship between the actor and the action, and that between the object and the action.

The inputs of the neural tensor network (NTN) are the word embeddings of A, P and O, and the outputs are event embeddings. We learn an initial word representation of d-dimensions ($d = 100$) from a large-scale financial news corpus, using the skip-gram algorithm (Mikolov et al., 2013). As most event arguments consist of several words, we represent the actor, action and object as the average of their word embeddings, respectively, allowing the sharing of statistical strength between the words describing each component (e.g. *Nokia's mobile phone business* and *Nokia*).

From Figure 2, $S_1 \in \mathbb{R}^d$ is computed by:

$$S_1 = g(A, P) = f\left(A^T T_1^{[1:k]} P + W \begin{bmatrix} A \\ P \end{bmatrix} + b\right), \quad (1)$$

where $T_1^{[1:k]} \in \mathbb{R}^{d \times d \times k}$ is a tensor, which is a set of k matrices, each with $d \times d$ dimensions. The bilinear tensor product $A^T T_1^{[1:k]} P$ is a vector $r \in \mathbb{R}^k$, where each entry is computed by one slice of the tensor ($r_i = A^T T_1^{[i]} P, i = 1, \cdots, k$). The other parameters are a standard feed-forward neural network, where $W \in \mathbb{R}^{k \times 2d}$ is the weight matrix, $b \in \mathbb{R}^k$ is the bias vector, and $f = tanh$ is the activation function. S_2 and C in Figure 2 are computed in the same way as S_1.

We also experiment with randomly initialized word vectors as the input of NTN, which are commonly used in previous work on structured embeddings from knowledge graphs (Bordes et al., 2011; Jenatton et al., 2012). In our case, pre-trained word embeddings give slightly better results as compared with randomly initialized embeddings.

We assume that event tuples in the training data should be scored higher than corrupted tuples, in which one of the event arguments is replaced with a random argument. Formally, the corrupted event tuple is $E^r = (A^r, P, O)$, which is derived by replacing each word in A with a random word w^r in our dictionary $\mathcal{D}$ (which contains all the words in the training data) to obtain a corrupted counterpart A^r. We calculate the *margin loss* of the two event tuples as:

$$L_{\mathcal{E}} = loss(E, E^r) = \max(0, 1 - g(E) + g(E^r)) + \lambda \|\Phi\|_2^2, \tag{2}$$

where $\Phi = (T_1, T_2, T_3, W, b)$ is the set of model parameters. The standard L_2 regularization is used, for which the weight λ is set as 0.0001. The algorithm goes over the training set for multiple iterations. For each training instance, if the loss $loss(E, E^r) = \max(0, 1 - g(E) + g(E^r))$ is equal to zero, the online training algorithm continues to process the next event tuple. Otherwise, the parameters are updated to minimize the loss using standard back-propagation (BP) (Rumelhart et al., 1985).

3.2 Knowledge Graph Embedding

Knowledge graph embedding is mainly used to encode whether two entities (e_1, e_2) are in a certain relationship R (e.g. (Steve Jobs, Apple Inc.) has a relation "created"). To incorporate categorical knowledge, we expand the definition of (e_1, R, e_2) so that e_2 can also be an attribute of e_1 and R can also be an attribute type (e.g. (Steve Jobs, Profession, CEO)). Inspired by recent studies on learning distributed representations of multi-relational data from knowledge graph (Socher et al., 2013), we use a neural tensor network framework for knowledge graph embedding.

There are two significant differences when a neural tensor network is used for knowledge graph embedding, compared to when it is used for event embedding. First, we model a relation type in a knowledge graph by using a tensor rather than a vector. This is because the number of relation types in knowledge graph is limited, and using a tensor can increase the expressive power. Second, we use a simpler neural tensor network model to learn knowledge graph embedding, which is easier to train. In contrast, the baseline event embedding model uses a recursive neural tensor network architecture to preserve the original structure of events.

The neural tensor network replaces a standard linear neural network layer with a bilinear tensor layer, which directly relates the two entity vectors across multiple dimensions. The model computes the probability that two entities are in a certain relationship by the following function:

$$g(e_1, R, e_2) = \mu_R^T f\left(e_1^T H_R^{[1:k]} e_2 + V_R \begin{bmatrix} e_1 \\ e_2 \end{bmatrix} + b_R\right), \tag{3}$$

where $f = tanh$ is the activation function, applied element-wise, $H_R^{[1:k]} \in \mathbb{R}^{d \times d \times k}$ is a tensor that consists of a set of $d \times d$ matrices, and the bilinear tensor product $e_1^T H_R^{[1:k]} e_2$ results in a vector $x \in \mathbb{R}^k$, where each entry is computed by on slice $i = 1, \cdots, k$ of the tensor: $x_i = e_1^T H_R^{[i]} e_2$. The other parameters for the relation R are the standard form of a neural network, where $V_R \in \mathbb{R}^{k \times 2d}$ and $b_R \in \mathbb{R}^k$.

The main method for training relation embeddings in knowledge graphs is similar to that for training the baseline event embeddings — each relation tuple in the training set $T^{(i)} = (e_1^{(i)}, R^{(i)}, e_2^{(i)})$ should receive a higher score than a corrupted tuple, in which one of the entities is replaced with a random

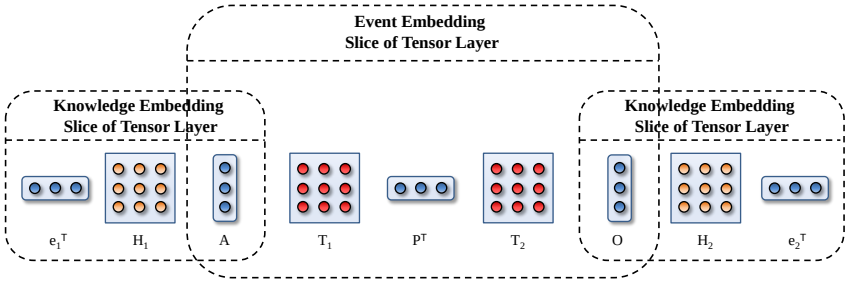

Figure 3: Architecture of the joint embedding model (only showing the tensor layer).

entity. Given a gold-standard tuple $T^{(i)} = (e_1^{(i)}, R, e_2^{(i)})$, the corresponding corrupted tuple is denoted as $T_c^{(i)} = (e_1^{(i)}, R^{(i)}, e_c^{(i)})$, where $e_c^{(i)}$ is the corrupted version of $e_2^{(i)}$. The set of all parameters is $\Omega = \{\mu, H, V\}$. We minimizing the following objective:

$$L_{\mathcal{K}} = \sum_{i=i}^{N} \sum_{m=1}^{M} max\left(0, 1 - g(T^{(i)}) + g(T_c^{(i)})\right) + \lambda \|\Omega\|_2^2, \tag{4}$$

where N is the number of training tuples, and the training objective scores the correct relation tuple higher than its corrupted version up to a margin of 1. For each correct tuple, we sample M randomly corrupted counterparts. We use standard L_2 regularization of all parameters, weighted by the hyperparameter λ.

3.3 Joint Knowledge and Event Embedding

Given a training event corpus $\mathcal{E}$ and a set $\mathcal{K}$ of relation tuples extracted from a knowledge graph, our model jointly minimizes a linear combination of the loss functions on both events and knowledge:

$$L = \alpha L_{\mathcal{E}} + (1 - \alpha) L_{\mathcal{K}} \tag{5}$$

where $\alpha \in [0, 1]$ is a model parameter to weight the two loss functions (the best development results were obtained with $\alpha = 0.4$). $\mathcal{E}$ and $\mathcal{K}$ share the same parameters — the embedding vectors for entities in events and their corresponding entities in knowledge graph are required to be the same.

Figure 3 shows the architecture of the proposed joint model. The algorithm is centralized on the event tuple (A, P, O), which is used to train the tensor values T_1, T_2 and T_3 in Figure 2. Two relations in the knowledge graph, H_1, H_2, which share entities A and O with the event, are shown on the two sides of Figure 3, respectively. By the shared entities A and O between events and knowledge relations. T_1, T_2, T_3, H_1 and H_2 can be trained simultaneously. Here relational knowledge can help incorporate information of the learned event representations by utilizing ground-truth relations between entities. Categorical knowledge can encode the entity information of the learned event representations by clustering similar entities together. The base event embedding model can preserve the structures of events.

Training The joint model is trained by taking the derivatives of the joint objective function with respect to the four groups of parameters T_1, T_2, H_1 and H_2, respectively. We have four derivatives for the i'th slice of the full tensor:

$$\frac{\partial g(e_1, R, A)}{\partial H_1^{[i]}} = \mu_i f'(z_i) e_1 A^T, z_i = e_1^T H^{[i]} A + V_i \begin{bmatrix} e_1 \\ A \end{bmatrix} + b_i; \frac{\partial g(A, P)}{\partial T_1^{[i]}} = \mu_i f'(z_i) A P^T, z_i = A^T T^{[i]} P + W_i \begin{bmatrix} A \\ P \end{bmatrix} + b_i$$

$$\frac{\partial g(O, R, e_2)}{\partial H_2^{[i]}} = \mu_i f'(z_i) O e_2^T, z_i = O^T H^{[i]} e_2 + V_i \begin{bmatrix} O \\ e_2 \end{bmatrix} + b_i; \frac{\partial g(P, O)}{\partial T_2^{[i]}} = \mu_i f'(z_i) P O^T, z_i = P^T T^{[i]} O + W_i \begin{bmatrix} P \\ O \end{bmatrix} + b_i$$

Table 1: Statistics of datasets.

	Training	Development	Test
#documents	442,933	110,733	110,733
#words	333,287,477	83,247,132	83,321,869
#events	295,791	34,868	35,603
time interval	02/10/2006 - 18/06/2012	19/06/2012 - 21/02/2013	22/02/2013 - 21/11/2013

z_i denotes the i'th element of the hidden tensor layer. We use minibatched L-BFGS (Nocedal, 1980) for optimization, which converges to a local optimum of our non-convex objective function. The rest of the model parameters, including μ, T_3, W, b and V, are trained in the same way as the baseline single models, for which the derivatives are calculated using standard back-propagation. It is the shared entities A and O that allow information exchange in training the values of T_1, T_2, H_1 and H_2, thereby improving the vector representations of structured events through relational and categorical knowledge.

4 Experiments

The performance of our knowledge-powered event embedding model is compared with state-of-the-art baselines by evaluating the quality of learned event embeddings on two tasks: event similarity and stock market prediction.

4.1 Experimental Settings

We use publicly available financial news from Reuters and Bloomberg over the period from October 2006 to November 2013, released by Ding et al. (2014). There are 106,521 documents in total from Reuters News, from which we extracted 83,468 structured events. From Bloomberg News, there are 447,145 documents, from which 282,794 structured events are extracted.

The structured events are extracted from news text using Open IE (Fader et al., 2011) and dependency parsing (Zhang and Clark, 2011), by strictly following the method of Ding et al. (2015). The timestamps of the news are also extracted, for alignment with stock price information. We conduct stock market prediction experiments on predicting the Standard & Poor's 500 stock (S&P 500) index and its individual stocks, obtaining indices and prices from Yahoo Finance. Detail statistics of the training, development (tuning) and test sets are shown in Table 1. For training knowledge-driven event embeddings, we use YAGO as the knowledge graph. The full knowledge graph consists of 10 million entities and 120 million facts, in more than 100 predefined relation types. We extract a sub knowledge graph of two thousand entities and more than 30 thousand relations for the experiments, which contains knowledge relevant to our news event data.

4.2 Task Description

Event Similarity We investigate whether the similarity between vector event representations is consistent with human-labeled event similarity, and whether better event representation is more useful for stock prediction. As there is no publicly available event similarity evaluation data, we conduct a set of human evaluations. Each event pair is associated with three independent human judgments on similarity and relatedness on a scale from 0 to 5, where 0 means that the event pair is completely dissimilar, and 5 indicates that the event pair has a strong similarity relation. For example, (Steve Jobs, quits, Apple) and (Steve Ballmer, quits, Microsoft) received an average score of 4.6, while (Steve Jobs, quits, Apple) and (John, leaves, Starbucks) received an average score of 0.4.

Similarity scores are computed by cosine similarity of embedding vectors for each event pair, based on which a ranked list is constructed. It is compared to the ranked list produced by the manual similarity scores according to human judgments. To evaluate the consistency between two ranking lists, we use Spearman's Rank Correlation ($\rho \in [-1, 1]$). A higher ρ corresponds to better event representation vectors. We compare our knowledge-driven event embedding (denoted as KGEB) with the baseline method proposed by Ding et al. (2015) (denoted as EB), and discrete event vectors with semantic lexicons based generalization method proposed by Ding et al. (2014) (denoted as DE).

Table 2: Experimental results on event similarity and its effect on S&P 500 index prediction. The improvement is significant at $p < 0.05$.

Methods	Spearman's Rank Correlation	Acc	MCC
DE	0.437	58.83%	0.1623
EB	0.591	64.21%	0.4035
KGEB	**0.616**	**66.93%**	**0.5072**

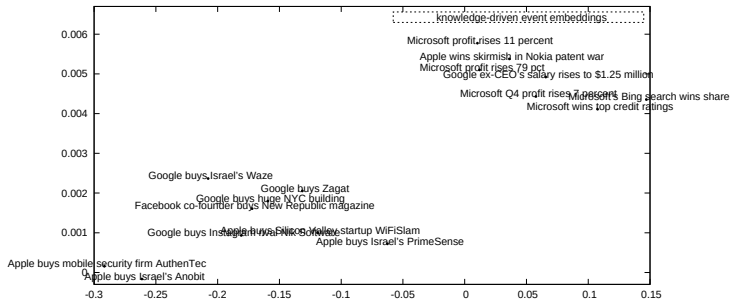

Figure 4: Two-dimensional PCA projection of 100-dimensional knowledge-driven event vectors.

Stock Prediction The stock prediction task can be treated as a binary classification problem. Following Tetlock et al. (2008), we automatically align 1,782 instances of daily trading data with news documents from the previous day. Specifically, we use the news information in day $t-1$ to predict price movements of stock market in day t. The output classification result [Class +1] represents that the stock closing price will increase compared with the opening price in day t, and [Class -1] represents that the stock closing price will decrease compared with the opening price in day t. Following Das and Chen (2007) and Xie et al. (2013), the standard measure of accuracy (Acc) and Matthews Correlation Cofficient (MCC) are used to evaluate the performances on S&P 500 index prediction and individual stock prediction.

The baseline methods are three state-of-the-art news-based stock market prediction systems: Luss and d'Aspremont et al. (2012) propose using bags-of-words to represent news documents, and constructing the prediction model by using Support Vector Machines (SVMs); Ding et al. (2014) report a system that uses structured event tuples $E = (A, P, O)$ to represent news documents, and investigate the complex hidden relationships between events and stock price movements by using a standard feedforward neural network; Ding et al. (2015) learn event embeddings for representing news documents, and build a prediction model based on a deep convolutional neural network. Ding et al. (2015) show that deep convolutional neural networks (CNN) are more powerful than SVMs and standard feedforward neural networks. As a result, we use CNN as the prediction model.

4.3 Results

Event Similarity As shown in Table 2, we compare the performance of different event representation methods and their effects on S&P 500 index prediction. We find that although discrete event vectors are generalized by semantic lexicons (WordNet and VerbNet), the performance of KGEB is dramatically better than DE. This is mainly because the word coverage of semantic lexicons is limited, and the discrete representation is highly sparse. KGEB achieves better performance compared with EB on this task. The main performance gain results from better similarity between semantically related but lexically different events, thanks to the integration of knowledge. For example, "Steve Jobs quits Apple" and "John leaves Starbucks" have dissimilar vectors although they share similar word embeddings, as Steve Jobs is the CEO of Apple Inc. but John has no relationship with Starbucks encoded in knowledge graph. With the best event representation method, KGEB-based stock prediction achieves the best performance.

Figure 4 shows case studies on events about Google, Apple, Microsoft and Facebook. In particular, we apply two-dimensional PCA projection on the 100-dimensional event embeddings. It can be seen from the figure that by incorporating knowledge graph information, the joint model allows those events that correspond to the same semantic or topic to be close to each other.

S&P 500 Index Prediction We test the influence of knowledge-driven event embeddings on stock prediction by comparing KGEB with bag-of-words representations (Luss and d'Aspremont, 2012), structured

Table 3: Experimental results on index prediction.

	Acc	MCC
Luss and d'Aspremont (2012)	56.38%	0.0711
Ding et al. (2014)	58.83%	0.1623
WB-CNN	60.57%	0.1986
Ding et al. (2015)	64.21%	0.4035
KGEB-CNN	**66.93%**	**0.5072**

Figure 5: Experimental results on individual stock prediction (companies are named by ticker symbols).

event representations (Ding et al., 2014), baseline event embedding representations (Ding et al., 2015) and word embedding representations on the test dataset. A word embedding input (WB) consists of the sum of each word vector in a document; it addresses sparsity in word-based inputs, and can serve as a baseline embedding method. The experimental results are shown in Table 3. We find that:

(1) Comparison between the word-based models and event-based models (e.g. Luss and d'Aspremont (2012) vs Ding et al. (2014), WB-CNN vs Ding et al. (2015), WB-CNN vs KGEB-CNN) shows that events are more capable for representing news documents for stock prediction.

(2) Comparison between Ding et al. (2015) and KGEB-CNN shows that knowledge-driven event embeddings are more powerful than the baseline event embeddings. The main reason is that knowledge graph provides valuable ground-truth knowledge, which is helpful for learning better event embeddings. For example, "Chrysler recalls 919,545 Jeep SUVs" and "GM recalls nearly 474,000 cars" can be related, as "Chrysler" and "GM" are two automobile manufacturers, and Jeep SUV is a car model, which are recorded in the knowledge graph.

Individual Stock Prediction We compare our knowledge-driven event embeddings with the baseline methods on individual stock prediction, using the 15 companies selected by Ding et al. (2015) from S&P 500. The list consists of samples from high-ranking, middle-ranking, and low-ranking companies from S&P 500 according to the Fortune Magazine. The results are shown in Figure 5 (as space is limited, we only show comparison between KGEB-CNN and the three baselines). We find that knowledge-driven event embeddings achieve consistently better performances compared to the three baseline methods, on both S&P 500 index prediction and individual stock prediction. In most previous work, the accuracies of individual stock prediction are higher when only company-related news are used as inputs, compared with when sector-related news are used (Ding et al., 2014). This is because it is difficult to investigate the relationship among companies, and therefore news about other companies can be noise for predicting the stock prices of a company. However, knowledge graph can provide attributes of entities and relations between them, hence it is possible to learn more information from related companies to help decide the direction of individual stock price movements. For example, given that the news "GM recalls nearly 474,000 cars" leads to its stock price decrease in the training data, it can be predicted that Ford shares will fall next day according to the news "Ford is recalling about 433,000 2015 Focus" in the test data.

5 Conclusion

High-quality event representations are valuable for many text mining and NLP downstream applications. This paper proposed to incorporate knowledge graph into the learning process of event embeddings, which can encode valuable background knowledge. Experimental results on event similarity and stock

prediction showed that knowledge-powered event embeddings can improve the quality of event representations and benefit the downstream application.

Abstract

In this paper, we propose an approach to learn distributed representations of users and items from text comments for recommendation systems. Traditional recommendation algorithms, e.g. collaborative filtering and matrix completion, are not designed to exploit the key information hidden in the text comments, while existing opinion mining methods do not provide direct support to recommendation systems with useful features on users and items. Our approach attempts to construct vectors to represent profiles of users and items under a unified framework to maximize word appearance likelihood. Then, the vector representations are used for a recommendation task in which we predict scores on unobserved user-item pairs without given texts. The recommendation-aware distributed representation approach is fully supported by effective and efficient learning algorithms over massive text archive. Our empirical evaluations on real datasets show that our system outperforms the state-of-the-art baseline systems.

1 Introduction

With the prosperity of Internet-based e-commerce in the last decade, millions of item (e.g., product/serivce) comments are now available online and even more are flooding in an explosive manner. Yelp (www.yelp.com), as the largest restaurant comment web site, for example, attracts more than 140 million users to contribute new text comments every month, covering almost all restaurants in USA. It is widely believed that text comments contain much richer information on users as well as items than dull scores, with far more precise descriptions on personal preferences and item features. To fully unleash the potential value underneath the text comments, huge research efforts are now devoted to the design and development of new technologies to capture and understand the semantics in the comments, particularly those associated with users and items. The text analytical outcomes are expected to support decision making and provide new business opportunities in e-commerce.

Recommendation is recognized as one of the most important components in e-commerce systems, driving the growth of profits. Traditional recommendation systems rely on scores over user-item pairs under a bipartite graph model, such that accurate score prediction over unobserved user-item pair helps the system to identify potential interested buyers. A huge bulk of prediction and recommendation strategies are proposed in this domain, e.g. collaborative filtering and matrix completion (Sarwar et al., 2001; Koren et al., 2009). Because of the limited information included in each individual score, such recommendation strategies commonly suffer from the cold-start problem (Zhou et al., 2011), which returns poor recommendations to newcoming users. While text mining on comment archive may provide important information to the recommendation engine, even for fresh users, the integration of such information adds new complexity and challenges to the system, since the text mining results are not directly useful to the recommendation algorithms. In particular, most of the opinion mining techniques available in the literature (Liu and Zhang, 2012; Melville et al., 2002) do not distinguish attributes on user preference from attributes of items. The recommendation engines are thus unable to understand the underlying reasons behind the good and poor opinions from the users on the items. While there are

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2143–2153, Osaka, Japan, December 11-17 2016.

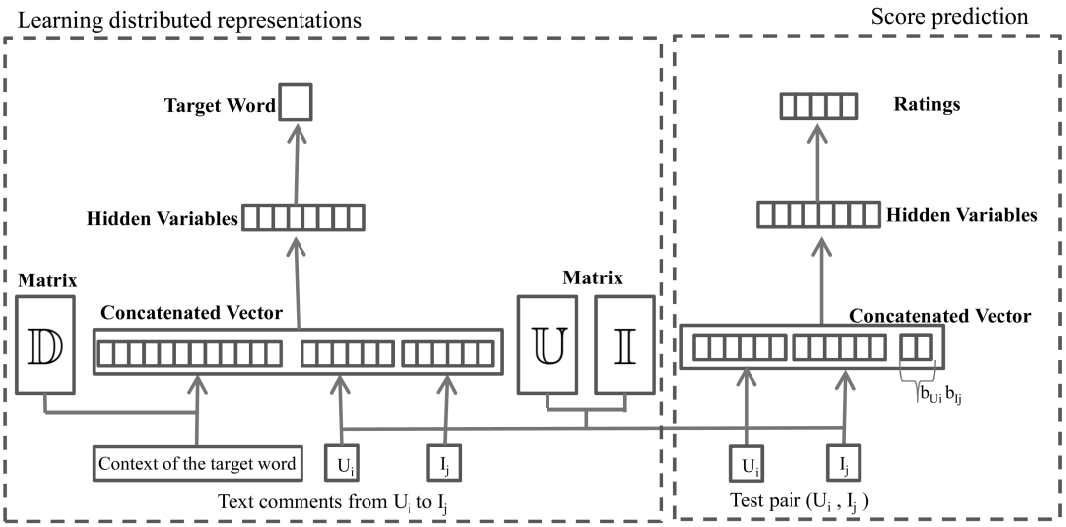

Figure 1: Our framework for learning distributed representations for recommendation

attempts on tightly connecting recommendation and text mining, e.g. (McAuley and Leskovec, 2013; Almahairi et al., 2015), these studies make strong assumptions on the generative mechanism behind the text comments and scores, which may not correctly reflect the interaction between user preferences and item attributes appropriately.

To better exploit the value of text comments for recommendation engine, we propose a simple yet effective approach inspired by the successful distributed representation models on text semantics extraction (Le and Mikolov, 2014; Mikolov et al., 2013). In our approach, we learn distributed representations from text comments to represent users and items. Our approach has a number of unique advantages, which make it a promising alternative to existing feature extraction methods used in comment-based recommendation systems. Firstly, the distributed representations on users and items are aligned, enabling the employment of a huge cluster of classification approaches on prediction and recommendation. Secondly, distributed representations do not rely on any assumption on the generative procedures over the user-generated contents. This feature generally avoids the potential bias on the analytical outcomes, caused by inappropriate setting on the priors, and finally saving computation overheads. Thirdly, the distributed representations work well on both long and short texts. It is thus likely to enhance the usefulness of the mining outcomes, by training over text data from multiple sources, e.g. food blogs and restaurant comments.

In our approach, we adapt the vectorization techniques used in the training of distributed representations over words and documents, to address the problem of factor decomposition between user preferences and item attributes. User vectors and item vectors are introduced as independent representations to the target users and items correspondingly and are learned by a neural network. In the model, the user vector is shared across the comments written by the same user and the item vector is shared across the comments written on the same item. Then, the vector representations are included in the training of the task of score prediction in which we predict rates on unobserved user-item pairs without given texts. The experimental results on real datasets show that our approach generates a significant margin of performance advantage over existing methods in the task of score prediction.

2 Preliminaries

In this section, we define the task of score prediction and introduce the background of distributed representations of words and documents.

2.1 Score Prediction

Assume that we have a fixed group of n users $\mathbb{U} = \{U_1, U_2, \ldots, U_n\}$ and a fixed group of m items $\mathbb{I} = \{I_1, I_2, \ldots, I_m\}$. Here, an item I_j can be either a product or a service, provided to all the users in $\mathbb{U}$ without any restriction. Each comment C_k in database $\mathbb{C} = \{C_1, C_2, \ldots, C_l\}$ composes a sequence of L_k words $\{w_1, w_2, \ldots, w_{L_k}\}$, with every word drawn from a known dictionary $\mathbb{D}$. Each comment C_k is also uniquely associated with a user $U_i \in \mathbb{U}$, an item $I_j \in \mathbb{I}$ and a score S_k. It indicates that user U_i purchases item I_j with score S_k and detailed text comments in C_k. The recommendation system is expected to return a group of items to each user U_i, such that the user U_i is more likely to buy these items with high scores and good comments. Therefore, the problem of recommendation is usually transformed into the score prediction problem, as formally defined below.

Problem 1 ***Score Prediction*** *Given $(\mathbb{U}, \mathbb{I}, \mathbb{C})$, the problem of score prediction is to estimate the score over unseen user-item pair (U_i, I_j) without text comments, where $U_i \in \mathbb{U}$ and $I_j \in \mathbb{I}$.*

Obviously, the score prediction is quite different from text-based sentiment classification which has text information in the testing stage. The recommendation system is more efficient, if the score prediction returns more accurate estimations.

2.2 Distributed Representations

Here, we briefly review the approaches of learning distributed representations of words and documents(Mikolov et al., 2013; Le and Mikolov, 2014). Word distributed representation denotes semantical meanings of the words extracted from large-scale text archive in a unified way (Mikolov et al., 2013). Each word is represented by a vector of fixed length L, such that 1) semantically similar words are close to each other in the new vector space; and 2) the semantics of words are compositional by vector operations. To simplify the notation, we use w to denote a word in the dictionary, as well as its corresponding vector representation. Given a sequence of words, i.e. $w_1, \ldots, w_T$, the distributed representations of the words are calculated by maximizing the likelihood of observing the words in the sequence, based on the neighbor words in the sequence. Mathematically, with the specified neighborhood width d, this objective is formalized as

$$\frac{1}{T}\sum_{i=1}^{T} \log \Pr\left(w_i \mid w_{i-d}, \ldots, w_{i-1}, w_{i+1}, \ldots, w_{i+d}\right).$$

For words at the beginning and end of the sequence, special null words are inserted as the padding words. To generate the vector representations of the words, the algorithm runs an optimization over the vectors as well as a group of weights, with a weight vector v_{w_i} of length $(2d-1)L$ associated with every word w_i. Given the representations of the words in form of vectors, the vector representations of the words in the neighborhood of w_i are concatenated, resulting in a long vector x_i of length $(2d-1)L$. The probability of observing w_i in the context of x_i is estimated by the following equation:

$$\Pr\left(w_i \mid x_i\right) = softmax(W \cdot x_i + b). \tag{1}$$

where W is the weight matrix connecting the input and the output and b is a bias vector. To efficiently optimize the weights and word representations, a number of optimization tricks, including hierarchical softmax and negative sampling are suggested in (Mikolov et al., 2013), in order to train the representations in reasonable time. The detail of learning procedure can be found in the paper of (Mikolov et al., 2013).

Paragraph (or document) vector is an extension of word distributed representation, by introducing a global vector indicating the topics of the whole paragraph (Le and Mikolov, 2014). When generating the representation of the neighborhood x_i, the paragraph vector, another vector of fixed length across paragraphs, is included. The paragraph vector is effective on capturing the context of the words, which can be used to enhance the accuracy of the word prediction model and extract overall topics of the whole paragraph.

3 Our Approach

Our approach for learning distributed representations is inspired by the models for learning the vectors of words and documents in (Le and Mikolov, 2014; Mikolov et al., 2013). In our solution, as presented in Figure 1, there are three types of distributed representations built and utilized in the learning phase, including word representation, user representation and item representation. Each representation is a vector of fixed length in its respective domain, say W, U and I respectively. Intuitively, the word representation denotes the conceptual meanings of the words in a latent space. Similarly, the user representation denotes the personal preferences over the items, and item representation denotes the important attributes of the items. The dimensions of the user representations, for example, are expected to indicate personal preference and behavior patterns, such as 1) whether the user prefers cheap items; or 2) whether the user prefers better service to good foods during dining in restaurants. We hereby emphasize that such preferences and profiles are automatically extracted from the data, without any supervision or manual labeling involved.

When the context is clear, we use U_i (resp. I_j) to denote both the user identity (resp. item identity) as well as its corresponding representation vector. Similarly, we misuse w to denote a word in dictionary $\mathbb{D}$ and its word representation vector. There are two parts in our approach: 1) Learning distributed representations of words, users, and items; 2) Score prediction for pairs of users and items without text comments.

3.1 The Learning Model

During the learning phase, the contexts are fixed-length and sampled from a sliding window over the text comments. The matrix $\mathbb{D}$, with stacked word vectors, is shared across all the text comments. However, the user vector is shared across the comments written by the same user and the item vector is shared across the comments written on the same item.

By looking up the matrices, we obtain the vectors of users, items, and words. After concatenating all relevant vectors in order, including user vector, item vector and neighborhood word vectors, a bi-layer neural network model is built on top of the concatenated vector to predict the words as shown in the left part of Figure 1.

Suppose that the target word is w and the input (the concatenated vector) is X_w. A intermediate layer is applied on the input vector X_w to generate a fixed length vector with L_h binary variables V_h. Each variable $v_i \in V_h$ is independently activated, based on the weight assignment on the edges between input vector and intermediate layer, following the logistic function:

$$\Pr(v_i = 1) = \frac{1}{1 + \exp\left(-\left(\sum_{x_j \in X_w} x_j \cdot w_{ij}\right)\right)}.$$

where w_{ij} is the weight connecting from the j^{th} dimension of the input to the i^th dimension of V_h. From the intermediate layer, our model predicts the word occurrence with another *prediction layer*. On this layer, the system employs exactly the same softmax function used in the existing word vector and paragraph vector models. The prediction function is,

$$\Pr\left(w \mid V_h\right) = softmax(W_w^h \cdot V_h + b^h).$$

where W_w^h is the weight vector connecting V_h to w and b^h is the bias vector.

Based on the model above, the training of the model with the text comment archive is in two folds. Firstly, the weights in the neural network are optimized to reflect the correlation between user/item/word representations and the word occurrence likelihood. Secondly, the construction of the representation identifies meaningful semantics into the vectors, especially for the user representation and item representation. When there are multiple users and items available in the comment database, the result representations automatically reveal the actual preferences of the users and the attributes of the items, because common topics across comments are merged and appear as a dimension in the representations.

3.2 Training the Parameters

During training, the parameters we should learn include the weights in the above equations and the vector representations of users, items and words. We use stochastic gradient descent to learn the parameters. Then the *backpropagation* algorithm is employed to push the gradients to the concatenated vector level, and thus used to update the weights on the edges as well as the user/item/word vectors by exactly the same mechanism. At every step of the learning phase, we sample a fixed-length context from a random comment.

To train the weights from hidden variables to the target words, we apply *negative sampling*. The negative sampling method is a simplified variation of Noise Contrastive Estimation (Gutmann and Hyvarinen, 2012; Mhih and Teh, 2012). To compute the probabilities efficiently, we use the negative sampling method proposed by (Mikolov et al., 2013), which approximates the probability by the correct example and K negative samples for each instance. The formulation to compute $\log(\Pr(w_i|V_h))$ is,

$$\log \sigma(z_{w_i}) + \sum_{k=1}^{K} \mathbb{E}_{w_k \sim P(w)}[\log \sigma(-z_{w_k})] \tag{2}$$

where $\sigma(z_w) = 1/(1+exp(-z_w))$, $z_w = W_w^h \cdot V_h + b^h$, w_i is the target word, V_h is the vector of hidden variables, and $P(w)$ is the noise distribution on the data. We set K as 5 in our experiments as used in (Mikolov et al., 2013). We perform the iterative update after predicting the target word,

$$\theta \leftarrow \theta - \alpha(\frac{\partial \sum log(\Pr(w_i|V_h))}{\partial \theta}) \tag{3}$$

where α is the learning rate and θ is the set of parameters to learn that includes the weights of the model. The initial value of α is 0.025. During training, the learning rate is halved if the log-likelihood does not improve significantly after one update. Then, the training stops if it does not improve again.

The computation efficiency on the training procedure is excellent, because most of the computation time is spent on the training between hidden variables and target words. The training between concatenated vectors and hidden variables is much more efficient, since the number of variables involved is highly constrained, depending on the specified size of the word neighborhood and the size of the hidden variable layer.

After the learning phase, we obtain the distributed representations of users and items shown as vectors. They are used in the score prediction task.

3.3 Predicting Scores

As is described in Problem 1, the problem of score prediction is to estimate the score of a user before he/she actually purchases the item. Thus, we do not have the text comment for the given pair when testing. We build a regression/classification model on top of the user/item representations. Specifically, a prediction model is a parameterized function $F(U_i, I_j)$ with inputs of user/item vectors and outputs of score estimation. While any regression model can be employed as the parameterized function $F(\cdot)$, we use the network shown in the right part of Figure 1. First, we learn a non-linear transformation which can project the input user/item representations into a space where it becomes linearly separable. The space is a intermediate layer referred to as a hidden layer. Then, a logistic regression classifier takes the transformed vectors for predicting the scores.

As indicated in Figure 1, the input layer contain the user and item representations and the average scores (b_{U_i} and b_{I_j}) of user and item, and the output layer has possible ratings.

Given the input x, $h(x) = s(W^1 x + b^1)$ represents the hidden layer, where W^1 is the weight matrix connecting the input vector to the hidden layer and b^1 is a bias vector for the transformation. Here, we use $tanh(a) = (e^a - e^{-a})/(e^a + e^{-a})$ for function s since it is fast when training the parameters.

Specifically, the prediction is then obtained by applying:

$$P(y|x) = softmax(W^2 h(x) + b^2) \tag{4}$$

	Yelp	Dianping	Amazon
review#	1.6M	1.2M	1.2M
item#	60,785	43,141	246,200
users#	366,715	350,936	641,380
review# per item	25.81	27.98	4.73
review# per user	4.27	3.44	1.81

Table 1: Statistics of data set

where W^2 is the weight matrix connecting the hidden layer to the output layer and b^2 is a bias vector for the classifier. We use stochastic gradient descent to learn all parameters of the model, including W^1, b^1, W^2 and b^2. Finally, the prediction of the model y_{pred} is the class whose probability is maximal:

$$y_{pred} = \text{argmax}_i P(Y = y_i|x) \tag{5}$$

4 Experiments

4.1 Dataset

We evaluate the systems on datasets from a variety of public sources. The first one is from Yelp Dataset Challenge[1], which contains about 1.6M reviews. The second one is from *Dianping* (www.dianping.com), which consists of user reviews on the restaurants located in China. We also include about 1.2M reviews from Amazon previously used for opinion analysis in (Jindal and Liu, 2008). In the datasets, each review contains a user ID, restaurant/product ID, numeric rating (from 1 to 5), and detailed comment text. We filter out the reviews that do not have comment texts. The detailed statistics of the data sets are summarized in Table 1. The reviews are written in two different languages, Yelp and Amazon using English, and Dianping using Chinese. The experiments with different languages and domains demonstrate the genericity of our approach.

For each dataset, we randomly split the whole set into two parts: 80% as training data and 20% as test data. We also randomly select 10% of training data as development data to tune the parameters of the systems.

4.2 Score Prediction

We report the mean absolute error (MAE) of the score predictor, i.e., $MAE = \frac{1}{N}\sum_{u,i\in T}|\hat{r}_{ui} - r_{ui}|$, where T is the test set, N is the total number of predicted ratings, $\hat{r}_{ui}$ and r_{ui} are the predicted rating and the user assigned rating scores for user u and item i, respectively.

We compare with four systems: 1) CF: This is a user-based Collaborative Filtering (CF) system in which we follow the description of (Sarwar et al., 2001). 2) FM: This is a latent factor model implemented in libfm[2](Rendle, 2012). 3) CTR: This is a collaborative topic regression model adapted from (Wang and Blei, 2011)[3], which is proposed to recommend scientific articles in citation networks. 4) HFT: This is the Hidden Factors as Topics (HFT) model proposed by (McAuley and Leskovec, 2013), which is a state-of-the-art system using text reviews[4]. The first two systems use rating information only and the other two systems utilize text reviews. The settings of all the systems are tuned on the development sets. According to the results on the development sets, we set user/item vectors size as 100 and number of hidden units as 50 in our system.

Table 2 shows the experimental results of score prediction, where DRT is our system. FM is better than the traditional Collaborative Filtering (CF) system. This shows that the factor model is very powerful. HFT and CTR achieve similar scores to FM on two datasets and perform better than FM on the Amazon

data. Our system provides the best performance on all the datasets and is significantly better than other systems ($p < 10^{-5}$).

System	Yelp	Dianping	Amazon
CF	1.0004	0.6906	0.9924
FM	0.9276	0.6609	0.8936
CTR	0.9243	0.6619	0.8693
HFT	0.9221	0.6615	0.8658
DRT	0.9064	0.6316	0.8165

Table 2: Results of score prediction (MAE)

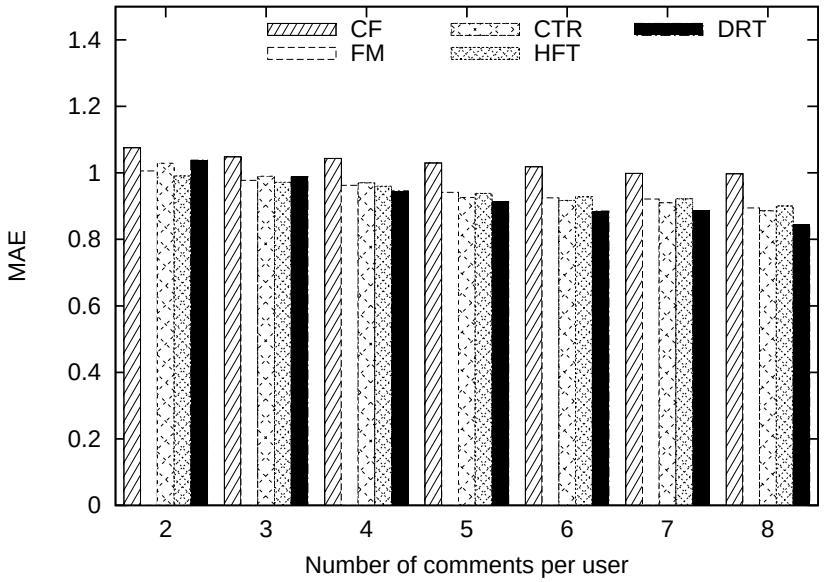

Figure 2: MAE vs number of training reviews per user (Yelp)

The number of training reviews is important for recommendation systems. We thus investigate the effect of training reviews per user. Figure 2- 4 show the MAE scores with varying number of training reviews per user. The trend of the results shows that all the systems are getting better scores, with increasing number of comments. When the number of training reviews grows larger, the performance gap between DRT and CF also grows. This fact indicates that our approach can make use of text comments to improve performance. The results also show that with 2 or 3 training reviews, DRT performs best on 3 among 6 cases, while with 4 or more training reviews, DRT can beat other approaches. In future work, we will try to improve the bad cases.

We also investigate the effect of different lengths of comments to our system (DRT). To reduce the effect of numbers of training reviews per user, we calculate the average lengths of comments written by the users who only have 4-10 training reviews. We ignore the users whose average comment length is no more than 20 words. We group the users into several groups by setting every 20 words as one BIN. For example, BIN-40 includes the users whose average comment length is in (20,40] and BIN-100 includes the users whose average comment length is in (80,100]. Figure 5 shows the relation between the MAE scores and the comment lengths. From the figure, we find that DRT roughly gets consistent performance along with the increase of comment lengths. However, this fact is against what we expect: the longer texts might result in better performance. We check some long comments in three datasets and find that most of the long comments indeed have more detailed information, but also bring some noise. For example, some users like to describe the experiences in other restaurants before commenting on the target restaurant. The results indicate that our system can partial reduce the effect of noisy information and achieve similar performance on both long and short texts.

5 Related Work

In this paper, we utilize user comments to enhance recommendation systems. Text mining techniques are now widely used on comment data on the Internet to support a large variety of applications in e-commerce. Liu et al. (2005) discuss the possibility of comparing comments available online to identify important opinions of the users on the items. Zhai et al. (2011) present an approach to select important sentences in the product comments. Zhang et al. (2015) design a customized solution to restaurant comment summarization on dishes. Topic modeling techniques based on Dirichlet allocation are recently popular in text analytics (Blei et al., 2003), which is particularly effective on long documents to find meaningful topics (Blei et al., 2004). However, we hereby emphasize that all these techniques are not directly helpful to improve recommendation systems.

A huge bulk of recommendation algorithms are proposed in the literature. Collaborative filtering is known as the most popular approach (Su and Khoshgoftaar, 2009; Sarwar et al., 2001) and matrix factorization has recently emerged as an effective strategy to improve the effectiveness of collaborative filtering (Koren et al., 2009; Rendle, 2012). Latent Factorization Model decomposes the matrix of user-item features and identifies the features connected to users and items respectively. Some other invariants, such as max-margin matrix factorization (Rennie and Srebro, 2005) and probabilistic matrix factorization (Salakhutdinov and Mnih, 2008), are proposed to improve the robustness of the factorization outputs. Singh and Gordon (2008) further encode genres of movies and roles of actors in movies as binary relations into a collective matrix factorization model. All these approaches require the generation of matrix with aligned features, and only can use very limited information besides scores.

There are a handful of attempts to incorporate rich text information into recommendation engines. Musat et al. (2013) revise the original collaborative filtering approach, by modeling user similarity based on the feature words shown in their text comments. In their approach, the feature words are nouns with the highest opinion counts. Zhang et al. (2014) adopt a similar strategy to support personalized recommendation based on text comments. Their approach utilizes existing sentiment analysis tools (Lu et al., 2011) to generate the feature words. These words are fed into latent factor model (Koren et al., 2009) to build profiles on the users and items. However, the feature extraction procedure used in their method does not distinguish user preference and item features in the opinion. He et al. (2015) tries to build tripartite graph model with user, item and discussion topic engaged. The recommendation system exploits the tripartite graph model to make personalized recommendation decisions. In their approach, the feature words are identified similarly as Zhang et al. (2014). All the above studies

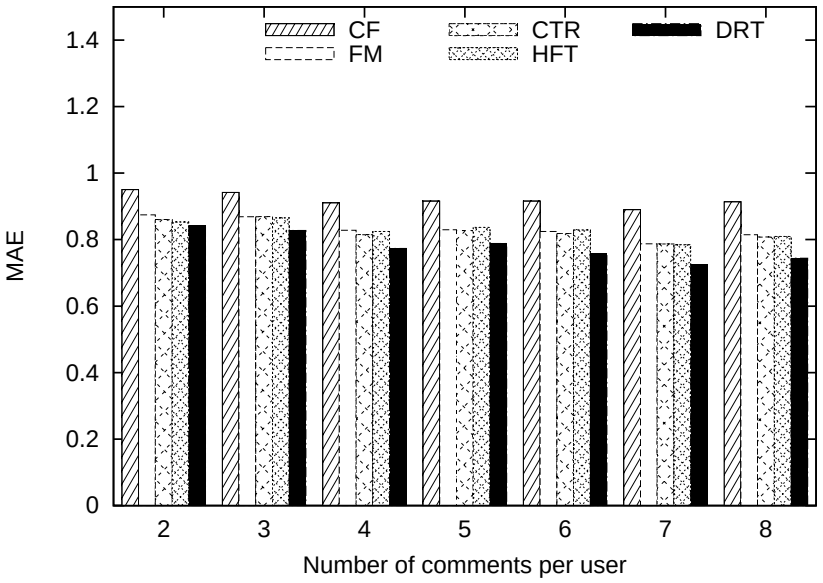

Figure 4: MAE vs number of training reviews per user (Amazon)

identify the feature words directly extracted from comments.

Recently some researchers try to learn latent aspects from comments (Wu and Ester, 2015). Wang et al. (2011) builds a regression model over the topic results from LDA. Their approach does not try to identify user profiles, and thus only applicable to score prediction on the text comments. Wang and Blei (2011) combine the merits of traditional collaborative filtering and topic modeling which provides a latent structure to recommend scientific articles in citation networks. Tang et al. (2015) learn representations of users and item for sentiment classification. Although similar concepts of user and item representations are used in (Tang et al., 2015), there are two major differences. Firstly, the problem we try to solve is completely different: they work on review sentiment classification, while our work focuses on score prediction without text. Secondly, the models are different: their approach includes user/product representation in CNN to enhance score prediction accuracy over text review, while out proposal attempts to maximize the likelihood of individual words. McAuley and Leskovec (2013) use a topic model to extract user and item profiles based on text comments. Although related, such approaches differ from ours in that they represent latent topics by keywords which are limited in representations. The approach of McAuley and Leskovec (2013) is the most relevant work to ours, but there are a number of limitations in their work. Firstly, they assume there is a one-to-one correspondence between the entries in the user profile and item profile. Secondly, their optimization relies on the assumption of LDA, such that the words are drawn independently from an unknown distribution. Our approach does not have any strong assumption on the generation mechanism.

6 Conclusion

In this paper, we have presented a simple yet effective approach to learn distributed representations of users and items from large amounts of text reviews. In our approach, the user vectors and item vectors are learned by a neural network. The user representation denotes the personal preferences over the items, while the item representation denotes the important attributes of the items. Finally, the distributed representations are used in recommendation systems. When tested on the datasets from different domains and languages, our systems achieve better performance than the state-of-the-art baseline systems.

Improving Statistical Machine Translation with Selectional Preferences

Abstract

Long-distance semantic dependencies are crucial for lexical choice in statistical machine translation. In this paper, we study semantic dependencies between verbs and their arguments by modeling selectional preferences in the context of machine translation. We incorporate preferences that verbs impose on subjects and objects into translation. In addition, bilingual selectional preferences between source-side verbs and target-side arguments are also investigated. Our experiments on Chinese-to-English translation tasks with large-scale training data demonstrate that statistical machine translation using verbal selectional preferences can achieve statistically significant improvements over a state-of-the-art baseline.

1 Introduction

Lexical translation error is one of the most urgent issues for statistical machine translation (SMT). Although phrase-based SMT can deal with local context dependencies well, it performs rather poorly with long-distance dependencies and therefore causes a lot of lexical translation errors. Verbs and their arguments form such long-distance dependencies and play important roles in translation as they build skeletons of sentences. However, many SMT systems are not sufficient to capture long-distance dependencies between arguments and their dominating verbs. Verbs and arguments are often either incorrectly translated or not translated at all according to the error study by Wu and Fung (2009a).

In order to address this issue, predicate-argument structures (PAS), which identify semantic frames within sentences by marking predicates, and labeling arguments with semantic roles, have been explored for SMT via various approaches in recent years. Wu and Fung (2009b) employ target-side PAS to pick out the most suitable translations among translation candidates after the decoding procedure is completed. Gildea (2010) integrates the PAS knowledge into decoding through projecting source-side PAS to the target-side via word alignments. In this paper, we are particularly interested in long-distance dependencies between verbs and their arguments in a predicate-argument structure. We propose to utilize selectional preferences (SPs) to handle these verb-argument dependencies for SMT.

Selectional preferences place semantic restrictions on words, with which words can co-occur in different syntactic patterns. To be more specific, the SPs of a verb can characterize the semantic restrictions that the verb imposes on its arguments. Violating these restrictions inevitably makes sentence senses odd or implausible. For example, in the sentence *"The ball drinks a potato."*, both subject and object preferences for the verb "drink" are violated. SPs have proven useful for numerous applications, e.g., semantic role labeling (Gildea and Jurafsky, 2002), pronoun resolution (Bergsma et al., 2008), textual inference (Pantel et al., 2007), word-sense disambiguation (Resnik, 1997) and many more. Therefore, we have sufficient theoretical foundation to believe that SPs between verbs and arguments can be used to alleviate translation errors that we pointed out above.

Our work consists of two parts: modeling SPs for verbs and incorporating SPs into an SMT system. In particular, we focus on the verb-object (v, obj) and verb-subject $(v, subj)$ selectional preference instances which can be extracted from our target-side corpus. SPs are computed in two ways: conditionally

*Corresponding author

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2154–2163, Osaka, Japan, December 11-17 2016.

probabilistic SPs and topic-based SPs. The former calculates conditional probabilities between verbs and arguments as the strengths of SPs in a traditional way. The latter builds a class-based SP model using topics as semantic classes of arguments. All these calculated SPs are monolingual SPs. Since we model SPs for translation, we are also interested in cross-lingual SPs, i.e., selectional preferences of source-side verbs over corresponding target-side arguments. Taking (v, obj) semantic restriction as an example, we want to extract source-side verbs v_s and target-side objects obj_t from our word-aligned bilingual corpus. With these semantic instances, we define a bilingual SP model to calculate cross-lingual SP strength that a source-side v_s impose on its target-side obj_t. We integrate SPs into a state-of-the-art phrase-based SMT system. Experiments on large-scale translation display that SPs can achieve an improvement of up to 0.83 BLEU points over our baseline.

To the best of our knowledge, this is the first attempt to successfully incorporate selectional preferences into SMT. Our contributions are as follows.

- We propose various models to incorporate target-side monolingual selectional preferences into SMT.
- We also present a model for cross-lingual selectional preferences.
- In order to address the unknown word issue in SP modeling, we further introduce a word embedding based similarity model.
- Finally, we conduct experiments and in-depth analysis to demonstrate how these SP models work for SMT.

The remainder of this paper is organized as follows. Section 2 introduces related studies about SPs induction and application. Section 3 elaborates our methods to learn verbal SPs from a large-scale corpus and three SP models for SMT. Section 4 discusses how to deal with unknown words in SPs. Section 5 describes how we integrate the verbal SPs into SMT. Section 6 reports the experimental results. In the last section, we conclude with future directions.

2 Related Work

Recent two decades have witnessed increasing efforts on automatic acquisition of SPs for verbs as well as wide applications of SPs in NLP tasks. Resnik (1996) is a pioneer on the induction of SPs from corpus, proposing a class-based approach named selectional association that uses WordNet synsets to provide conceptual classes for nouns co-occurring with a specific predicate in a particular relation. Li and Abe (1998) also rely on WordNet and use the principle of Minimum Description Length to find a suitable generalization level of a noun. But entirely relying on WordNet to generalize nouns to semantic classes has a fatal disadvantage because WordNet is lack of coverage of proper nouns. Therefore, Rooth et al. (1999) propose a probabilistic latent variable model using Expectation-Maximization (EM) clustering algorithm to induce class-based SPs. Erk (2007) investigates a similarity-based model which takes advantage of a corpus-based distributional similarity metrics between arguments for SPs. More recently, a number of researchers come up with methods modeling SPs via unsupervised topic models where topics express a set of latent classes for preferences with different grammatical relations. Séaghdha (2010) describes a model using latent Dirichlet allocation (LDA) (Blei et al., 2003) to compute SPs composed of a predicate and a single argument. In contrast, Ritter et al. (2010) study acquiring selectional preferences of a predicate and multiple arguments with topic models.

SPs are useful for numerous NLP tasks. Resnik (1997) uses automatically acquired SPs for word sense disambiguation. Zapirain et al. (2009) employ SPs to process semantic role classification in a large dataset. Many researchers apply SPs to conduct pseudo-disambiguation tasks (Van de Cruys, 2014; Erk, 2007) in order to evaluate the performance of their methods of acquiring SPs. In contrast to plenty of applications of SPs in monolingual tasks, rather few efforts are devoted to incorporate SPs into SMT. To the best of our knowledge, we are the first to model SPs in the context of SMT.

From the perspective of verb and argument translation, the most related work to ours is Xiong et al. (2012). They propose two translation models to incorporate source-side PAS into SMT. One is the predicate translation model exploring both lexical and semantic contexts to predict target-side predicates. The other is the argument reordering model which estimates the direction of target-side arguments movement relative to their predicates. The significant difference is that they separately model the translation of verbs and arguments while we model them in a unified fashion via SPs.

3 Selectional Preference Model

Most approaches represent SPs for verbs as a function $\sigma : (v, r, c) \rightarrow s$ that maps each verb v and the semantic class c of its argument with respect to role r to a real-valued selectional preference strength s (Light and Greiff, 2002). The higher the value of s is, the more arguments semantically fit their dominating verb. In this paper, we are interested in the degree to which an object or subject semantically fits a given verb. Additionally, we are wondering which semantic relation is more helpful for a phrase-based machine translation. We propose two approaches: a conditional probability-based method and a topic-based method to model verbal SPs. Due to the space limit, we only describe how we compute the SP strength of (v, obj). The strength of $(v, subj)$ can be calculated in a similar way.

3.1 Conditional Probability-Based SPs

The conditional probability-based method is the most primitive corpus-based way to capture SPs that a verb imposes on its arguments. The conditional probability can be computed as follows.

$$P(n|v, r) = \frac{f(v, r, n)}{f(v, r)} \tag{1}$$

where $f(v, r, n)$ represents the number of times that a noun n co-occurs with a verb v in a grammatical relation r. Considering r as a relation of a direct object of v, n is correspondingly specified as the headword of r. Thus we simplify formula (1) to calculate the SP strength between a verb and its object as follows.

$$P_c(obj|v) = \frac{f(v, obj)}{f(v)} \tag{2}$$

where obj is the headword of the object of v.

3.2 Topic-Based SPs

Topic-based SP is a typical of class-based SP that models how well a particular class of words fits a verb. We use latent topics that are learned from a collection of documents as our semantic classes. We choose the most widely used LDA (Blei et al., 2003) topic model to infer topics for our arguments. Each word in our corpus is assigned a topic. Then we compute the SP for a verb and its object headword as follows.

$$\begin{aligned} P_t(obj|v) &= \sum_{tp \in T} P(tp|v) P(obj|v, tp) \\ &\approx \sum_{tp \in T} P(tp|v) P(obj|tp) \end{aligned} \tag{3}$$

where T denotes the collection of topics that the current obj belongs to and tp stands for a topic assignment of the object. The first part $P(tp|v)$ can be calculated with relative counts that a verb co-occurs with objects that are assigned a topic tp. The second part $P(obj|tp)$ can be directly retrieved from the per-topic word distribution of topic tp over words computed by the LDA topic model.

3.3 Bilingual SPs

The two models introduced above are used to calculate SPs for verbs only on the target side. We also want to model cross-lingual SPs that source-side verbs impose on their corresponding target-side arguments.

Translation Category / Selectional Pairs	#0#	#1#	#2#	#3#
target-side (v, obj)	10.67%	27.46%	48.32%	13.54%
target-side $(v, subj)$	4.95%	34.45%	48.79%	11.80%

Table 1: Proportion of source-side verb-argument translation categories on the development set.

We therefore adapt the above two models to compute bilingual SPs. The conditionally probabilistic bilingual SP variant is calculated as follows.

$$P_{cbil}(obj_t|v_s) = \frac{f(v_s, obj_t)}{f(v_s)} \tag{4}$$

where obj_t is the target translation of obj_s. If obj is translated into a multi-word phrase, we use the first word of the phrase as obj_t.

For the bilingual topic-based SP model, we still use the LDA topic model to infer topics on the target language. We compute bilingual topic-based SPs via the following formula.

$$\begin{aligned} P_{tbil}(obj_t|v_s) &= \sum_{tp \in T} P(tp|v_s) P(obj_t|v_s, tp) \\ &\approx \sum_{tp \in T} P(tp|v_s) P(obj_t|tp) \end{aligned} \tag{5}$$

where T denotes the set of topics that the current obj_t belongs to and tp is the topic assigned to the object by LDA. $P(tp|v_s)$ is calculated with counts that the source-side verb v_s co-occurs with an object whose target-side counterpart is labeled with a topic tp. $P(obj_t|tp)$ is calculated by the LDA model.

4 SPs of Unseen Words

Conditional probability-based SPs cannot make any predictions for object headwords that have never occurred in our extracted selectional preference instances (v, obj). As our corpus cannot cover any phenomena in real world, a zero co-occurrence count between v and obj is not sufficient to show that the v has no selectional preference for that obj as its object. The method we employ to obtain source-side verb-argument pairs corresponding target-side verb-argument pairs during decoding has an obvious defect that word alignments directly affect the generation of translations. In this case, there may be many unseen word combinations. In order to investigate the proportion of unseen word combinations during decoding, we define four labels to classify these generated phrases. Label #0# represents phrases whose verb or object is translated into "#NULL#" due to incorrect word alignments. Phrases whose verbs or arguments are unseen in our trained SP models are labeled with #1#, #2# respectively. The remaining phrases appearing in our trained SP models are annotated with label #3#.

Table 1 shows the distribution of these phrases over the four categories on our development set (see details in Section 6.1). There are 53,268 (v, obj) pairs and 42,385 $(v, subj)$ pairs generated on the target side during decoding. Among these phrases, Only 13.54% (v, obj) pairs and 11.80% $(v, subj)$ pairs appear in our trained SP models. Most phrases, accounting for nearly 50%, are those whose argument headwords are unseen for our trained SP models. Hence, it is quite necessary to take some measure to model the SPs that verbs impose on their unseen argument headwords.

Instead of assigning a uniform value as the selectional strength for those unseen verb-argument combinations, we exploit a similarity-based model to compute SPs of a verb for an unseen argument headword during decoding, similar to the model by Erk (2007). Assuming (v, w_{un}) is a generated selectional preference instance according to word alignment information and w_{un} is an unseen object headword of v. The formulation to compute the selectional strength that v imposes on w_{un} is as follows.

$$P_c(w_{un}|v) = \sum_{w \in Seen(obj)} sim(w_{un}, w) \times wt_{obj}(w) \tag{6}$$

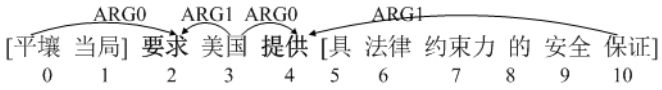

Figure 1: A source sentence with its predicate-argument structure. The verbs in the sentence are bold.

where $Seen(obj)$ is the set of seen headwords for an argument obj of a verb v, $sim(w_{un}, w)$ is the similarity between the seen and potential headword, and $wt_{obj}(w)$ is the weight of a seen headword w.

For the headword weight $wt_{obj}(w)$, we employ the selectional preference that the verb v imposes on the seen headword w to compute the value. $sim(w_{un}, w)$ is calculated with word2vec[1] and the similarity metric: Cosine. After each word on the target-side corpus is projected into a multidimensional vector space, $sim(w_{un}, w)$ is computed as follows.

$$Sim(\overrightarrow{w_{un}}, \overrightarrow{w}) = \frac{\overrightarrow{w_{un}} \bullet \overrightarrow{w}}{||\overrightarrow{sw_{un}}|| \times ||\overrightarrow{w}||} = \frac{\sum_i (a_i \times b_i)}{\sqrt{\sum_i {a_i}^2 \times \sum_i {b_i}^2}} \tag{7}$$

where a_i and b_i are the value of ith dimension of their word embeddings.

5 Decoding

In this section, we mainly elaborate how to integrate the proposed SP models into a phrase-based SMT system built on bracketing transduction grammars (BTG) (Wu, 1997). Before we introduce the integration algorithm for SP models, we define two functions F and G on a source sentence and its predicate-argument structure following Xiong et al. (2012). We use the sentence in Figure 1 as an example to make the two functions easier to be understood.

- $F(i, j)$: The function is used to find positions of all verbs and their object headwords pairs from the predicate-argument structure. These pairs are completely located within the source span (i, j). For example, in Figure 1, $F(0, 4)$=$\{$(2,3)$\}$, $F(0, 10)$=$\{$(2,3), (4,10)$\}$ while $F(0, 2)$=$\{\}$ because the object headword "美国" is located outside of the span $(0, 2)$ and $F(5, 10)$=$\{\}$ for the reason that the verb "提供" is located outside of the span $(5, 10)$.

- $G(i, k, j)$: The function finds positions of all verbs and their object headwords pairs that cross two neighboring spans (i, k) and $(k+1, j)$. It can also be formulated as $F(i, j) - (F(i, k) \cup F(k+1, j))$. In Figure 1, $G(0, 4, 10)$=$F(0, 10) - (F(0, 4) \cup F(5, 10))$=$\{$(4,10)$\}$.

In order to calculate SP strengths of target-side verbs and arguments as well as bilingual verb-argument pairs, we store word alignment information for each phrase pair in the phrase table. Given a source sentence with its predicate-argument structure, if a BTG lexical rule is applied to translate a source phrase c spanning (i, j) to a target phrase e, we use $F(i, j)$ to detect all verb-object pairs and build a translation set $A(i, j) = \{(v_t, obj_t), (\cdots), \cdots\}$ to store corresponding verb-object translations on the target side through word alignments. Since our decoder is a log-linear model which is easy to incorporate new features, we define another function P_r to calculate the score of SPs as a new feature over span (i, j) as follows.

$$P_r(A(i, j)) = \prod_{(v_t, obj_t) \in A(i,j)} P_{\cdot}(obj_t | v_t) \tag{8}$$

where $P_{\cdot}(obj_t|v_t)$ can be the conditionally probabilistic model P_c or topic-based model P_t. For the bilingual SP models, we only need to change v_t to its source-side counterpart v_s.

If a BTG merging rule is applied to combine its two sub-spans (i, k), $(k + 1, j)$ in a straight $((i, k) + (k + 1, j) \rightarrow (i, j))$ or inverted order $((k + 1, j) + (i, k) \rightarrow (i, j))$, we directly use $P_r(A(i, k))$ and $P_r(A(k + 1, j))$ that have been already computed for the two sub-spans (i, k) and $(k + 1, j)$ in

[1] https://code.google.com/archive/p/word2vec/

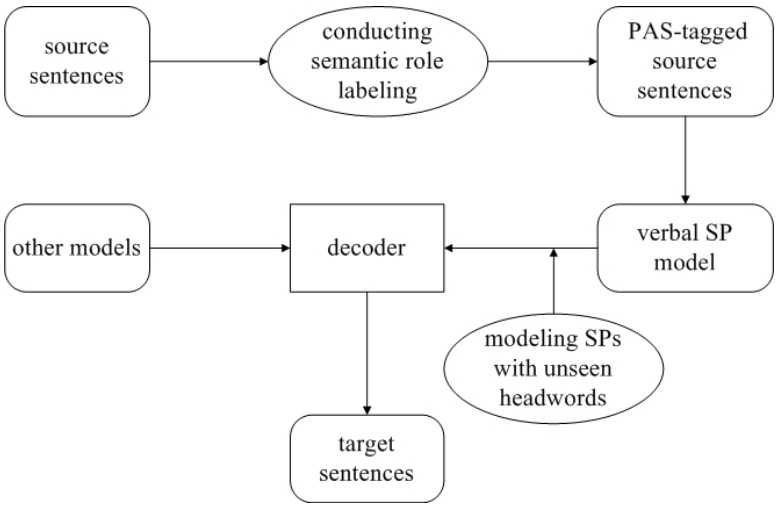

Figure 2: Architecture of SMT system equipped with verbal SPs.

the dynamic programming decoding algorithm. In this way, we only need to set another translation set $B(i,j) = \{(v_t, obj_t), (\cdots), \cdots\}$ to store the translations of source-side verb-object pairs found by $G(i,k,j)$ according to word alignments and calculate $P_r(B(i,j))$ for verb-object pairs that cross the two sub-spans.

In order to expedite the decoding process, we compute corresponding SPs for each (v, obj) semantic pairs extracted from the training corpus before decoding and load them when decoding instead of computing them on the fly. As for unseen object headword w_{un} of a verb, we use Eq. (6) to model SPs when integrating conditional probability-based SP model and Eq. (3) to model SPs when integrating topic-based SP model. We store the selectional strength of (v, w_{un}) for each unknown word so as to avoid repetitive computation. Figure 2 shows the architecture of the SMT system equipped with verbal SPs translation model. Since the system we used is based on a CKY-style decoder, the integration algorithm introduced here can be easily adapted to other CKY-based decoding systems such as the hierarchical phrasal system (Chiang, 2007).

6 Experiments

In order to validate the effectiveness of our SMT system enhanced with SPs, we perform a series of experiments on Chinese-to-English translation, which are trained with massive data. Specially, we aim at investigating:

- Whether integrating SPs into SMT can improve the system translation accuracy.
- Which can achieve better performance, conditionally probabilistic SP model or topic-based SP model?
- Whether semantic similarity-based approach is more reasonable than assigning a uniform value as the selectional strength that a verb imposes on its unseen argument headwords.
- Whether bilingual SPs are more effective than monolingual SPs for SMT.

6.1 Setup

The baseline is a state-of-the-art BTG-based phrasal system (Xiong et al., 2006). Our training data corpora[2] consist of 2.9M sentence pairs with 80.9M Chinese words and 86.4M English words. We ran GIZA++ on these corpora in both directions and then applied the "grow-diag-final" refinement rule to obtain final word alignments. Then we used all these word-aligned corpora to generate our phrase table.

[2]The corpora include LDC2003E14, LDC2004T07, LDC2005T06, LDC2005T10 and LDC2004T08 (Hong Kong Hansards/Laws/News).

Base+$P_{cbil}(obj_t\|v_s)$	37.15**	34.21**

Table 2: Results of conditionally probabilistic SPs with two selectional relations: (v, obj) and (v, sub). **/*: significantly better than the baseline at $p < 0.01$ and $p < 0.05$ respectively.

Our 4-gram language model was trained on the Xinhua section of the English Gigaword corpus using the SRILM toolkit with modified Kneser-Ney smoothing.

In order to automatically learn SPs for verbs, we first parsed all source sentences using Stanford Parser and then ran the Chinese semantic role labeler (Li et al., 2010) on all source parse trees to annotate semantic roles for all verbs. At the same time, we ran SENNA on the target side to not only parse all target sentences but also conduct semantic role labeling for all verbs. It is easy to extract (v_t, obj_t) pairs or (v_t, sub_t) pairs after we obtained semantic roles on both sides. As for extracting (v_s, obj_t) selectional tuples, we first extracted (v_s, obj_s) pairs from source sentences with PAS and then used word alignments to get the target-side translation obj_t of obj_s. We used GibbsLDA++ to infer topics for our topic-based SP models. We set the number of topics from 50 to 350 with an incremental interval 50. We found the best number of topics according to results on our development set.

We trained word embeddings with word2vec using continuous bag-of-words model (Mikolov et al., 2013). The word vector dimensionality was set to 200 and we set the value of threshold for occurrence of words to 0.00001. Values of other parameters such as the training algorithm and the size of the window were all set by default.

We adopted the NIST MT03 evaluation test data as our development set, and the NIST MT04, MT05 as the test sets. We used the case-insensitive BLEU-4 (Papineni et al., 2002) to evaluate translation quality and run MERT (Och, 2003) three times. We finally recorded average BLEU scores over the three runs for all our experiments and used MultEval toolkit[3] to perform the significance test.

6.2 Results

Our first group of experiments is to investigate whether a simple conditional probability method for modeling SPs is able to improve translation accuracy in terms of BLEU. Moreover, we also would like to know whether the similarity-based SP model for unseen argument headwords will achieve further improvements. Experimental results are shown in Table 1. From the experiments which are conducted only using monolingual SPs, we can find that the verb-object SP model $P_c(obj_t|v_t)$ performs slightly better than $P_c(sub_t|v_t)$ on both test sets. Using semantic similarity metric rather than a uniform value to evaluate the selectional preference of a verb for its unseen argument can achieve better performance. It can also be observed that bilingual SPs marginally outperform than monolingual SPs on average. All SP models in this table are statistically better than the baseline on the test set MT05.

Our second group of experiments is to validate whether the topic-based SPs are more effective than conditionally probabilistic SPs in improving the accuracy of lexical choice. Table 2 shows our results. First, we have observations similar to what we have found in Table 1: verb-object SPs are better than verb-subject SPs while cross-lingual SPs better than monlingual SPs. Second, comparing Table 2 against Table 1, we find that topic-based SPs are better than conditional probabilistic SPs with a uniform value for unseen headwords, but similar to that with a similarity-based SP model for unseen headwords.

Analysis on translations reveals that our SP models are helpful for reducing verb-argument translation errors. Due to the space limit, we only show two translation examples. Figure 3 displays a translation example which shows that the system equipped with verbal SP model can solve the problem that the

Figure 3: A translation example shows that verbal SPs can help SMT system alleviate the translation error that verb is not translated at all. The verbs in the sentence are bold.

baseline is unable to translate each verb in the source sentence to a target string. From the example, we can easily find that the baseline cannot correctly translate a $(verb, obj)$ selectional tuple like (参与，任务) where only obj "任务" is translated. Instead, in the system enhanced with verbal SPs, in addition to the object, $verb$ "参与" is also correctly translated into a target string. Figure 4 shows another example to demonstrate that verbal SPs are useful for selecting the proper translation for an object. The source word "发放" is not translated at all in the baseline while it is translated into "release" by our SP model.

7 Conclusion

We have presented three different models to compute SPs on verb-object and verb-subject pairs and successfully integrate them into a phrase-based SMT system. From a series of experiments on Chinese-to-English translation, we have found:

- Verbal SPs can significantly improve SMT in alleviating translation errors of verbs and their arguments.
- Verb-subject SPs perform similarly to verb-object SPs but slightly worse.

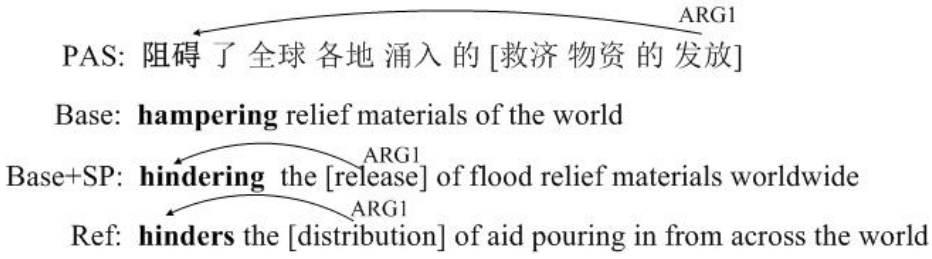

Figure 4: A translation example shows that verbal SPs can help SMT system alleviate the translation error that the argument of a verb is not translated at all. The verbs in the sentence are bold.

- Similarity-based SPs is helpful for conditional probability-based SP model to evaluate the SPs of a verb's unseen argument headword.
- Topic-based SPs are better than conditionally probabilistic SPs and bilingual SPs marginally better than monolingual SPs.

In the future, we would like to acquire bilingual SPs using a neural network approach (Van de Cruys, 2014). We also want to model SPs for verbs that are unseen in the training corpora and to explore a unified method to obtain SPs that a verb impose on its subject and object at the same time.

Hierarchical Permutation Complexity for Word Order Evaluation

Miloš Stanojević **Khalil Sima'an**
Institute for Logic, Language and Computation (ILLC)
University of Amsterdam
{initial.last}@uva.nl

Abstract

Existing approaches for evaluating word order in machine translation work with metrics computed *directly* over a *permutation* of word positions in system output relative to a reference translation. However, every permutation factorizes into a permutation tree (PET) built of *primal permutations*, i.e., atomic units that do not factorize any further. In this paper we explore the idea that permutations factorizing into (on average) *shorter primal permutations* should represent *simpler ordering* as well. Consequently, we contribute *Permutation Complexity*, a class of metrics over PETs and their extension to forests, and define *tight metrics*, a sub-class of metrics implementing this idea. Subsequently we define example tight metrics and empirically test them in word order evaluation. Experiments on the WMT13 data sets for ten language pairs show that a tight metric is more often than not better than the baselines.

1 Introduction

MT evaluation involves at least two factors, word order (syntactic) and adequacy (semantic). Conceivably, MT system developers could use diagnostic tools based on metrics dedicated to each factor separately. Word order metrics are frequently used to evaluate pre-ordering components, e.g., (Herrmann et al., 2011; Bisazza and Federico, 2013), or for analyzing specific reordering phenomena, e.g., (Bisazza and Federico, 2013; Xiang et al., 2011; Braune et al., 2012). Other uses include, ordering component tuning, e.g., (Gao et al., 2011; Neubig et al., 2012; DeNero and Uszkoreit, 2011; Katz-Brown et al., 2011; Hall et al., 2011), measuring divergence between languages (Birch et al., 2008), and matching gene sequences in bioinformatics (Eres et al., 2004).

For evaluating word order, a permutation is induced between a system output and the corresponding reference translation. Existing work uses metrics over permutations such as Kendall's tau (Lapata, 2006; Birch and Osborne, 2011), Spearman (Isozaki et al., 2010), Hamming, Ulam (Birch et al., 2010) and Fuzzy Score (Talbot et al., 2011). Approximately, Kendall's tau, Spearman and Hamming measure correct individual position or correct relative pairs, whereas Ulam and Fuzzy Score measure monotone units (contiguous or not).

A word order metric measures how similar a permutation is to the monotone (or identity) permutation. Here we advocate the idea that a suitable metric must *also* assign similar values to similar permutations. Crucially, factorizing a permutation into a Permutation Tree (PET) reveals its atomic building blocks, called *primal* permutations (Albert and Atkinson, 2005; Gildea et al., 2006). In this view, permutations that factorize into similar PETs should be similar. Some previous work (Stanojević and Sima'an, 2014a; Stanojević and Sima'an, 2014b) has used PETs for evaluation, but without attempting to explain the effect of factorization. Next we motivate the idea that, all other things being equal, *the more factorizable a permutation the simpler it is* in terms of ordering.

Informally, a PET for permutation π is a tree where the nodes are labeled with *operators* (Figure 1). The fringe of every subtree in a PET is a *sub-permutation* of π, i.e., a contiguous sub-sequence isomorphic with a permutation.[1] Consider $\pi_a = \langle 6, 1, 4, 2, 3, 5 \rangle$ and $\pi_b = \langle 6, 1, 5, 2, 3, 4 \rangle$. Their PETs (two

[1] Akin to a phrase pair in MT.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2164–2173, Osaka, Japan, December 11-17 2016.

left-most in Figure 1) are built from monotone $\langle 1,2 \rangle$ or inverted $\langle 2,1 \rangle$ operators only. Two local inversions $\langle 2,1 \rangle$ could turn each of π_a and π_b into monotone. Permutation $\pi_c = \langle 2,4,5,6,1,3 \rangle$ (right-most Figure 1) demands $\langle 2,4,1,3 \rangle$ at the root to bring it to monotone. In contrast, $\pi_d = \langle 6,2,4,1,5,3 \rangle$ does not yield to factorization because it does not properly contain sub-permutations; Non-factorizable permutations are called *primal permutations*,[2] and they constitute the *atomic building blocks for all permutations* (Albert and Atkinson, 2005) – see Section 3. Hence, π_d demands itself to convert it into monotone. In this view, π_a and π_b signify potentially simpler ordering than π_c, which is simpler than π_d.

Conveniently, PETs show two aspects of permutations: *recursive grouping and primal building blocks*. In this paper we introduce *Permutation Complexity*, a class of metrics over PETs, exploiting hitherto untapped discerning properties of permutations. **A.** Similarity: different permutations often share primal permutations. **B.** Factorizability: some permutations factorize into shorter primal permutations but others do not. **C.** Hierarchy: factorizing permutations exposes their hierarchical grouping. Practically speaking, metrics over PETs should be attractive because they parameterize in terms of primal permutations and bracketing structure.

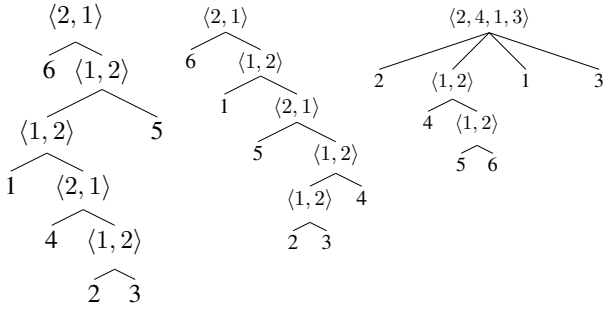

Figure 1: Three permutations and their PETs

From our Permutation Complexity viewpoint we see PET factorization as *compression* using a *code book* of primal permutations. Consequently, we introduce *tight* metrics, a sub-class that assigns a smaller complexity to a PET than to any less factorized structure of the same permutation, with the intuition that more factorization should reveal simpler building blocks. In this paper, we contribute: (1) Foundational formalization of tight complexity metrics over permutations, (2) An extension of PETs (Gildea et al., 2006) to forests to capture the potential relevance of brackettings for evaluation, (3) Novel metrics for reordering evaluation, and (4) Experiments on system ranking in MT. Our experiments show that the new tight (and semi-tight) metrics perform competitively over a range of language pairs, which provides the first evidence for a complexity-based factor in evaluation.

2 Existing metrics (Baselines)

We define evaluation metrics in the range $[0,1]$ with the interpretation *the higher the score the better*. Whilst this is natural for MT evaluation, for a formal treatment of complexity, as in Section 4, it is natural that complexity is interpreted as "the higher the more complex". The two notions are easily converted to each other after normalization.

A permutation π over $[1..n]$ (subrange of the positive integers) is a bijective function from $[1..n]$ to itself. To represent permutations we will use angle brackets as in $\langle 2,4,3,1 \rangle$. Given a permutation π over $[1..n]$, the notation π_i $(1 \leq i \leq n)$ stands for the integer in the i^{th} position in π; $\pi(i)$ stands for the index of the position in π where integer i appears; and π_i^j stands for the (contiguous) sub-sequence of integers $\pi_i, \ldots \pi_j$. The *length* of π is simply $|\pi| = n$.

$$\textsc{Kendall}(\pi) = \frac{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\delta[\pi(i)<\pi(j)]}{(n^2-n)/2}$$

$$\textsc{Hamming}(\pi) = \frac{\sum_{i=1}^{n}\delta[\pi_i=i]}{n}$$

$$\textsc{Spearman}(\pi) = 1 - \frac{3\sum_{i=1}^{n}(\pi_i-i)^2}{n(n^2-1)}$$

$$\textsc{Ulam}(\pi) = \frac{LCS(\pi,\textsc{Id}_1^n)-1}{n-1}$$

$$\textsc{Fuzzy}(\pi) = 1 - \frac{c-1}{n-1}$$

where c is # of monotone sub-permutations

Figure 2: Common metrics over permutations

The baselines are the existing metrics over permutations, including KENDALL's tau, HAMMING and ULAM used in (Birch and Osborne, 2010; Birch and Osborne, 2011; Birch et al., 2010; Isozaki et al., 2010); SPEARMAN rho used in (Isozaki et al., 2010); and FUZZY *Reordering Score* used in (Talbot et al., 2011), which is a reordering measure extracted from

[2] Also known as simple or non-decomposable (Brignall, 2010) – note the analogy with prime numbers.
