Abstract

Semantic classification of words using distributional features is usually based on the semantic similarity of words. We show on two different datasets that a trained classifier using the distributional features directly gives better results. We use Support Vector Machines (SVM) and Multi-relational Matrix Factorization (MRMF) to train classifiers. Both give similar results. However, MRMF, that was not used for semantic classification with distributional features before, can easily be extended with more matrices containing more information from different sources on the same problem. We demonstrate the effectiveness of the novel approach by including information from WordNet. Thus we show, that MRMF provides an interesting approach for building semantic classifiers that (1) gives better results than unsupervised approaches based on vector similarity, (2) gives similar results as other supervised methods and (3) can naturally be extended with other sources of information in order to improve the results.

1 Introduction

In this paper we consider the task of classifying words into a large number of semantic categories. For this, we use two different data sets: 1. A dataset which is used in literature (Bullinaria and Levy, 2007) - to enable compare our results with results reported in the literature, 2. A larger dataset that is derived from a large thesaurus. The second dataset comes close to practical applications for semantic word classification. Organizations maintaining thesauri usually try to keep their thesaurus up to date and frequently add new terminology to the thesaurus. For each new term, they have to decide at what point it has to be inserted. Automatic semantic classification supports exactly this task. However, the classifier should be able to choose from hundreds or even thousands of semantic classes, not just from a dozen.

For semantic word classification, it is a common approach to represent words by context features. Usually, co-occurrence statistics are used as context features. According to the distributional hypothesis, words with similar context features have a similar meaning. Thus, we can use any distance measure between the feature vectors as a measure of semantic similarity. These distances are now commonly used in a nearest neighbor or a nearest centroid (or nearest prototype) classifier. Recently, distributional features have also been used directly to train classifiers that classify pairs of words as being synonymous or not (Hagiwara, 2008; Weeds et al., 2014; Aga et al., 2016). In these approaches, first a vector representation for a pair is build, that is used by a machine learning algorithm. In the following we will use the distributional features directly to categorize the words into a large number of categories. We will also see that the supervised methods outperform the unsupervised ones.

For the given task, we obtain similar results with SVM and MRMF. However, MRMF enables easy integration of different sources which improves the results furthermore. The MRMF does not just aggregate results from different sources, but is also able to model the interaction between the different types of information. As a second source of information we use hypernym information from WordNet. Since, we

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2708–2717, Osaka, Japan, December 11-17 2016.

do not have a mapping from wordnet hypernym classes to our target classes, we have a second learning task. In the first place we show that classification using WordNet is possible, but gives worse results than classification based on distributional features. In the second place, MRMF using both distributional features and WordNet Hypernyms outperforms all other methods. For the SC53 data set that introduced by Bullinaria and Levy (2007) using the Montague and Battig (Battig and Montague, 1969) semantic classes, we get an accuracy of $0,93$. The best result found in literature for the complete data set is 0,86 (Bullinaria and Levy, 2012).

The rest of the paper is organized as follows. Section 2 briefly reviews the related work. Section 3 explains the methodology of the work in detail. Section 4 explains the multi-relational matrix factorization method in detail. Section 5 and Section 6 explain briefly the evaluation of the models and explain the result, respectively. Finally, Section 7 concludes the paper.

2 Related Work

In distributional semantics, words are represented by context features, usually co-occurrence numbers between words or the pointwise mutual information between each word and each context word. It turns out that words with a similar meaning have similar vectors of context features; In other words, semantically similar words occur in similar contexts (Rubenstein and Goodenough, 1965; Saif and Hirst, 2012; Bullinaria and Levy, 2007; Turney and Pantel, 2010; Bullinaria and Levy, 2012; Kiela and Clark, 2014).

Classification of words into different semantic categories was studied by Pekar et al. (2004), who use a k-Nearest Neighbor classifier and investigate different feature weighting schemes and distance measures; Fan and Friedman (2007) study the classification of medical terms using a nearest centroid classifier; Both Bullinaria and Levy (2012) and Keith et al. (2015) use a nearest centroid classifier for the same data set that is also included in our study. However, Keith et al. report only the result for one arbitrary split into test and training set. Thus, their results cannot be compared directly to our and also Bullinaria and Levy results.

Matrix factorization has been used in distributional semantics, e.g. by Giesbrecht (2010) and Van de Cruys et al. (2013) in order to reduce the size of the feature space, but not directly for predicting missing values or for classification. We are not aware of any work using matrix factorization for classification of words into semantic categories.

The integration of distributed and lexical information is an obvious way to go and was also used in a number of studies. Usually a (weighted) average of similarities based on different types of information is used. E.g. Finkelstein et al. (2001) used distributional features (occurrence frequencies of words in various domains) and the cosine of these feature vectors as a distributional similarity measure. This measure is combined linearly with a WordNet based similarity measure. Yih and Qazvinian (2012) use different similarity methods, like corpus based and web based distributional similarity for binary classification tasks (synonymous or not-synonymous). They also used WordNet similarity. For this, they represent a word as a vector in a Synset-space. The vector, thus indicates, to which synsets a word belongs. They finally aggregated the various similarities by taking the average cosine similarity. Camacho-Collados et al. (2015) combined distributional similarity of words based on their occurrence in Wikipedia with a WordNet based similarity measure. They also combined the similarities from both sources by computing the average. Pennacchiotti et al. (2008) also investigate the contribution of distributional models and their combination with Wordnet. They use the a simple back-off model to combine distributional similarity and Wordnet based similarity.

3 Methodology

The task that we considered is to classify words into their semantic category. In this section, we will describe the datasets, the feature construction for the representation of the words and the classification methods that we have used.

3.1 Data Description

Our first dataset is the same with the one used by Bullinaria and Levy (2007). This data set uses 53 of the 56 basic semantic categories introduced by Battig and Montague (1969). In total, the dataset contains 530 words which have been taken from 53 semantic categories. For each category there are 10 typical words. We will refer to this dataset as SC53.

We have compiled a second, similar but much larger dataset from the Eurovoc Thesaurus (Office for Official Publications of the European Communities, 1995). Eurovoc is a multilingual thesaurus developed by the European Commissions Publications Office as a controlled vocabulary for the manual indexation of documents. The Eurovoc thesaurus is divided into 127 micro-thesauri. From each of these micro-thesauri we took the top-level concepts, 528 in total, as semantic categories. For each category we collected all narrower concepts and considered their preferred and alternative labels as terms for that category. We then removed all terms that belong to more than one category or that consist of more than two words. Finally, we removed all categories for which less than 10 terms were found. Now 190 categories with a total of 2386 terms are left. After further cleaning the dataset by removing the words that have a very high or low frequencies in UkWaK, which is a corpus that has been used to construct word representation vectors, 1447 words with 95 semantic categories are left, each containing 10 to 44 terms. We call this dataset $Eurovoc$. Table 1 shows some examples from both datasets.

Dataset	Category	Words
SC53	Fruits	Orange, Strawberry, Banana
	Furniture	Chair, Table, Bed
Eurovoc	ACP countries	Bahamas, Barbados,Cameroon
	Health policy	Dispensary, Hospitalization

Table 1: Some example classifications from the used datasets

3.2 Feature Construction

We use two different representations for each word. The first one is a distributional representation based on word co-occurrences.The second one uses WordNet hypernyms. The two types of representation will be explained in the following subsections.

3.2.1 Distributional Representation

We construct vectors of co-occurring words to represent each word and use them as an input for all our experiments. For building the context vectors, we used UkWaC English corpus.

There are a number of choices that have to be made when building the context vectors for each word. In the following we will use the choices that turned out to yield the best results in a number of different tasks in recent studies by Bullinaria and Levy (2007; 2012) and Kiela and Clark (2014).

After some preliminary experiments we found that including all words in the frequency range from $4 \cdot 10^3$ to $1 \cdot 10^6$ in the UkWaC Corpus as context feature is a good compromise between optimal results and acceptable storage and computing efforts. Each word is now represented by a vector of 17 400 features. All experiments have been done using these distributional features.

Next we have to determine the size of the window for co-occurrence. If the training corpus is large enough all studies show that smaller windows yield better results. We first remove all stop words and then use a window size of two words on the stopped text while respecting sentence boundaries. Syntactic relations are not used to determine the context of a word.

We use positive pointwise mutual information (PPMI) as a degree of co-occurrence, since it was shown to give better results than raw co-occurrence probabilities in a number of different studies (see e.g. (Bullinaria and Levy, 2007; Bullinaria and Levy, 2012)). For a context word c and a (target) word t the PPMI is defined as

$$ppmi(c,t) = \max\left(\log\frac{p(c|t)}{p(c)}, 0\right). \quad (1)$$

3.2.2 WordNet Categories Representation

In order to classify words into semantic categories, we could directly use the semantic categories of the words from WordNet. However, we do not know the relation between the WordNet categories and the target categories. Moreover, our data set contains lots of terms that are not found in WordNet. Thus, we represent each word by the set of all its WordNet hypernyms, i.e. the transitive closure of the hypernym relation applied to each possible meaning of the word. E.g. the word *Mansion* is represented by the set {artifact.n.01, building.n.01, dwelling.n.01, entity.n.01, house.n.01, housing.n.01, location.n.01, mansion.n.02, object.n.01, physical_entity.n.01, region.n.01, sign_of_the_zodiac.n.01, structure.n.01, whole.n.02b }. Finally, each word is represented as a boolean vector in the space of all possible hypernyms.

For the SC53 dataset we could construct WordNet vectors for 520 out of 530 words; in the Eurovoc dataset, 1198 out of 1447 terms were found in WordNet. The average number of hypernyms for each term found in WordNet was 66. The total number of distinct hypernyms for all words is 2896 for the SC53 and 4938 for the Eurovoc data.

3.3 Classification Methods

Bullinaria and Levy (2012) use a nearest centroid classifier for classifying words based on distributional features. In this approach, for every semantic category a feature vector is created by averaging the feature values of all words in the training set belonging to that category. Now the cosine between the feature vector of the word and each centroid vector is computed and the word is assigned to the class with the closest center.

The second classification method is a support vector machine (SVM). We used linear SVM from the liblinear package (Fan et al., 2008) to learn a model and classify words, that words represented by feature vector, to their category. Liblinear is efficient for training, large-scale problems (Fan et al., 2008). The hyper-parameters of the models have been tuned using a grid search from LIBSVM. To find the best C parameter value, we tested the numbers in between 0 and 20 in step 0.05.

The third and main classification method that is used in this paper is multi-relational matrix factorization. We will explain MRMF in detail in the following section.

If we want to use both lexical and distributional information, we can use MRMF as we will show in the following section. An obvious alternative is an ensemble classifier, that uses the results of the classifiers using only one type of information. Thus we also trained an SVM on the results of the SVMs using WordNet and distributional features. Since we have only boolean results from the SVM (a word is assigned to a category or not) we use also a logistic regression classifier. Logistic regression gives probabilities for each class and selects the class with the highest probability. The ensemble classifier now can use the probabilities for each class. Though we expect logistic regression to be inferior to SVM, it might have an advantage to use its class probabilities in an ensemble classifier.

4 Multi-Relational Matrix Factorization

MRMF was introduced by Lippert et al. (2008) for relation prediction in multi-relational domains using matrix factorization. Weighted MRMF as we have used here, was defined by Drumond et al. (2014) to model the different degrees of influence various relations involved in a domain might have.

For MRMF we have three matrices that can be used: the matrix of words and semantic classes, the matrix of words and context features and the matrix of words and WordNet features. The task for MRMF now is to predict values for new words in the first matrix using one or both of the other matrices.

4.1 MRMF on two Matrices

For the problem to classify words that are represented by vectors of WordNet categories and context words, we have followed the same procedure.

Let's assume the following problem: We have

- m words;

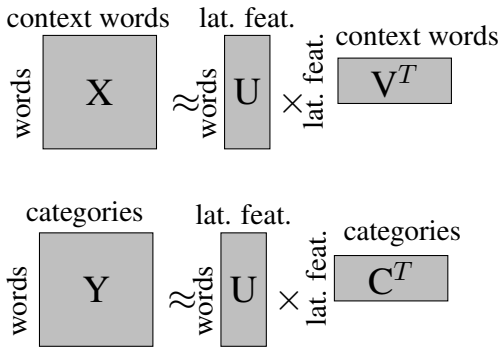

Figure 1: Visual overview of the matrix decomposition used for semantic categorization on two matrices

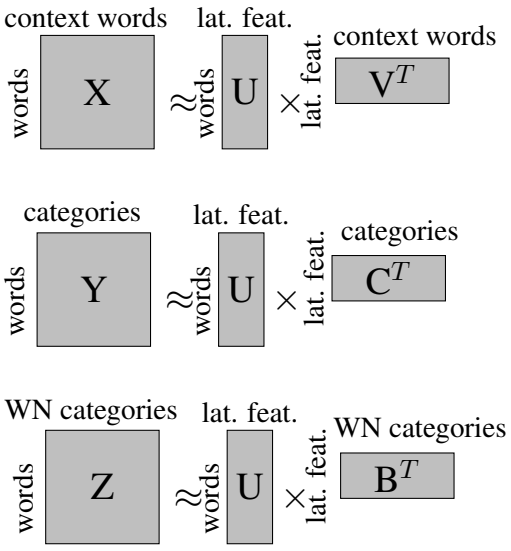

Figure 2: Visual overview of the matrix decomposition used for semantic categorization on three matrices.

Algorithm 1 Block coordinate descent optimization algorithm for L2-MRMF

procedure MRMF-COORDINATE DESCENT
input: X, Y, k, *weight constants* α_X, α_Y, *regularization constants* λ_U, λ_V, λ_C
  $U \sim \mathcal{N}(0, \sigma\mathbf{I})$
  $V \sim \mathcal{N}(0, \sigma\mathbf{I})$
  $C \sim \mathcal{N}(0, \sigma\mathbf{I})$
  repeat
    $U \leftarrow (\alpha_X XV + \alpha_Y YC)\left(\alpha_X V^T V + \alpha_Y C^T C - \lambda_U \mathbf{I}\right)^{-1}$
    $V \leftarrow \left(\left(\alpha_X U^T U - \lambda_V \mathbf{I}\right)^{-1} \alpha_X U^T X\right)^T$
    $C \leftarrow \left(\left(\alpha_Y U^T U - \lambda_C \mathbf{I}\right)^{-1} \alpha_Y U^T Y\right)^T$
  until convergence
  return U, V, C
end procedure

- n features for each word (e.g. positive point wise mutual information (PPMI) values based on the co-occurrence data);
- c semantic categories;

The features are represented by a matrix $X \in \mathbb{R}^{m \times n}$ where each row of X represents the feature vector of a word. We use a second matrix, $Y \in \{0, 1\}^{m \times c}$ with the relation between words and categories. $Y_{i,j}$ has value 1 if the word i belongs to the category c and 0 otherwise.

The idea of matrix factorization is that X can be approximated by the product of two smaller matrices U and V, where U is a matrix of words and latent features and V is a matrix of context features and the same latent features. The number k of latent features can be chosen freely with $k << n$. The second matrix, Y, can be decomposed in the same way. The idea of MRMF is that both decompositions use the same factor matrix U of words and latent features. Thus the latent features now form the link between the context features and the categories. The situation is visualized in Figure 1. The matrices U, V and C are constructed using the training data. If we have a new word w in the test data, we can add it to X and compute it's latent features using V, and thus extend U. From the extended matrix U and C we get the new row for w in Y, that gives us the classification for w.

More formally, X and Y can be factorized as:

$$X \approx UV^T \tag{2}$$

$$Y \approx UC^T \tag{3}$$

for some $U \in \mathbb{R}^{m \times k}$, $V \in \mathbb{R}^{n \times k}$ and $C \in \mathbb{R}^{c \times k}$. The problem is now to minimize the following objective with respect to L2 loss function

$$\begin{aligned} \underset{U,V,B,C}{\arg\min} \quad & \alpha_X \frac{1}{2}||X - UV^T||_F^2 + \alpha_Y \frac{1}{2}||Y - UC^T||_F^2 \\ & + \frac{\lambda_U}{2}||U||_F^2 + \frac{\lambda_V}{2}||V||_F^2 + \frac{\lambda_C}{2}||C||_F^2 \end{aligned} \tag{4}$$

L2 loss function is basically minimizing the sum of the square of the differences between the target value and the estimated values.

4.1.1 Learning Algorithm and Predictions

One of the most often used optimization algorithms is block coordinate descent. Coordinate descent optimizes the objective function through a sequence of one-dimensional optimizations. Coordinate descent is based on the idea that the minimization of a multi-variable function

First U, V and C are initialized with random values. Then the minimization problem is solved for each one of the matrices individually. This is repeated until convergence. The coordinates descent algorithm for the objective with respect to L2 loss function in Equation 4 is given in Algorithm 1

Now, for a set of new words X^{test}, Equation 5 can predict their semantic categories.

$$Y^{\text{test}} \approx U^{\text{test}} C^T \tag{5}$$

However, U^{test} is unknown. The standard way to estimate U^{test} is through a fold-in:

$$U^{\text{test}} = \underset{\hat{U}}{\arg\min} ||X^{\text{test}} - \hat{U}V^T||_F^2 \tag{6}$$

$$U^{\text{test}} = X^{\text{test}} V (V^T V)^{-1} \tag{7}$$

4.1.2 MRMF on three Matrices

The MRMF method allows to integrate elegantly many different sources of information. In our experiment we have integrated the lexical and distributional information by extending the MRMF method described in section 4.1.

Matrices X and Y are the same matrices that we have seen in section 4.1. The newly added matrix Z has the lexical information which has the hypernym information from WordNet. X, Y and Z can be factorized as follows:

$$X \approx UV^T \tag{8}$$

$$Y \approx UC^T \tag{9}$$

$$Z \approx UB^T \tag{10}$$

The overall decomposition of the three matrices for MRMF method is visualized in Figure 2. Besides adding the Z matrix information in the objective function and in the coordinate decent algorithm, we have modified Equation 7 for U^{test} and add the third matrix information as follows:

$$U^{\text{test}} = X^{\text{test}} V (V^T V)^{-1} + Z^{\text{test}} B (B^T B)^{-1} \tag{11}$$

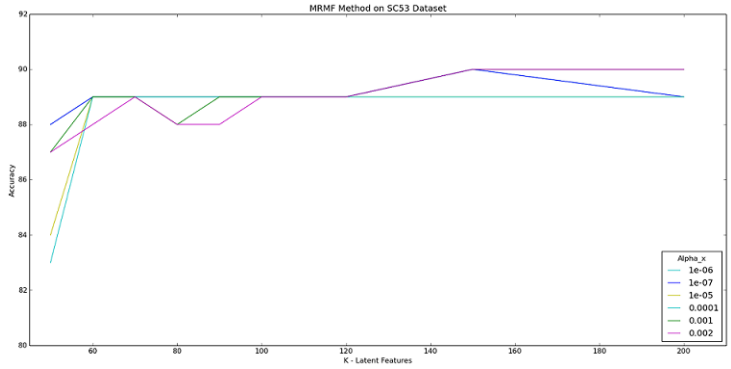

Figure 3: Accuracy of MRMF with different k and α_x parameter values on the SC53 dataset

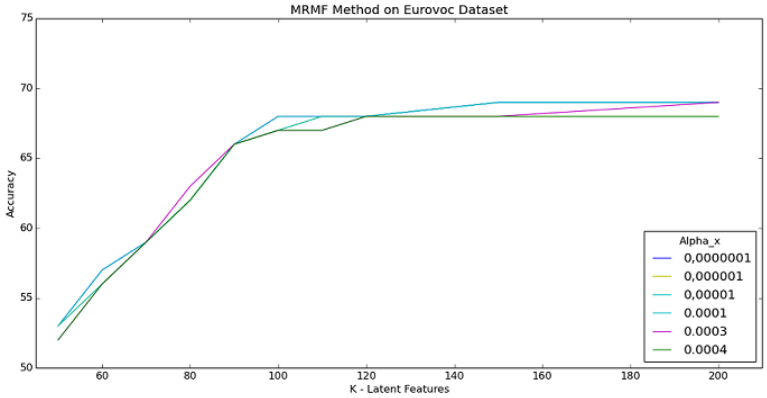

Figure 4: Accuracy of MRMF with different k and α_x parameter values on the Eurovoc dataset

4.2 Parameter Selection

For MRMF, a combination of weight constant, latent features and regularization parameters with a wide range of values was tested to find the best parameter setting. For SC53 dataset, the weight constant α_x and α_z range is in between $\frac{1}{\#\_SC53\_instances}$ and $1{\cdot}10^{-7}$, and in between $\frac{1}{\#\_Eurovoc\_instances}$ and $1{\cdot}10^{-7}$ for the Eurovoc dataset. The weight constant α_y is set to 1; Because Y is the matrix that we are building the model for, and Y^{test} is the matrix we want to predict. The regularization constants λ_u, λ_v and λ_b have used the same range of value which is in between $1 \cdot 10^{-17}$ and $1 \cdot 10^{-22}$. For the latent features k, we considered a range between 50 and 200.

Figure 3 and Figure 4 show the parameters α_x and k performance for the SC53 and Eurovoc datasets, respectively. As both figures show, the k parameter gives high accuracy on value 200 and goes flat after that for both datasets on MRMF_2 method, and also on method MRMF_3. In method MRMF_2, the k parameter has performed better with the α_x parameter value around 0.002 for SC53 and between 0.0003 and 0.0001 for the Eurovoc dataset. MRMF_3 gives optimal results when α_x is 0.001 and α_z is 0.0004 for SC53 dataset and when α_x is $1 \cdot 10^{-6}$ and α_z is $1 \cdot 10^{-7}$ for the Eurovoc derived data.

5 Evaluation

For evaluation we used 10 fold cross validation. For all experiments we used the same stratified split. This is basically the same as the leave-one out setup used by Bullinaria and Levy (2012). However, for equal size classes, in a leave–one–out experiment an intelligent classifier eventually might learn that the element to be classified always belongs to the smallest class. By using stratified croiss-validation we avoid this problem.

	Methods	Eurovoc	Stand. Err.	SC53	Stand. Err.
	Nearest Centroid (reported)	-	-	0,86	-
	Nearest Centroid (reproduced)	0,58	0,14	0,86	0,04
WN	LR	0,45	0,17	0,74	0,11
	SVM	0,50	0,16	0,73	0,10
	MRMF_2M	0,48	0,17	0,79	0,07
DF	LR	0,56	0,16	0,90	0,04
	SVM	0,69	0,10	0,90	0,03
	MRMF_2M	0,69	0,10	0,90	0,03
DF + WN	MRMF_3M	**0,71**	0,10	**0,93**	0,02
	2xLR + SVM	-	-	0,89	-
	2xSVM+ SVM	-	-	0,92	-

Table 2: Accuracy of classification on Eurovoc and SC53 datasets. Results are averages from 10-fold cross validation.

6 Result

Table 2, the result table, summarizes the performance of the methods on each dataset with their standard error (Stand. Err.). Bullinaria and Levy (2007; Bullinaria and Levy (2012) study different design and parameter choices for distributional similarity. The best accuracy, that they reached for the SC53 dataset (using a nearest centroid classifier), was $0,86$. We could reproduce this result using roughly the same choices and parameter settings that were given by Bullinaria and Levy. Applying the same method to the Eurovoc dataset gives an accuracy of 0,58. We used the hypernym features (WN) only in the supervised and hybrid settings.

For both datasets, we see that both SVM and MRMF are superior to the nearest centroid classifier. We see no big differences between the SVM and MRMF. As expected the results from logistic regression (LR) stay a bit behind those results.

Finally, we see that the integration of lexical and distributional information using MRMF clearly improves the result for both data sets. The ensemble methods can also improve the results, but stay behind the result of MRMF_3M. Since the logistic regression results for the Eurovoc data stay much behind the SVM and MRMF results, we did not test the ensemble based on those classifiers.

For the SC53 dataset, both the supervised classifiers using only distributional features and the classifier using a combination of distributional (DF) and lexical (WN) features outperform the best result reported up to now. Keith et al. (2015) report an accuracy of $0,96$ when reproducing the experiment of Bullinaria and Levy, but, as mentioned before, this result is not comparable to ours, since they used only a part of the data for evaluation.

If we look at the word classes predicted by the MRMF for the SC53 data, using both sources of information, we still have a small number of real errors. E.g. the word *mixer* is classified as a non-alcoholic beverage and *nun* as a relative. Most errors, however, are not real errors, like the word *foot* that is classified as a body part by MRMF and is a unit of distance in the dataset. A *knife* is classified as a weapon instead of a kitchen utensil; *shoes* as a type of footwear instead of clothing; and a *bass* as a musical instrument instead of a fish.

Given the type of errors that is made, we can conclude that to the SC53 data set we are close to the highest possible accuracy that can be reached. The Eurovoc dataset clearly is much harder and has still room for improvement.

7 Conclusion

We have studied semantic classification of words using distributional features directly in a strongly supervised learning setting. We have shown on two different data sets, that both SVM and MRMF outperform a distance based classifier, that is commonly used for this task. On a dataset which was used before for the same task, we thus could obtain results that are beyond state of the art.

In order to make a classification task that is closer to real applications, we compiled a new data set with more semantic categories. This data set is clearly much harder, but experiments on this dataset confirm all conclusions from the experiment on the smaller dataset.

In order to improve the results we finally investigated the possibility to include information from WordNet. While an ensemble classifier was not very successful in combining the two sources of information, MRMF was able to integrate the two types of information and improve the results substantially.

Since we are close to the optimal result for the SC53 dataset, we will concentrate on future work on datasets with a larger number of classes. In addition, we will try to find more sources of information that successfully can be integrated in order to improve the accuracy and to explore the possibilities of MRMF.

Abstract

Prepositions are very common and very ambiguous, and understanding their sense is critical for understanding the meaning of the sentence. Supervised corpora for the preposition-sense disambiguation task are small, suggesting a semi-supervised approach to the task. We show that signals from unannotated multilingual data can be used to improve supervised preposition-sense disambiguation. Our approach pre-trains an LSTM encoder for predicting the translation of a preposition, and then incorporates the pre-trained encoder as a component in a supervised classification system, and fine-tunes it for the task. The multilingual signals consistently improve results on two preposition-sense datasets.

1 Introduction

Preposition-sense disambiguation (Litkowski and Hargraves, 2005; Litkowski and Hargraves, 2007; Schneider et al., 2015; Schneider et al., 2016), is the task of assigning a category to a preposition in context (see Section 2.1). Choosing the correct sense of a preposition is crucial for understanding the meaning of the text. This important semantic task is especially challenging from a learning perspective as only little amounts of annotated training data are available for it. Indeed, previous systems (see Sections 2.1.1 and 5.4) make extensive use of the vast and human-curated WordNet lexicon (Miller, 1995) in order to compensate for the small size of the annotated data and obtain good accuracies.

Instead, we propose to deal with the scarcity of annotated data by taking a semi-supervised approach. We rely on the intuition that word ambiguity tends to differ between languages (Dagan et al., 1991), and show that multilingual corpora can provide a good signal for the preposition sense disambiguation task. Multilingual corpora are vast and relatively easy to obtain (Resnik and Smith, 2003; Koehn, 2005; Steinberger et al., 2006), making them appealing candidates for use in a semi-supervised setting.

Our approach (Section 4) is based on representation learning (Bengio et al., 2013), and can also be seen as an instance of multi-task (Caruana, 1997), or transfer learning (Pan and Yang, 2010). First, we train an LSTM-based neural network (Hochreiter and Schmidhuber, 1997) to predict a foreign (say, French) preposition given the context of an English preposition. This trains the network to map contexts of English prepositions to representations that are predictive of corresponding foreign prepositions, which are in turn correlated with preposition senses. The learned mapper, which takes into account large amounts of parallel text, is then incorporated into a monolingual preposition-sense disambiguation system (Section 3) and is fine-tuned based on the small amounts of available supervised data. We show that the multilingual signal is effective for the preposition-sense disambiguation task on two different datasets (Section 5).

pages 2718–2729, Osaka, Japan, December 11-17 2016.

2 Background

2.1 Preposition Sense Disambiguation

Prepositions are very common, very ambiguous and tend to carry different meanings in different contexts. Consider the following 3 sentences: "You should book a room *for* 2 nights", "*For* some reason, he is not here yet" and "I went there to get a present *for* my mother". The preposition "for" has 3 different readings in these sentences: in the first sentence it indicates DURATION, in the second it indicates an EXPLANATION, and in the third a BENEFICIARY. The preposition-sense disambiguation task is defined as follows: given a preposition within a sentential context, decide which category it belongs to, or what its role in the sentence is. Choosing the right sense of a preposition is central to understanding the meaning of an utterance (Baldwin et al., 2009).

2.1.1 Previous Work and Available Corpora

The preposition-sense disambiguation task was the focus of the SemEval 2007 shared task (Litkowski and Hargraves, 2007), based on the set of senses defined in The Preposition Project (TPP) (Litkowski and Hargraves, 2005), with three participating systems (Ye and Baldwin, 2007; Yuret, 2007; Popescu et al., 2007). Since then, it was tackled in several additional works (Dahlmeier et al., 2009; Tratz and Hovy, 2009; Hovy et al., 2010; Tratz, 2011; Srikumar and Roth, 2013b), some of which used different preposition sense inventories and corpora, based on subsets of the TPP dictionary. Srikumar and Roth (2013b) modeled semantic relations expressed by prepositions. For this task, they presented a variation of the TPP inventory, by collapsing related preposition senses, so that all senses are shared between all prepositions (Srikumar and Roth, 2013a). Schneider et al (2015) further improve this inventory and define a new annotation scheme.

There are two main datasets for this task: the corpus of the SemEval 2007 shared task (Litkowski and Hargraves, 2007), and the Web-reviews corpus (Schneider et al., 2016):

SemEval 2007 Corpus This corpus covers 34 prepositions with 16,557 training and 8096 test sentences, each containing a single preposition example. The sentences were extracted from the FrameNet database,[1] based mostly on the British National Corpus (with 75%/25% of informative-writings/literary). Each preposition has a different set of possible senses, with a range of 2 to 25 possible senses for a given preposition. We use the original split to train and test sets.

Web-reviews Corpus Schneider et al (2015) introduce a new, unified and improved sense inventory and corpus (Schneider et al., 2016) in which all prepositions share the same set of senses (senses from a unified inventory are often referred to as supersenses). This corpus contains text in the online reviews genre. It is much smaller than the SemEval corpus, with 4,250 preposition mentions covering 114 different prepositions which are annotated into 63 fine-grained senses. The senses are grouped in a hierarchy, from which we chose a coarse-grained subset of 12 senses for this work: AFFECTOR, ATTRIBUTE, CIRCUMSTANCE, CO-PARTICIPANT, CONFIGURATION, EXPERIENCER, EXPLANATION, MANNER, PLACE, STIMULUS, TEMPORAL, UNDERGOER. We find the Web-reviews corpus more appealing than the SemEval one: the unified sense inventory makes the sense-predictions more suitable for use in downstream applications. While our focus in this work is the Web-reviews corpus, we are the first to report results on this dataset. For the sake of comparison to previous work, we also evaluate our models on the SemEval corpus.

2.2 Neural Networks and Notation

We use $w_{1:n}$ to indicate a list of vectors, and $w_{n:1}$ to indicate the reversed list. We use $\circ$ for vector concatenation, and $x[j]$ for selecting the j^{th} element in a vector x.

A multi-layer perceptron (MLP) is a non linear classifier. In this work, we focus on MLPs with a single hidden layer and a softmax output transformation, and define the function $MLP(x)$ as:

$$MLP(x) = \text{softmax}(U(\text{g}(Wx + b1)) + b2)$$

[1] http://framenet.icsi.berkeley.edu/

where g is a non-linear activation function such as $ReLU$ or $tanh$, W and U are input-to-hidden and hidden-to-output transformation matrices, and $b1$ and $b2$ are optional bias terms. We use subscripts (MLP_{f1}, MLP_{f2}) to denote MLPs with different parameters.

Recurrent Neural Networks (RNNs) (Elman, 1990) allow the representation of arbitrary sized sequences, without limiting the length of the history. RNN models have been proven to effectively model sequence-related phenomena such as line lengths, brackets and quotes (Karpathy et al., 2015).

In our implementation we use the long short-term memory network (LSTM), a subtype of the RNN (Hochreiter and Schmidhuber, 1997). $LSTM(w_{1:i})$ is the output vector resulting from inputing the items $w_1, ..., w_i$ into the LSTM in order.

3 Monolingual Preposition Sense Classification

We start by describing an MLP-based model for classifying prepositions to their senses. For an English sentence $s = w_1, ..., w_n$ and a preposition position i,[2] we classify to the sense y as:

$$y = \underset{j}{\text{argmax}}\, MLP_{sense}(\phi(s, i))[j]$$

where $\phi(s, i)$ is a feature vector composed of 19 features. The features are based on the features of Tratz and Hovy (2009), and are similar in spirit to those used in previous attempts at preposition sense disambiguation. We deliberately do not include WordNet based features, as we want to focus on features that do not require extensive human-curated resources. This makes our model applicable for use in other languages with minimal change. We use the following features: (1) The embedding of the preposition. (2) The embeddings of the lemmas of the two words before and after the preposition, of the head of the preposition in the dependency tree, and of the first modifier of the preposition. (3) The embeddings of the POS tags of these words, of the preposition, and of the head's head. (4) The embeddings of the labels of the edges to the head of the preposition, to the head's head and to the first modifier of the preposition. (5) A boolean that indicates whether one of the two words that follow the preposition is capitalized. The English sentences were parsed using the spaCy parser.[3]

The network (including the embedding vectors) is trained using cross entropy loss. This model performs relatively well, achieving an accuracy of 73.34 on the Web-reviews corpus, way above the most-frequent-sense baseline of 62.37. On the SemEval corpus, it achieves an accuracy of 74.8, outperforming all participants in the original shared task (Section 5). However, these results are limited by the small size of both training sets. In what follows, we will improve the model using unannotated data.

4 Semi-Supervised Learning Using Multilingual Data

Our goal is to derive a representation from unannotated data that is predictive of preposition-senses. We suggest using multilingual data, following the intuition that preposition ambiguity usually differs between languages (Dagan et al., 1991). For example, consider the following two sentences, taken from the Europarl parallel corpus (Koehn, 2005): "What action will it take to defuse the crisis and tension *in* the region?", and "These are only available *in* English, which is totally unacceptable". In the first sentence, the preposition "in" is translated into the French preposition "dans", whereas in the second one, it is translated into the French preposition "en". Thus, a representation that is predictive of the preposition's translation is likely to be predictive also of its sense.

Learning a representation from a multilingual corpus We train a neural network model to encode the context of an English preposition as a vector, and predict the foreign preposition based on the context vector. The resulting context encodings will then be predictive of the foreign prepositions, and hopefully also of the preposition senses.

We derive a training set of roughly 7.4M instances from the Europarl corpus (Koehn, 2005). Europoarl contains sentence-aligned data in 21 languages. We started by using several ones, and ended up with a

[2] We also support multi-word prepositions in this work. The extension is trivial.

[3] `https://spacy.io/`

subset of 12 languages[4] that together constitute a good representation of the different language families available in the corpus. Though adding the other languages is possible, we did not experiment with them. To extract the training set, we first word-align[5] the sentence-aligned data, and then create a dataset of English sentences where each preposition is matched to its translation in a foreign language. Since the alignment of prepositions is noisier than that of content words, we use a heuristic to improve precision: given a candidate foreign-preposition, we verify that the two words surrounding it are aligned to the two words surrounding the English preposition. Additionally, we filter out, for each English preposition, all foreign prepositions that were aligned to it in less than 5% of the cases.

We then train the context representations according to the following model. For an English sentence $s = w_1, ..., w_n$, a preposition position i and a target preposition p in language L, we encode the context as a concatenation of two LSTMs, one reading the sentence from the beginning up to but not including the preposition, and the other in reverse:

$$ctx(s, i) = LSTM_f(w_{1:i-1}) \circ LSTM_b(w_{n:i+1})$$

This is similar to a BiLSTM encoder, with the difference that the encoding does not include the preposition w_i but only its context. By ignoring the preposition, we force the model to focus on the context, and help it share information between different prepositions. Indeed, including the preposition in the encoder resulted in better performance in foreign preposition classification, but the resulting representation was not as effective when used for the sense disambiguation task.

The context vector is then fed into a language specific MLP for predicting the target preposition:

$$\hat{p} = \underset{j}{\text{argmax}}\, MLP_L(ctx(s, i))[j]$$

The context-encoder and the word embeddings are shared across languages, but the MLP classifiers that follow are language specific. By using multiple languages, we learn more robust representations.

The English word embeddings can be initialized randomly, or using pre-trained embedding vectors, as we explore in Section 5.1. The network is trained using cross entropy loss, and the error is back-propagated through the context-encoder and the word embeddings.

Using the representation for sense classification Once the encoder is trained over the multilingual data, we incorporate it in the supervised sense-disambiguation model by concatenating the representation obtained from the context encoder to the feature vector. Concretely, the supervised model now becomes:

$$y = \underset{j}{\text{argmax}}\, MLP_{sense}(ctx(s, i) \circ \phi(s, i))[j]$$

where $ctx(s, i)$ is the output vector of the context-encoder and $\phi(s, i)$ is the feature vector as before.

The network is trained using cross entropy loss, and the error back-propagates also to the context-encoder and to the word embeddings to maximize the model's ability to adapt to the preposition-sense disambiguation task. The complete model is depicted in Figure 1.

5 Empirical results

Implementation details The models were implemented using PyCNN.[6] All models were trained using SGD, shuffling the examples before each of the 5 epochs. When training a sense prediction model, we use early stopping and choose the best performing model on the development set. The sense-prediction MLP uses $ReLU$ activation, and foreign preposition MLPs use $tanh$, with no bias terms. Unless noted otherwise, we use randomly initialized embedding vectors. For each experiment, we chose the parameters that maximized the accuracy on the dev set.[7] The accuracies we report are the average accuracies over 5 different seeds.

[4] Bulgarian, Czech, Danish, German, Greek, Spanish, French, Hungarian, Italian, Polish, Romanian and Swedish.

[5] Word-alignment is done using the `cdec` aligner (Dyer et al., 2010).

[6] `https://github.com/clab/cnn`

[7] In most of the experiments, the best results are achieved when the hidden-layer of the sense-prediction MLPs is of the size 500, and the preposition embedding is of size 200. In some cases, the best results are achieved with different dimensions.

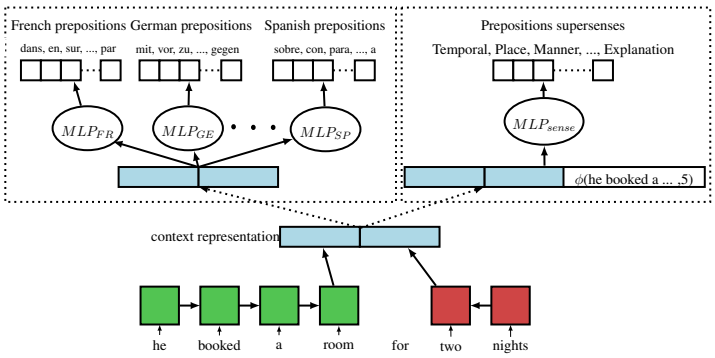

Figure 1: The suggested model for incorporating multilingual data in classifying prepositions to senses. First, a context-encoder (at the bottom, the green and red squares are LSTM cells) is trained on the Europarl corpus, with a different MLP for each language (left dashed frame). Then, the representation obtained from the context-encoder is added to the feature vector when classifying a preposition to senses (right dashed frame).

5.1 Evaluation on the Web-reviews corpus

Using multilingual data Our main motivation in this work was to train a representation which is useful for the preposition-sense disambiguation task. Thus, we compare the performance of our model using the representation obtained from the context-encoder (multilingual model) with the model that does not use this representation (base model). We use the train/test split provided with the corpus. We further split the train set into train and dev sets, by assigning every fourth example of each sense to the dev set, yielding 2552/845/853 instances of train/dev/test.

The results are presented in Table 1. We see an improvement of 2.86 points when using the pre-trained context representations, improving the average result from 73.34 to 76.20.

To verify that the improvement stems from pre-training the context-encoder on multilingual data and not from adding the context-encoder as is, we also evaluated the performance of a model identical to the multilingual model, but with no pre-training on the multilingual data (context model, middle row of Table 1). The context model achieved a very similar result to that of the base model – 73.76, indicating that adding the context-encoder to the base model is not the source of the improvement.

Model	Accuracy
base	73.34 (71.63-73.97)
+context	73.76 (71.86-75.38)
+context(multilingual)	**76.20** (74.91-77.26)

Table 1: The average accuracies on the test set of the Web-reviews corpus on 5 different seeds. Numbers in brackets indicate the min and max accuracy across seeds.

Using monolingual or bilingual data only In order to verify the contribution of incorporating information from 12 languages, we also experiment with monolingual and bilingual models. For the monolingual model we train a model similar to our multilingual one, but when trying to predict the English preposition itself, rather than the foreign one, ignoring the multilingual signal altogether. For the bilingual models we train 12 separate models similar to our multilingual model, where each one is trained only on the training examples of a single language.

As shown in Table 2, both the monolingual and the bilingual models improve over the base model (with the exception of Czech), but no improvement is as significant as that of the multilingual model. In addition, we see that the strength of the model does not depend solely on the number of training examples.

Adding external word embeddings Another way of incorporating semi-supervised data into a model is using pre-trained word embeddings. We evaluate our model when using external word embeddings

These two parameters were tuned on the dev set. The embeddings of the features are of dimension 4, with the exception of the lemmas, which are of dimension 50. The dimension of the input to the LSTMs (word embeddings) is 128. Both LSTMs have a single layer with 100 nodes, thus, the representation of the context obtained from the context-encoder is of dimension 200. The hidden-layer of the foreign-preposition MLP is of size 32.

Language	Accuracy	Improvement	Num. of training examples
None (base model)	73.34 (71.63-73.97)	–	–
Czech	73.06 (72.57-73.86)	-0.28	190,850

German	74.73 (73.74-75.62)	+1.39	603,861
Danish	75.08 (74.21-77.49)	+1.74	1,131,915
Greek	75.12 (74.09-76.20)	+1.78	586,494
French	75.43 (74.21-77.02)	+2.09	1,033,267
English (monolingual)	75.68 (74.79-76.55)	+2.34	7,483,206
Swedish	75.87 (74.68-77.49)	+2.53	1,153,999
All 12 languages	**76.20** (74.91-77.26)	**+2.86**	7,483,206

Table 2: The average accuracies on the test set of the Web-reviews corpus on 5 different seeds, using monolingual and bilingual models, along with the improvement over the base model and the number of training examples in each language. Numbers in brackets indicate the min and max accuracy across seeds.

instead of randomly initialized word embeddings. We perform three experiments: 1. using external word embeddings only for the words that are fed into the context-encoder. 2. using external word embeddings only for the lemmas of the features. 3. using external word embeddings for both.

We use two sets of word embeddings: 5-window-bag-of-words-based and dependency-based, both trained by Levy and Goldberg (2014) on English Wikipedia.[8] As shown in Table 3, both pre-trained embeddings improve the performance of all models in most cases. In all cases, the multilingual model outperforms the base model and the context model, both achieving similar results. Using external word embeddings for both the features and the context-encoder helps the most. The best result of 78.55 is achieved by the multilingual model, improving the result of the base model under the same conditions by 1.71 points.

Model	Context-encoder embeddings only		Feature embeddings only		Embeddings for both	
	Bow	Deps	Bow	Deps	Bow	Deps

Table 3: The average accuracies on the test set of the Web-reviews corpus with different pre-trained embeddings on 5 different seeds. Numbers in brackets indicate the min and max accuracy across seeds. **Bow**: 5-words window; **Deps**: dependency-based.

5.2 Evaluation on the SemEval corpus

Adaptations to the SemEval corpus In the SemEval corpus each preposition has a different set of senses, and the natural approach is to learn a different model for each one. We call this the *disjoint* approach. However, we found this approach a bit wasteful in terms of exploiting the annotated data, and we propose a model that uses the information from all prepositions simultaneously (*unified*). In the unified approach, we create an MLP classifier for each preposition, but all of them share a single input-to-hidden transformation matrix and a single bias term. Formally, for a preposition p, we define its MLP as follows:

$$MLP_p(x) = \text{softmax}(U_p(\text{g}(Wx + b1)) + b2_p)$$

where W is the shared input-to-hidden transformation matrix, $b1$ is the shared bias term, and U_p and $b2_p$ are preposition-specific hidden-to-output transformation matrix and bias term, respectively. This unified model is trained over the training examples of all prepositions together.

The SemEval corpus sometimes provides multiple senses for a given preposition instance. In both the disjoint and the unified approaches we treat these cases by generalizing the cross entropy loss for multiple correct classes. In the common case, where each training example has a single correct class, the

[8] https://levyomer.wordpress.com/2014/04/25/dependency-based-word-embeddings/

cross entropy loss is defined as $-\log p_i$, where p_i is the probability that the model assigns to the correct class. Here, instead of using $-\log p_i$, we use $-\log(\sum_{i \in C} p_i)$, where C is the set of correct classes.

Results The model performs well also on the SemEval corpus, achieving an accuracy of 76.9. Note that we use the exact same parameters that were tuned on the dev set of the Web-reviews corpus, with no additional tuning on this corpus.

As shown in Table 4, the unified model, which trains on all prepositions simultaneously, performs better than a separate model for each preposition (disjoint model), and achieves an improvement of 1.3 points when using the multilingual model. In addition, in both cases we get a significant improvement over the base model when using the pre-trained context-representation. In the unified model, adding the pre-trained context-representation improves the result by 2.1 points. As in the case of the Web-reviews corpus, we can see that this improvement does not stem from adding the context representation as is. Pre-training the representation is essential for achieving these improved results.

Model	Disjoint	Unified
base	73.7 (73.3-74.1)	74.8 (74.4-75.4)
+context	73.8 (73.6-74.0)	75.4 (74.8-75.8)
+context(multilingual)	75.6 (75.4-75.8)	**76.9** (76.4-77.7)

Table 4: The average accuracies on the test set of the SemEval corpus on 5 different seeds, with both the disjoint and the unified models. Numbers in brackets indicate the min and max accuracy across seeds.

Similar to the results on the Web-reviews Corpus, when using external word embeddings both for the words that are fed into the context-encoder and for the features, we get an improvement in all models, with an average improvement of 3 points when using the 5-words-window based embeddings. The best result amongst the three models is of 79.6 and is achieved by the multilingual model, improving over the base model by 2.5 points. The results are shown in Table 5.

Note that unlike previous experiments, adding external word embeddings improves the context model over the base model significantly, approaching the results of the multilingual model. For this reason, we also evaluated a model in which we concatenate both contexts: that of the context model (no pre-training), and that of the multilingual model (pre-trained on the multilingual data). In the case where both models achieve similar results, combining both contexts further improves the result, which indicates that they are complementary. The best result of 80.0 is achieved when using both contexts with the 5-window-bag-of-words-based embeddings. We also evaluated this combined model on the Web-reviews corpus, but got no improvement in most cases. This was predictable since in all experiments on that corpus we had a large difference between the results of the context model and of the multilingual model. The only case where we saw an improvement with both contexts was when using dependency-based embeddings for both the features and the context-encoder. The difference between the two datasets can be explained by the much larger size of the SemEval dataset, which allows the context encoder to learn from more data, even without pre-training on multilingual data.

Model	Bow	Deps	None
base	77.1 (76.9-77.2)	76.6 (76.3-76.9)	74.8 (74.4-75.4)

Numbers in brackets indicate the min and max accuracy across seeds. **Bow**: 5-words window; **Deps**: dependency-based; **None**: no external word embeddings.

5.3 Using Ensembles

We create an ensemble by training 5 different models (each with a different random seed), and predict test instances using a majority vote over the models. The results are presented in Table 6. As expected, results in all models further improve when using the ensemble. Using the multilingual context helps also when using the ensemble. We see an improvements of 1.99 points on the web-reviews corpus, improving the

result to 80.54. The performance on the SemEval corpus improves by 1.7 points, and reaches an accuracy of 81.7. These results are higher than those of the base model by 2.93 and 2.2 points, respectively.

Model	Web-reviews Corpus		SemEval Corpus	
	Average	Ensemble	Average	Ensemble
base	76.84 (76.32-77.26)	77.61	77.1 (76.9-77.2)	79.5
+context	77.73 (77.14-78.43)	78.90	79.5 (78.8-79.9)	81.1
+context(multilingual)	78.55 (77.37-79.37)	**80.54**	79.6 (79.3-79.9)	81.2
+both contexts	79.34 (78.43-80.19)	79.84	80.0 (79.8-80.2)	**81.7**

Table 6: The results on both datasets on 5 different seeds as reported in Tables 3 and 5 in comparison to the results using the ensemble. Numbers in brackets indicate the min and max accuracy across seeds.

5.4 Comparison to previous systems

Table 7 compares our SemEval results with those of previous systems. The system of Ye and Baldwin (2007) got the highest result out of the three participating systems in the SemEval 2007 shared task. They extracted features such as POS tags and WordNet-based features, and also high level features (e.g semantic role tags), using a word window of up to seven words, in a Maximum Entropy classifier. Tratz and Hovy (2009) got a higher result with similar features by using a set of positions that are syntactically related to the preposition instead of a fixed window size. The best performing systems are of Hovy et al (2010) and of Srikumar and Roth (2013b). Both systems rely on vast and thoroughly-engineered feature sets, including many WordNet based features. Hovy et al (2010) explored different word choices (i.e, a fixed window vs. syntactically related words) and different methods of extracting them, while Srikumar and Roth (2013b) improved performance by jointly predicting preposition senses and relations.

In contrast, our models do not include any WordNet based features, making them applicable also for languages lacking such resources. Our models achieve competitive results, outperforming most previous systems, despite using relatively few features and performing hyper-parameter tuning only on the different domain Web-reviews corpus.

Model	Accuracy
base	74.8
+context	75.4
+context(multilingual)	76.9
+context(multilingual) + embeddings	79.6
+both contexts + embeddings	80.0
+both contexts + embeddings + ensemble	81.7
Hovy et al (2010) – using WordNet features	84.8
Srikumar and Roth (2013b) – using WordNet features	84.78
Tratz and Hovy (2009) – using WordNet features	76.4
MELB-YB (Ye and Baldwin, 2007) – using WordNet features	69.3
KU (Yuret, 2007)	54.7
IRST-BP (Popescu et al., 2007)	49.6
Most Frequent Sense	39.6

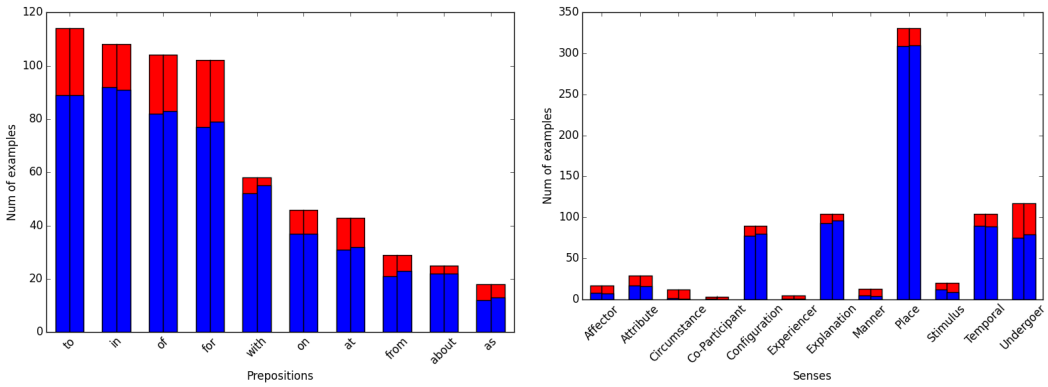
Table 7: The accuracies on the test set of the SemEval corpus, in comparison to previous systems.

5.5 Error Analysis

Figure 2 depicts the percentage of correct assignments of the base model, in comparison to the multilingual model, per sense and per preposition (only the 10 most common prepositions are shown). Both models use pre-trained word embeddings and ensembles. Clearly, there is a systematic improvement across most prepositions and senses.

6 Related work

Transfer learning and representation learning Transfer learning is a methodology that aims to reduce annotation efforts by first learning a model on a different domain or a closely related task, and then transfer the gained knowledge to the main task (Pan and Yang, 2010). Multi-task learning (MTL) is an approach of transfer learning in which several tasks are trained in parallel while using a shared representation. The different tasks can benefit from each other through this representation (Caruana, 1997). In



(a) prepositions (b) senses

Figure 2: Assignments on the dev set of the Web-reviews corpus per preposition (a) and per sense (b). Left bars stand for the base model, right bars stand for the multilingual model. In blue are correct assignments, and in red incorrect ones.

this work we use MTL to improve preposition-sense disambiguation, by using an auxiliary multilingual task – predicting translations of prepositions.

A simple method for sharing information in transfer learning as well as in MTL, is using representations that are shared between related tasks. Representation learning (Bengio et al., 2013) is a closely related field that aims to establish techniques for learning robust and expressive data representations. A well-known effort in this field is that of learning word embeddings for use in a wide range of NLP tasks (Mikolov et al., 2013; Al-Rfou et al., 2013; Levy and Goldberg, 2014; Pennington et al., 2014). While those representations are highly effective in many cases, other scenarios require representations of a full sentence, or of a context around a target word, rather than representations of single words. Contexts are often represented by some manipulation over the embeddings of their words. Such representations have been successfully used for tasks such as context-sensitive similarity (Huang et al., 2012), word sense disambiguation (Chen et al., 2014) and lexical substitution (Melamud et al., 2015). An alternative approach for context representation is encoding a context of arbitrary length into a single vector using LSTMs. This approach has been proven to outperform the previous attempts in a variety of tasks such as Semantic Role Labeling (Zhou and Xu, 2015), Natural Language Inference (Bowman et al., 2015) and Sentence Completion (Melamud et al., 2016). We follow the LSTM-based approach for context representation.

Learning from multilingual data The use of multilingual data for improving monolingual tasks has a long tradition in NLP, and has been used for target word selection (Dagan et al., 1991); word sense disambiguation (Diab and Resnik, 2002); and syntactic parsing and named entity recognition (Burkett et al., 2010), to name a few examples. A dominant approach for exploiting multilingual data is that of cross-lingual projection. This approach assumes a good model exists in one language, and uses annotations in that language in order to constrain possible annotations in another. Projections were successfully used for dependency grammar induction (Ganchev et al., 2009), and for transferring tools such as morphological analyzers and part-of-speech taggers from English to languages with fewer resources (Yarowsky et al., 2001; Yarowsky and Ngai, 2001). A different approach is applying multilingual constraints on existing monolingual models, as done for parsing (Smith and Smith, 2004; Burkett and Klein, 2008) and for morphological segmentation (Snyder and Barzilay, 2008).

Of much relevance to this work are also previous attempts to improve monolingual representations using bilingual data (Faruqui and Dyer, 2014). Previous works focus on creating sense-specific word embeddings instead of the common word-form specific embeddings (Ettinger et al., 2016; Šuster et al., 2016), and also on representing words using their context (Kawakami and Dyer, 2015; Hermann and Blunsom, 2013). While we rely on the assumption most of these works have in common, according to which translations may serve as a strong signal for different senses of words, the novelty of our work is in focusing on prepositions rather than content words, and in jointly representing a context for both a multilingual and a monolingual tasks, which results in an improvement of the monolingual model.

7 Conclusions and Future Work

We show that multilingual data can be used to improve the accuracy of preposition-sense disambiguation. The key idea is to train a context-encoder on vast amounts of parallel data, and by that, to obtain a context representation that is predictive of the sense. We show an improvement of the accuracy in all experiments upon using this representation. Our model achieves an accuracy of 80.54 on the Web-reviews corpus, and an accuracy of 81.7 on the SemEval corpus, with significant improvements over models that do not use the multilingual signals. Our result on the SemEval corpus outperforms most previous works, without using any manually curated lexicons.

Exploring the Automatic Recognition of Irony in English tweets

Cynthia Van Hee, Els Lefever and Véronique Hoste

Abstract

Recognising and understanding irony is crucial for the improvement natural language processing tasks including sentiment analysis. In this study, we describe the construction of an English Twitter corpus and its annotation for irony based on a newly developed fine-grained annotation scheme. We also explore the feasibility of automatic irony recognition by exploiting a varied set of features including lexical, syntactic, sentiment and semantic (Word2Vec) information. Experiments on a held-out test set show that our irony classifier benefits from this combined information, yielding an F_1-score of 67.66%. When explicit hashtag information like *#irony* is included in the data, the system even obtains an F_1-score of 92.77%. A qualitative analysis of the output reveals that recognising irony that results from a polarity clash appears to be (much) more feasible than recognising other forms of ironic utterances (e.g., descriptions of situational irony).

1 Introduction

With the emergence of the social web, a large part of our daily communication has moved online. As a result, the past decade has seen an increased research interest in text mining on social media data. The frequent use of irony in this genre (Ghosh and Veale, 2016; Maynard and Greenwood, 2014) has important implications for tasks such as sentiment analysis and opinion mining (Liu, 2015), which aim to extract positive and negative opinions automatically from online text. Irony detection is therefore crucial if we want to push the state of the art in sentiment analysis or, more broadly, any task involving text interpretation (e.g., cyberbullying detection).

Most computational approaches to date model irony by relying solely on categorical labels like irony hashtags (e.g., *#irony, #sarcasm*) assigned by the author of the text. To our knowledge, no guidelines presently exist for the more fine-grained annotation of irony in social media content without exploiting this hashtag information. In order to understand how irony is linguistically realised and how it can be recognised in text, we developed a set of annotation guidelines for identifying specific aspects and forms of irony that are susceptible to computational analysis. We collected a Twitter corpus containing 3,000 English tweets with an irony hashtag and, based on these guidelines, manually annotated them for the presence of irony. We explored the feasibility of automatic irony detection by relying on a varied set of features, including lexical, shallow syntactic, sentiment and lexical semantic information.

The remainder of this paper is structured as follows. Section 2 includes an overview of existing work on defining and modelling irony. Section 3 zooms in on the corpus construction and annotation. Section 4 outlines the experiments, and Section 5 presents the results. Section 6 concludes the paper with some prospects for future research.

2 Related Research

Since many years, irony has been a frequent topic of discussion in linguistics and philosophy. More recently, researchers in the field of natural language processing (NLP) have shown an increasing interest in the subject, trying to formalise the concept of irony, and detect it automatically. Different types of irony can be distinguished. Kreuz and Roberts (1993) define four types of irony: (i) Socratic irony and (ii) dramatic irony, both explained as a tension between what the hearer knows and what the speaker pretends

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2730–2739, Osaka, Japan, December 11-17 2016.

to know (with the latter entailing a performance aspect), (iii) Irony of fate, which involves an incongruence between two situations, similarly to what is commonly understood as situational irony (Lucariello, 1994), and (iv) verbal irony, which implies a speaker who intentionally says the opposite of what they believe.

In this research, we focus on verbal irony and (written forms of) situational irony. A popular definition of verbal irony is saying the opposite of what is meant (Grice, 1975). Though often criticised (e.g., Giora (1995); Sperber and Wilson (1981)), this definition is commonly used in contemporary research on the automatic modelling of irony (Kunneman et al., 2015). When describing how irony works, many studies struggle to distinguish between verbal irony and sarcasm. Some consistently use one of the two terms (e.g., Grice (1975); Sperber and Wilson (1981)), or consider both as essentially the same phenomenon (e.g., Attardo (2000); Reyes et al. (2013)). Other studies claim that sarcasm and verbal irony do differ in some respects, stating that ridicule (Lee and Katz, 1998), hostility and denigration (Clift, 1999), and the presence of a victim (Kreuz and Glucksberg, 1989) play a more important role in sarcasm than in irony. To date, however, experts do not formally agree on the distinction between irony and sarcasm. For the present research, we elaborated a working definition (Section 3.1) that does not distinguish between the two either, and refer to this linguistic form as (verbal) irony.

Automatic irony detection has received increased research interest in the past few years, with one of the main motivations being the improvement of sentiment analysis systems. In effect, as irony implicitly alters the polarity of an utterance, its recognition is important for the development and refinement of sentiment classification systems. Computational approaches to irony detection involve supervised or semi-supervised learning. More recently, researchers have been investigating deep learning by defining neural networks for irony detection. Twitter is a popular data genre when training supervised models for irony detection, one of the main advantages being that it minimises (or even discards) the annotation effort as it contains self-describing hashtags like *#sarcasm* and *#irony*. Davidov et al. (2010) experimented with 6 million tweets and 66,000 Amazon product reviews. They built an algorithm (*SASI*) based on semi-supervised learning and exploited syntactic patterns and punctuation as features, yielding F-scores of 0.79 (Amazon) and 0.83 (Twitter). Reyes et al. (2013) built a corpus of 40,000 tweets and divided it into four topics based on hashtag information (*irony, education, humour* and *politics*). They made use of Decision trees and Naïve Bayes exploiting a rich set of features capturing *style* (e.g., n-grams), *emotional scenarios* (e.g., imagery), *signatures* (e.g., pointedness), and *unexpectedness* (e.g., temporal imbalance). Their approach yields F= 0.72 on recognising the irony topic. Barbieri and Saggion (2014) experimented with the same corpus as Reyes et al. (2013) and used Random Forest and Decision Tree as classifiers. They made use of a varied set of features (word frequency, writing style, punctuation, ambiguity, etc.), and performed binary classification experiments to distinguish irony from each one of the three other topics: education (F= 0.73), humour (F= 0.75), and politics (F= 0.75). Riloff et al. (2013) presented a bootstrapping algorithm to automatically learn sequences of positive sentiment and negative situation phrases from ironic tweets. When adding n-grams and sentiment lexicon features, their SVM classifier achieved an F-score of 0.51. Kunneman et al. (2015) collected a dataset of 800,000 tweets. They made use of Balanced Winnow, exploiting word uni-, bi- and trigrams as features, and obtained an accuracy of 87% on the ironic tweets. In line with Wallace's (2015) claim that text-based features are too shallow and that context and semantics are required for reliable irony detection, a recent study from Ghosh and Veale (2016) describes neural-network-based semantic modelling for irony detection. The researchers compared the performance of an SVM model exploiting shallow features to that of neural networks capturing semantic information and demonstrated that the latter outperformed the SVM model (F= 0.92 vs. 0.73).

It is important to note that, in the above-described papers, training data is often obtained by collecting tweets with hashtags like *#sarcasm* and *#irony* and labelling them accordingly (i.e., tweets containing such hashtags are labeled as ironic, whereas tweets devoid of such hashtags are considered non-ironic). An important contribution of this paper is that, after collecting data based on irony hashtags, all tweets were manually labeled for irony based on a fine-grained annotation scheme (Van Hee et al., 2016b). Furthermore, to estimate the impact of irony hashtags on a detection system, we evaluate the performance

of our classifier before and after removing them from the corpus.

3 Corpus Description

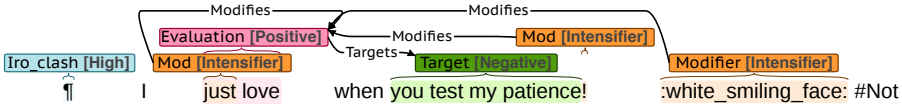
We collected a dataset of 3,000 English tweets by searching for the hashtags *#irony*, *#sarcasm* and *#not*. Unlike many other approaches, all tweets were manually annotated for irony presence based on a newly developed annotation scheme (Van Hee et al., 2016b), which resulted in 2,396 ironic and 604 non-ironic tweets. Some example annotations are presented in Section 3.1.

3.1 Corpus Annotation

The main goal of our annotation guidelines was to develop a set of reproducible coding principles to mark irony in (social media) text. As we ultimately want to be able to model irony in text, without relying on additional (i.e., hashtag) information provided by the writer of the message, our main focus was on disentangling expressions of verbal irony. In accordance with the classic account of irony, i.e., 'saying the opposite of what is meant' (Grice, 1975), we define verbal irony as an *evaluative expression whose polarity (i.e., positive, negative) is inverted between the literal and the intended evaluation, resulting in an incongruence between the literal evaluation and its context*. While a detailed overview of the annotation procedure is provided in the guidelines (Van Hee et al., 2016b), we briefly discuss the main principles below. Brat was used as annotation environment (Stenetorp et al., 2012).

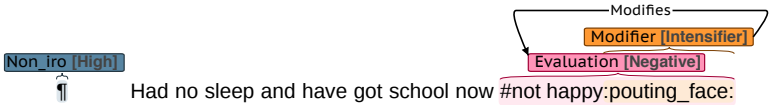
At the **tweet level**, annotators indicated whether the tweet was (i) ironic by means of a clash (example 1), (ii) contained another type of irony (e.g., situational irony, example 2), or was (iii) not ironic (example 3).

(1)



(2)

(3)



In order to better understand how this irony is realised, the tweets were also annotated **below tweet level**. In case of irony expressed by means of a clash, it was also indicated whether an irony-related hashtag (e.g., *#sarcasm*, *#irony*, *#not*) was required for recognising the irony. Furthermore, annotators were asked to signal variants of verbal irony that are particularly harsh (i.e., carrying a mocking or ridiculing tone with the intention to hurt someone), since it has been shown that harshness may be a useful feature to distinguish between irony and sarcasm (Barbieri and Saggion, 2014). Sentence 4 shows an example of such a harsh tweet.

(4) Shout outs to the guy who took a shower in 1 Million before heading out. The WHOLE BUS thanks you #Sarcasm

The annotators also marked all evaluations contained by the tweet and indicated text spans that contrast with the polarity expressed by that evaluation (i.e., *targets*) (See sentence 5 for an example). For each evaluation:

- the polarity was indicated;
- modifiers were annotated (if present);
- (in the case of ironic tweets) the target of the evaluation was indicated. Also, the implicit polarity of the target was defined based on context, world knowledge or common sense.

(5) The most hideous spider, that makes me feel sooo much better. #not
→ Evaluations: *most hideous* (neg. polarity), *makes me feel sooo much better* (pos. polarity).
→ Modifiers: *most*, and *sooo much*.
→ Targets: *the most hideous spider* (as target of *makes me feel sooo much better*), which holds a negative implicit polarity.

3.2 Annotation Statistics

To assess the validity of the annotations, inter-annotator agreement was measured between three independent annotators. Kappa scores for (i) the annotation of irony (ironic vs. not ironic) and (ii) the decision whether an irony hashtag was required to recognise the irony are 0.72 and 0.67, respectively.

Table 1 presents the distribution of the corpus as divided by the different annotation labels[1]. As can be inferred from the table, most instances that were labeled as ironic belong to the category *ironic by means of a clash*. When we zoom in on the category *other type of irony*, we can distinguish two subcategories: *situational irony* and *other verbal irony*. Whereas the former encompasses (written instances of) ironic situations and comprises the majority of this annotation class, the latter contains instances of irony that describe neither situational irony, nor a clash between two polarities (viz. the literal and the intended one). Nevertheless, they are still considered to be ironic. We refer to Van Hee et al. (2016a) for more details on the corpus statistics.

Ironic by means of a clash	**Other type of irony**		**Not ironic**	**Total**
	Situational irony	*Other verbal irony*		
1,728	401	267	604	3,000

Table 1: Statistics of the annotated corpus: number of instances per annotation category.

For our binary classification experiments, we merged the categories *ironic by means of a clash* and *other type of irony*. As we wanted a balanced dataset (ironic vs. not ironic), we added 1,792 non-ironic tweets to the current corpus. These tweets are from the same Twitter users from which we collected the initial 3,000 tweets (Table 1) and contain no irony-related hashtags. As such, our experimental corpus consists of 4,792 tweets, of which 2,396 are ironic and another 2,396 are not ironic.

4 Experiments

In our classification experiments, we evaluated the viability of automatically recognising verbal irony in tweets. To this end, we constructed a pipeline and ran a series of experiments while exploiting different feature groups. These include standard text classification features (i.e., bags-of-words, lexical and syntactic features), and features based on existing sentiment lexicons. Furthermore, we added semantic features based on Word2Vec clusters, which is, to our knowledge, novel in SVM-based approaches to irony detection.

For the classification experiments, we split the randomised corpus (4,792 instances) into an 80% training and 20% test set for evaluation, resulting in a training set of 3,834 instances and a held-out test set of 958 instances. Both sets show a balanced irony distribution (50% ironic vs. 50% not ironic). Furthermore, all annotation categories (Table 1), as well as the extra non-ironic instances that were added (Section 3.2) are equally distributed among the train and test sets.

4.1 Preprocessing

After constructing the corpus, all emoji were replaced by their name or a description using the Python Emoji module[2] to facilitate annotation and processing of the data. Furthermore, we normalised hyperlinks and @-replies or mentions to *http://someurl* and *@someuser*, respectively.

Other preprocessing steps involve tokenisation and PoS-tagging (Gimpel et al., 2011), lemmatisation (Van de Kauter et al., 2013) and named entity recognition (Ritter et al., 2011).

[1] Due to a refinement of the annotations, the corpus statistics are slightly different from a first version of the annotated corpus described in Van Hee et al. (2016a).

4.2 Information Sources

For the automatic irony detection system, we implemented a variety of features that represent every instance within a (sparse) feature vector.

- As **lexical** features, we included bags-of-words (BoW) features that represent a tweet as a 'bag' of its words or characters. We incorporated token unigrams and bigrams and character trigrams and fourgrams. Furthermore, a set of numeric and binary features were included containing information about (i) character and (ii) punctuation flooding, (iii) punctuation and (iv) capitalisation, (v) hashtag frequency and (vi) the hashtag-to-word ratio, (vii) emoticon frequency, and (viii) tweet length. Where relevant, numeric features were normalised by dividing them by the tweet length in tokens.

- As **syntactic** features, we integrated four Part-of-Speech features for each of the 25 tags in the tagset. These indicate for each PoS-tag (i) whether it occurs in the tweet or not, (ii) whether the tag occurs 0, 1, or > 2 times, (iii) the frequency of the tag in absolute numbers and (iv) as a percentage. Also the number of interjections was added as a feature. Furthermore, we included a binary feature indicating a 'clash' between verb tenses in the tweet (see Reyes et al. (2013)). Finally, we integrated four features indicating the presence of named entities in a tweet: one binary feature and three numeric features, indicating (i) the number of named entities in the text, (ii) the number and (iii) frequency of tokens that are part of a named entity.

- Six **sentiment lexicon** features were implemented based on existing sentiment lexicons: AFINN (Nielsen, 2011), General Inquirer (GI) (Stone et al., 1966), MPQA (Wilson et al., 2005), the NRC Emotion Lexicon (Mohammad and Turney, 2013), Liu's opinion lexicon (Hu and Liu, 2004), and Bounce (Kökciyan et al., 2013). For each lexicon, five numeric and one binary feature were derived:

  - the number of positive, negative and neutral lexicon words averaged over text length;
  - the overall tweet polarity (i.e., the sum of the values of the identified sentiment words);
  - the difference between the highest positive and lowest negative sentiment values;
  - a binary feature indicating whether there is a polarity contrast (i.e., at least one positive and one negative sentiment word from the lexicon are present in the tweet).

  The sentiment lexicon features were extracted in two ways: (i) by considering all tokens in the instance and (ii) by considering only hashtag tokens (e.g., *lovely* from *#lovely*). We took negation cues into account by flipping the polarity of a sentiment word when it occurred in a negation relation.

- As **semantic** information, we used word embedding cluster features generated with Word2Vec (Mikolov et al., 2013). The word embeddings were generated from a separate background corpus of 45,251 English tweets, collected with the hashtags *#sarcasm*, *#irony* and *#not*. More precisely, we ran Word2Vec on this corpus, applying the CBoW model, a context size of 8, a word vector dimensionality of 200 features, and a cluster size of $k = 2{,}000$[3]. The following are two example clusters: [#chistecorto #dailysarcasm #fun #sarcastically #sarcastichumor] and [#exams #nosleep #10am editing essay grading psychology stress revision]. The clusters were implemented as binary features, indicating for each cluster whether a word contained by that cluster occurs in the tweet.

In total, we have four feature groups. Based on each of them, we trained a binary classifier which was then tested on the held-out set. After evaluating the performance of each feature group individually, another experiment was run with the combined feature groups (comprising 100,278 individual features).

[3]To define k, we performed 5-fold cross validation experiments on the training data, exploiting features based on different cluster sizes (100; 200; 500; 1,000 and 2,000).

4.3 Experimental Setup

As mentioned earlier, we conducted binary classification experiments for detecting ironic tweets by exploiting lexical, syntactic, sentiment lexicon and semantic features. One of the contributions of this paper is to measure the impact of irony-related hashtags (e.g., *#irony*) in the dataset. To this end, we ran two sets of experiments based on each feature group: one before and another after removing such hashtags from the corpus.

We used LIBSVM (Chang and Lin, 2011) with the standard RBF kernel as the classification algorithm. As shown by Keerthi and Lin (2003), a nonlinear kernel like RBF (or *Gaussian*) is at least as good as a linear one if it is properly tuned. The LIBSVM parameters C and γ were therefore optimised for each experiment exploiting a different feature group, and by means of a cross-validated grid search on the complete training data. During the parameterisation, γ is varied between 2^{-15} and 2^{3} (stepping by factor 4), while the cost parameter C is varied between 2^{-5} and 2^{15} (stepping by factor 4). In both setups, the optimised values for C and γ were 2^{3} and 2^{-11}, respectively. These optimal parameter settings were then used to build a model for each feature group using all the training data, which was evaluated on the held-out test set (Section 5).

5 Results

This section presents the experimental results. As mentioned earlier, we tested the validity of four different feature groups for automatic irony detection, comprising lexical, syntactic, sentiment and semantic features. Finally, all feature groups were combined to see whether they provide complementary information to the classifier. Each feature group was evaluated in two experimental setups: one where irony hashtags like *#irony*, *#sarcasm* and *#not* were removed from the corpus, and another where this hashtag information was included.

5.1 Experimental Results on the Held-out Test Set

Table 2 presents the results obtained with each feature group separately, and with the combined set. Besides accuracy, we report F_1-score, precision and recall (on the positive class) as the evaluation metrics.

For the baseline system, we included only bag-of-words features. No parameter tuning was done. As the system consistently predicts the positive class (i.e., *ironic*), its recall is 100% while its accuracy is equal to the positive class distribution.

	Setup 1: without hashtag information				*Setup 2: with hashtag information*			
Features	**Accuracy**	**F_1-score**	**Precision**	**Recall**	**Accuracy**	**F_1-score**	**Precision**	**Recall**
BoW (baseline)	48.96	65.73	48.96	100	48.96	65.73	48.96	100
Lexical	66.91	66.38	66.03	66.74	90.92	91.41	85.11	98.72
Syntactic	63.57	64.57	61.63	67.80	80.48	81.68	75.54	88.91
Sentiment	59.29	55.78	59.56	52.45	74.95	71.22	81.37	63.33
Semantic	64.41	63.53	63.73	63.33	88.73	89.45	82.52	97.65
Combined	68.16	**67.66**	67.30	68.02	92.48	**92.77**	87.67	98.51

Table 2: Experimental results on the held-out test set in both setups.

Evidently, the experimental setup with hashtags included (setup 2) performs best. To understand the performance of this system better, we compare its accuracy (92.48%) to a baseline that simply classifies all tweets containing an irony-related hashtag as ironic and all other tweets as not ironic, yielding an accuracy of 87%. In both setups, the best performance is achieved by the combined feature set (F= 67.66 and 92.77). This partly supports the findings of Wallace (2015) that verbal irony cannot be recognised through lexical clues alone. Nevertheless, lexical information does seem to be of key importance for this task, as the corresponding system obtained the second best score (F= 66.38 and 91.41). An explanation could be the nature of Twitter data: due to its limited length, a tweet is prone to be misunderstood, which may encourage people to use explicit lexical clues when speaking ironically. In both setups, sentiment features perform least well for this task (F= 55.78 and 71.22), which demonstrates that (explicit) polarity

information is not sufficient for decent irony recognition. Nevertheless, the annotations revealed that many ironic tweets showed a polarity contrast (mostly between evaluations and *targets*). In future work, we will therefore explore methods to model this clash between explicit and implicit (i.e., inferred from world knowledge) sentiment expressions.

5.2 Analysis of the Results

Judging from the raw performance results, irony detection in Twitter data benefits from a combined set of information sources (i.e., lexical, syntactic, sentiment and semantic). In a next step, we investigate whether the combined system is significantly better than the baseline and the systems we built based on each feature group. To this end, we applied 10 paired samples t-test (α= 0.05) after bootstap resampling (Noreen, 1989): one for each system (including the baseline) that we compare against the combined system, in the two experimental setups. Concretely, we drew samples (n= 10,000) with replacement from the output of each system and of equal size of the output (n= 958, the number of test instances). Each sample was then evaluated using macro-averaged F_1-score (on the positive class), after which we applied a paired samples t-test to compare the mean scores for both systems. We found a significant difference ($p<$ 0.05) for all system pairs.

For the experiments in this paper, we concentrated on two classification labels being ironic and not ironic, thus casting the problem into a detection (or binary classification) task. To this end, the annotation labels *ironic by clash*, *other type of irony* and *situational irony* were combined into the positive class in both our training and test sets. In the following paragraph, we zoom in on these 'subclasses' of irony and evaluate the performance of our system on each one of them in the test set. The subclasses are represented by 346 (*irony by clash*), 62 (*other irony*) and 61 (*situational irony*) instances in the test set. We will also take a closer look at the two types of non-ironic tweets (i.e., with and without an irony-related hashtag) in the dataset.

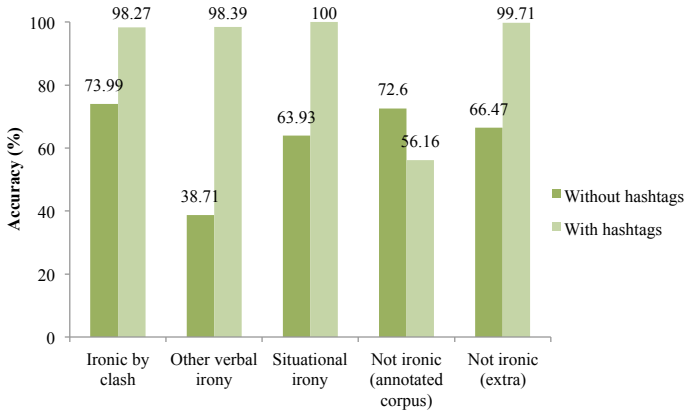

Figure 1: System accuracy on different types of ironic and non-ironic tweets.

As shown in Figure 1, the performance of the system increases significantly when hashtag information is included, reaching an accuracy of up to 100% for the recognition of tweets that describe situational irony. Without this hashtag information, the best performance is achieved on *ironic by clash* (acc.= 73.99%), followed by *situational irony* (acc.= 63.93%). The score on *other verbal irony* is low, however (acc.= 38.71%). This would suggest that detecting verbal irony is (much) more feasible when the irony results from contrasting evaluations, as opposed to other types of verbal irony.

We also had a closer look at the category 'not ironic'. Important to recapitulate is that 25% of these tweets contain an irony hashtag (they were part of the originally collected 3,000 tweets (cf. Table1)). When looking at the classification performance on these tweets, we observe that, when irony hashtags are included in the data, the accuracy obtained is 56%. This demonstrates that the system does not simply rely on hashtag information (since this would result in an accuracy of 0% on this category). Another category that is subject to a qualitative analysis, are the tweets for which annotators had indicated that an

explicit hashtag (e.g., *#irony*) was required to recognise the irony. Intuitively, the system would perform better on the instances where no such hashtag is needed, especially when these hashtags are removed from the data. Effectively, this hypothesis was confirmed by our experiments (setup 1), revealing a higher accuracy on ironic tweets where no hashtag was required to recognise the irony (83.43%) than on those where it was (63.64%). The accuracy on the latter still being relatively high, we can conclude that the irony in our dataset is moderately to strongly lexicalised. This conclusion is in line with the performance of the system exploiting lexical features (cf. Table 2).

We see that our combined system (F_1= 67.66) compares favourably to that of Riloff et al. (2013) (F_1= 0.51), who describe a similar experimental setup to the one presented here. However, comparison with state of the art is not trivial, given the size of our dataset and the different definitions of irony that are used among researchers. In effect, most studies make use of large corpora that are labeled based on hashtag information (e.g., Kunneman et al. (2015), Reyes et al. (2013)). Furthermore, some approaches (e.g., Riloff et al. (2013)) focus on one particular type of irony, whereas the present research takes different types into account.

6 Conclusion and Future Work

In this paper we developed and tested a system for irony detection in English Twitter data. We collected 3,000 tweets with irony hashtags (i.e., *#irony*, *#sarcasm*, and *#not*) and manually annotated them according to a newly developed annotation scheme for verbal irony. To balance the ironic vs. not ironic classes in the experiments, another 1,792 non-ironic tweets from a random Twitter sample were added, which resulted in an experimental corpus of 4,792 tweets. We explored the viability of automatic irony detection using different feature groups (lexical, syntactic, sentiment, semantic and combined). Additionally, we compared the system's performance on our dataset with and without removing the irony-related hashtags. The results on a held-out test set revealed that irony detection benefits from a combined feature set: our binary classifier yields an F_1-score of 67.66% on the dataset devoid of irony hashtags, while obtaining F_1= 92.77% with irony hashtags included in the dataset. Although lexical features are assumed insufficient for decent irony recognition (Wallace, 2015), we experimentally show that they do provide relevant information, as the corresponding system scored second best, after the combined system.

A qualitative analysis of the different types of ironic tweets revealed that our classifier performed best on tweets where the irony results from a polarity contrast (i.e., the polarity of the expressed sentiment is opposite to what is meant). Given that ironic tweets are prone to implicit sentiment, future research will focus on recognising and understanding such implicit evaluations by making use of world knowledge or common sense. This would allow to identify a polarity contrast in typically ironic utterances where a part of the evaluation is implicit, such as *monday mornings* in the sentence *Monday mornings are my fave! :)*.

Abstract

When processing arguments in online user interactive discourse, it is often necessary to determine their bases of support. In this paper, we describe a supervised approach, based on deep neural networks, for classifying the claims made in online arguments. We conduct experiments using convolutional neural networks (CNNs) and long short-term memory networks (LSTMs) on two claim data sets compiled from online user comments. Using different types of distributional word embeddings, but without incorporating any rich, expensive set of features, we achieve a significant improvement over the state of the art for one data set (which categorizes arguments as factual vs. emotional), and performance comparable to the state of the art on the other data set (which categorizes propositions according to their verifiability). Our approach has the advantages of using a generalized, simple, and effective methodology that works for claim categorization on different data sets and tasks.

1 Introduction

Argumentation mining is a relatively new subfield in natural language processing that aims to automatically identify and extract arguments, and their underlying structures, from textual documents (Moens et al., 2007; Palau and Moens, 2009; Wyner et al., 2010; Feng and Hirst, 2011; Ashley and Walker, 2013; Stab and Gurevych, 2014). Some such documents are written by professionals and contain well-formed, explicit arguments—i.e., propositions supported by evidence and connected through reasoning. However, informal arguments in online argumentative discourses can exhibit different styles. Recent work has begun to model different aspects of these naturally occurring lay arguments, with tasks including stance classification (Somasundaran and Wiebe, 2009; Walker et al., 2012), argument summarization (Misra et al., 2015), sarcasm detection (Justo et al., 2014) and classification of propositions and arguments (Park and Cardie, 2014; Park et al., 2015; Oraby et al., 2015). Of particular interest is the fact that arguments in online user comments, unlike those written by professionals, often have inappropriate or missing justifications. Recognizing such propositions and determining the appropriate types of support can be useful for assessing the strength of the supporting information and, in turn, the strength of the whole argument.

To this end, two previous studies have produced data sets and methods for classifying propositions in online argumentative discourse. The first of these studies (Park and Cardie, 2014) compiled online user comments from a discussion website and developed a framework for automatically classifying each proposition as either "unverifiable", "verifiable non-experiential", or "verifiable experiential", where the appropriate types of support are reason, evidence, and optional evidence, respectively. The second study, Oraby et al. (2015), uses a different online corpus (Walker et al., 2012) of short argumentative responses to quotes, and classifies each response as either "factual" or "feeling" according to whether the support invoked appeals to facts or to emotions. In this paper, we use the term "claim" loosely to refer to an individual proposition (a sentence or independent clause) in an argument, or to a short argumentative text containing one or more propositions.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2740–2751, Osaka, Japan, December 11-17 2016.

In classifying propositions, Park and Cardie (2014) followed previous work such as Reed et al. (2008) and Palau and Moens (2009), employing supervised learning methods. Despite using a rich set of linguistic features, these approaches suffer from low accuracy. Moreover, generating these features can be a tedious and complex process. In this paper, we show that state-of-the-art performance in claim classification for online user comments can be achieved without the need for expensive features. Our work, which employs CNN- and LSTM-based deep neural networks, is inspired by advances in sentence classification (Kim, 2014) and sequence classification (Hochreiter and Schmidhuber, 1997) using distributional word representations and deep learning. In particular, our approach leverages word2vec[1] distributional embeddings, dependency context–based embeddings (Levy and Goldberg, 2014), and factuality/certainty-indicating embeddings for improving claim classification. (We refer to these embeddings as *linguistic embeddings*, as these are compiled from linguistic annotations such as dependency relations, verb modalities, and actuality information.) In this paper, we separately evaluate the usefulness of word and linguistic embeddings in the claim classification task on both the aforementioned data sets. We also concatenate (stack) these embeddings and show how these stacked embeddings, as well as tuning of the hyper-parameters, further improves claim classification performance.

2 Background

In this section, we introduce two main approaches for claim classification: feature-rich supervised learning and distributional word embeddings. We then discuss the recent use of convolutional neural networks and long short-term memory networks in the related task of sentence classification.

2.1 Methods Based on a Rich Set of Features

Oraby et al. (2015) classify arguments as emotional or factual using a set of linguistic patterns extracted from unlabelled arguments, provided the argument matches at least three patterns in the category. Although this approach has good precision, its recall is significantly lower than that of a supervised unigram baseline using Bayesian classifier.

Park and Cardie (2014) classify propositions as verifiable non-experiential, verifiable experiential, or unverifiable using a support vector machine (SVM). The classifier employs a rich set of features including *n*-grams, part of speech tags, imperative expressions, speech events, emotions, sentiment, person, and tense. Though this approach classifies unverifiable statements reasonably well, its performance on the two classes of verifiable propositions is low (44–70% F_1). In light of the observation that certain types of propositions tend to occur together, Park et al. (2015) propose an intuitive extension to this approach, framing the proposition classification task as a sequence-labelling problem. This extended approach employs conditional random fields (CRF) using dictionary-based features along with all the features from the original technique. However, it resulted in lower accuracy than the SVMs.

Ferreira and Vlachos (2016) addressed the task of determining the stance of news article headlines with respect to claims from a data set of rumours. The authors used a logistic regression classifier using various features, such as bag of words, paraphrase entailment alignment scores, and word2vec embedding features, that examine the headline and its agreement with the claim. The work in this paper is focused on stance classification but the claims in the data set are related to the data sets used in our work.

2.2 Distributional Word Embeddings

Traditional supervised learning approaches to NLP tasks depend heavily on manual annotation, and often suffer from data sparseness. Distributional representations of words, also known as word embeddings, can be learned from large, unlabelled corpora using neural networks, and encode both syntactic and semantic properties of words. Studies have found the learned word vectors to capture linguistic regularities and to collapse similar words into groups (Mikolov et al., 2013b). Their utility in tasks such as sentiment classification (Kim, 2014) is well attested.

[1] `https://code.google.com/archive/p/word2vec/`

Dependency-based Embeddings. Claims containing multiple clauses or propositions might be better distinguished with the help of dependency embeddings inferred from the respective proposition contexts. Consider the following claim from one of our data sets: "The Governor said that he enjoyed it." In this claim, the main clause, "The Governor said", is the core proposition, which excludes consideration of the remainder. The reason is that "said" is a reporting predicate, so it is unnecessary to verify whether or not the governor really has enjoyed the object mentioned in the subordinate clause. In some other claims, it is the subordinate rather than the main clause predicate that decides the claim type. Park and Cardie (2014) extracted clause-specific features using the Stanford syntactic parser and the Penn Treebank. (Merely using clause tags without capturing dependencies for important clauses may not help much in distinguishing objective verifiable claims from unverifiable subjective ones.) Park and Cardie (2014) also used tense and person counts for distinguishing verifiable claims from unverifiable claims. We hypothesize that word2vec and dependency context–based embeddings can inherently capture these linguistic characteristics and can replace these features. Dependency context based embeddings capture functional similarities across the words using different contexts (Levy and Goldberg, 2014). Komninos and Manandhar (2016) have shown that dependency-based models produce word embeddings that better capture functional properties of words for question type classification and relation detection.

Task-specific Embeddings. Compiling embeddings for the specific vocabulary present in the task data can also be helpful in a classification task. Tang et al. (2014) use enriched task-specific word embeddings and show improvement in a Twitter sentiment classification task. Park and Cardie (2014) compiled a speech-event lexicon containing the most frequent speech anchors (predicates such as "said" and "wrote") from MPQA 2.0, a corpus manually annotated for opinions and other private states. These anchors can help in correctly distinguishing verifiable claims from unverifiable ones when the propositions contain both objective and subjective expressions. In our work, we use factual embeddings learned from the labelled FactBank corpus (Saurí and Pustejovsky, 2009) containing various speech event predicates (see §3.3). Such factual embeddings could help in resolving various predicate ambiguities present in the argumentative propositions.

2.3 Deep Neural Networks for Text Classification

Deep neural networks, with or without word embeddings, have recently shown significant improvements over traditional machine learning–based approaches when applied to various sentence- and document-level classification tasks.

Kim (2014) have shown that CNNs outperform traditional machine learning–based approaches on several tasks, such as sentiment classification, question type classification, and subjectivity classification, using simple static word embeddings and tuning of hyper-parameters. Zhang et al. (2015) proposed character-level CNNs for text classification. Lai et al. (2015) and Visin et al. (2015) proposed recurrent CNNs, while Johnson and Zhang (2015) proposed semi-supervised CNNs for solving a text classification task. Tang et al. (2015) used a document classification approach based on recurrent neural networks (RNNs) and showed an improvement on a sentiment classification task. Palangi et al. (2016) proposed sentence embedding using an LSTM network for an information retrieval task. Zhou et al. (2016) proposed attention-based, bidirectional LSTM networks for a relation classification task. Augenstein et al. (2016) employed a weakly supervised conditional LSTM encoding approach to stance detection for unseen targets on Twitter stance detection data, and presented improved results. RNNs model text sequences effectively by capturing long-range dependencies among the words. LSTM-based approaches based on RNNs effectively capture the sequences in the sentences when compared to the CNN and SVM-based approaches.

3 Claim Classification

Here we present two deep learning–based methods for claim classification, the first of which uses CNNs and the second of which uses LSTMs. In §3.3, we also show how different pre-trained distributional linguistic embeddings are incorporated into CNNs and LSTMs to improve the classification results.

3.1 CNN-based Claim Classification

Collobert et al. (2011) adapted the original CNN proposed by LeCun and Bengio (1995) for modelling natural language sentences. Following Kim (2014), we present a variant of the CNN architecture with four layer types: an input layer, a convolution layer, a max pooling layer, and a fully connected softmax layer. Each claim in the input layer is represented as a sentence comprised of distributional word embeddings. Let $\vec{v}_i \in \mathbb{R}^k$ be the k-dimensional word vector corresponding to the ith word in the sentence. Then a sentence S of length ℓ is represented as the concatenation of its word vectors:

$$S = \vec{v}_1 \oplus \vec{v}_2 \oplus \cdots \oplus \vec{v}_\ell. \tag{1}$$

Word2vec embeddings which are learned using the bag-of-words representation of the contexts yield broad topical similarities, while using dependency-based contexts yields more functional similarities (Levy et al., 2015). In addition, with word2vec (E) embeddings, we use linguistically motivated pre-trained dependency embeddings (D) and task-specific factual embeddings (F) for capturing syntactic and functional regularities encoded in the propositions, in order to better distinguish different types of claims.

To incorporate these linguistic embeddings at word level into the learning process, we extend the network as illustrated in Figure 1a. Inspired by Baroni et al. (2012)'s supervised distributional concatenation method and a linguistically informed CNN (Ebert et al., 2015), we concatenate word2vec (E), dependency (D), and factual (F) word embeddings corresponding to the ith input word into a merged vector $\vec{c}_i \in \mathbb{R}^{k+m+n}$:

$$\vec{c}_i = [\vec{e}_i, \vec{d}_i, \vec{f}_i], \tag{2}$$

where $\vec{e}_i$, $\vec{d}_i$, and $\vec{f}_i$ represent, respectively, the concatenated word2vec, dependency, and factual embeddings corresponding to i_{th} word in the sentence. In the final representation, every input claim from the data set is represented using combined word2vec and linguistic embeddings in the network as in Equation 1, where each $\vec{v}_i = \vec{c}_i$.

In the convolution layer, for a given word sequence within a claim, a convolutional word filter P is defined. Then, the filter P is applied to each word in the sentence to produce a new set of features. We use a non-linear activation function such as rectified linear unit (ReLU) for the convolution process and max-over-time pooling (Collobert et al., 2011; Kim, 2014) at pooling layer to deal with the variable claim size. After a series of convolutions with different filters with different heights, the most important features are generated. Then, this feature representation, Z, is passed to a fully connected penultimate layer and outputs a distribution over different labels:

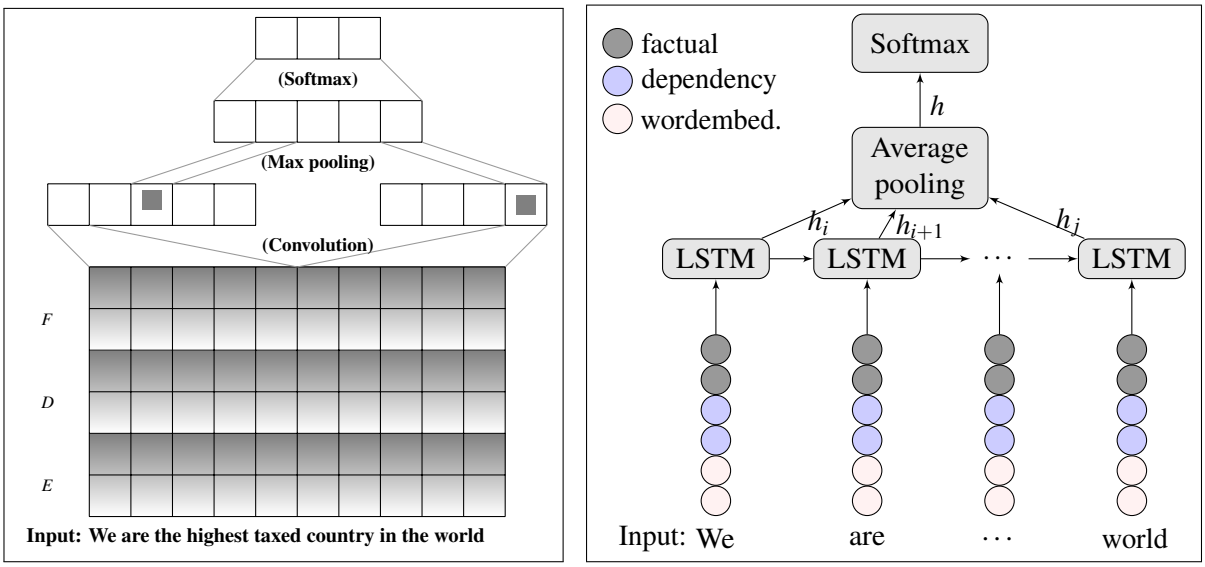
$$y = \text{softmax}(W \cdot Z + b), \tag{3}$$

where y denotes a distribution over different claims labels, W is the weight vector learned from the stacked representation of all embeddings from the training corpus, and b is the bias term.

3.2 LSTM-based Claim Classification

In case of CNN, concatenating words with various window sizes, works as n-gram models but do not capture long-distance word dependencies with shorter window sizes. A larger window size can be used, but this may lead to data sparsity problem. In order to encode long-distance word dependencies, we use long short-term memory networks, which are a special kind of RNN capable of learning long-distance dependencies. LSTMs were introduced by Hochreiter and Schmidhuber (1997) in order to mitigate the vanishing gradient problem (Gers et al., 2000; Gers, 2001; Graves, 2013; Pascanu et al., 2013).

The model illustrated in Figure 1b is composed of a single LSTM layer followed by an average pooling and a softmax regression layer. Each claim is represented as a sentence (S) in the input layer. Thus, from an input sequence, $S_{i,j}$, the memory cells in the LSTM layer produce a representation sequence $h_i, h_{i+1}, \ldots, h_j$. This representation sequence is then averaged over all time steps, resulting in a final feature representation h. Finally, this representation is fed to a logistic regression layer to predict the claim labels for unseen input claims.



(a) CNN with multiple word embeddings

(b) LSTM with multiple word embeddings

Figure 1: Illustration of two methods for claim classification

[There *always* **seems** to be some other amount] [I *later* **must** pay]
predicate (possibility) *modal (obligation)*

Figure 2: Example verifiable non-experiential claim with signals indicating factuality and certainity

As with the CNN architecture shown in the previous section, for each claim, we encode word2vec, dependency, and factual embeddings in the input layer into a variation of the standard LSTM network. As our results demonstrate, the LSTM encoder can effectively capture informative features from the concatenated embedding representation and classify different types of argumentative claims.

3.3 Word Embeddings

In order to better capture the syntactic contexts of words and the factuality indicators of propositions, we employ two linguistically motivated word embeddings in addition to the usual word2vec ones: dependency-based embeddings, and factuality- and certainty-signalling emeddings.

Word2vec Embeddings. We use word embeddings from word2vec which are learned using the skip-gram model of Mikolov et. al (2013a,b) by predicting linear context words surrounding the target words. These word vectors are trained on about 100 billion words from a Google News corpus. As word embeddings alone have shown good performance in various classification tasks, we also use them in isolation, with varying dimensions, in our CNN and LSTM experiments. In the case of CNN, a word embedding size of 300, together with other network parameters, resulted in high accuracy on the claim verifiability data set. In the case of LSTM, word embeddings of size 300 also produced good accuracy on the claim verifiability data set.

Dependency-based Word Embeddings. We use Levy and Goldberg's (2014) dependency-based word embeddings in our claim classification task. These embeddings are learned using dependency-based contexts from an English Wikipedia corpus containing about 175 000 words and over 900 000 distinct syntactic contexts. Dependency-based embeddings are encoded in the input layers of both our CNN and LSTM, as shown in Figure 1. Dependency embeddings of size 100 are concatenated with equally sized word2vec and factual embeddings, resulting in a 300-dimension concatenated embedding vector.

Factuality- and Certainty-signalling Embeddings. We investigate the use of certainty- and factuality-related distributed signals for distinguishing claims. In online argumentative discourse, claims often

	Factual	Feeling	Total
Train	2426	1667	4093
Test	347	239	586
Total	2773	1906	4679

Table 1: Data splits (factual/feeling data set)

	Ver. exp.	Ver. non-exp.	Unver.	Total
Train	900	987	4459	6346
Test	367	370	1687	2424
Total	1267	1357	6146	8770

Table 2: Data splits (verifiability data set)

serve as implicit arguments with inappropriate or missing justification (Park and Cardie, 2014). The certainty and factuality signals present in such claims may be appropriate for determining its factuality or verifiability. As the claims in our data set are objective, subjective and factual types, predicates, adverbs and other modals (related to certainty and factuality) present in FactBank 1.0 may help in better distinguishing various types of claims.

As an example, consider the sentence in Figure 2, a complex claim of type "verifiable non-experiential". The predicate "seems" and the modal verb "must" can be viewed as certainty and factuality information related to the speaker's commitment to their utterance. Factual embeddings of these co-occurrence indicators can help in better identifying the type of the claim. We compile these extra linguistic factual and certainty signals from FactBank (Saurí and Pustejovsky, 2009), a corpus annotated with factuality and certainty indicators very much similar to the word2vec embeddings. These annotations are basically related to certainty, possibility, and probability, with positive and negative polarities. We used the gensim (Řehůřek and Sojka, 2010) word2vec program to compile embeddings from FactBank. We compiled 300-dimensional factual embedding vectors for the words that appear at least five times in FactBank, and for rest of the vocabulary, embedding vectors are assigned uniform distribution in the range of $[-0.25, 0.25]$. In our CNN and LSTM experiments, we integrate factual embeddings (denoted by F above). We also concatenate factual embeddings with other dependency and word embeddings, as shown in Figure 1.

4 Data Sets and Experimental Setup

4.1 Data Sets

Our experiments use the two claim data sets introduced in §1, further details of which are given below.

Factual and Feeling Debate Forum Posts (Walker et al., 2012). This corpus is compiled from the Internet Argument Corpus. It consists of quote–response pairs that are manually annotated according to whether the response is primarily a "factual"- or "feeling"-based argument. In our experiments, we use the training and test splits from Oraby et al. (2015); these consist of claims that can span multiple sentences. The annotation distribution for these splits is shown in Table 1. We also use a development set to tune the hyper-parameters of the model.

Verifiable and Unverifiable User Comments (Park and Cardie, 2014). This corpus consists of 9476 manually annotated sentences and independent clauses from 1047 user comments extracted from the Regulation Room website.[2] Park and Cardie (2014) and Park et al. (2015) used this corpus for examining each proposition with respect to its verifiability to determine the desirable types of support for the analysis of arguments. The propositions are manually annotated with three classes—"verifiable experiential", "verifiable non-experiential", and "unverifiable"—where the support types are evidence, optional evidence, and reason, respectively. The annotation distribution and our train/test splits are shown in Table 2.

4.2 Experimental Setup

We model claim classification as a sentence classification task. We perform binary classification on the factual/feeling data set, and multi-class classification on the verifiability data set. We used Kim's (2014) Theano implementation of CNN for training the CNN model and a variant of the standard Theano implementation[3] for training the LSTM network. We initialized the word2vec, dependency, and factual

[2] `http://www.regulationroom.org/`

[3] `http://deeplearning.net/tutorial/lstm.html`

embeddings in both the CNN and LSTM models. Unknown words from the pre-compiled embeddings were initialized randomly in the range $[-0.25, 0.25]$. We updated all three embedding vectors during the training. We also produced a stacked embedding where all three types of embeddings, with dimensionality 100, were concatenated. In the CNN approach, we used a stochastic gradient descent–based optimization method for minimizing the cross entropy loss during the training with the Rectified Linear Unit (ReLU) non-linear activation function. Window filter sizes were set at $[3, 4, 5]$. In the case of LSTM, model was trained using an adaptive learning rate optimizer, ADADELTA (Zeiler, 2012), over shuffled mini-batches with the sigmoid activation function at input, output and forget gates, and the tanh non-linear activation function at cell state.

Tuning Hyper-parameters. We manually explored hyper-parameters such as drop-out (for avoiding over-fitting), and batch size and learning rates (for improving performance) on development sets of both data sets. We performed tuning on the verifiability development data set obtained by splitting the corpus into an 85% training set and a 15% development set. We tuned the hyper-parameters on a 20% development set obtained from Oraby et al. (2015) on the factual vs. feeling data set. We varied batch sizes (12–64), drop-out (0.1–0.6), embedding sizes (50–300), and learning rate (0.0001–0.001) on both data sets and across all embeddings. We obtained the best CNN performance with learning rate decay 0.95, batch size 50, drop-out 0.5, and embedding size 300. For LSTM, we got the best results with learning rate 0.001, drop-out 0.5, and embedding size 300 for both data sets; the optimal batch size was 24 for the verifiability data set but 32 for the factual vs. feeling data set.

SVM Classification on the Factual vs. Feeling Data Set. SVM classifiers find the hyperplane that best discriminates between positive and negative instances (Cristianini and Shawe-Taylor, 2000). We used the SVM classifier SMO (Hall et al., 2009) from the DKPro TC framework (Daxenberger et al., 2014) for factual vs. feeling claims classification. Surface-level top k n-grams are used as features for building the model. We used uni-, bi-, and trigrams, and varied k from 500 to 5000. We obtained the best results with the top 500 n-gram features.

5 Results and Analysis

We compare our methods with several state-of-the-art methods for claim classification, as described in §2. In these tables, the highest accuracy values for precision, recall and F_1 measure are specified in bold font.

Verifiability Data Set. Park and Cardie (2014) and Park et al. (2015) performed claim classification on this data set using SVM and CRF classifiers. The former classifier was found to yield better results. Both approaches employed various lexical and shallow semantic features. The authors also report baseline results using simple unigram features. We considered the SVM-based results[4] a baseline for comparison with ours. The results of our own experiments on the same data set, using CNN and LSTM methods together with the various embeddings mentioned in §3.3, are shown in Table 3. We macro-averaged F_1 across all the classes. Using word embeddings alone in the CNN method, our results (70.47%) were comparable to those of the SVM (68.99%) and exceeded those of the CRF method (63.63%). In a concatenated embeddings setting, CNN achieves 70.34% F_1. The LSTM performance is low when compared to the CNN approach, but comparable to the SVM-based approach. LSTM also performed better than the sequential CRF baseline.

We computed train, validation, and test error rates with respect to the number of epochs during training for the CNN and LSTM approaches. In the case of LSTM, the best classification accuracy is obtained between 5 and 12 epochs, and in case of CNN, at between 5 and 20 epochs. Confusion matrices showing the assignments of our best-performing LSTM and CNN classifiers are shown in Tables 4 and 5, respectively. Both classifiers show a similar pattern of errors. Verifiable experiential and non-experiential claims were not confused as much with each other as they were with unverifiable claims; this may be an artifact of the latter being the majority class. When unverifiable claims were misclassified, they were more

likely to be labelled as verifiable non-experiential, suggesting that the vocabulary employed in the two classes of claims is similar.

Factual vs. Feeling Claims Data Set. In this data set, claims can span more than one sentence, but we treat these as single sentences for the purposes of our experiments. Oraby et al. (2015) performed unsupervised claim classification on this data set using bootstrapped patterns from both unlabelled and labelled data and report accuracy (F_1) of 41.41%. They also report an F_1 of 64.98% for a naïve Bayes supervised classifier using simple unigram and binary features. The focus of their experiment was to discover more factual- and feeling-related patterns from the unlabelled corpus using a small amount of labelled data. In our experiments, both the CNN (79.56% F_1) and the LSTM-based (75.10% F_1) methods using distributional embeddings show significant improvements over the naïve Bayes and SVM-based approaches as shown in Table 6. CNN achieved good accuracy in all embeddings setting. Sequential LSTM's performance is not better than the CNN approach, but LSTM together with word2vec and factual embeddings performed better on this data set.

Confusion matrices for our best LSTM and CNN classifiers are shown in Tables 7 and 8, respectively. We manually examined those factual claims misclassified as feeling and found that they contained a relatively high proportion of personal pronouns, wh-questions, and negations. While these vocabulary terms are typically associated with feeling claims, they are missing from the factuality embeddings learned from FactBank. By contrast, when feeling claims were misclassified as factual, we found that they tend to contain several distinct propositions or clauses, only one of which was emotional in nature. Properly handling these type of claims would require modelling them with intrapropositional relations.

6 Conclusion and Future Work

In this paper, we presented LSTM- and CNN-based deep neural network methods leverging word2vec and linguistic embeddings, and applied these to argumentative claim classification on two data sets.

On the data set of verifiable and unverifiable claims, our CNN approach using word2vec and concatenated embeddings has shown results comparable to those of a state-of-the-art, feature-rich, SVM-based

Table 8: Confusion matrix for CNN with word2vec (factual vs. feeling data set)

method. When using an LSTM-based method, the accuracy was somewhat lower, but still better than a CRF. In this case, however, the concatenated embeddings were not any better than the individual ones. On the factual vs. feeling data set, our CNN-based method using word2vec and linguistic embeddings showed good improvements (over 14 percentage points in F_1) over the state-of-the-art Bayes classifier and a 9-point improvement over the SVM baseline, while the LSTM-based method using word2vec and factual embeddings yielded a 10-point improvement over the Bayes classifier and a 5-point improvement over SVM. The LSTM-based method using word2vec and factual embeddings performed better than using other embeddings. We also observed that the performance of sequential LSTM is lower than the CNN but better than the SVM baseline and the sequential CRF method described in prior work.

Our methods are simpler than those described in prior work, and we have demonstrated that they generalize well across claim data sets. Our framework can also be easily adapted to other stacked embeddings to perform various sentence- and document-level classification tasks. In future work, we plan to investigate usage of richer linguistic embeddings, such as factual and word sense embeddings compiled from a larger corpus. We may also consider incorporating inter-proposition predicate relations.

Abstract

Some expressions can be ambiguous between idiomatic and literal interpretations depending on the context they occur in, e.g., *sales **hit the roof*** vs. ***hit the roof** of the car*. We present a novel method of classifying whether a given instance is literal or idiomatic, focusing on verb-noun constructions. We report state-of-the-art results on this task using an approach based on the hypothesis that the distributions of the contexts of the idiomatic phrases will be different from the contexts of the literal usages. We measure contexts by using projections of the words into vector space. For comparison, we implement Fazly et al. (2009)'s, Sporleder and Li (2009)'s, and Li and Sporleder (2010b)'s methods and apply them to our data. We provide experimental results validating the proposed techniques.

1 Introduction

Researchers have been investigating idioms and their properties for many years. According to traditional approaches, an idiom is — in its simplest form— a string of two or more words for which meaning is not derived from the meanings of the individual words comprising that string (Swinney and Cutler, 1979). As such, the meaning of *kick the bucket* ('die') cannot be obtained by breaking down the idiom and analyzing the meanings of its constituent parts, to kick and the bucket. In addition to being influenced by the principle of compositionality, the traditional approaches are also influenced by theories of generative grammar (Flores, 1993; Langlotz, 2006) The properties that traditional approaches attribute to idiomatic expressions are also the properties that make them difficult for generative grammars to describe. For instance, idioms can be syntactically ill-formed (e.g., *by and large*), resistant to grammatical transformations (e.g., *the bucket was kicked by him* $\neq$ 'die'), impervious to lexical substitutions (e.g., *kick the pail* $\neq$ 'die'), and semantically ambiguous without context. This last property of the idioms is what we address in our work. The examples below illustrate the ambiguity[1].

(A1) After the last page was sent to the printer, an editor would **ring a bell**, walk toward the door, and holler " Good night! " (Literal)

(A2) His name never fails to **ring a bell** among local voters. Nearly 40 years ago, Carthan was elected mayor of Tchula... (Idiomatic)

(B1) ...that caused the reactor to literally **blow its top**. About 50 tons of nuclear fuel evaporated in the explosion... (Literal)

(B2) ...He didn't pound the table, he didn't **blow his top**. He always kept his composure. (Idiomatic)

(C1) ...coming out of the fourth turn, slid down the track, **hit** the inside **wall** and then hit the attenuator at the start of pit road. (Literal)

(C2) ...job training, research and more have **hit** a Republican **wall**. (Idiomatic)

Fazly et al. (2009)'s analysis of 60 idioms from the British National Corpus (BNC) has shown that close to half of these also have a clear literal meaning; and of those with a literal meaning, on average

[1]These examples are extracted from the Corpus of Contemporary American English (COCA) (`http://corpus.byu.edu/coca/`)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2752–2761, Osaka, Japan, December 11-17 2016.

around 40% of their usages are literal.

Just to motivate our work, idioms present great challenges for many Natural Language Processing (NLP) applications. Current machine translation systems (MT), unfortunately, more frequently than not, are not able to translate idiomatic expressions correctly.

Here's an example how the English utterance *He didn't pound the table, he didn't **blow his top**. He always kept his composure.* is translated by Bing and Google Translate from English into Russian and Chinese.

(1) a. English original: He didn't pound the table, he didn't **blow his top**. He always kept his composure.
b. Bing: Chinese: 他没拍几下桌子，他并没有**打击他的上方**。他总是保持镇静。
c. Google: Chinese: 他没有拍桌子，他没有**吹他的上面**。他始终保持着镇定。
d. Bing: Russian: Он не фунт за столом, он не взорвать его сверху. Он всегда держал его спокойствие.
e. Google:Russian: Он не фунт стол, он не взрывал его вершину. Он всегда держал его хладнокровие.

In all the examples above, *blow his top* is translated as 'destruction/explosion of his top/summit', which is clearly not the intended meaning.

In this paper we describe an algorithm for automatic classification of idiomatic and literal expressions. Similar to Peng et al. (2014), we treat idioms as semantic outliers. Our assumption is that the context word distribution for a literal expression will be different from the distribution for an idiomatic one. We capture the distribution in terms of covariance matrix in vector space.

2 Proposed Techniques

We build our work on the following hypotheses:

1. Words representing local topics are likely to associate strongly with a literal expression appearing in that text segment;

2. The context word distribution for a literal expression in word vector space is different from the distribution of an idiomatic one. (This hypothesis is central to the distributional approach to meaning (Firth, 1957; Katz and Giesbrecht, 2006).)

2.1 Projection Based On Local Context Representation

The local context of a literal target verb-noun construction (VNC) must be different from that of an idiomatic one. We propose to exploit recent advances in vector space representation to capture the difference between local contexts (Mikolov et al., 2013a; Mikolov et al., 2013b).

A word can be represented by a vector of fixed dimensionality q that best predicts its surrounding words in a sentence or a document (Mikolov et al., 2013a; Mikolov et al., 2013b). Given such a vector representation, our first proposal is the following. Let v and n be the vectors corresponding to the verb and noun in a target verb-noun construction, as in *blow whistle*, where $v \in \Re^q$ represents *blow* and $n \in \Re^q$ represents *whistle*. Let $\sigma_{vn} = v + n \in \Re^q$. Thus, σ_{vn} is the word vector that represents the composition of verb v and noun n, and in our example, the composition of *blow* and *whistle*. As indicated in Mikolov et al. (2013b), word vectors obtained from deep learning neural net models exhibit linguistic regularities, such as additive compositionality. Therefore, σ_{vn} is justified to predict surrounding words of the composition of, say, *blow* and *whistle* in the literal usage of *blow whistle*. Our hypothesis is that on average, inner product $\sigma_{blowwhistle} \cdot v$, where vs are context words in a literal usage, should be greater than $\sigma_{blowwhistle} \cdot v$, where vs are context words in an idiomatic usage.

Suppose that we have the following sentences: "are you going to *blow the whistle* on the whole lot I mean the university people as well?" and "I *blew the whistle* to start the timed run, and the students ran as hard as they could". *blow the whistle* in the first sentence is idiomatic, while it is literal in the second one. Let v_{blow} be the word vector representing *blow*, and $v_{whistle}$ be the vector representing *whistle*. Thus, in

our notation, we have that $\sigma_{blowwhistle} = v_{blow} + v_{whistle}$. It follows that $p = \sigma_{blowwhistle} \cdot v$ represents the inner product of $\sigma_{blowwhistle}$ and a context word v. The following table shows the inner products of $\sigma_{blowwhistle}$ and context words v in the two sentences, after removing functional words. From the above

Table 1: Inner products with $\sigma_{blowwhistle}$

are	you	going	whole	lot	mean	university	people	well
-0.13	0.28	0.20	-0.03	0.04	0.00	-0.17	-0.14	-0.05
start	timed	run	students	ran	hard	they	could	
0.15	0.12	0.19	-0.22	0.14	0.15	-0.02	0.04	

table, $\sigma_{BlowWhistle}$ has a larger inner product value (0.069) with context words in the literal usage than with context words in the idiomatic usage (0.000), on average.

For a given vocabulary of m words, represented by matrix $V = [v_1, v_2, \cdots, v_m] \in \Re^{q \times m}$, we calculate the projection of each word v_i in the vocabulary onto σ_{vn}

$$P = V^t \sigma_{vn} \tag{1}$$

where $P \in \Re^m$, and t represents transpose. Here we assume that σ_{vn} is normalized to have unit length. Thus, $P_i = v_i^t \sigma_{vn}$ indicates how strongly word vector v_i is associated with σ_{vn}. This projection, or inner product, forms the basis for our proposed technique.

Let $D = \{d_1, d_2, \cdots, d_l\}$ be a set of l text segments (local contexts), each containing a target VNC (i.e., σ_{vn}). Instead of generating a term by document matrix, where each term is $tf \cdot idf$ (product of term frequency and inverse document frequency), we compute a term by document matrix $M_D \in \Re^{m \times l}$, where each term in the matrix is

$$p \cdot idf, \tag{2}$$

the product of the projection of a word onto a target VNC and inverse document frequency. That is, the term frequency (tf) of a word is replaced by the projection (inner product) of the word onto σ_{vn} (1). Note that if segment d_j does not contain word v_i, $M_D(i, j) = 0$, which is similar to $tf \cdot idf$ estimation. The motivation is that topical words are more likely to be well predicted by a literal VNC than by an idiomatic one. The assumption is that a word vector is learned in such a way that it best predicts its surrounding words in a sentence or a document (Mikolov et al., 2013a; Mikolov et al., 2013b). As a result, the words associated with a literal target will have larger projection onto a target σ_{vn}. On the other hand, the projections of words associated with an idiomatic target VNC onto σ_{vn} should have a smaller value. We also propose a variant of $p \cdot idf$ representation. In this representation, each term is a product of p and typical $tf \cdot idf$. That is,

$$p \cdot tf \cdot idf. \tag{3}$$

2.2 Local Context Distributions

Our second hypothesis states that words in a local context of a literal expression will have a different distribution from those in the context of an idiomatic one. We propose to capture local context distributions in terms of scatter matrices in a space spanned by word vectors (Mikolov et al., 2013a; Mikolov et al., 2013b).

Let $d = (w_1, w_2 \cdots, w_k) \in \Re^{q \times k}$ be a segment (document) of k words, where $w_i \in \Re^q$ are represented by a vectors (Mikolov et al., 2013a; Mikolov et al., 2013b). Assuming w_is have been centered without loss of generality, we compute the scatter matrix

$$\Sigma = d^t d, \tag{4}$$

where Σ represents the local context distribution for a given target VNC.

Given two distributions represented by two scatter matrices Σ_1 and Σ_2, a number of measures can be used to compute the distance between Σ_1 and Σ_2, such as Chernoff and Bhattacharyya distances

(Fukunaga, 1990). Both measures require the knowledge of matrix determinant. In our case, this can be problematic, because Σ (4) is most likely to be singular, which would result in a determinant to be zero.

We propose to measure the difference between Σ_1 and Σ_2 using matrix norms. We have experimented with the Frobenius norm and the spectral norm. The Frobenius norm evaluates the difference between Σ_1 and Σ_2 when they act on a standard basis. The spectral norm, on the other hand, evaluates the difference when they act on the direction of maximal variance over the whole space.

3 Experiments

3.1 Methods

We have carried out an empirical study evaluating the performance of the proposed techniques. For comparison, the following methods are evaluated.

1. $tf \cdot idf$: compute term by document matrix from training data with $tf \cdot idf$ weighting.
2. $p \cdot idf$: compute term by document matrix from training data with proposed $p \cdot idf$ weighting (2).
3. $p \cdot tf \cdot idf$: compute term by document matrix from training data with proposed $p \cdot tf \cdot idf$ weighting (3).
4. $CoVAR_{Fro}$: proposed technique (4) described in Section 2.2, the distance between two matrices is computed using Frobenius norm.
5. $CoVAR_{Sp}$: proposed technique similar to $CoVAR_{Fro}$. However, the distance between two matrices is determined using the spectral norm.
6. *Context+ (CTX+)*: supervised version of the CONTEXT technique described in Fazly et al. (2009) (see below).
7. *TextSim*: supervised classification using the Dice coefficient (see below).
8. *GMM*: Gaussian Mixture Model as described in Li and Sporleder (2010b) (see below).

For methods from **1** to **3**, we compute a latent space from a term by document matrix obtained from the training data that captures 80% variance. To classify a test example, we compute cosine similarity between the test example and the training data in the latent space to make a decision.

For methods **4** and **5**, we compute literal and idiomatic scatter matrices from training data (4). For a test example, we compute a scatter matrix according to (4), and calculate the distance between the test scatter matrix and training scatter matrices using the Frobenius norm for method **4**, and the spectral norm for method **5**.

Method **6** corresponds to a supervised version of CONTEXT described in (Fazly et al., 2009). CONTEXT is unsupervised because it does not rely on manually annotated training data, rather it uses knowledge about automatically acquired canonical forms (C-forms). C-forms are fixed forms corresponding to the syntactic patterns in which the idiom normally occurs. Thus, the gold-standard is "noisy" in CONTEXT. Here we provide manually annotated training data. That is, the gold-standard is "clean." Therefore, CONTEXT+ is a supervised version of CONTEXT. We implemented this approach from scratch since we had no access to the code and the tools used in the original article and applied this method to our dataset and the performance results are reported in Table 3.

Method **7** corresponds to a supervised classifier described in Sporleder and Li (2009). In the experiments described in Sporleder and Li (2009), this method achieved the best performance. We used the Dice coeffiient as implemented in Ted Pedersen's Text::Similarity module (`http://www.d.umn.edu/œtpederse/text-similarity.html` to determine the word overlap of a test instance with the literal and non-literal instances in the training set (for the same expression) and then assign the label of the closest set. A similar approach has been described in Katz and Giesbrecht (2006).

Method **8** is based on Li and Sporleder (2010b). Li and Sporleder (2010b) assume that literal and nonliteral data are generated by two different Gaussians. The detection of idiomatic tokens is done by

comparing which Gaussian has the higher probability of generating a specific instance. While the original Li and Sporleder (2010b)'s work uses Normalized Google Distance to model semantic relatedness in computing features (Cilibrasi and Vitányi, 2007; Cilibrasi and Vitányi, 2009), we use inner product between word vectors as described in section 3.3. The main reason is that Google's custom search engine API is no longer free. The detection task is done by a Bayes decision rule, which chooses the category by maximizing the probability of fitting the data into different Gaussian components: $c(x) = \arg\max_{i \in \{l,n\}} \{w_i \times N(x|\mu_i, \Sigma_i)\}$, where c is the category of the Gaussian, μ_i is the mean, Σ_i is the covariance matrix, and w_i is the mixture weight.

Table 2: Datasets: Is = idioms; Ls = literals

Expression	Train	Test
BlowWhistle	20 Is, 20 Ls	7 Is, 31 Ls
LoseHead	15 Is, 15 Ls	6 Is, 4 Ls
MakeScene	15 Is, 15 Ls	15 Is, 5 Ls
TakeHeart	15 Is, 15 Ls	46 Is, 5 Ls
BlowTop	20 Is, 20 Ls	8 Is, 13 Ls
BlowTrumpet	50 Is, 50 Ls	61 Is, 186 Ls
GiveSack	20 Is, 20 Ls	26 Is, 36 Ls
HaveWord	30 Is, 30 Ls	37 Is, 40 Ls
HitRoof	50 Is, 50 Ls	42 is, 68 Ls

HoldFire	20 Is, 20 Ls	98 Is, 6 Ls
HoldHorse	80 Is, 80 Ls	162 Is, 79 Ls

3.2 Data Preprocessing

We use BNC (Burnard, 2000) and a list of verb-noun constructions (VNCs) extracted from BNC by Fazly et al. (2009) and Cook et al. (2008) and labeled as L (Literal), I (Idioms), or Q (Unknown). The list contains only those VNCs whose frequency was greater than 20 and that occurred at least in one of two idiom dictionaries (Cowie et al., 1983; Seaton and Macaulay, 2002). The dataset consists of 2,984 VNC tokens. For our experiments we only use VNCs that are annotated as I or L. We only experimented with idioms that can have both literal and idiomatic interpretations. We should mention that our approach can be applied to any syntactic construction. We decided to use VNCs only because this dataset was available and for fair comparison – most work on idiom recognition relies on this dataset.

We use the original SGML annotation to extract paragraphs from BNC. Each document contains three paragraphs: a paragraph with a target VNC, the preceding paragraph and following one. Our data is summarized in Table 2.

Since BNC did not contain enough examples, we extracted additional ones from COCA, COHA and GloWbE (http://corpus.byu.edu/). Two human annotators labeled this new dataset for idioms and literals. The inter-annotator agreement was relatively low (Cohen's kappa = .58); therefore, we merged the results keeping only those entries on which the two annotators agreed.

3.3 Word Vectors

For our experiments reported here, we obtained word vectors using the word2vec tool (Mikolov et al., 2013a; Mikolov et al., 2013b) and the text8 corpus. The text8 corpus has more than 17 million words, which can be obtained from `mattmahoney.net/dc/text8.zip`. The resulting vocabulary has 71,290 words, each of which is represented by a $q = 200$ dimension vector. Thus, this 200 dimensional vector space provides a basis for our experiments.

3.4 Datasets

Table 2 describes the datasets we used to evaluate the performance of the proposed technique. All these verb-noun constructions are ambiguous between literal and idiomatic interpretations. The examples below (from the corpora we used) show how these expressions can be used *literally*.

BlowWhistle: *we can immediately turn towards a high-pitched sound such as whistle being blown. The ability to accurately locate a noise* $\cdots$ **LoseHead**: *This looks as eye-like to the predator as the real eye and gives the prey a fifty-fifty chance of losing its head. That was a very nice bull I shot, but I lost his head.* **MakeScene**: $\cdots$ *in which the many episodes of life were originally isolated and there was no relationship between the parts, but at last we must make a unified scene of our whole life.* **TakeHeart**: $\cdots$ *cutting off one of the forelegs at the shoulder so the heart can be taken out still pumping and offered to the god on a plate.* **BlowTop**: *Yellowstone has no large sources of water to create the amount of steam to blow its top as in previous eruptions.*

4 Results

Table 3 shows the average precision, recall and accuracy of the competing methods on 12 datasets over 20 runs. Table 4 shows the performance of the models by class. The best performance is in bold face. The best model is identified by considering precision, recall, and accuracy together for each model. We calculate accuracy by summing true positives and true negatives and normalizing the sum by the number of examples. Figure 1 shows the aggregated performance in terms of precision, recall and accuracy by the eight competing methods on the 12 data sets. The results show that the $CoVAR$ model outperforms the rest of the models overall and on individual classes.

Table 4: Performance results by class: I denotes the idiom class and L denotes the literal class.

Interestingly, the Frobenius norm outperforms the spectral norm. One possible explanation is that the spectral norm evaluates the difference when two matrices act on the maximal variance direction, while the Frobenius norm evaluates on a standard basis. That is, Frobenius measures the difference along all basis vectors. On the other hand, the spectral norm evaluates changes in a particular direction. When the difference is a result of all basis directions, the Frobenius norm potentially provides a better measurement. The projection methods ($p \cdot idf$ and $p \cdot tf \cdot idf$) outperform $tf \cdot idf$ overall but not as pronounced as $CoVAR$.

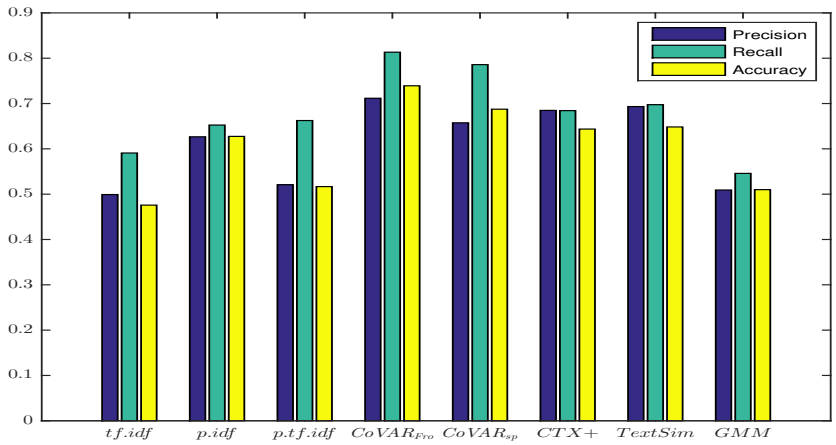

Figure 1: Aggregated performance by the eight competing methods on the 12 data sets.

Finally, we have noticed that even the best model ($CoVAR_{Fro}$) does not perform as well on certain idiomatic expressions. We hypothesize that the model works the best on highly idiomatic expressions. to be more easily interpretable than others.

We decided to conduct a small experiment, in which we asked two human annotators to rank VNCs in our datasets, i.e., rank each VNC token as "highly idiomatic" to "easily interpretable/compositional" on a scale of 5 to 1 (5: highly idiomatic; 1: low idiomaticity) given the context. We averaged the results in Table 5. This task is highly subjective and having two annotators is merely enough to make strong claims. The agreement was very low (30%), because the annotators often disagreed on idiomaticity

scores, such as 2 vs. 3. The annotators tried to avoid ranking the expressions as 100% idiomatic or 100% literal. Measuring the agreement using ranges is reasonable. Thus, if both annotators marked an idiom as 1 or 2, we considered them to be in agreement. The ranges were 1-2, 2-3, 3-4 and 4-5. Applying this method, the annotator agreement increased significantly – 80% (Cohen's Kappa 0.68).

The table shows that the low ranking scores often correspond to the low performance scores of our best model: the model did not perform well on *HaveWord* and the idiomaticity score produced by the human annotators is relatively low (=2). Low idiomaticity suggests indeterminate contexts, which affects the performance of our context-based models. There is a positive correlation between the degree of idiomaticity and the accuracy of the best model ($r = .47$, $p =< .001$).

Table 5: Idiomaticity Rank: 1=low; 5 = high

VNC	HitWall	GiveSack	HaveWord	LoseHead	MakeScene	BlowTop	BlowWhistle	HoldFire	HoldHorse	HitRoof	TakeHeart
Rank	1.5	2	2	2	2.5	3	3	3.5	3.5	4	4

5 Related Work

Previous approaches to idiom detection can be classified into two groups: 1) type-based extraction, i.e., detecting idioms at the type level; 2) token-based detection, i.e., detecting idioms in context. Type-based extraction is based on the idea that idiomatic expressions exhibit certain linguistic properties such as non-compositionality that can distinguish them from literal expressions (Sag et al., 2002; Fazly et al., 2009). While many idioms do have these properties, all idioms fall on the continuum from being compositional to being partly unanalyzable to completely non-compositional (Cook et al., 2007). Katz and Giesbrecht (2006), Birke and Sarkar (2006), Fazly et al. (2009), Li and Sporleder (2009), Li and Sporleder (2010a), Sporleder and Li (2009), and Li and Sporleder (2010b), among others, notice that type-based approaches do not work on expressions that can be interpreted idiomatically or literally depending on the context and thus, an approach that considers tokens in context is more appropriate for idiom recognition. To address these problems, Peng et al. (2014) investigate the bag of words *topic* representation and incorporate an additional hypothesis–contexts in which idioms occur are more affective. Still, they treat idioms as semantic outliers.

6 Conclusions

In this paper we described an original algorithm for automatic classification of idiomatic and literal expressions. We also compared our algorithms against several competing idiom detection algorithms in the literature. The performance results show that our algorithm generally outperforms Fazly et al. (2009)'s, Sporleder and Li (2009), and Li and Sporleder (2010b)'s models (see Table 4). In particular, our method is especially effective when idioms are highly idiomatic. A research direction is to incorprate affect into our model. Idioms are typically used to imply a certain evaluation or affective stance toward the things they denote (Nunberg et al., 1994; Sag et al., 2002). We usually do not use idioms to describe neutral situations, such as buying tickets or reading a book. Even though our method was tested on verb-noun constructions, it is independent of syntactic structure and can be applied to any idiom type. Unlike Fazly et al. (2009)'s approach, for example, our algorithm is language-independent and does not rely on POS taggers and syntactic parsers, which are often unavailable for resource-poor languages. Our next step is to expand this method and use it for idiom detection rather than for idiom classification.

Abstract

Several tasks in argumentation mining and debating, question-answering, and natural language inference involve classifying a sequence in the context of another sequence (referred as bi-sequence classification). For several single sequence classification tasks, the current state-of-the-art approaches are based on recurrent and convolutional neural networks. On the other hand, for bi-sequence classification problems, there is not much understanding as to the best deep learning architecture. In this paper, we attempt to get an understanding of this category of problems by extensive empirical evaluation of 19 different deep learning architectures (specifically on different ways of handling context) for various problems originating in natural language processing like debating, textual entailment and question-answering. Following the empirical evaluation, we offer our insights and conclusions regarding the architectures we have considered. We also establish the first deep learning baselines for three argumentation mining tasks.

1 Introduction

Argumentation mining is a relatively new challenge in corpus-based discourse analysis that involves automatically identifying argumentative structures within a corpus. Many tasks in argumentation mining (Lippi and Torroni, 2015a) and debating technologies (Slonim et al., 2014) involve categorizing a sequence in the context of another sequence. For example, in *context dependent claim detection* (Levy et al., 2014), given a sentence, one task is to identify whether the sentence contains a claim relevant to a particular debatable topic (generally given as a context sentence). Similarly in *context dependent evidence detection* (Rinott et al., 2015), given a sequence (possibly multiple sentences), one task is to detect if the sequence contains an evidence relevant to a particular topic. We refer to such class of problems in computational argumentation as *bi-sequence classification* problems—given two sequences s and c we want to predict the label for the target sequence s in the context of another sequence c[1]. Apart from the debating tasks, several other natural language inference tasks fall under the same paradigm of having a pair of sequences. For example, *recognizing textual entailment* (Bowman et al., 2015), where the task is to predict if the meaning of a sentence can be inferred from the meaning of another sentence. Another class of problems originated from question-answering systems also known as *answer selection*, where given a question, a candidate answer needs to be classified as an answer to the question at hand or not.

Recently, deep learning approaches have obtained very high performance across many different natural language processing tasks. These models can often be trained in an end-to-end fashion and do not require traditional, task-specific feature engineering. For many single sequence classification tasks, the state-of-the-art approaches are based on recurrent neural networks (RNN variants like Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Cho et al., 2014)) and convolution neural network based models (CNN) (Kim, 2014). Whereas for bi-sequence classification, the context sentence c has to be explicitly taken into account when performing the classification for the

[1] In this paper, we shall ignore the subtle distinction between sentence and sequence and both will mean just a text segment composed of words.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2762–2773, Osaka, Japan, December 11-17 2016.

target sentence s. The context can be incorporated into the RNN and CNN based models in various ways. However there is not much understanding in current literature as to the best way to handle context in these deep learning based models. In this paper, we empirically evaluate(see Section 4) the performance of five different ways of handling context in conjunction with target sentence(see Section 3) for multiple bi-sequence classification tasks(see Section 2) using architectures composed of RNNs and(/or) CNNs.

In a nutshell, this paper makes the two major novel contributions:

1. We establish the first deep learning based baselines for three bi-sequence classification tasks relevant to argumentation mining with zero feature engineering.

2. We empirically compare the performance of several ways handling context for bi-sequence classification problems in RNN and CNN based models. While some of these variants are used in various other tasks, there has been no formal comparison of different variants and this is the first attempt to actually list all the variants and compare them on several publicly available benchmark datasets.

2 Bi-Sequence classification tasks

In this section, we will briefly mention the various bi-sequence tasks of interest in the literature of argumentation mining and in the broader natural language inference domain.

2.1 Argumentation Mining

We mainly consider two prominent tasks in argumentation mining, namely, detecting the claims (Levy et al., 2014) and evidences (Rinott et al., 2015), within a given corpus, which are related to a prespecified topic. These two tasks together helps to automatically construct persuasive arguments out of a given corpora. We will define the following four concepts:
Motion - The topic under debate, typically a short phrase that frames the discussion.
Claim - A general, typically concise statement that directly supports or contests the motion.
Motion text - A document/article/discourse that contain claims with high probability.
Evidence - A set of statements that directly supports the claim for a given motion.

2.1.1 Context Dependent Claim Detection (CDCD)

Given a sentence in a motion text the task is to identify whether the sentence contains a claim relevant to the motion or not. This is the claim sentence task introduced by Levy et al. (2014). For example, each of the following sentences includes a claim, marked in italic, for the motion topic in brackets.

1. (**the sale of violent video games to minors**) Recent research has suggested that some *violent video games may actually have a pro-social effect in some contexts, for example, team play*.

2. (**the right to bear arms**) Some gun control organizations say that *increased gun ownership leads to higher levels of crime, suicide and other negative outcomes*.

2.1.2 Context Dependent Evidence Detection (CDED)

Given a segment in a motion text the task is to identify whether the segment contains an evidence relevant to the motion or not (Rinott et al., 2015). We consider evidences of two types in this paper, *Study* and *Expert*. Evidences of type study are generally results of a quantitative analysis of data given as numbers, or as conclusions. The following are two examples for study evidence relevant to the motion topic in brackets.

- (**the sale of violent video games to minors**) A 2001 study found that exposure to violent video games causes at least a temporary increase in aggression and that this exposure correlates with aggression in the real world.

- (**the right to bear arms**) In the South region where there is the highest number of legal guns per citizen only 59% of all murders were caused by firearms in contrast to 70% in the Northeast where there is the lowest number of legal firearms per citizen.

Evidence of type expert is a testimony by a person/group/commitee/organization with some known expertise/authority on the topic. The following are two examples for expert evidence relevant to the motion topic in brackets.

1. (**the sale of violent video games to minors**) This was also the conclusion of a meta-analysis by psychologist Jonathan Freedman, who reviewed over 200 published studies and found that the majority did not find a causal link.

2. (**the right to bear arms**) University of Chicago economist Steven Levitt argues that available data indicate that neither stricter gun control laws nor more liberal concealed carry laws have had any significant effect on the decline in crime in the 1990s.

2.2 Textual Entailment (TE)

This task (Bowman et al., 2015) corresponds to a multiclass setting, where given a pair of sentences (*premise* and *hypothesis*), the task is to identify whether one of them (*premise*) entails, contradicts or is neutral with respect to the other sentence (*hypothesis*). Unlike the other debating tasks seen previously, we cannot call these pair of sentences as context and target as these are more symmetric in nature. Typical examples[2] are the following (premise followed by hypothesis):

- Entailment: A soccer game with multiple males playing - Some men are playing a sport.
- Contradiction: A black race car starts up in front of a crowd of people - A man is driving down a lonely road.
- Neutral: A smiling costumed woman is holding an umbrella - A happy woman in a fairy costume holds an umbrella.

2.3 Answer Selection for Questions

Question Answering (QA) System is a natural extension to the traditional commercial search engines as it is concerned with fetching answers to natural language queries and returning the information accurately in natural human language. A QA system can be either closed-domain or open-domain, the former being restricted to a particular domain while the latter is not. *Answer sentence selection is a crucial subtask of the open-domain question answering problem, with the goal of extracting answers from a set of pre-selected sentences* (Yang et al., 2015). This is again bi-sequence classification task where the pair of sequences being a question and a candidate answer to be selected.

3 Deep Learning models for sequence pairs

All the tasks described in the previous section can be formulated as bi-sequence classification problems where we have to predict the label for the given pair of sequences. For simpler single sequence text classification tasks, RNN or CNN based architectures have become standard baselines. In this section, we will briefly introduce RNN and CNN and then subsequently describe RNN and CNN based architectures for bi-sequence classification tasks. Specifically, we talk about five different ways of handling context along with the target sentence.

3.1 Continuous Bag of Words (CBOW)

One of the simplest forms of sequence representation is the CBOW model, where every word in the sequence produces some word embedding (say, based on word2vec (Mikolov et al., 2013)) and the average of the word embedding vectors over the words produces the representation of the sequence. As is evident, this form of representation totally disregards the word order of the sequence.

3.2 Recurrent neural networks (RNNs)

The RNN model provides a framework for conditioning on the entire history of the sequence without resorting to the Markov assumption traditionally used for modelling sequences. Unlike CBOW, RNNs encode arbitrary length sequences as fixed size vectors without disregarding the word order.

Given an ordered list of n input vectors $\mathbf{x}_1, ..., \mathbf{x}_n$ and an initial state vector $\mathbf{s}_0$, a RNN generates an ordered list of n state vectors $\mathbf{s}_0, ..., \mathbf{s}_n$ and an ordered list of n output vectors $\mathbf{y}_1, ..., \mathbf{y}_n$, that is, $RNN(\mathbf{s}_0, \mathbf{x}_1, ..., \mathbf{x}_n) = \mathbf{s}_1, ..., \mathbf{s}_n, \mathbf{y}_1, ..., \mathbf{y}_n$. The input vectors $\mathbf{x}_i$ (which corresponds to a fixed dimensional representation for each word in the sequence) are presented to the RNN in a sequential fashion and $\mathbf{s}_i$ represents the state of the RNN after observing the inputs $\mathbf{x}_1, ..., \mathbf{x}_i$. The output vector $\mathbf{y}_i$ is a

[2] http://nlp.stanford.edu/projects/snli/

function of the corresponding state vector $\mathbf{s}_i$ and is then used for further prediction. An RNN is given by the following update equations:

$$\mathbf{s}_i = R(\mathbf{x}_i, \mathbf{s}_{i-1}) \quad (1)$$

$$\mathbf{y}_i = O(\mathbf{s}_i) \quad (2)$$

The recursively defined function R takes as input the previous state vector $\mathbf{s}_{i-1}$ and the current input vector $\mathbf{x}_i \in \mathbb{R}^{d_x}$ and results in an updated state vector $\mathbf{s}_i \in \mathbb{R}^{d_s}$. An additional function O maps the state vector $\mathbf{s}_i$ to an output vector $\mathbf{y}_i \in \mathbb{R}^{d_y}$. Different instantiations of R and O will result in the different network structures (Simple RNN, LSTM (Hochreiter and Schmidhuber, 1997), GRU (Cho et al., 2014), etc.). The final state vector $\mathbf{s}_n$ can be thought of as encoding the entire input sequence into a fixed size vector, which can be passed to a softmax layer to produce class probabilities.

3.3 Convolutional Neural Networks (CNNs)

CNNs are built on the premise of locality and parameter sharing which has proven to produce very effective feature representation for images. Following the groundbreaking work by Kim (2014), there has been a lot of interest shown by the text community towards applying CNNs for modelling text representation.

As in case of RNNs defined above, an n-word sentence consists of embedding vectors $\mathbf{x}_1, ..., \mathbf{x}_n \in \mathbb{R}^{d_x}$, one for each word in the sentence. Let $\mathbf{x}_{i:i+j}$ denote the concatenation of words $\mathbf{x}_i, \mathbf{x}_{i+1}, ..., \mathbf{x}_{i+j}$. A convolution operation defined by a non-linear function f applies a filter $\mathbf{w} \in \mathbb{R}^{hd_x}$ to a window of h words to produce a single feature value as given below:

$$c_i = f(\mathbf{w}.\mathbf{x}_{i:i+h-1} + b) \quad (3)$$

$$\mathbf{c} = [c_1, c_2, ..., c_{n-h+1}] \quad (4)$$

In the next step, max-pooling is applied which essentially produces a single feature value $\hat{c} = max\{\mathbf{c}\}$, corresponding to one filter that has been used. The model can have multiple feature values, one for each applied filter, thus producing a feature representation for the input sentence, which can again be passed to a softmax layer to produce class probabilities.

3.4 Bi-Sequence RNN models

For bi-sequence classification tasks we use two RNNs, one RNN to encode the context sentence (*context RNN*) and another separate RNN encode the target sentence (*target RNN*). We define the following five different variants of combining these two RNNs for bi-sequence classification tasks (see Figure 1 for illustration of these variants).

1. **conditional-state**: The final state of the context RNN is fed as the initial state of the target RNN. This way of handling context for RNNs has been previously used in conversational systems (Vinyals and Le, 2015), image description (Vinyals et al., 2015) and image question answering (Ren et al., 2015) systems.

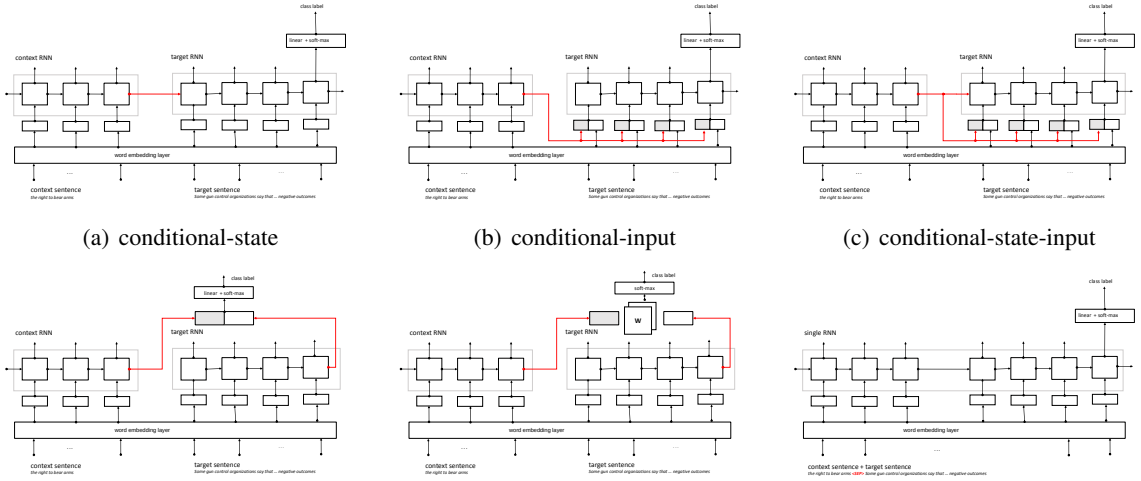
2. **conditional-input**: The final state of the context RNN is fed as auxiliary input (concatenated with every input) for the target RNN. This way of handling context has been previously used in machine translation tasks (Sutskever et al., 2014).

3. **conditional-state-input**: The final state of the context RNN is fed as the initial state of the target RNN and also fed as input for target RNN concatenated with every input.

4. **concat**: The final states of both the context and the target RNN are concatenated and then fed to a softmax layer for the label prediction.

5. **bi-linear**: The final states of both the context and the target RNN are combined using a bi-linear form ($\mathbf{x}^\top \mathbf{W}\mathbf{y}$) with a softmax function for the final prediction. There are different $\mathbf{W}$ for different classes under consideration.

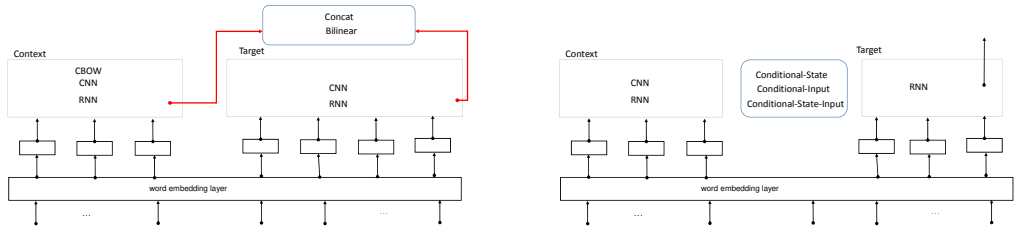
From here on, we would refer to architecture types 1, 2 and 3 as *conditional* variants while the others will be addressed as is. In addition, we consider another baseline variant **concat-sentence**, in which we concatenate the context and the sentence with a special separator token and feed the entire concatenated sequence to a single RNN. For all these variants we use a common embedding layer. Also note that the conditional variants require a common RNN size for both the context and the target RNNs. Even though that restriction is not there for other variants, we choose the same RNN size anyways for convenience.



(a) conditional-state (b) conditional-input (c) conditional-state-input

(d) concat (e) bilinear (f) concat-sentence

Figure 1: RNN based Architectures for bi-sequence classification.



(a) concat-bilinear-all-combinations (b) conditional-all-combinations

Figure 2: Multiple model variants for bi-sequence classification.

3.5 Bi-Sequence model variants

In this paper, we consider multiple ways of extending the bi-sequence architectures mentioned in section 3.4, by replacing RNN with CBOW or CNN either for context or target or both. For the variations *concat* and *bi-linear* (see Fig. 2(a)), we have considered CBOW, RNN and CNN for context representation whereas we have RNN and CNN for target representation. In tasks where context has very few words (say debating tasks or question-answering), a simple representation like CBOW may work for context. However, we haven't considered modelling target using CBOW as targets are usually of larger length. For the *conditional* variants (see Fig. 2(b)), we haven't considered CBOW due to their limited modelling capacity and there is no softmax layer directly on top of context representation to compensate for it (even though softmax is only on top of target RNN). Moreover, target can only be RNN as there is no concept of hidden state for CNNs. Hence, we use CNN and RNN for context whereas RNN for target. In addition, we consider the concat-sentence (mentioned in section 3.4) as a baseline. This leads to 19 architectures for empirical comparison (12 from Fig. 2(a) and 6 from Fig. 2(b) and the baseline).

4 Experiments

We have carried out extensive evaluation of the above architecture variants over a wide range of datasets related to argumentation mining as well as datasets appealing to the larger natural language community

like textual entailment and question answering data. We consider data with class imbalance problem as well as balanced and we do not restrict ourselves to binary classification by working with multiclass dataset as well. As can be found in the Table 1, we consider the following tasks related to the domain of argumentation mining(Aharoni et al., 2014), which is available here [3] :

- Claim Sentence : This is the dataset for the CDCD task defined in section 2.1.1. This is the current benchmark dataset for the Claim Detection task. There are a total 47183 canditate claims distributed among 33 motions.
- EXPERT Evidence : This is corresponding to the CDED task defined in section 2.1.2 for evidence type EXPERT. There are 56985 labelled candidates for 57 different motion topics.
- STUDY Evidence : For evidence type STUDY, the dataset consists of 33534 labelled candidates for 49 motion topics.

Table 1 summarizes all of the datasets above. Interesting point to be noted here is that all the datasets above have very low number of positives and the architectures we are evaluating need to be resilient to the class imbalance problem for these datasets. Other than the debating datasets listed above, we also consider two datasets related to more popular problems in the natural language processing community:

- Textual Entailment (TE) [4] (Bowman et al., 2015) :This dataset consist of around 500K instances evenly distributed across all three classes. So, here we have a multiclass problem in a balanced setting.
- WikiQA [5] (Yang et al., 2015) : There are around 29K labelled question/answer pairs at our disposal.

Task	Motions	Data Size	Positives
Claim Sentence	33	47183	2.77%
EXPERT Evidence	57	56985	4.56%
STUDY Evidence	49	33534	3.74%

Table 1: Argument Mining Datasets.

Task	Train	Dev	Test	Problem	Class
TE	549367	9842	9824	Multiclass	Balance
WikiQA	20360	2733	6165	Binary	Imbalance

Table 2: More Datasets.

4.1 Experimental Setup

For each of the architectures mentioned in section 3.5, we choose the best configuration of hyperparameters based on the validation portion of the particular dataset (For Claim and Evidence datasets, we consider a train:valid:test split of 60:10:30 while for the TE and WikiQA datasets we consider their corresponding given split).

Performance of the best performing configuration for every architecture is reported on the test data using the appropriate metric. As the claim and expert and study Evidences had similar data characteristics (in terms of data size and context and target lengths), we did extensive hyperparam tuning only on the claim dataset and applied the best configurations without further tuning to the expert and study datasets. Exhaustive hyperparam tuning was done on the TE dataset as well because its data characteristics are very different from other datasets.

In addition to reporting the test metrics for argumentation datasets, we carried out Leave-One-Out(leaving one motion out for testing) Mode training and evaluation which is more appropriate for this problem setting as it is crucial that we generalize well to totally unseen motion topics. In this case, we report the macro-average metrics over all motions.

4.2 Hyperparameter Tuning

Considering the number of variations of combinations of architectures we have considered, we have a huge hyperparameter space to deal with. Hence, we decided to fix insignificant hyperparameters and focus only on the relevant ones. We have decided to use word2vec (Mikolov et al., 2013) pretrained models for initializing the word embeddings across CBOW, CNN and RNNs and made them trainable specific to task at hand. In addition we have found through minimal tuning that the Adam (Kingma and Ba, 2015) optimizer seems to work best. We have also found that a learning rate of 0.001 works best

[3] https://www.research.ibm.com/haifa/dept/vst/mlta_data.shtml
[4] http://nlp.stanford.edu/projects/snli/
[5] http://aka.ms/WikiQA

in most scenarios except when the parameter space in some architectures (for ex, *bi-linear*) is large, in which case lower learning rates of 0.0001 or 0.00001 worked well. Rather than tuning the maximum sequence length for context and target sentence, we tried to fix it by getting reasonable values by plotting histogram of sequence lengths and had a cut-off at around 98-99 percentile. The max lengths turned out to be 14 for context and 60 for target for Claim, Evidence and WikiQA datasets while for textual entailment, they turned out to be 30 in both due to the symmetrical nature between premise and hypothesis. We tuned the following hyperparameters:

RNN Model : GRU or LSTM.

RNN Size : 50,100,200,300,400,500,1000.

CNN Filter Sizes : 3,3+4,3+4+5,2+3+4+5.

CNN Number of Filters : 10,20,40,64,128.

L2 Reg coeff for CNN : 0, 0.01, 0.001, 0.0001.

For every architecture type, we carried out the optimization of the relevant hyperparams from the above list over the whole grid. One point to note is that for certain architectures like conditional-state, as output of context is fed in to the hidden state of target RNN, there are some restrictions in the allowable context RNN/CNN hyperparam configurations based on the target RNN settings as the output dimension of the context RNN/CNN needs to match the hidden state dimension of the target RNN.

4.3 Evaluation Metrics

For the datasets Claim, Expert, Study Evidence and WikiQA datasets, we have used standard evaluation measures like Average Precision (Area under Precision Recall Curve) and AUC to choose best hyperparam configurations based on validation data as well as report test metrics. For argument mining specific tasks, we have reported other additional metrics like P@200, R@200, F1@200, P@50, R@50 and F1@50 (Levy et al., 2014) in addition to reporting AUC and Average Precision. Please note for leave-one-out mode, the reported metrics are macro-average over all motion topics. For Textual entailment, since it is a more balanced dataset, reporting valid and test accuracies are standard in the literature and we have done the same.

Task	Context	Target	Architecture	Test AVGP
Claim Sentence	RNN	CNN	**Concat**	**0.307**
	CNN	CNN	Concat	0.304
	Concat-Sentence baseline			0.17
EXPERT Evidence	RNN	RNN	**Conditional-State-Input**	**0.257**

Table 7: Numbers in Leave-One-Motion-Out mode for all three debating tasks using our approach.

4.4 Results and Discussion

Tables 3 and 4 report the two top ranking architectures for four datasets based on Test AUC and Test Avg Precision. We find that **Concat** is the winning architecture variant across majority of the datasets considered. Moreover, the runner-up architecture type **Conditional-State-Input** is also similar to 'Concat' in the sense that concatenation of context representation is done at the input of the sentence RNN. Now the four datasets we considered are asymmetric in nature as there are significantly fewer contexts (motions or questions) than the targets. Hence the context model does not see enough data for learning and hence, if the learnt context model is fed directly to the hidden state of the target RNN, the improperly learnt context model can play a big role. In contrast if a Concat kind of architecture is used, the linear plus softmax layer can decide on how much importance to give to the context model. Hence, Concat is doing better in this case.

From Textual entailment dataset(which is symmetric in nature), we found that conditional type of architectures are doing better at the Test accuracies. In fact, the winning architecture was **Conditional-State** with RNN-RNN combo, which did better in terms of test accuracy than the feature based models (Bowman et al., 2015) and one tree-based model (Mou et al., 2016). However, it came close to the state-of-the-art attention based model (Parikh et al., 2016). In our work we are empirically evaluating simple architectures for bisequence classification without using more sophisticated tree-based or attention-based models. It is possible that adding attention on top of this will improve the results further.

The *bi-linear* model, is supposed to capture the interaction between the context and target reps via a quadratic form (section 3.4). For the asymmetric datasets, this is not doing well again due to insufficient data for context. Whereas, it does well for the TE data. However, due to the huge parameter space for bi-linear, training times are considerably higher and requires lower learning rate than other architecture types. The runtimes are comparable for the other architecture variants.

From Table 6, the main takeaway is that we are the only deep learning based method with zero feature engineering and we have come very close to the state-of-the-art systems (Levy et al., 2014) and (Lippi and Torroni, 2015b), which are heavily feature-engineered. Here again the winner is a 'Concat' based combination of architecture. Moreover, Tables 6 and 7 are the first deep learning zero feature engineered baselines for all argument mining datasets. Appendix A contains the details of the exhaustive

experiments on all architectures on the different datasets in terms of the best hyperparameters used.

5 Conclusion

In this work, we have considered taking up multiple architectures for bisequence classification tasks, for which not much understanding is there in the current literature. In addition to suggesting winning architecture recipes for different kinds of datasets, we have established deep learning based baselines for argument mining tasks with zero feature engineering. As future work, it remains to be seen how adding attention on top of winning simple architectures fare in terms of benchmark performance.

6 Acknowledgements

We would like to thank Mitesh M. Khapra for the multiple discussions that we had with him leading to this paper. In addition, we are also grateful to our colleagues at IBM Debating Technologies for the numerous suggestions and feedback at different points of time.

Abstract

The recent proliferation of smart devices necessitates methods to learn small-sized models. This paper demonstrates that if there are m features in total but only $n = o(\sqrt{m})$ features are required to distinguish examples, with $\Omega(\log m)$ training examples and reasonable settings, it is possible to obtain a good model in a *succinct* representation using $n \log_2 \frac{m}{n} + o(m)$ bits, by using a pipeline of existing compression methods: L1-regularized logistic regression, feature hashing, Elias–Fano indices, and randomized quantization. An experiment shows that a noun phrase chunking task for which an existing library requires 27 megabytes can be compressed to less than 13 kilobytes without notable loss of accuracy.

1 Introduction

The age of smart devices has arrived. Cisco reports that, as of 2015, smartphones and tablets account for 15% of IP traffic (against 53% for PCs), and further predicts that, by 2020, this share will have grown to 43%, surpassing the 29% of PCs (Cisco Systems, 2016). This trend increases the need for intelligent processing for these platforms. Hence, the study of statistical methods for natural language processing (NLP) systems on mobile devices has received considerable attention in recent years (Ganchev and Dredze, 2008; Hagiwara and Sekine, 2014; Chen et al., 2015).

Among the various issues in this setting, storage costs pose a particular challenge, because the size of the resulting models often grow quickly. Even a simple noun phrase (NP) chunker can easily take dozens of megabytes if naïvely implemented. Suppose we have m features. A direct implementation then consumes $Z(\mathcal{A}) + O(m\zeta)$, where $Z(\mathcal{A})$ represents the size of an *alphabet* $\mathcal{A}$, or a *feature dictionary* that maps a feature string to an index into its parameter vector, and $O(m\zeta)$ represents the space complexity of a dense real vector as the parameter where using ζ bits to achieve a certain amount of float precision ($64m$ if using double-precision floats). These large-sized models are not only inefficient in terms of network bandwidth, but also significantly increase energy consumption (Han et al., 2016). Therefore, it is vital to devise a method that achieves as small a model as possible.

One of the basic properties of information theory says that, to represent a set of n non-negative integers less than m (or, equivalently, a bit vector of size m containing n 1s), we need at least $B_{m,n} = \lceil \log_2 \binom{m}{n} \rceil \approx n \log_2 \frac{m}{n}$ bits. Recent studies in theoretical computer science show that it is possible to compress a set of non-negative integers while keeping some primitive operations under *succinct* representations, that is, data structures using only $B_{m,n} + o(m)$ bits.

As an analogy to succinct data structures, one may ask a question: if there are m features, but only n of these are useful for distinguishing data, how many bits are required to obtain a good classifier? This paper shows that under several reasonable assumptions such as $n = o(\sqrt{m})$, with $\Omega(\log m)$ examples, it is possible to obtain a model that performs similarly to the original classifier, by using only $B_{m,n} + o(m)$ bits.

To evaluate our method, we implemented conditional random fields (CRFs) by using our pipelined architecture and conducted an experiment on an NP chunking model. The results show that 27 megabytes can be reduced to about 13 kilobytes.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2774–2784, Osaka, Japan, December 11-17 2016.

In summary, our work is significant in that

1. we present a pipelined method to acquire a *succinct* model that also has almost the same predictive performance as the model of Ng (2004),
2. although the above method is achieved under some conditions and penalties, the conditions are not ungrounded for NLP tasks and the the penalties are neglible for large m,
3. we also introduce a bitwise trick to perform fast unbiased feature hashing, a part of the pipeline,
4. and our experimentations on sequential labeling tasks achieve smaller models than existing libraries by a factor of one thousand, demonstrating the high practical value of our approach.

This paper is organized as follows. In Section 2, we mention related work. In Section 3, we explain the notation used in the paper. In Section 4, we introduce and analyze our methods. In Section 5, we evaluate our approach by an experiment.

2 Related Work

Ganchev and Dredze (2008) were one of the earliest groups to recognize the importance of acquiring small models for mobile platforms. They also showed that naïve hashing tricks for features (now commonly known as *feature hashing*) can greatly improve the memory efficiency without much loss of accuracy. Shi et al. (2009) showed that feature hashing could be applied to graph models. Weinberger et al. (2009) proposed an unbiased version of feature hashing. Bohnet (2010) applied the method to dependency parsing, and found that it improves not only memory efficiency, but also speed performance. Recent studies (Chen et al., 2015) suggest that hashing tricks also work well in deep neural networks too.

Feature selection through the L1 regularization is also known to be effective, since, roughly speaking, the number of features in the final model results in being logarithmic to the number of total features (Ng, 2004). Online optimization (vis-á-vis batch optimization) with the L1-regularization term gained attention from around 2010 (Duchi and Singer, 2009; Tsuruoka et al., 2009), and with the AdaGrad (Duchi et al., 2011) method becoming particularly popular, because of its theoretical and practical performance.

Compression by quantization is closely related to machine learning. For eaxmple, the Lloyd quantization (Lloyd, 1982) is now used as a popular clustering method known as the K-means clustering. Golovin et al. (2013) showed that simple (simplistic, in fact) quantization techniques actually exhibit good performance in common settings used in NLP; although their methods themselves were basic, they analyzed theoretical effects in detail, and these serve as the key ingredients for our error analysis in Section 4.

The compression of indices is a classical topic in information retrieval (IR). Vigna (2013) introduced the Elias–Fano structure (Fano, 1971; Elias, 1974) into IR, although this was already a popular theme in the succinct data structures community (Grossi and Vitter, 2005; Okanohara and Sadakane, 2007; Golynski et al., 2014). Although other types of succinct structures are common in NLP as well (Watanabe et al., 2009; Sorensen and Allauzen, 2011; Shareghi et al., 2015), the Elias–Fano structure is in that, if regarded as a binary vector, the order of compression ratio depends on the number of 1s (rather than the total length of a vector) and achieves better compression ratio than other succinct models for binary vectors if the ratio of 1s is very low (empirically, below 10%); to put it more concretely, the structure is very attractive when unnecessary indices are culled by some techniques such as L1-regularization. Because of its simplicity and compression ratio, the Elias–Fano structure even gained a certain degree of popularity in industry; for example, as of 2013, it is used as one of the backbones of Facebook's social graph engine (Curtiss et al., 2013). Several variants have been proposed, including sdarry (Okanohara and Sadakane, 2007) and the partitioned Elias–Fano indices (Ottaviano and Venturini, 2014).

Driven by these successes, the study of pipelining compression techniques has flourished in recent years. The web-based morphological parser developed by Hagiwara and Sekine (2014) is similar to our work in its aim and basic scheme, but some parts were not implemented and they gave no theoretical explanation of why pipelined compression would work well. For large-scale neural networks, by using

Han et al. (2015)'s three-step pruning process, Han et al. (2016) gained great empirical success using deep compression, or pipelined compression for a deep neural network with pruning, trained quantization, and Huffman coding.

3 Notation

The base of logarithm is e if not stated explicitly. If the base is x ($x \neq e$), we write $\log_x$. $\mathbb{E}$ denotes an expectation, $\mathbb{R}$ denotes a set of real values, and $\mathbb{N}$ denotes a set of non-negative integers. $\delta_{i,j}$ represents the Kronecker's delta, that is, $\delta_{i,j} = 1$ if $i = j$, and 0 otherwise. $B_{m,n}$ represents the information-theoretic lower bound of encoding a bit vector of size m with n 1s, that is, $n \left\lceil \log_2 \binom{m}{n} \right\rceil$.

4 Learning Succinct Models

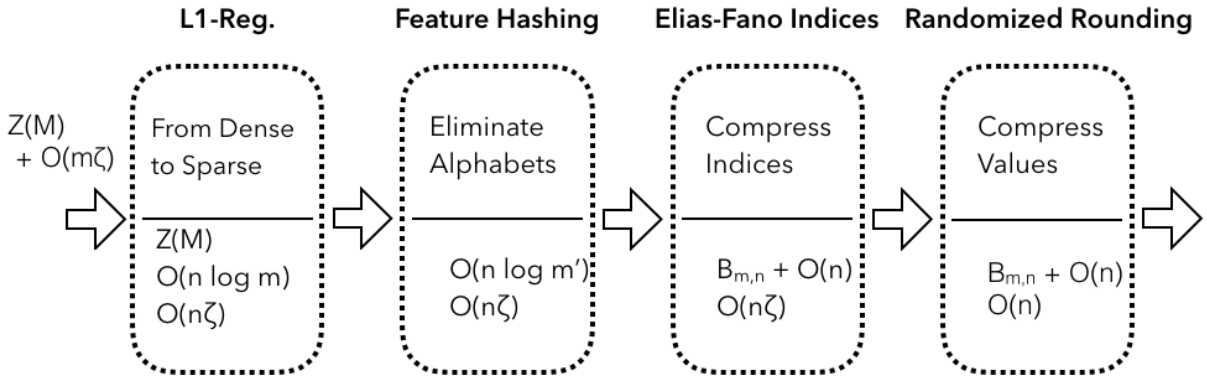

Figure 1: Overview of pipelined compression.

In this section, we present a supervised learning method to obtain a small-sized model for classification tasks. For simplicity, we assume binary classification for each label $y \in \{0, 1\}$ by logistic regression. Suppose there is a set of m features and a dataset $\mathcal{T} = \left\{(\mathbf{x}^{(0)}, y^{(0)}), (\mathbf{x}^{(1)}, y^{(1)}, ..., (\mathbf{x}^{(T-1)}, y^{(T-1)})\right\}$ of T training examples drawn i.i.d. from some distribution $\mathcal{D}$.

Consider the following optimization problem with the L1-regularization term $R(\boldsymbol{\theta}) = ||\boldsymbol{\theta}||_1$

$$\begin{aligned} \max_{\boldsymbol{\theta}} \quad & \sum_{i=0}^{T-1} \log p(y_i \mid \mathbf{x}_i \,;\, \boldsymbol{\theta}) \\ \text{subject to} \quad & R(\boldsymbol{\theta}) \leq B. \end{aligned} \tag{1}$$

Our goal is to obtain a good parameter $\boldsymbol{\theta}$ that minimizes the expected logistic log loss, that is,

$$\varepsilon(\boldsymbol{\theta}) = \mathbb{E}_{(\mathbf{x},y)\sim\mathcal{D}}[-\log p(y \mid \mathbf{x} \,;\, \boldsymbol{\theta})] \tag{2}$$

with as small a model as possible. We also define the empirical loss

$$\hat{\varepsilon}(\boldsymbol{\theta}) = \hat{\varepsilon}_{\mathcal{T}}(\boldsymbol{\theta}) = \frac{1}{T} \sum_{i=0}^{T-1} -\log p(y_i \mid \mathbf{x}_i \,;\, \boldsymbol{\theta}). \tag{3}$$

The m-dimensional vector $\boldsymbol{\theta}$ is often implemented as a float array of size m, consuming $O(m\zeta)$ bits. Concretely, it occupies $64m$ bits if we use double-precision ($\zeta = 64$) and $32m$ bits if single-precision ($\zeta = 32$). As m can be millions, billions, or more in NLP tasks, this size complexity is often non-negligible for mobile and embedded devices (e.g., 762.9 megabytes for 100,000,000 features when using double-precision).

In addition to the parameter vector, we need to store an *alphabet* or a *feature dictionary* $\mathcal{A}\colon \mathbb{N} \to \{0, ..., m-1\}$ such that $\mathcal{A}(\mathfrak{f}_i) = i$ for $\mathfrak{f}_0, ..., \mathfrak{f}_{m-1} \in \mathbb{N}$. For example, if the 12-th element in a feature set

represents "the current token is `appropriate`, the previous token is `I`, and the current label is `VERB`", one possible formulation is $\mathfrak{f}_{12}$ = `utf8("bigram[-1:0]=I:appropriate&label=VERB")`, where `utf8` denotes a non-negative integer given by the UTF-8 bit representation of a string. A weight value for this feature can then be accessed as $\boldsymbol{\theta}_{\mathcal{A}(\mathfrak{f}_{12})}$. There are two problems with the use of alphabets. First, they consume too much storage space (Ganchev and Dredze, 2008). Second, if implemented with a hash table (as is often the case), they are so slow that they become the bottleneck of the entire learning system (Bohnet, 2010). In the following, $Z(\mathcal{A})$ denotes the size of an alphabet $\mathcal{A}$.

4.1 Pipelined method

Let us now introduce a pipelined method to reduce both $O(m\zeta)$ and $Z(\mathcal{A})$.

Definition 4.1. Given inputs $\mathcal{T}$,

1. Train the model by using L1-regularization according to the method of Ng (2004):
   (a) Divide the data $\mathcal{T}$ into a training set $\mathcal{T}_1$ of the size $(1-\gamma)T$ and a development set $\mathcal{T}_2$ of the size γT, for some $\gamma \in \mathbb{R}$.
   (b) For $B = 0, 1, 2, 4, ..., C$, solve the optimization under each of these hyperparameters with $\mathcal{T}_1$, giving $\boldsymbol{\theta}_0, ..., \boldsymbol{\theta}_C$.
   (c) Choose $\boldsymbol{\theta} = \arg\min_{\{i \in 0,1,2,...,C\}} \hat{\varepsilon_{\mathcal{T}_2}}(\boldsymbol{\theta}_i)$, or the best model for the development data set.

   As we performed the L1-regularization, it is safe to assume that the non-zero components are quite small. $Z(\mathcal{A}) + O(n \log m) + O(n\zeta)$; $Z(\mathcal{A})$ for the alphabet, $\lceil \log m \rceil$ bits for each of the n indices, and $zeta$) bits for each of the n values.

2. Eliminate the alphabet and reduce the dimensionality of vectors by using the *unbiased feature hashing* (Weinberger et al., 2009). Given two hash functions $h\colon \mathbb{N} \to \{0, ..., m'-1\}$ and $\xi\colon \mathbb{N} \to \{-1, 1\}$, we define the (unbiased) *hashed feature map* ϕ such that $\phi^{(h,\xi)(\mathbf{x})} = \sum_{j\colon h(j)=i} \xi(i)\mathbf{x}_i$. We apply this ϕ to the parameter vector and all future input vectors. As this map acts as a proxy for the alphabet, we no longer need to store the alphabet. As a side-effect, if we choose $m' < m$, the dimensionality is reduced from m to m'. Note that this is said to be unbiased because given $\langle \mathbf{x}, \mathbf{x}' \rangle_\phi := \left\langle \phi^{(h,\xi)}(\mathbf{x}), \phi^{(h,\xi)}(\mathbf{x}') \right\rangle$, $\mathbb{E}\langle \mathbf{x}, \mathbf{x}' \rangle_\phi = \langle \mathbf{x}, \mathbf{x}' \rangle$. In other words, on average, prediction using a hashed map space is the same as the original version.

   At this point, the size has been reduced to $O(n \log m') + O(n\zeta)$; $\lceil \log m' \rceil$ for each of the n indices and ζ) bits for each of the n values.

3. Compress the set of n indices by using the Elias–Fano scheme (Fano, 1971; Elias, 1974). In brief, n integers are compressed to $n\lceil \log_2 m/n \rceil + f(n)$, where $f(n) = O(n)$ and $f(n) \leq 2Sn$ for some speed-memory trade-off hyperparameter $1 \leq S < 2$ (usually less than 1.01). We omit the details here, but interested readers may consult Vigna (2013)'s good introduction.

   At this point, the size has been reduced to $n\lceil \log_2 m'/n \rceil + O(n) + O(n\zeta)$.

4. Compress the set of values by using the *unbiased randomized rounding* (Golovin et al., 2013). Let μ and ν be some non-negative integers, then it encodes each value as a fixed-point number with Q$\mu.\nu$ encoding, that is, as μ integer bits and ν fractional bits (e.g., if $\mu = \nu = 2$, we can represent a maximum of $(11.11)_2 = 3.75$). Including a sign bit, $\mu + \nu + 1$ for each value. μ and ν are chosen so that they satisfy the conditions of the error anaysis in the following subsection.

   At this point, the size has been reduced to $n\lceil \log_2 m'/n \rceil + O(n)$.

Overall, because $n\lceil \log_2 m/n \rceil = B_{m,n} + O(n)$ (Golynski et al., 2014), choosing $m' < m$ and assuming $n = o(m)$ achieves a model with $B_{m,n} + o(m)$. In the next subsection, however, we assume tighter conditions such as $n = o(\sqrt{m})$ to achieve good error bounds.

4.2 Error analysis

Each compression technique (except Elias–Fano) adds several penalties to the predictive performance. Therefore, intuitively, pipelined compression should lower the performance significantly. Contrary to such intuition, however, the increase in the error is negligible under certain circumstances.

Theorem 4.2. *Suppose that there exist m features in total, but only n features are important, so that the optimal parameter vector $\theta^* \in \mathbb{R}^m$ has only n non-zero components with indices $0 \leq i_0, i_1, ..., i_{n-1} < m$. Further, assume that each non-zero component is bounded by some constant no less than 1, that is, $0 < |\theta_{i_j}| \leq K$ for $j = 0, ..., n-1$ with $K \geq 1$.*

Let us be given a training data set $\mathcal{T} = \left\{(\mathbf{x}^{(0)}, y^{(0)}), (\mathbf{x}^{(1)}, y^{(1)}, ..., (\mathbf{x}^{(T-1)}, y^{(T-1)})\right\}$ of T training examples drawn i.i.d. from some distribution $\mathcal{D}$. Assume that the number of non-zero components of each input is always bounded by some non-negative constant much smaller than m, and that n is also much smaller than m as follows:

$$||\mathbf{x}||_0 \leq k \text{ for any } (\mathbf{x}, y) \sim \mathcal{D}, k \geq 0, k = o(\sqrt{m}), n = o(\sqrt{m}), \text{ and } K = o(m). \tag{4}$$

Then, with probability at least $(1-\delta)(1+f_1(m))$ where $f_1(m) = o(1)$, it is possible to obtain a model with size (in bits) at most

$$B_{m,n} + o(m) \tag{5}$$

with errors to the expected logistic loss

$$\varepsilon(\hat{\theta}) \leq \epsilon_{mul} \left(\varepsilon(\theta^*) + \epsilon_{add}\right) \tag{6}$$

where $\epsilon_{mul} = 1 + f_2(m)$ with f_2 such that $f_2(m) = o(1)$, by performing $C \geq nk$ iterations to find a good hyperparameter and by using the T examples such that

$$T = \Omega((\log m) \cdot \textit{poly}(n, K, \log(1/\delta), 1/\epsilon_{add}, C)). \tag{7}$$

Prior to its proof, let us explain what the above theorem says. If we omit the conditions of Equation (4), we have the same setting used in Ng (2004, Theorem 3.1). Thus, if we perform L1-regularized learning as defined in 1 of Definition 4.1, Ng's theorem implies that Equations (6) and (7) hold, satisfying $f_1(m) = 0$ and $f_2(m) = 0$.

In other words, the above theorem implies that if we add the conditions defined in Equation (4)) to Ng's theorem, it is possible to obtain a succinct representation (Equation (5)) whose predictive performance is nearly as good as that of Ng's theorem, albeit with a probabilistic penalty $f_1(m)$ and an error penalty $f_2(m)$. However, the penalties are negligible because $f_1(m) = o(1)$ and $f_2(m) = o(1)$.

Note that for NLP tasks, some of the conditions can be justified to a certain extent by the power law. Let us follow the discussion presented by Duchi et al. (2011, Section 1.3). In NLP tasks, the appearance of features often follows the power law. Thus, we can assume that the i-th most frequent feature appears with probability $p_i = \min(1, ci^{-\alpha})$ for some $a \in (1, +\infty)$ and a positive constant c. Given $\mathbf{x}$, $\mathbb{E}||\mathbf{x}||_0 \leq c\sum_{i=1}^{m} i^{-\alpha/2} = O(\log d)$ for $\alpha \geq 2$ and $||\mathbf{x}||_0 \leq O(m^{1-\alpha/2})$ for $\alpha \in (1, 2)$. Thus $\mathbb{E}||\mathbf{x}||_0 = o(\sqrt{m})$ for any $\mathbf{x}$ and $\alpha \in (1, +\infty)$. This assumption and derivation by Duchi et al. imply that the condition $k = o(\sqrt{m})$ is not ungrounded. The same discussion applies to $n = o(\sqrt{m})$ too. The condition $K = o(m)$ is less obvious than the other two, but we often assume a good parameter does not have any excessively large values.

We now prove the above theorem.

Proof. If we omit the conditions of Equation (4)), then the method in 4.1.1 can be used to show that Equations (6) and (7) hold, satisfying $\epsilon_{mul} = 1$ (Ng, 2004, Theorem 3.1).

Next, we apply the unbiased feature hashing defined in 4.1.2. As the expected dot-product between vectors in a reduced space is the same as the original, this does not change the expected error (Weinberger et al., 2009). There is, however, one problem: hash collisions. When a collision occurs for an input $\mathbf{x}$, for the vector converted from $\mathbf{x}$, the absolute value for some index may exceed 1. However, the error

analysis of randomized rounding requires the absolute value of any index to be bounded by 1. Hence, applying feature hashing before randomized rounding can break the subsequent analysis. Thankfully, if we use $h : \mathbb{N} \to 0, ..., m'$ such that $||\mathbf{x}||_0 = o(m')$ for any $\mathbf{x} \in \mathcal{D}$, with *high probability* (that is, $1 - o(1)$), collisions never occur. This is a well-known fact resulting from Sterling's approximation (in the following , f, g, h, i are $o(1)$ and irrelevant to the rest of this proof).

$$
\begin{aligned}
\binom{n}{k} = \frac{n!}{k!(n-k)!} &= \frac{(1+f(n))\sqrt{2\pi n}e^{-n}n^n}{k!(1+g(n-k))\sqrt{2\pi(n-k)}e^{-(n-k)}(n-k)^{n-k}} \\
&= \frac{(1+f(n))}{(1+g(n-k))} \cdot \frac{1}{k!} \cdot \left(\frac{n}{n-k}\right)^{1/2} e^{-k} \left(\frac{n}{n-k}\right)^{-k} \left(\frac{n}{n-k}\right)^{n} n^k \\
&= \frac{(1+f(n))}{(1+g(n-k))} \cdot \frac{n^k}{k!} \cdot \left(1-\frac{k}{n}\right)^{k-1/2} e^{-k} \left(1-\frac{k}{n}\right)^{-n} \\
&= \frac{(1+f(n))}{(1+g(n-k))} \cdot \frac{n^k}{k!} \cdot (1+o(1))e^{-k} \frac{1}{\left(1-\frac{k}{n}\right)^n} \\
&= \frac{(1+f(n))(1+h(k))}{(1+g(n-k))(1+i(n))} \cdot \frac{n^k}{k!} \cdot e^{-k} \cdot \frac{1}{e^{-k}} = \frac{(1+f(n))(1+h(k))}{(1+g(n-k))(1+i(n))} \cdot \frac{n^k}{k!}
\end{aligned}
$$

Using this equation, it is possible to estimate the hash collision ratio. If we assume Equation (4), $m' = c\sqrt{m}$ for some positive c satisfies the condition we mentioned above.

We then apply the Elias–Fano structure defined in Definition 4.1.3. Because this is a lossless compression method for indices, the error analysis remains the same. The remaining problem is how to store the values in $o(m)$ bits.

Finally, we apply the unbiased randomized rounding as in Definition 4.1.4. Golovin et al. (2013, Theorem 4.3) implies that if the value of each non-zero component of θ^* is bounded by some K and the number of non-zero components of any input is bounded by some k such that $K \geq 1$ and $k \geq 0$, then it is possible to derive a new parameter vector $\hat{\theta}$, with each value using $(1 + \mu + \nu)$ bits, such that $\varepsilon(\hat{\theta}) \leq \epsilon_{mul} \cdot \varepsilon(\theta^*)$, where

$$
0 \leq \epsilon_{mul} \leq 2\chi\sqrt{2\pi k} \exp\left(\frac{\chi^2 n}{2}\right), \tag{8}
$$

$\mu = \lceil \log_2 K \rceil (= o(\log m)$ if $K = o(m))$, and $\nu = -\log_2 \chi$ (so $\chi = \frac{1}{2^\nu}$). If we use $\nu = \lceil cm^{1/2} \rceil (= \Theta(\sqrt{m}))$ for some positive constant c, assuming the conditions (4) hold, $\epsilon_{mul} = f_2(m)$ with f_2 such that $f_2(m) = o(1)$. Here $f_2(m) = o(1)$ holds because $\lim_{m\to+\infty} \chi\sqrt{k} = \lim_{m\to+\infty} \sqrt{k \cdot \chi^2} = \lim_{m\to+\infty} \sqrt{o(\sqrt{m})/O(2^{m^{1/2}})} = 0$ and the same limit also applies to the $\chi^2 n$ term.

Thus, to store the values, we need $n(1 + \mu + \nu) = o(\sqrt{m}) \cdot (1 + o(\log m) + \Theta(\sqrt{m})) = o(m)$ bits in total. This completes the proof. □

4.3 Practical settings

In practical situations, several violations of the method can make it more efficient.

For example, as presented by Weinberger et al. (2009), it is possible to reduce both storage and RAM usage during training by applying feature hashing prior to training with L1-regularization. In this case, it is not clear whether the above theorem holds, as we solve the optimization problem in the reduced-dimension space rather than the original one. Nevertheless, the predictive performance of resulting models will not change significantly. Weinberger et al. (2009, Corollary 5) pointed out that the number of instances enters logarithmically into the analysis of the maximal canonical distortion. Additionally, Ng (2004) showed that the number of features m affects the number of required instances only logarithmically. Combining these results implies that, if we carefully choose informative instances for training, the distortion in the reduced space is only affected by $\log \log m$, which should be negligible. Thus, we expect the theorem to virtually hold even in this setting.

Another issue involves solving Equation (1). Several concrete optimization algorithms such as AdaGrad (Duchi et al., 2011) solve the dual problem of Equation (1), that is, $\arg\max_{\boldsymbol{\theta}} \sum_{i=0}^{T-1} \log p(y_i|\mathbf{x}_i;\boldsymbol{\theta}) - \lambda R(\boldsymbol{\theta})$ where $\lambda \propto \frac{1}{B}$ for $B > 0$. This is said to be dual because, for any $\boldsymbol{\theta}$ obtained by Equation (1) with some hyperparameter B, there is exactly one hyperparameter λ that gives the same $\boldsymbol{\theta}$. Unfortunately, it is often impossible to get the exact relationship between the hyperparameters B and λ. However, because $\lambda \propto \frac{1}{B}$, a good value may be found by trying $\lambda = 1, \frac{1}{2}, \frac{1}{4}, \frac{1}{8}, ...$

4.4 Bitwise feature hashing

On first examination, unbiased feature hashing (Weinberger et al., 2009) may appear to be twice as costly as the naïve version (that is, always $\xi(i) = 1$ in Definition 4.1.2), as it requires two hash functions to be computed: h and ξ. Actually, by leveraging some bitwise operations, we need only one hash computation and just another three CPU cycles per feature to perform the unbiased version. Let us consider the following algorithm to convert k items of an original index–value pair to the same number of items of pairs under feature hashing. In the algorithm, `>>` denotes an arithmetic right shift (also called a signed right shift).

Data: A 2-tuple of indices and values $(I; V)$ such that $I \in \mathbb{N}^k$ and $V \in \mathbb{R}^k$ for some k.
Dimensionality m' satisfying $m' = 2^a$ for some $a \in \mathbb{N}$.
Result: A 2-tuple of indices and values $(I^*; V^*)$ such that $I^* \in \mathbb{N}^k$ and $V^* \in \mathbb{R}^k$ for some k and $0 \leq i' < m' < 2^{32}$ for any $i \in I^*$.

$MASK \leftarrow m' - 1$;
for *int* $i = 0$*;* $i < k$*;* $i \leftarrow i + 1$ **do**
  $t \leftarrow h(I_i)$;
  sign $\leftarrow (t \ \texttt{>>}\ 31) \mid 1$;
  $I_i^* \leftarrow t \ \texttt{\&}\ MASK$;
  $V_i^* \leftarrow sign \cdot V_i$;
end
return $(I^*; V^*)$;

Algorithm 1: Bitwise unbiased feature hashing

The improvements over the original version are:

1. the original version requires two hash functions, whereas our version requires only one,
2. the resulting index–value pairs are not merged—because the dot-product between two vectors is distributive ($a \cdot (b + c) = a \cdot b + a \cdot c$), there is no need to merge indices—so there is no need to use slow data structures such as hash maps for merging, and
3. compared with Bohnet (2010)'s approach, which uses a `%` (modulo) operator to gain the desired dimension, our approach uses `&` (bitwise mask), so it runs faster in common architectures. The downside is that the resulting dimension will be limited to a power of two.

5 Experimental Results

To evaluate our approach, we implemented a linear-chained conditional random field (CRF) (Lafferty et al., 2001; Sha and Pereira, 2003) and tested it on an NP chunking task. For the optimization problem, we used the AdaGrad, an online optimization algorithm, with the L1-regularization term by diagonal primal-dual subgradient update (Duchi et al., 2011).

5.1 Implementation

We implemented our CRF library with ECMAScript 6, but its core component for optimization computation was handwritten by asm.js[1], a subset of ECMAScript 6 (that is, so-called JavaScript 6). The language

[1] ".js" is not a file extension, but a part of the name of the language.

was designed mainly by Mozilla as a performance improvement technique for web platforms. Although it is conformant to ECMAScript 6, the language is actually lower-level than C, and Mozilla claims it is only at most twice as slow as native code. We used the language because, by using a JavaScript-compatible language, it is possible to embed the resulting classifier in web pages for use as a fundamental library in web systems, not only on desktop machines but also on mobile platforms.

5.2 NP chunking

μ \ ν	3	2	1
3	0.9720	0.9703	0.9621
2	0.9673	0.9681	0.9610
1	0.9470	0.9460	0.9392

Table 1: Macro-averaged F1 values under various μ and ν values for $Q\mu.\nu$ encoding.

To test our CRF implementation, following Sha and Pereira (2003), we performed an NP chunking task using the CoNLL-2000 text chunking task data (Tjong Kim Sang and Buchholz, 2000). In the shared task data, the labels B-NP and I-NP were retained, but all other labels were converted to O. Therefore, this is basically a sequential labeling problem with three labels. The features are the same as those used by Sha and Pereira (2003), except that they reformulated two consecutive labels as a new one, whereas we used the original labels. The total number of features is 1,015,621.

The training dataset consists of 8,936 instances, and the test dataset contains 2,012. Of the training data set, we used 7,148 instances (4/5) for training and the remaining 1,788 instances as development data.

For feature hashing, we used 2^{20} as the resulting dimension. There are three hyperparameters for AdaGrad: δ, η, and λ. For the first two, we simply used $\delta = \eta = 1.0$. To find a good value for λ, or the coefficient of the regularization term, we tried $\{1.0, 0.5, 0.25, 0.125, ..., \}$, and found that $\lambda = 0.5^{14} \sim 0.00006104$ gave the best results, with a macro-averaged F1 score of 0.9722. The number of active features (L0-norm) was 8,824. We also tested various μ and ν for the unbiased randomized rounding, and found that $\mu = \nu = 3$ gave a macro-averaged F1 score of 0.9720, which is slightly less than the original. In this case, the number of active features further decreased to 6,785. Overall, the size of our model was compressed to 12,745 bytes.

We compared our implementation with CRFSuite 1.2, a popular linear-chained CRF library written in C++ (Okazaki, 2007). The library has a convenient functionality that allows strings to be used as feature IDs. The downside is that the resulting model tends to be large, because it requires an alphabet to be stored. Using this library, the obtained model had a size of 27 megabytes, and achieved a macro-averaged F1 score was 0.973009.

In summary, although our method is inferior to the existing implementation by 0.001 in terms of F1 score, the size efficiency is more than 2,000 times better.

5.3 Performance of bitwise feature hashing

We also tested the performance of the bitwise feature hashing described in Section 4.4. For comparison, we prepared three functions as follows.

1. *Unbiased* feature hashing. The algorithm is similar to the one given by Bohnet (2010) but we employed two hash functions to implement the unbiased version and added values when collisions occurred, whereas Bohnet's method just overwrites the previous value. We used JavaScript's built-in object type as a dictionary (or hash map).

2. *Non-merge* feature hashing. This is almost identical to the standard version, but instead of using a dictionary (or hash map) structure, it emits the resulting index–value pairs into array structures

without merging the indices. The code was implemented without asm.js tuning, as this does not leverage bitwise operations.

3. *Bitwise* feature hashing with asm.js tuning (Section 4.4).

The environment used in this experiment was OS X 10.11.6 with 2.2 GHz Intel Core i7. The code was micro-benchmarked by Benchmark.js 2.1.0, developed by Mathias Bynens [2], under the following web browsers: Apple Safari 10.0 (with the JavaScript engine JavaScriptCore, also known as Nitro), Google Chrome 53.0.2785.143 (V8), and Mozilla Firefox 49.0.1 (SpiderMonkey). The experimental results are shown below.

	Standard	Non-merge	Bitwise
Apple Safari 10	1,108	3,426	**6,670**
Google Chrome 53	506	2,524	**4,710**
Mozilla Firefox 49	239	737	**4,446**

Table 2: Performance of each feature hashing implementation. Higher is better. Unit: 1k ops/sec.

The results in this table show that the bitwise version is more than five times faster than the standard one in all environments.

As we see, Safari was faster than the other browsers, possibly because the code was run under Apple's OS. Firefox was slightly slower than Chrome in general settings, but with asm.js enabled it achieved almost the same performance.

In conclusion, the bitwise feature hashing can offer powerful performance improvement when the task involves a number of features and processing those features is the bottleneck of the learning system.

6 Conclusions

This paper showed that pipelining compression methods for machine learning can achieve a succinct model, both theoretically and practically. Although each technique is classical and well-studied, our result is significant in that these techniques actually complement each other, leading to drastic compression without harming the predictive power. We also examined bitwise feature hashing, a subtle but powerful modification for improving processing performance. In future work, we will try to incorporate other compression techniques to build various pipeline configurations and compare the performance of each configuration.

Abstract

We assess the reliability and accuracy of (neural) word embeddings for both modern and historical English and German. Our research provides deeper insights into the empirically justified choice of optimal training methods and parameters. The overall low reliability we observe, nevertheless, casts doubt on the suitability of word neighborhoods in embedding spaces as a basis for qualitative conclusions on synchronic and diachronic lexico-semantic matters, an issue currently high up in the agenda of Digital Humanities.

1 Introduction

Distributional methods applied to large-sized, often temporally stratified corpora have markedly enhanced the methodological repertoire of both synchronic and diachronic computational linguistics and are getting more and more popular in the Digital Humanities (see Section 2.2). However, using such quantitative data as a basis for qualitative, empirically-grounded theories requires that measurements should not only be accurate, but also reliable. Only under such a guarantee, quantitative data can be assembled from different experiments as a foundation for trustful theories.

Measuring word similarity by word neighborhoods in embedding space can be used to detect diachronic shifts or domain specific usage, by training word embeddings on suited corpora and comparing these representations. Additionally, lexical items near in the embedding space to the lexical item under scrutiny can be considered as approximating its meaning at a given point in time or in a specific domain. These two lines of research converge in prior work to show, e.g., the increasing association of the lexical item *'gay'* with the meaning dimension of homosexuality (Kim et al., 2014; Kulkarni et al., 2015). Neural word embeddings (Mikolov et al., 2013) are probably the most influential among all embedding types (see Section 2.1). Yet, we gathered evidence that the inherent randomness involved in their generation affects the reliability of word neighborhood judgments and demonstrate how this hampers qualitative conclusions based on such models.

Our investigation was performed on both historical (for the time span of 1900 to 1904) and contemporary texts (for the time span of 2005 to 2009) in two languages, English and German. It is thus a continuation of prior work, in which we investigated historical English texts only (Hellrich and Hahn, 2016a), and also influenced by the design decisions of Kim et al. (2014) and Kulkarni et al. (2015) which were the first to use word embeddings in diachronic studies. Our results cast doubt on the reproducibility of such experiments where neighborhoods between words in embedding space are taken as a computationally valid indicator for properly capturing lexical meaning (and, consequently, meaning shifts).

2 Related Work

2.1 Word Embeddings

Word embeddings, i.e., low (several hundred) dimensional vector word representations encoding both semantic and syntactic information, are currently one of the most influential methods in computational

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2785–2796, Osaka, Japan, December 11-17 2016.

linguistics. The word2vec family of algorithms, developed from heavily trimmed artificial neural networks, is a widely used and robust way to generate such embeddings (Mikolov et al., 2013; Levy et al., 2015). Its skip-gram variant predicts plausible contexts for a given word, whereas the alternative continuous bag-of-words variant tries to predict words from contexts; we focus on the former as it is generally reported to be superior (see e.g., Levy et al. (2015)). There are two strategies for managing the huge number of potential contexts a word can appear in. Skip-gram hierarchical softmax (SGHS) uses a binary tree to more efficiently represent the vocabulary, whereas skip-gram negative sampling (SGNS) updates only a limited number of word vectors during each training step. SGNS is preferred in general, yet SGHS showed slight benefits in some reliability scenarios in our prior investigations (Hellrich and Hahn, 2016a).

There are two sources of randomness involved in the training of neural word embeddings: First, the random initialization of all word vectors before any examples are processed. Second, the order in which these examples are processed. Both can be replaced by deterministic alternatives,[1] yet this would simply replace a random distortion with a fixed one, thus providing faux reliability only useful for testing purposes. A range of other word embedding algorithms was inspired by word2vec, either trying to avoid the opaqueness stemming from its neural network heritage (GloVe; still using random initialization, see Pennington et al. (2014)) or adding capabilities, like using syntactic information during training (Levy and Goldberg, 2014) or modeling multiple word senses (Bartunov et al., 2016; Panchenko, 2016). Levy et al. (2015) created SVD_{PPMI}, a variant of the classical pointwise mutual information co-occurrence metric (see e.g., Manning and Schütze (1999, pp.178–183)), by transferring pre-processing steps and hyper-parameters uncovered by the development of these algorithms, and reported similar or slightly better performance than SGNS on evaluation tasks. It is conceptually not affected by reliability problems, as there is no random initialization or relevant processing order.

Word embeddings capture both syntactic and semantic information (and arguably also social biases, see Bolukbasi et al. (2016)) in vector form and can thus be evaluated by their ability to calculate the similarity of two words and perform analogy-based reasoning; there exist several other evaluation methods and more test sets than discussed here, see e.g., Baroni et al. (2014). Mikolov et al. (2013) provide an analogy test set for measuring performance as the percentage of correctly calculated analogies for test cases such as the frequently cited *'king'–'queen'* example (see Section 3). Word similarity is evaluated by calculating Spearman's rank coefficient between embedding-derived predictions and a gold standard of human word similarity judgments. Finkelstein et al. (2002) developed a widely used test set with 353 English word pairs,[2] a similar resource for German with 350 word pairs was provided by Zesch and Gurevych (2006).[3] Recent work cautions that performance on such tasks is not always predictive for performance in down-stream applications (Batchkarov et al., 2016).

2.2 Diachronic Application

Word embeddings can be used rather directly for tracking semantic changes, namely by measuring the similarity of word representations generated for one word at different points in time—words which underwent semantic shifts will be dissimilar with themselves. These models must either be trained in a continuous manner where the model for each time span is initialized with its predecessor (Kim et al., 2014; Hellrich and Hahn, 2016b), or a mapping between models for different points in time must be calculated (Kulkarni et al., 2015; Hamilton et al., 2016). The first approach cannot be performed in parallel and is thus rather time-consuming, if texts are not subsampled. We nevertheless discourage using samples instead of full corpora, as we observed extremely low reliability values between different samples (Hellrich and Hahn, 2016a). Word embeddings can also be used in diachronic studies without any kind of mapping to track clusters of similar words over time and, thus, model the evolution of topics (Kenter et al., 2015) or compare neighborhoods in embedding space for preselected words (Jo, 2016). Besides temporal variations, word embeddings can also used to analyze geographic ones, e.g., the distinction between US American and British English variants (Kulkarni et al., 2016). Most of these studies were

[1] In fact, in some implementations, yet not in ours, vectors are initialized via a deterministic process.

performed with algorithms from the `word2vec` family, respectively `GloVe` in Jo (2016), and are thus likely to be affected by the same systematic reliability problems on which we focus here. Only Hamilton et al. (2016) used SVD_{PPMI} in some of their very recent experiments and showed it to be adequate for exploring historical semantics.

The Google Books Ngram corpus (GBN; Michel et al. (2011), Lin et al. (2012)) is used in most of the studies we already mentioned, including our current study and its predecessor (Hellrich and Hahn, 2016a). It contains about 6% of all books published between 1500 and 2009 in the form of n-grams (up to pentagrams), together with their frequency for each year. This corpus has often been criticized for its opaque sampling strategy, as its constituent books remain unknown and can be shown to form an unbalanced collection (Pechenick et al., 2015). GBN is multilingual, with its English part being subdivided into regional segments (British, US) and topic categories (general language and fiction texts). Diachronic research focuses on the English Fiction part, with the exception of some work relating to German data (Hellrich and Hahn, 2016b).

3 Evaluation Methods

Reliability, in this study, is judged by training three identically parametrized models for each experiment and by comparing the n next neighbors (by cosine distance) for each word modeled by the experiments with a variant of the Jaccard coefficient (Manning and Schütze, 1999, p.299). The 3-dimensional array $W_{i,j,k}$ contains words ordered by closeness (i) for a word in question (j) according to an experiment (k). The reliability r for a specific value of n ($r@n$) is defined as the magnitude of the intersection of similar words produced by all three experiments with a rank of n or lower, averaged over all t words modeled by these experiments and normalized by n, which is the maximally achievable score for this value of n:

$$r@n := \frac{1}{t * n} \sum_{j=1}^{t} || \bigcap_{k=1}^{3} \{W_{1 \leq i \leq n,j,k}\} || \tag{1}$$

Accuracy, in this study, is measured considering two different approaches—analogy and similarity. The *analogy* approach uses the English test set developed by Mikolov et al. (2013) by calculating the percentage of correct analogies made by a `word2vec` model. It contains groups of four words connected via the analogy relation '::' and the similarity relation '$\sim$', as exemplified by the expression *'king'* $\sim$ *'queen'* :: *'man'* $\sim$ *'woman'*. The *similarity* approach covers both English and German by calculating Spearman's rank correlation coefficient between the similarity judgments made by a `word2vec` model for a word pair (e.g., *'bread'* and *'butter'*) and the human judgment thereof (Finkelstein et al., 2002; Zesch and Gurevych, 2006). Pairs containing words not modeled for the time span in question, such as the at that time non-existent *'FBI'* in the early 20th century, are simply ignored. All three test sets are based on contemporary language and current world knowledge and might thus not fully match the requirements for historical texts, yet are also used for these due to the lack of a suitable alternative. Accuracy values were calculated independently for each of the three identically parametrized models and subsequently averaged, but resulting deviations were negligible.

4 Experimental Set-up

4.1 Corpus

Our experiments[4] were performed on the German part and the English Fiction part of the GBN; the latter is known to be less unbalanced than the general English part (Pechenick et al., 2015). Both corpus splits differ in size and contain mainly contemporary texts (from the past fifty years), as is evident from Figure 1; note the logarithmic axis and the negative impact of both World Wars on book production. Following Kulkarni et al. (2015), we trained our models on all 5-grams occurring during five consecutive years for the two time spans,[5] 1900–1904 and 2005–2009; the number of 5-grams[6] for each time span

[4]Code used in experiments available from `https://github.com/hellrich/coling2016`

[5]This is due to computational demands, e.g., using 8 parallel processes on a server with Intel Xeon E5649@2.53Ghz processors five days were necessary to complete each of ten training epochs for SGNS with 2005–2009 English Fiction data.

[6]Note that we treat 5-grams with k occurrences during the same time span as k different 5-grams.

is listed in Table 1. The two languages share a similar number of 5-grams for 1900–1904, yet not for 2005–2009. 5-grams from both corpus parts were lower cased for training. The German part was not only taken as is, but also orthographically normalized using the CAB service (Jurish, 2013).[7] We incorporated this step because major changes in German orthography occurred during the 20th century, an issue that could hamper diachronic comparisons, e.g., archaic *'Gemüth'* (in English: "mind, emotional disposition") became modern *'Gemüt'*. Table 1 shows the resulting reduction in the number of types, bringing the morphologically richer German to levels below English (yet this reduction is in line with the respective corpus sizes).

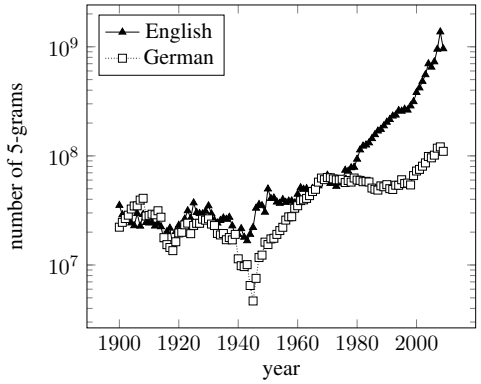

Figure 1: Number of 5-grams per year (on the logarithmic y-axis) in the English Fiction part and the German part of the GOOGLE BOOKS NGRAM corpus.

Language	Time Span	5-grams	Types
English	1900–1904	143M	80k
English	2005–2009	4,658M	216k
German	1900–1904	135M	111k
Normalized German			72k
German	2005–2009	546M	243k
Normalized German			179k

Table 1: Number of 5-grams and lemma types contained in the English Fiction part and the German part of the GOOGLE BOOKS NGRAM corpus for the two time spans used in our experiments.

4.2 Training

We used the PYTHON-based GENSIM[8] implementation of `word2vec` to independently train word embeddings for each time span with 200 dimensions, a context window of 4 (limited by the 5-gram size), a minimum frequency of 10, and 10^{-5} as the threshold for downsampling frequent words. We processed the full subcorpora for each time span, due to the extremely low reliability values between samples we observed in previous investigations (Hellrich and Hahn, 2016a). We tested both SGNS with 5 noise words and SGHS training strategies and trained for 10 iterations, saving the resulting embeddings after each epoch. During each epoch the learning rate was decreased from 0.025 to 0.0001. The averaged cosine values between word embeddings before and after an epoch are used as a convergence measure c (Kim et al., 2014; Kulkarni et al., 2015). It is defined for a vocabulary with n words and a matrix W containing word embedding vectors (normalized to length 1) for words i from training epochs e and e-1:

$$c := \frac{1}{n} \sum_{i=1}^{n} W_{i,e} \cdot W_{i,e-1} \tag{2}$$

We also define Δc, the change of c during subsequent epochs e-1, as another convergence criterion:

$$\Delta c := c_e - c_{e-1} \tag{3}$$

5 Results

Table 2 shows the performance of the systems trained according to the settings described in Section 4.2, as measured by similarity accuracy and top-1 reliability (see below for other cut-offs). We make the following observations:

[7] `www.deutschestextarchiv.de/demo/cab/`
[8] `www.radimrehurek.com/gensim/`

1. Both accuracy and reliability are higher for SGNS than for SGHS for all tested combinations of languages and time spans, if 10 training epochs are used.
2. If only one training epoch is used—as in many other experimental set-ups reported in the literature—there is only little difference in accuracy between SGNS and SGHS, but SGHS is clearly better in terms of reliability.
3. Accuracy is higher for 2005–2009 than for the 1900–1904 interval, with the exception of non-normalized German (which can most likely be explained by the temporal currency of the test sets).
4. Normalization of German data slightly decreases reliability, yet increases accuracy.

Training Scenario			Top-1 Reliability			Similarity Accuracy		
Language	Time Span	Embeddings	1 Epoch	5 Epochs	10 Epochs	1 Epoch	5 Epochs	10 Epochs
English Fiction	1900–1904	SGNS	0.11	0.33	0.40	0.45	0.51	0.51
		SGHS	0.23	0.33	0.33	0.46	0.45	0.45
	2005–2009	SGNS	0.36	0.54	0.57	0.58	0.58	0.57
		SGHS	0.36	0.39	0.38	0.55	0.52	0.52
German	1900–1904	SGNS	0.20	0.47	0.54	0.45	0.56	0.56
		SGHS	0.34	0.43	0.42	0.48	0.49	0.47
	2005–2009	SGNS	0.31	0.50	0.53	0.51	0.54	0.54
		SGHS	0.34	0.38	0.36	0.49	0.48	0.47
Normalized German	1900–1904	SGNS	0.19	0.45	0.52	0.47	0.55	0.57
		SGHS	0.32	0.42	0.42	0.47	0.48	0.48
	2005–2009	SGNS	0.30	0.48	0.52	0.54	0.59	0.60
		SGHS	0.33	0.37	0.36	0.51	0.52	0.52

Table 2: Accuracy and reliability among top-1 words for threefold repetition of different training scenarios after completing 1, 5 and 10 training epochs, respectively.

We also measured analogy accuracy for the English Fiction data sets, and observed no negative effect of multiple training epochs, yet a more pronounced gap between training methods, e.g., 36% of all analogies were correct for SGNS and only 27% for SGHS after one epoch on 1900–1904 data.

In the following, we further explore system performance as influenced, e.g., by word frequency, word ambiguity and the number of training epochs. For German, we focus on the normalized version due to the overall similar performance and suitability for further applications.

Influence of Neighborhood Size. Reliability at different top-n cut-offs is very similar for all languages and time spans under scrutiny, confirming previous observations in Hellrich and Hahn (2016a) and strengthening the suggestion to use only top-1 reliability for evaluation. Figure 2 illustrates this phenomenon with an SGNS trained on 1900–1904 English Fiction data. We assume this to be connected with the general decrease in `word2vec` embedding utility for high values of n already observed by Schnabel et al. (2015).

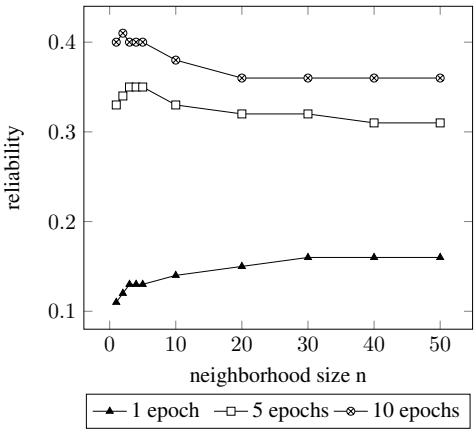

Figure 2: Effect of neighborhood size parameter n in reliability calculation for SGNS embeddings trained on 1900–1904 English Fiction data.

Influence of Word Frequency. Figures 3 and 4 depict the influence of word frequency (as percentile ranks) for English, as well as orthographically normalized German. Negative sampling is overall more reliable, especially for words with low or medium frequency. Word frequency has a less pronounced effect on reliability for German and negative sampling is again preferable, especially for low or medium frequency words. The 21 English

words reported to have undergone traceable semantic changes in prior work[9] are all frequent with percentiles between 89 and 99—for such high-frequency words hierarchical softmax performs similarly or even slightly better. The relatively low reliability for medium-frequency English words, as compared to German ones, could be caused by a peculiar pattern of word co-occurrences, illustrated in Figures 5 and 6 for 1900–1904 English Fiction, respectively normalized German. Medium-frequency English words have fewer co-occurrences with low-frequency words than German ones, which might result in a lack of specific contexts for these words during training and thus hamper embedding quality.

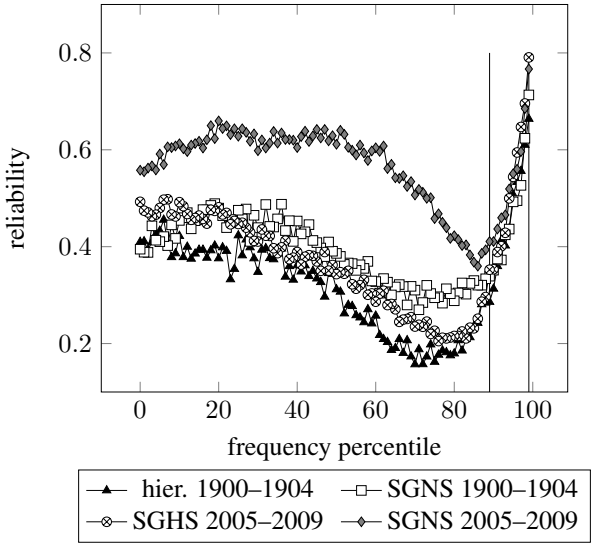

Figure 3: Influence of frequency percentile on reliability for models trained for 10 epochs on English Fiction data from 1900–1904 and 2005–2009. Words reported to have changed their semantics during the 20th century fall into the frequency range marked by the vertical lines.

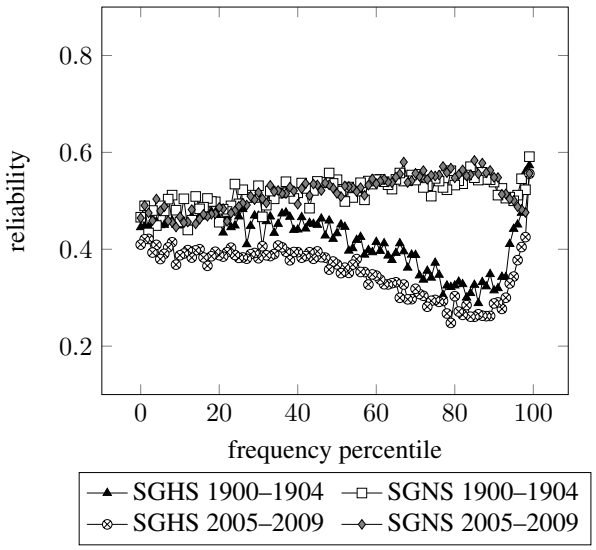

Figure 4: Influence of frequency percentile on reliability for models trained for 10 epochs on orthographically normalized German data from 1900–1904 and 2005–2009.

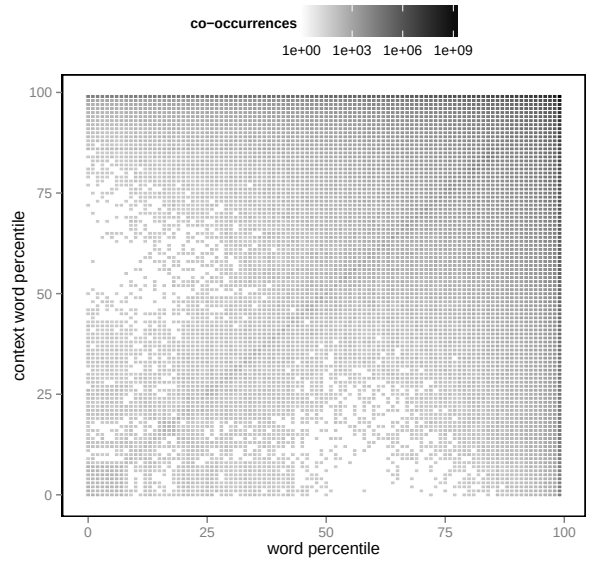

Figure 5: Number of co-occurrences (indicated by shade; only values above mode) between words and context words per frequency percentile for English Fiction 1900–1904 data.

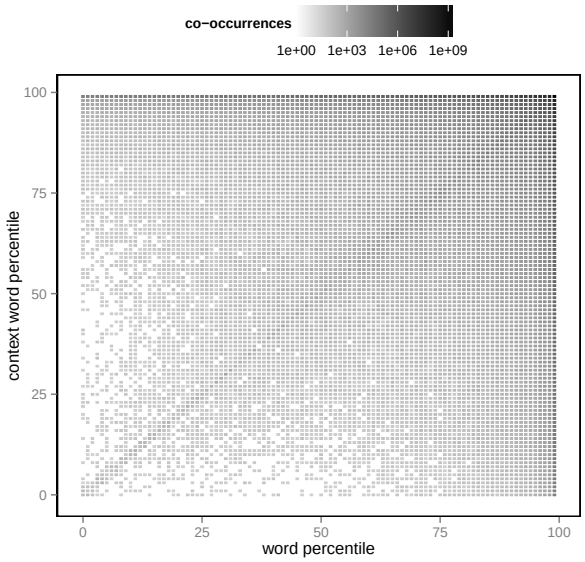

Figure 6: Number of co-occurrences (indicated by shade; only values above mode) between words and context words per frequency percentile for normalized German 1900–1904 data.

[9]Kulkarni et al. (2015) compiled the following list based on prior work (Wijaya and Yeniterzi, 2011; Gulordava and Baroni, 2011; Jatowt and Duh, 2014; Kim et al., 2014): *card*, *sleep*, *parent*, *address*, *gay*, *mouse*, *king*, *checked*, *check*, *actually*, *supposed*, *guess*, *cell*, *headed*, *ass*, *mail*, *toilet*, *cock*, *bloody*, *nice* and *guy*.

Influence of Word Ambiguity. Entries in lexical databases, such as WORDNET[10] (Fellbaum, 1998) and its German counterpart GERMANET[11] (Lemnitzer and Kunze, 2002), can be employed to approximate the effect of word ambiguity on reliability. The number of synsets a word belongs to (i.e., the number of its senses) seems to be positively correlated with top-1 reliability for English, as shown in Figure 7, whereas orthographically normalized German is less affected by ambiguity as Figure 8 reveals. This counter-intuitive effect for English seems to be caused by the low ambiguity of infrequent words—results become more uniform, if analysis is limited to high frequency words (e.g., 90th frequency percentile or higher).

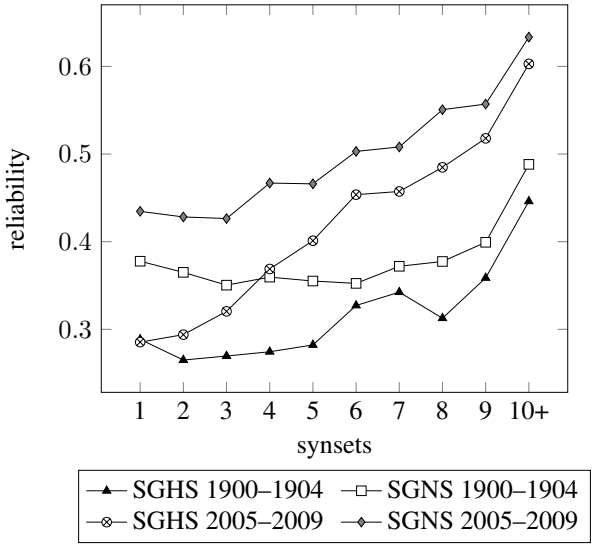

Figure 7: Influence of ambiguity (measured by the number of WORDNET synsets) on top-1 reliability for models trained for 10 epochs on English Fiction data from 1900–1904 and 2005–2009.

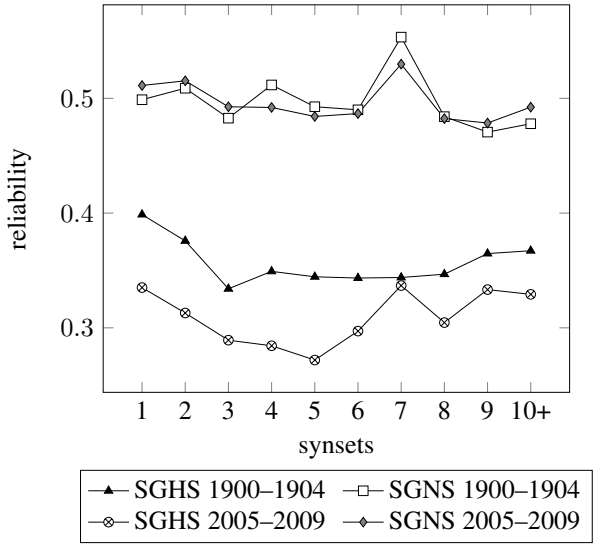

Figure 8: Influence of ambiguity (measured by the number of GERMANET synsets) on top-1 reliability for models trained for 10 epochs on orthographically normalized German data from 1900–1904 and 2005–2009.

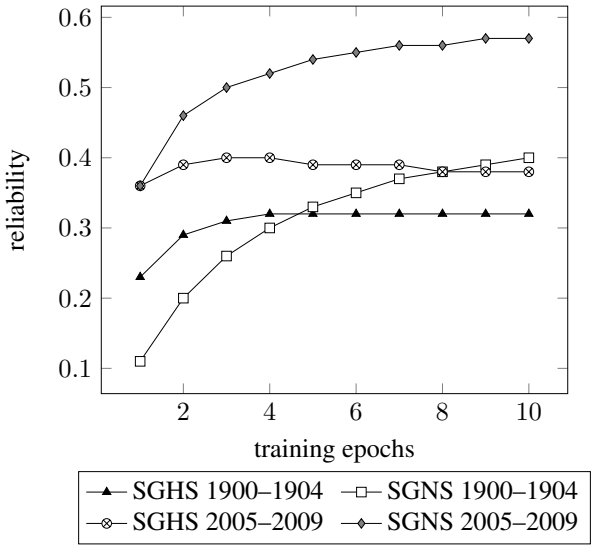

Figure 9: Top-1 reliability as influenced by the number of training epochs, for English Fiction data relative to the 1900–1904 and 2005–2009 time slices.

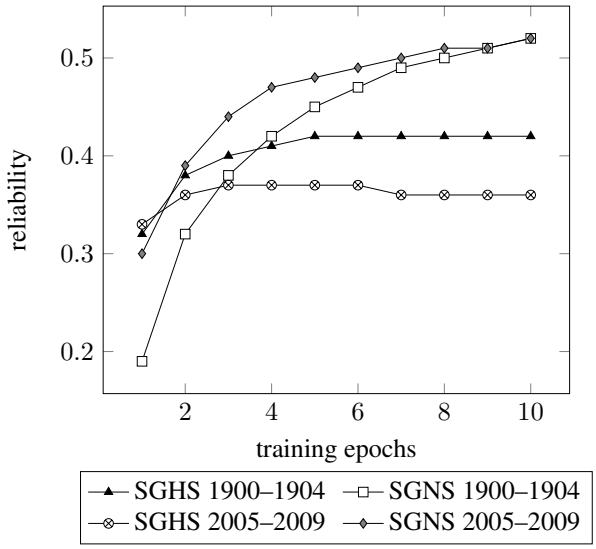

Figure 10: Top-1 reliability as influenced by the number of training epochs, for orthographically normalized German data relative to the 1900–1904 and 2005–2009 time slices.

Influence of the Number of Training Epochs. Model reliability and accuracy depend on the number of training epochs, as shown in Figures 9 and 10 for English and normalized German, respectively. For

[10]We used WORDNET 3.0 and the API provided by the Natural Language Toolkit (NLTK): `www.nltk.org`

[11]We used GERMANET 11.0 and the PYGERMANET API: `https://pypi.python.org/pypi/pygermanet`

both languages and time spans negative sampling outperforms hierarchical softmax, if training lasts for a sufficient number of epochs. The number of necessary epochs for negative sampling to become superior seems to be linked to both language and corpus size, as it is lower for 2005–2009 than for 1900–1904 data. While reliability continues to increase for each subsequent epoch under negative sampling, there are clear diminishing returns and even regression under hierarchical softmax.

To test for potential overfitting effects, we analyzed similarity accuracy as influenced by the number of training epochs (some values are already given in Table 2). Figures 11 and 12 show the results for English and orthographically normalized German, respectively. Note that accuracy is assessed on a test set for modern-day language, and can thus not be considered a fully valid yardstick. Accuracy behaves similar to reliability, as under the negative sampling condition it clearly profits from multiple training epochs. This effect is more pronounced for smaller corpora; the biggest corpus (i.e., English Fiction 2005–2009) shows a slight regression in accuracy after more than 5 training epochs.

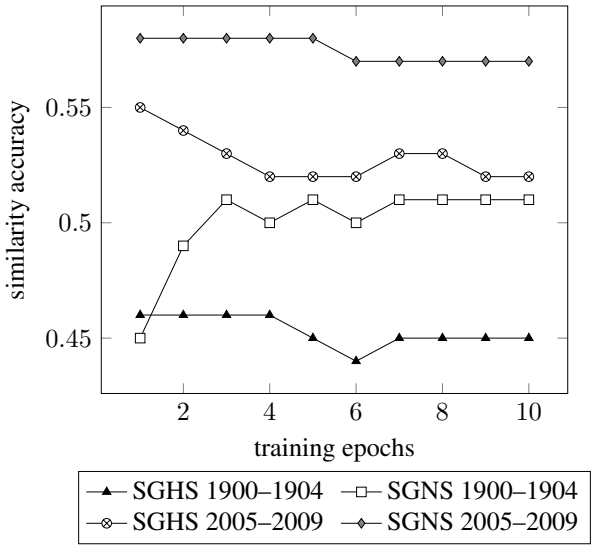

Figure 11: Similarity accuracy as influenced by the number of training epochs for English Fiction data data relative to the 1900–1904 and 2005–2009 time slices. Error bars are not displayed on purpose due to constant values for each training method.

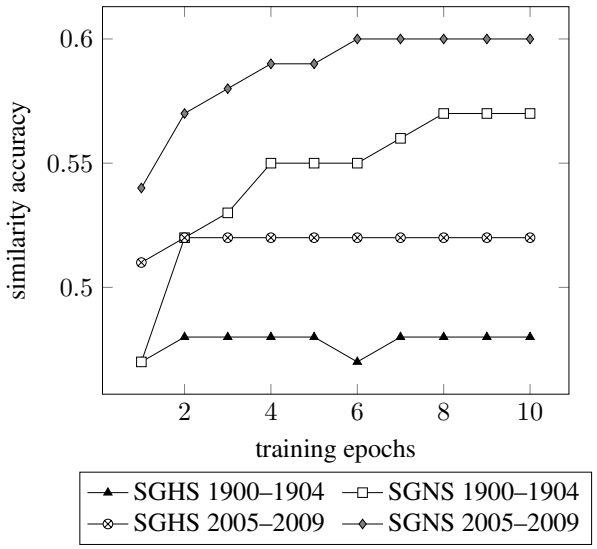

Figure 12: Similarity accuracy as influenced by the number of training epochs for orthographically normalized German data relative to the 1900–1904 and 2005–2009 time slices. Error bars are not displayed on purpose due to constant values for each training method.

Conclusions. Both reliability and accuracy point towards negative sampling with 4 to 6 training epochs (6 being better for smaller and 4 being better for larger corpora) as the optimal training regime for all tested combinations of languages and time spans (implicitly, this is also a test on largely varying corpus sizes, see Table 1). Such a training scheme yields models with high reliability without losses in accuracy (that would indicate overfitting). Figure 13 shows Δc, i.e., the difference of the convergence measure c (Equations (2) and (3) averaged over all three models) between subsequent epochs, for both German and English data from the intervals 1900–1904 and 2005–2009. Few changes occur after 4–6 epochs, which could be alternatively expressed as a Δc of about 0.003. The convergence criterion proposed by Kulkarni et al. (2015), i.e., $c = 0.9999$, was never reached (this observation might be explained by Kulkarni et al.'s decision not to reset the learning rate for each training epoch, as was done by us and Kim et al. (2014)).

SVD_{PPMI}, which are conceptually not bothered by the reliability problems we discussed here, were not a good fit for the hyperparameters we adopted from Kulkarni et al. (2015). Hamilton et al. (2016) reports similarity accuracy superior to SGNS, whereas for our set-up results in pretests were about 10 percent points worse than skip-gram embeddings, e.g., only 0.35 for 1900–1904 English Fiction.

Finally, to want to illustrate how this reliability problem affects qualitative conclusions. In Table 3 we provide some examples in which three negative sampling models for 1900–1904 English Fiction did not agree on the closest neighbor for words in question (mostly drawn from the list in Footnote 9). The most

inconsistent word neighborhoods are provided for *'romantic'* which is connected to *'lazzaroni'*,[12] *'fanciful'* and *'melancholies'*. This holds despite the high frequency (94th percentile) and moderate ambiguity (5 synsets) of the target item *'romantic'*.

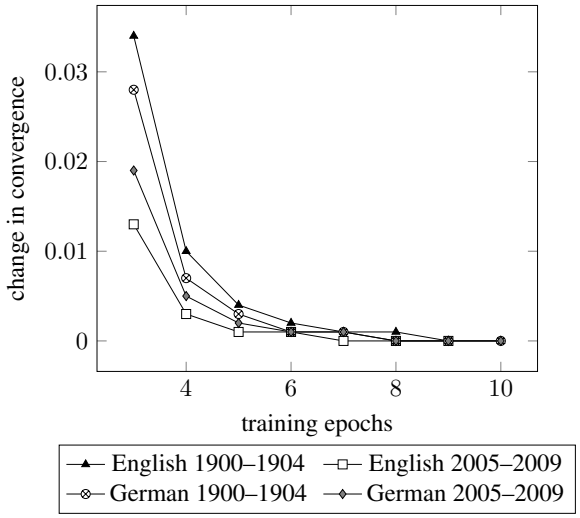

Figure 13: Change of averaged convergence measurement c between each epoch and its predecessor for models of orthographically normalized German and English Fiction trained with negative sampling on the 1900–1904 and 2005–2009 time slices. Values for epochs 1 and 2 would be one magnitude higher and are thus not displayed.

Word	Disputed Closest Neighbor
romantic	lazzaroni, fanciful, melancholies
parent	child, child, mother
mouse	mice, rat, cat
checked	checking, check, checking
check	cheque, checked, cheque
guess	reckon, reckon, suppose
headed	headedness, haired, haired
ass	atheist, fool, fool
toilet	ironing, dressing, dressing
cock	cocks, arty, hen
bloody	mistyken, mistyken, wreaks
nice	stunner, fine, fine

Table 3: A sample list of target lexical items for which three identically parametrized systems (trained with negative sampling on 1900–1904 English Fiction data) disagreed on the closest neighbor. Examples are mostly drawn from the list of the twenty-one aforementioned words (see Footnote 9) that were claimed to have undergone changes during the 20th century.

6 Discussion

Our investigation into the accuracy and reliability of skip-gram word embeddings shows even the most reliable systems too often provide inconsistent word neighborhoods. This carries unwarranted potential for erroneous conclusions on a word's semantic evolution as was shown, e.g., for the lexical item *'romantic'* and English Fiction texts from the 1900–1904 time slice. We are thus skeptical about using word neighborhoods in skip-gram embedding space to adequately capture natural languages' lexical semantics (for English and German, at least). While we found some mitigation strategies, i.e., training for multiple epochs or using our convergence criterion of $\Delta c \lesssim 0.003$, we assume SVD_{PPMI} to be conceptually superior. Future work might try to provide general guidelines for proper hyperparameter selection for SVD_{PPMI}, especially regarding complete temporal slices of the GBN (Hamilton et al. (2016) used samples). Alternatively, training several identically parametrized SGNS/SGHS models and combining them into an ensemble might constitute an easy way to reduce the reliability problems we described, yet at the price of exorbitant computational costs.

Acknowledgments

This research was conducted within the Graduate School *"The Romantic Model. Variation – Scope – Relevance"* (`http://www.modellromantik.uni-jena.de/?lang=en`) supported by grant GRK 2041/1 from the *Deutsche Forschungsgemeinschaft (DFG)*.

Abstract

In this paper, we outline an approach to build graph-based reverse dictionaries using word definitions. A reverse dictionary takes a phrase as an input and outputs a list of words semantically similar to that phrase. It is a solution to the Tip-of-the-Tongue problem. We use a distance-based similarity measure, computed on a graph, to assess the similarity between a word and the input phrase. We compare the performance of our approach with the Onelook Reverse Dictionary and a distributional semantics method based on *word2vec*, and show that our approach is much better than the distributional semantics method, and as good as Onelook, on a 3k lexicon. This simple approach sets a new performance baseline for reverse dictionaries.[1]

1 Introduction

A *forward dictionary* (FD) maps words to their definitions. A *reverse dictionary* (RD) (Sierra, 2000), also known as an *inverse dictionary*, or *search-by-concept dictionary* (Calvo et al., 2016), maps phrases to single words that approximate the meaning of those phrases. In the Oxford Learner's Dictionary[2], one definition of 'brother' is 'a boy or man who has the same mother and father as another person'. A reverse dictionary will map not only this phrase to 'brother', but also phrases such as 'son of my parents'. A reverse dictionary is primarily a solution to the *Tip of the Tongue* problem (Schwartz and Metcalfe, 2011) which regularly plagues people when they want to articulate their thoughts. It can also be used in the treatment of *word selection anomic aphasia* (Rohrer et al., 2008), a neurological disorder in which patients can identify objects and understand semantic properties, but cannot name the object or produce one word to describe the concept.

Popular languages let us create a multitude of phrases from a finite number of words. A static database of all possible phrases is unbound, if not infinite (Ziff, 1974). We need to dynamically compute the output word(s) from the input phrase. To map a phrase to a word, we have to compute the meanings of the phrase and the word (Fromkin et al., 2011). The *principle of compositionality* states that the meaning of an expression is composed of the meaning of its parts and the way they are combined structurally. The most basic parts, words, can be defined in terms of word definitions, references to objects, or lexical relations and hierarchies. Computing the meaning of a phrase requires constructing the constituent tree and recognising the relationship between the constituents, which is a complex, open problem.

Compositional Distributional Semantic Models have been used towards computing the meaning of a phrase, with partial success (Baroni, 2013; Erk, 2012). Recurrent neural networks show promise in learning continuous phrase representations. They are used towards syntactic parsing beyond discrete categories such as NP and VP, in an attempt to capture phrasal semantics (Socher et al., 2010). A recent work has used neural language embedding models (RNNs with LSTMs) to understand phrases by embedding dictionaries (Hill et al., 2015). But it doesn't perform exceptionally better than the existing reverse dictionaries (OneLook, etc.)

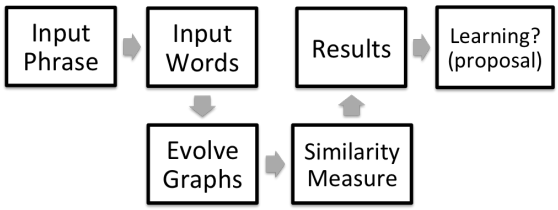

Figure 1

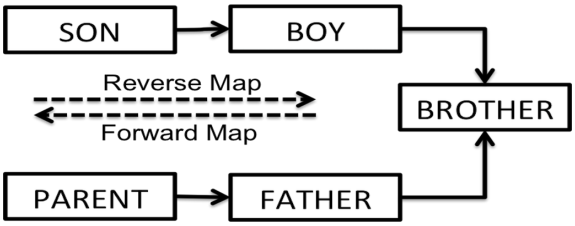

Figure 2

Figure 1: Operation of the Reverse Dictionary. The graphs' connectivities are based on the *reverse map*, a concept we will introduce shortly.
Figure 2: Each solid arrow indicates a *in the definition of* relation. This is the reverse map leading the phrase 'Son of my parents' to the word 'brother', after extraction of the input words. Note that this is one of the many sets of connections to all words on the graph from that phrase.

If we are to ignore the ordering of words in a phrase, the performance of such a system would not be maximal. But we could then work just with well-studied lexical relations. Research into building reverse dictionaries has mainly focused on lexical relations than the structural or contextual combination of words. The attempts in defining a *similarity measure* between words have been summarised in (Mihalcea et al., 2006). An attempt towards situational understanding and contextual selection of words can be seen in (Granger, 1982). The creation of WordNet (Miller, 1995) boosted the use of lexical relations and hierarchies, as in (Dutoit and Nugues, 2002; El-Kahlout and Oflazer, 2004; Shaw et al., 2013; Méndez et al., 2013; Calvo et al., 2016). Most of these approaches extract *input words* from the input phrase and expand their search through lexical relations and hierarchies, towards a similarity measure between the phrase and the words. (Zock and Schwab, 2008) take inspiration from human word synthesis and implement a user-guided search to the desired word. All the mentioned approaches have achieved partial success, but the problem stays unsolved.

We explore the possibility of using word definitions towards establishing semantic similarity between words and phrases. Definitions are dense sources of semantic information about the words (which makes it difficult to extract information from them without using exact syntactic structures such as constituent trees), and we employ them exclusively in our approach. We assume that the significance of the meaning of a word to a definition is proportional to its frequency throughout the definitions in the FD. We extract the meaning from the *content words* (Fromkin et al., 2011) contained in the phrase. We split the input phrase into these component *input words*, implement a graph-search through related words (relation through definition), and use a *distance-based* similarity measure to compute words which are representative of the meaning of the input phrase. A graph encodes the word relations in its connectivity matrix, on which the similarity measures are computed. We now detail our approach.

2 System Description

The block diagram of the operation of the RD is depicted in Fig. 1. We now discuss the concept of the reverse map, central to the structure of our graph, and the process of obtaining the connectivity matrix underlying our graph.

2.1 The Reverse Map

In a *forward map*, words branch out to the words that are contained in their definitions. In a *reverse map*, words branch out to the words whose definitions they are contained in. An example of a reverse map[3] is shown in Fig. 2.

If the input phrase is a definition, a search depth of one (branching out from the words of the input phrase to the definitions they are contained in) of the reverse map will lead to the required word. A search depth beyond one provides us with semantic information about the words whose definitions encompass

[3]Based on the definitions from the Oxford Learner's Dictionary.

or relate to the concepts that encompass or relate to the input words, and so on. Increasing search depth obscures the relationship between words, which is the basis for the definition of the similarity measure we employ. A reverse map suggests semantic convergence in a shallow search, although the convergence might occur on multiple words, which is acceptable as they might be semantically-similar words. Intuitively, a forward search seems to 'fragment' the meaning of the input word, and is expected to perform worse than the reverse search in defining word relationships in our approach.

2.2 Connectivity Matrix of the Reverse Map

The steps in the construction of the connectivity matrix, based on the reverse map, are as follows. Our inputs are a forward dictionary, a list of functional words, and a lemmatizer. We process the forward dictionary to retain content words in their base form. We then construct the forward-linked list, transform it into a back-linked list, and then construct the back-linked connectivity matrix. We can also construct the forward-linked connectivity matrix in a similar way.

2.2.1 Processing the Forward Dictionary

A forward dictionary (FD) is a two-dimensional list. The rows in the first column contain the words, and the rows in the second column contain the corresponding definitions. We reduce all words in column one to their lemmas, their base forms[4]. We then delete all the *functional words*[5] (Fromkin et al., 2011), and the corresponding definitions in column two. For our purposes, we pool all the definitions of a particular word into a single cell, parse them through the lemmatizers and delete all the functional words within them. We term the resulting list the *forward-linked list*. We now generate the *back-linked matrix*.

2.2.2 The Back-Linked Matrix

We number the words in column one of the forward-linked list in the alphabetical order (word-id). We substitute all the words in column two by their word-ids. We then create a list which points a word (written in column one) to the words whose definitions it lies in (written in column two). We call this list the back-linked list.

We then generate the *back-linked matrix* (BLM) which represents the connections (weights) between the nodes (words, in this case). If j is a word-id in the second column of the back-linked list, and i is the word-id in the corresponding row, but in column one, then the element (j, i) in the BLM is turned to 1. After iterating through all the elements in the list, we set the diagonals of the BLM to zero (no self-connections).

We will see in section 3 that many words in a dictionary do not appear in any definition, and so cannot contact all words in the wordlist through the reverse map. But we would like to obtain the similarity measure between any two words in the wordlist. As a simple measure in ensuring complete connectivity, we build a *mixed back-linked matrix* (mBLM) which has forward-linked connections for words that do not have sufficient back-linked connections (they cannot connect to all the words in the lexicon, through the reverse map). We will assess in section 4 the change in performance by the inclusion of the said forward links.

2.3 The Node-Graph Architecture

Each word is represented by a node in the graph. The connections between the nodes in our graph are given by the BLM. We create a graph for each *input word* (we obtain these from the input phrase by parsing it through the same operations as the definitions), and activate the input word node in its corresponding graph (the explanation is provided in section 5). We then simultaneously evolve the graphs one hop at a time. We are, in effect, expanding the tree of words to be able to effectively implement the similarity measure. If we implement n hops, we term it a *n-layered search* (n is also termed as the 'depth' of search).

[4]Using the *pattern lemmatizer* (Smedt and Daelemans, 2012) and *wordnet morphy* (Bird et al., 2009).

[5]The functional words were obtained from Higgins, 2014: http://myweb.tiscali.co.uk/wordscape/museum/funcword.html

2.4 The Similarity Measure

We use a distance-based measure of similarity.

We define the distance $d_{Y,X}$ from a word X to another word Y as the depth of search required to evolve a state with only $S_X = 1$, to the first state with $S_Y = 1$. Note that $d_{Y,X} \neq d_{X,Y}$.

We calculate the frequencies of appearances, $\{\nu_Z\}$ throughout definitions, for all words $\{Z\}$ in the wordlist.

We define the similarity measure $E_{W,P}$ of a word W to an input phrase P containing the input words $\{P_i\}$ as:

$$\mathrm{E}_{W,P} = \frac{\sum_i \left(\nu_{P_i} \times d_{W,P_i}\right)^{-1}}{\sum_i \nu_{P_i}^{-1}}$$

We weighted the inverse of the distances between the words with the inverse of the frequencies of the input words. So, the similarity measure includes a measure of 'semantic importance' of each input word in the input phrase. We calculate the similarity measure of each word to the input phrase, and output the words in the decreasing order of similarity. As every word is connected to every other word in the reverse map given apt search depth, the similarity measure becomes important in finding relevant output. Our similarity measure states, the smaller the distances from the input words, the more similar is the word to the input phrase. Minimal distances ensure that the semantic similarity remains meaningful.

2.5 System Summary

The user inputs a phrase. Input (content) words are extracted from the phrase. Graphs are generated for each input word, and in each graph, the state of the node corresponding to the input word is turned to 1. The graphs are evolved to the *maximum non-redundant* search depth (see section 3). The similarity measure, to the input phrase, is computed for every word in the lexicon, and the words are ranked according to their similarity measures, leading to the output.

3 Graph exploration

We construct BLMs and mBLMs based on the processed[6] Oxford 3000 wordlist[7], and a BLM for the entire WordNet (Miller, 1995) lexicon (WL). We use the Oxford Learner's dictionary (OLD), Merriam-Webster dictionary[8] (MW), and WordNet (WN) as forward dictionaries for the Oxford 3000 wordlist, and WordNet for the WordNet lexicon (WL). We also build a BLM and a mBLM by pooling definitions (Fusion BLM) from the three forward dictionaries, for the 3k wordlist, to check the effect of using multiple dictionaries on performance.

Before we move on to analyse the performances, let's look deeper into the connectivity matrices we generated. All the BLMs and mBLMs are sparse[9]. We use the *compressed sparse row* format from SciPy (Jones et al., 2001) to store and process our matrices.

In the 3k wordlist case, the number of connections in the Fusion BLM is greater than the BLMs built with individual FDs. In Fig. 3(a), we see that there are 190 words which cannot excite the entire graph through the Fusion BLM. So, we build a mBLM, as proposed in section 2.2.2, and ensure complete connectivity of the graph, as seen in Fig. 3(b). As all words can connect to all other words at the most in 9 steps, a search depth greater than 9 would be redundant when we use the Fusion BLM. The *maximum non-redundant* search depths for the individual BLMs are as follows: 11 (OLD), 9 (WN), and 11 (MW).

The maximum required search depth for the WordNet lexicon BLM is 19. 53, 711 words out of 82, 603 do not map to any word in the reverse map. Those words are infrequent in the language and are not used to define other words. Fig. 4(b) depicts the distribution of the number of back-linked connections from the words in the reverse map for the 80k WL BLM ($\mu = 7.81$, $\sigma = 62.86$, max $= 6163$), as compared to the distribution for the 3k WN BLM ($\mu = 18.10$, $\sigma = 36.14$, max $= 615$) in Fig. 4(a). The huge number

[6]Words which appeared in Oxford Learner's dictionary definitions, but were not part of the wordlist, were added to the wordlist for consistency. The modified wordlist contains 3107 words, and is referred to as 3k, in this paper.

Figure 4: Distribution of the number of back-linked connections, for each word, in the reverse map.

of backward-linked connections for some words in 80k WL BLM would confound the accuracy of the similarity measures, and a drop in performance is expected.

4 Performance Analysis

The only available online reverse dictionary is the Onelook Reverse Dictionary (Beeferman, 2003), with which we will compare our algorithm's performance. Onelook is a commercial application, and its architecture is proprietary. We know that it indexes 1061 dictionaries and resources such as Wikipedia and WordNet. The lexicon of Onelook is much bigger than 3k. In the performance comparison, we state the performance with (termed as 'corr') and without adapting the outputs to the 3k lexicon.

We also compare our approach with a distributional semantics method, based on *word2vec* which represents words as vectors in a linear structure that allows analogical reasoning. In that vector space, the vector 'king + woman - man' will have a high similarity with the vector for 'queen' (Mikolov et al., 2013a; Mikolov et al., 2013b). We average the vector representations of input words, and search the word vectors most similar to the resulting vector (cosine similarity). This is an established method of building phrase representations from word representations (Mitchell and Lapata, 2010). The performance of such an approach[10] is shown in Table. 1 (as W2V).

4.1 Performance Test

The reverse dictionary outputs multiple candidate words. We introduced users to the concept of the reverse dictionary and asked them to generate phrases they would use to get to a given word, if they would have forgotten the word but retained the concept. 25 such users generated 179 phrases, a sample of which is presented in Figure. 5. The performance is gauged by the ranks of the words in the outputs of their user-generated phrases[11].

We also test all the approaches on one-line definitions for the 179 words, obtained from the Macmillian Dictionary[12].

4.2 Performance results

Example runs of the RD, using the 3k Fusion mBLM, are presented in Fig. 6. The distributions of ranks, for the various BLMs/mBLMs (whichever has greater % of ranks under 100 for each case), *word2vec*, and Onelook, are stated in Table. 1. Onelook did not provide any outputs for 18 phrases out of the 179 user-generated phrases, and 72 out of the 179 definitions from the Macmillan dictionary. Instead of

[10]Based on the implementation of $word2vec$ by Daniel Rodriguez at https://github.com/danielfrg/word2vec, trained on a corpus with 15.8 million words, and a vocabulary of 98k.

[11]An input phrase can have multiple semantically similar words. Analysing the semantic quality of each output would be the ideal test. This could be done using a function of the sum of the ranks of each output weighted with their distances (in a high-dimensional semantic space such as $word2vec$) from the target word. However, previous approaches have used just the rank of the target word (which is nevertheless a good indicator of performance), and here we do the same.

Table 1: Performance of the various models. Accuracy @n is the fraction of the phrases with the rank of the target word less than or equal to n, in their outputs. σ is the standard deviation. Only the phrases with target words having ranks less than 100 were considered in calculating the median and variance. The 3k cases (OLD, WN, MW, Fusion) were evaluated at a search depth of 11, and the 80k case (WL) at a search depth of 19. **corr* indicates the cases where the outputs were truncated to fit in the 3k lexicon, for fair comparison. (Note: Accuracy - higher is better; Rank median - lower is better; Rank variance - lower is better.)

considering these as failures, we factor out these phrases while evaluating Onelook. The performance of all approaches is significantly better than chance, as seen through the comparison of performance with 'Chance' which represents the expected values of performance for random rank assignments to the target words[13] (considering the 3k lexicon). The cases of interest are highlighted in the table.

All the 3k cases using a BLM/mBLM have a higher performance than the 3k Fusion forward-linked matrix (FLM). Fusion of the individual 3k BLMs yields better performance. The 3k Fusion BLM performs at least as well as Onelook. The use of mBLMs is fruitful as they increase the performance in some cases. The performance does not change much across search depth as seen in Table. 2, suggesting that our approach works well even at a shallow search. Deeper search is required only when a phrase is semantically vague or non-specific, and markedly different from dictionary definitions. Both our ap-

[13]The expected value of the accuracy @k, over random rank assignments, is given by: $\sum_{n=0}^{P_r} \frac{n}{P_r} \cdot \frac{^{P_r}C_n k^n (N-k)^{P_r-n}}{N^{P_r}} = \frac{k}{N}$, where P_r is the number of test phrases, and N is the size of the lexicon.

Accuracy ↓	$n = 1$	$n = 2$	$n = 3$	$n = 10$

@10	**.25**	.22	.23	.23
@100	**.55**	.52	.53	.53

Table 2: Performance across search depth (n) for the Fusion mBLM case. The output becomes stable beyond a search depth of 3. The search depth at which the output becomes stable varies with the BLMs.

proach and Onelook outperform the W2V approach. We conclude that our approach works well with a 3k wordlist. Although the ranks' median and variance are indicative of the performance (hit rate, and robustness), they are marred by the accuracies, so we do not use them in our inferences.

However, the performance drops significantly when the entire processed WordNet lexicon (WL, 80k) is the FD. The words that lie in the definitions of other words are a small subset of the WL wordlist. As seen in Fig. 4, there are 163 words in the WL wordlist which map to more than 500 words in the reverse map. Therefore, the distances of multiple words to the input words are similar, obscuring the semantic content of the similarity measure. This is a potential limitation of our approach, for which there is no trivial fix.

We also assessed the performance of the Fusion mBLM on the 200 test phrases used in (Hill et al., 2015). The size of their lexicon is 66k. We cannot upscale the outputs of our 3k cases to 66k, so a direct fair comparison with their results is not possible. However, we can downscale the outputs of Onelook (on the 200 phrases) to 3k and compare with it, thus providing an indirect comparison with the approach used by Hill et al. The @1/10/100 accuracies of the Fusion mBLM are .16/.39/.62. But 33 target words do not lie in the 3k lexicon. The accuracies excluding the corresponding phrases are **.19**/**.46**/**.74**. The @1/10/100 accuracies of the Onelook (scaled to 3k) are .08/.21/.30. But 101 phrases do not return any outputs. The accuracies excluding those phrases are **.16**/**.42**/**.61**. The accuracies of Onelook and the RNN approaches in Hill et al. are equivalent. We thus conclude that the performance of our approach is at least as good as the RNN approaches, on a 3k lexicon.

5 Recommendations

The graph structure opens up a semantic dimension by letting us mutate the level of significance a word has in a definition, through the connectivity matrix. We can introduce this information in the similarity measure by scaling the weights of the connections between the words with distances equal to *one*. The definitions provided in the dictionary cannot populate the new dimension. One could consider the use of semantic rules, or lexical relations, or user feedback. Such a learning algorithm could use further exploration.

There are multiple points in our approach which could use either improvement or emphasis. We use multiple graphs for calculating the similarity measure. This is done because we do not want the distance of a word from an input word to be a function of all the input words. Using *Spiking Neural Networks* (Ghosh-Dastidar and Adeli, 2009), we could implement the similarity measure using a single graph by frequency tagging the distances from each input word, although it isn't clear how much advantage it would confer in terms of performance.

A matrix of pair-wise distances between all words could be used to evaluate the similarity measures, instead of evolving a graph. Such a matrix won't be sparse, and in the case of a 80k lexicon would be 50 gigabytes in size (compared to 10 megabytes in CSR sparse format for the BLM), making it impractical to deploy the algorithm on mobile devices. Execution time and memory requirement are not a problem for our approach. Our approach is an easy and computationally cheap method of implementing semantic search with a graph, which performs at least as well as the Onelook reverse dictionary.

The performance drops significantly when the WordNet 80k lexicon is used (the mBLM doesn't help). Use of multiple forward dictionaries might boost the performance, as in the case of Fusion mBLM, but as mentioned in section 4.2, the branching factor of the graph is too high, obscuring the similarity measure. Although this might make the approach impractical, it does serve as a new baseline. A simple approach

like ours can rival the performance of sophisticated algorithms used by Onelook and (Hill et al., 2015), suggesting that the information being retrieved by those algorithms is somewhat basic. This calls for methods which could significantly outperform a simple approach like ours, towards encoding deeper phrasal semantics.

Dealing with multi-word expressions isn't straightforward in our approach. We separate all words in the input phrase towards implementing our similarity measure. Detecting multi-word expressions would require recursive parsing of the phrase, something which is more suited to recurrent neural network-based approaches (Hill et al., 2015). This isn't a major concern for our task though, as the input phrase is supposed to be a simple description of the concept in mind, in which case the user is more likely to input 'to die' than 'kick the bucket'. Multi-word expressions are also rarely used to define words or other multi-word expressions. So, they could be treated as one node with no back-linked connections but with multiple forward-linked connections (the definition of that expression), and thus be encompassed in our approach as outputs, but not as inputs (which we do in the 80k WordNet case).

6 Concluding Remarks

We reported the construction of a reverse dictionary based on a node-graph architecture, which derives its semantic information exclusively from dictionary definitions. The approach works at least as well as the Onelook reverse dictionary and a RNN-based approach described in (Hill et al., 2015), on a lexical size of 3k words, but the performance deteriorates, to below Onelook's, when scaled to a lexicon with 80k words. The performance still stays significant (as compared to the 'Chance'), and greater than a forward map approach. Furthermore, this approach can be generalised to any language given an appropriate forward dictionary, lemmatizer, and a list of functional words.

Recent distributional approaches use vector representations for word meaning, derived through similarities gauged by the occurrences and co-occurrences of words in a large corpus (Erk, 2012). The performance of one of these approaches, known as *word2vec* (Mikolov et al., 2013a; Mikolov et al., 2013b), on our test is poor, as seen in Table. 1 (under 'W2V'). The performance suggests that phrasal semantics doesn't necessarily follow a linear additive structure. Indeed, researchers have been trying to find other mathematical structures and approaches which would be suitable for phrasal semantics (Baroni and Zamparelli, 2010; Socher et al., 2011), but with partial success and on specific types of phrases.

A class of Artificial Neural Networks (ANNs), called Recurrent Neural Networks (RNNs) are being used for tasks such as machine translation (Cho et al., 2014) and generating natural image captions (Karpathy and Fei-Fei, 2015), among others (Zhang and Zong, 2015). These 'deep' networks are not trained on, or to obtain, discrete syntactic categories such as NP and VP. Instead they are provided with the inputs and expected outputs (task-dependent) while training. The learning paradigm generates features (often incomprehensible in terms of classical linguistics) to effectively implement the given task[14], which seems to be better than using predetermined features. (Hill et al., 2015) use such a network to implement a reverse dictionary, and it performs at least as well as Onelook. The performance is noteworthy, but the fact that a simple approach like ours can rival it suggests that the RNN-based approaches require further research before doing for reverse dictionaries (and phrasal semantics, in general) what Convolutional Neural Networks (CNNs) did for visual object classification (Chatfield et al., 2014).

It seems that the focus on constituent trees and the structural combination of words cannot be compromised upon. RNNs might be the way forward, in this regard, as they could develop properties encompassing and surpassing those classical linguistic features.

Abstract

Human concept representations are often grounded with visual information, yet some aspects of meaning cannot be visually represented or are better described with language. Thus, vision and language provide complementary information that, properly combined, can potentially yield more complete concept representations. Recently, state-of-the-art distributional semantic models and convolutional neural networks have achieved great success in representing linguistic and visual knowledge respectively. In this paper, we compare both, visual and linguistic representations in their ability to capture different types of fine-grain semantic knowledge—or attributes—of concepts. Humans often describe objects using attributes, that is, properties such as shape, color or functionality, which often transcend the linguistic and visual modalities. In our setting, we evaluate how well attributes can be predicted by using the unimodal representations as inputs. We are interested in first, finding out whether attributes are generally better captured by either the vision or by the language modality; and second, if none of them is clearly superior (as we hypothesize), what type of attributes or semantic knowledge are better encoded from each modality. Ultimately, our study sheds light on the potential of combining visual and textual representations.

1 Introduction

Vision and language capture complementary information that humans automatically integrate in order to build mental representations of concepts. Certain concepts or properties of objects cannot be explicitly visually represented while, at the same time, not all the properties are easily expressible with language. For example, there are clearly visual differences between cats and dogs although these are not easy to describe with language. Recent advances in deep learning had led to breakthroughs in learning unimodal representations (a.k.a. embeddings) in both, computer vision (CV) and natural language processing (NLP) (LeCun et al., 2015). However, the automatic integration of visual and linguistic modalities is still a challenging—and usually task-dependent—problem that has gained increasing popularity within the NLP and CV communities. Lately, several studies have achieved reasonable success in integrating visual and linguistic representations, showing improvement over the unimodal baselines in simple linguistic tasks such as concept similarity (Lazaridou et al., 2015; Kiela and Bottou, 2014; Silberer and Lapata, 2014)—which is only possible if vision and language encode complementary knowledge.

In this paper we do not tackle the problem of *how* to integrate both modalities, but instead, we systematically study *what* type of fine-grain semantic knowledge is encoded in each modality, shedding light on the potential benefit of combining vision and language. By fine-grain semantics we refer to the recognition of different types of *attributes* or properties (e.g., shape, function, sound, etc.) that concrete nouns might exhibit. A recent study by Rubinstein et al. (2015) evidenced that state-of-the-art linguistic-only representations do not succeed at capturing all types of attributes equally well. Here, we extend their work into the multimodal domain by comparing the performance between visual and linguistic representations at encoding different types of attributes. In contrast with Rubinstein et al. (2015)'s unimodal research, here we aim to answer two different research questions. First, whether either vision or

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2807–2817, Osaka, Japan, December 11-17 2016.

language provide a superior ground for capturing fine-grain attributes; and second, if none of them is clearly superior—as we hypothesize—what type of attributes are better captured by each modality. To the best of our knowledge, no studies have systematically compared vision and language in these terms. Ultimately, this work provides insight on building better representations of concepts, which in turn is essential towards improving automatic language understanding.

The rest of the paper is organized as follows. In the next section we review and discuss related work. In Section 3 we describe our design for evaluating the success of visual and text embeddings in encoding attributes. Next, we present and discuss our experimental results. Finally, in conclusions and future work, we summarize our findings and suggest future lines of research.

2 Related Work

2.1 Unimodal Representations

Convolutional neural networks (CNN) have rapidly become the state-of-the-art approach in computer vision (Krizhevsky et al., 2012). To some extent, CNN algorithms emulate human visual perception, in which the learning occurs at different levels of abstraction—or layers of a network. On the language side, distributional models (DMs) have been employed for learning semantic representations a long time ago. These are based on the distributional hypothesis: *Words which are similar in meaning occur in similar contexts* (Rubenstein and Goodenough, 1965). Recently, neural-based distributional models or word embeddings (Mikolov et al., 2013; Pennington et al., 2014) have achieved great success, rapidly replacing the old DMs (Turney et al., 2010) based on word co-occurrence counts (Baroni et al., 2014). Instead of counting words, neural-based DMs capture words co-occurrences by trying to predict the context given a word (skip-gram) or by trying to predict a word given its context (CBOW). Alternative approaches such as generative probabilistic models that learn the probability distribution of a vocabulary word in a context window as a latent variable have also been proposed (Deschacht et al., 2012; Deschacht and Moens, 2009).

2.2 Multimodal Representations

There exist certain properties of perceptible objects that are poorly captured by language. For example, everyone can easily tell from an image whether a face is attractive, yet if one has to describe with language what properties make a face attractive will certainly struggle. Recently, CNN-based computer vision models have achieved reasonable success in the task of recognizing attractiveness (Rothe et al., 2015). Furthermore, psychological research evidences that human concept formation is strongly grounded in visual perception (Barsalou, 2008). All this suggests that linguistic representations can benefit from visual grounding. In this direction, recent studies have shown that multimodal embeddings are often able to outperform text-only embeddings in simple semantic tasks such as concept similarity (Lazaridou et al., 2015; Silberer and Lapata, 2014; Kiela and Bottou, 2014) or categorization (i.e., grouping objects into categories such as "fruit", "furniture", etc.) (Silberer and Lapata, 2014). Several ways of combining representations from both modalities have been devised so far—yet an exhaustive review of them would deviate from the target of this work. To name a few, Kiela and Bottou (2014) proposed the simple concatenation of visual and text representations, although more sophisticated methods such as the extension of skip-gram models into the multimodal domain (Lazaridou et al., 2015) or to apply stacked autoencoders to the unimodal representations (Silberer and Lapata, 2014) have also been considered.

2.3 Attribute Representations

Previous multimodal research often evaluates representations in word similarity tasks (Lazaridou et al., 2015; Silberer and Lapata, 2014; Kiela and Bottou, 2014) which offer rather a coarse-grain indicative of the quality of the embeddings and are not very informative about fine-grain aspects of meaning—or attributes. This gap is thus an important motivation for the present study. Attributes are often used by humans to describe objects (McRae et al., 2005), providing a powerful way to represent knowledge in terms of shape, color, taxonomic information, etc. Several studies have leveraged attributes to build representations that can be used in linguistic and visual tasks. For example, Silberer and Lapata (2014)

used an attribute-based hidden representation from stacked autoencoders as multimodal embeddings. The attributes were learned from both, visual and textual input. In contrast with Silberer and Lapata (2014), here we aim at spotting differences on the fine-grain semantic knowledge encoded by vision and language instead of building multimodal representations and to use them in a task. Furthermore, attribute representations exhibit the advantage that they can be learned transcending the task or the modality at hand, e.g., from either linguistic or visual input. Leveraging this transcendence, Lampert et al. (2009) showed that it is possible to classify objects from unseen classes (i.e., zero-shot learning) by training with attributes specified by humans—such as shape or color—instead of using images. Afterwards, new classes can be identified provided that one has their list of attributes at hand. Further, attributes transcend class boundaries. For instance, the attribute "stripped" can be learned from zebras, bees or tigers (Lampert et al., 2009). In this direction, Farhadi et al. (2009) proposed that the goal of image recognition should be describing rather than naming, that is, for instance, labeling "spotty dog" instead of just "dog" or replacing "unknown class" by "hairy and four-legged."

2.4 Attribute Prediction

The categorization of attributes proposed by McRae et al. (2005) has been widely used in NLP and CV studies (Baroni and Lenci, 2008; Silberer and Lapata, 2014; Rubinstein et al., 2015). Their attribute taxonomy includes individual attributes that belong to more general attribute types (e.g., *tactile* or *taxonomic*). For example, *has_legs* is a *form_and_surface* attribute, while *is_a_bird* or *is_a_fruit* are instances of *taxonomic* attributes.

Rubinstein et al. (2015) distinguished between two types of attributes: *taxonomic* and *attributive* properties. An *attributive* property is any of the remaining attribute types from McRae et al. (2005) categorization that are not taxonomic (Tab. 1). These include attribute types such as *tactile* (e.g., *is soft*), *form_and_surface* (e.g., *is made of metal*) or *encyclopedic* (e.g., *is_dangerous*). By trying to predict attributes using word embeddings as input, Rubinstein et al. (2015) concluded that DMs are significantly better at capturing *taxonomic* attributes rather than *attributive* properties—showing thus a limitation of the distributional hypothesis for certain attributes. Their findings align with previous research that showed that *taxonomic* attributes are generally more abundant in text compared to *attributive* properties (Baroni and Lenci, 2008). While Rubinstein et al. (2015) investigated whether DMs are equally good at capturing each type of attribute, our research questions are different. First, we want to answer whether there are differences between textual and visual representations in the type of attributes that they encode; and second, where these differences are. In other words, we present an inter-modality analysis while Rubinstein et al. (2015) performed only intra-modality comparisons.

In addition to the survey of Rubinstein et al. (2015), the closest work to ours is a study by Bruni et al. (2012) who showed that a very particular type of attribute, namely *color*, is better captured by visual representations than by DMs. Here, we go one step further and compare performance between visual and text embeddings for a larger number of visual attributes, as well as for other non-visual attributes such as *taxonomic*, *functional* or *encyclopedic*.

3 Approach and Experimental Settings

In this section we describe the procedure that we follow in order answer our research questions. An explanatory diagram is shown in Fig. 1.

3.1 Visual Representations

We use ImageNet (Russakovsky et al., 2015) as our source of visual information. ImageNet is currently the largest labeled image bank, with a coverage of 21,841 WordNet synsets (or meanings) (Fellbaum, 1998) and 14,197,122 images. Our choice of ImageNet is motivated by: (i) large word coverage; (ii) images are generally clean and with the relevant object at the foreground; and (iii) replicability of our experiments. Here, we only keep synsets with more than 50 images, and we set an upper bound of 500 images per synset for computational reasons. After this selection, 11,928 synsets are kept.

We extract a 4096-dimensional vector of features for each image using the output of the last layer

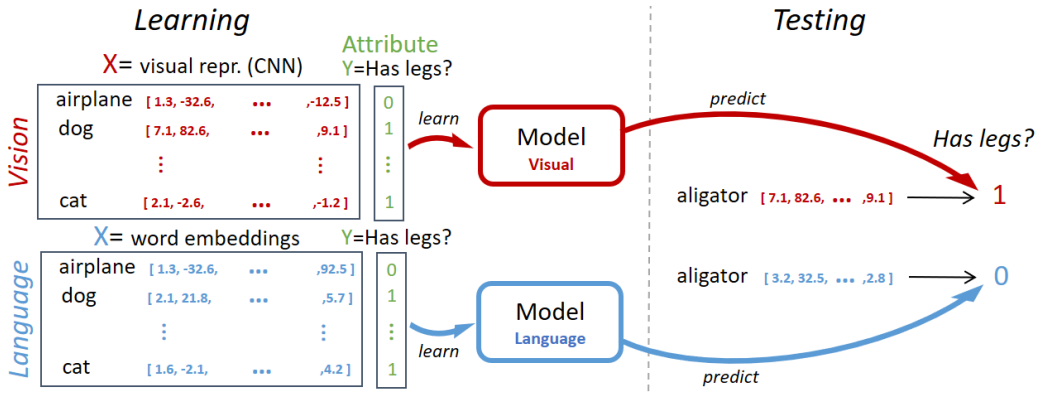

Figure 1: Overview of our experimental setting. Attributes are learned from the embeddings of each modality (left side), and afterwards new concepts are classified on whether the attribute is present or not (classification) or to which degree the attribute is present (regression). For clarity, we omitted the regression problem since its setting is identical to classification except for a continuous output $\mathcal{Y}$ instead of 0/1.

(before the softmax layer) of a pre-trained AlexNet CNN model implemented with Caffe toolkit (Jia et al., 2014). Other than CNN, there exist a variety of methods for obtaining visual features such as SIFT (Lowe, 1999), HOG (Dalal and Triggs, 2005) or SURF (Bay et al., 2006); to name a few. An exhaustive comparison will deviate from the goal of this paper, which is to show that at least some visual embeddings are able to better represent certain attributes than state-of-the-art DMs. Thus, we employ an off-the-shelf CNN model, as CNNs generally outperform the old approaches such as SIFT, HOG or SURF (LeCun et al., 2015). Additionally, we have repeated our experiments with ResNet (He et al., 2015), a more recent CNN model known to outperform AlexNet in image classification. Similar results are obtained with both models, suggesting thus that our vision-language comparisons are relatively independent of the CNN choice.

For each concept, several ways of integrating the representations from its individual images into a single vector could be devised. Here, we apply the following two common approaches (Kiela and Bottou, 2014):

(i) Averaging: Computes the component-wise average of the CNN feature vectors of individual images. This is equivalent to the cluster center of the individual representations.

(ii) Maxpool: Computes the component-wise maximum of the CNN feature vectors of individual images. This approach makes sense intuitively because CNN vector components can be interpreted as "visual properties."

For simplicity of notation we henceforth refer to the averaged and maxpooled visual representations as VIS_{avg} and VIS_{max} respectively.

3.2 Word Embeddings

We employ 300-dimensional GloVe vectors (Pennington et al., 2014) pre-trained in the largest available corpus (840B tokens and a 2.2M words vocabulary from Common Crawl corpus) from the author's website[1]. For completeness, we have repeated our experiments with word2vec embeddings (Mikolov et al., 2013) and we have found GloVe to perform slightly better. Thus, we report results with GloVe as it provides a stronger baseline to compare visual representations with.

3.3 McRae et al. Dataset

The data set collected by McRae et al. (2005) consists of data gathered from human participants that were asked to list properties—attributes—of concrete nouns. For each noun, 30 participants listed its attributes. For example, for "airplane", the attribute *has_wings* (i.e., a *form_and_surface* attribute) was

[1] http://nlp.stanford.edu/projects/glove

listed by 20 subjects, while the attribute *used_for_travel* (i.e., a *function* attribute) was listed by 7. The McRae et al. (2005) data contains 541 concepts, 2,526 different attributes, and 10 attribute types.

3.4 Binary Classification Setup

To evaluate fine-grain semantic understanding of the different embeddings, we evaluate how well the attributes from McRae et al. (2005) can be predicted by using the embeddings as input (Fig. 1). We use both a classification and a regression setting.

For each attribute a, we build a data set with the concepts to which this attribute applies as the positive class instances and the rest of concepts form the negative class. For example, a "beetle" is a negative instance and "airplane" a positive instance for the attribute a = *is_large*. We consider that an attribute applies to a noun if a minimum of 5 people have listed it[2]. Table 1 shows a summary of the number of positive class concepts per attribute type. For each attribute a we learn a predictor:

$$f_a : \mathcal{X} \rightarrow \mathcal{Y}$$

where $\mathcal{X} \subset \mathbb{R}^d$ is the input space of (d-dimensional) concept representations and $\mathcal{Y} = \{0, 1\}$ the binary output space.

To guarantee that the number of positive instances is enough to actually learn the attributes, only attributes with at least 25 positive instances are kept. This leads to a total of 43 attributes (Fig. 3), which can be seen as a total of 43 data sets. The concept selection in ImageNet described in Sect. 3.1 results in a visual coverage of 400 concepts (out of 541 from McRae et al. (2005) data), and, for a fair vision-language comparison, only the word embeddings (from GloVe) of these nouns are employed. Hence, our training data $\{(\overrightarrow{x_i}, y)\}_{i=1}^{400}$ consists of 400 instances. Since we have three types of representations (GloVe, VIS_{avg} and VIS_{max}), three different models f_a^{GloVe}, f_a^{avg} and f_a^{max} are learned from the three different input data $X_{GloVe} \in \mathbb{R}^{400\times300}$, $X_{avg} \in \mathbb{R}^{400\times4096}$ and $X_{max} \in \mathbb{R}^{400\times4096}$ respectively, where $X = \{\overrightarrow{x_i}\}_{i=1}^{400}$ and $\overrightarrow{x_i} \in \mathcal{X}$, $y \in \mathcal{Y}$.

Classification performance is evaluated with the F1 measure of the positive class—that is, the harmonic mean of precision and recall—since F1 is insensitive to class imbalance.

Attribute type	# Attr.	Avg. # concepts	SD
encyclopedic	4	32.7	1.5
function	3	46	27.9
sound	1	34	-
tactile	1	26	-
taste	1	33	-
taxonomic	7	42	24.8
color	7	42.4	12.0
form_and_surface	14	63.7	29.9
motion	4	37.5	5.7

Table 1: Attribute types, number of attributes per attribute type (# Attr.), and average number of concepts (i.e., positive instances) per attribute type (Avg. # concepts) with their respective standard deviations (SD).

3.5 Regression Setup

Let us consider the same scenario as in the classification one above, yet with a continuous output space $\mathcal{Y} = [0, 1]$ instead of a binary. The proportion of participants (out of 30) who have listed the attribute a for a given concept is taken as ground truth $y \in \mathcal{Y}$. This can be interpreted as the saliency of attribute a for this concept. Regression performance is evaluated with the Spearman ρ correlation coefficient between the predicted outputs and the ground truth.

[2] This threshold was set by McRae et al. (2005)

3.6 Experimental Setup

In both classification and regression we perform 2 runs of 5-fold stratified cross validation. That is, we create 5 (stratified) disjoint splits, repeating it with two different seeds. The use of 5 folds is convenient since the data set is small and contains just a few instances of the minority class—which ranges from 6.25% to 30.5% of the data. Thus, the use of $4/5$-th of the data for learning (and $1/5$-th for testing) is more likely to yield well-learned attributes than smaller training proportions. To handle class imbalance in classification we set the training class weights inversely proportional to the class priors.

This work relies on the basic assumption that, if a given attribute can be predicted using some embeddings as input (e.g., by means of a classifier or a regressor), then these embeddings contain encoded information about this attribute. The inverse is not necessarily true, that is, if an attribute cannot be predicted from a given embedding, this does not necessarily mean that the information is not present. In this case, the bottleneck might be any sort of technical issue such as our classifier choice, regularizer choice, data scaling, etc. Thus, in order to validate our conclusions, we repeated the same experiments with different classifier choices (SVM, logistic regression, bagging ensemble of decision trees and AdaBoost); different regressors (SVM, neural networks, ensemble of regression trees and gradient boosting); and data scalings (max/min scaling and component-wise centering plus normalizing by the standard deviation). We found results to be notably stable across classifier and regressor choices. We report results with a linear SVM regressor and a linear SVM classifier, both implemented with the scikit machine learning toolkit (Pedregosa et al., 2011). Data scaling affected only the performance of VIS_{max}, conceivably because their values are extreme by definition.

4 Results and Discussion

4.1 Intra-Modality Performance per Attribute Type

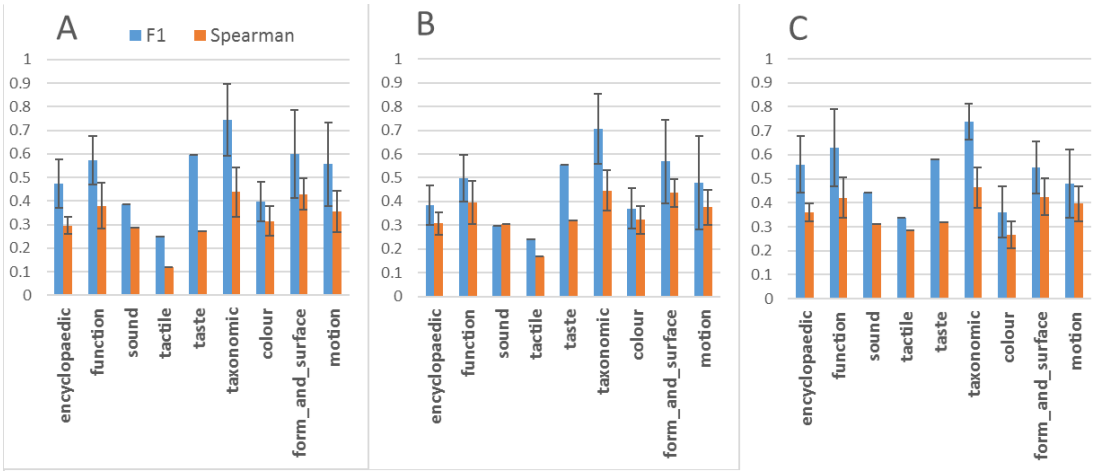

Figure 2: Averages of F1 (classification) and Spearman (regression) measures per attribute type (i.e., averaging individual attributes) for VIS_{avg} (A), VIS_{max} (B) and GloVe (C). Error bars show standard error.

As a first noteworthy finding, one may observe from Fig. 2 the—perhaps unexpected—resemblance that visual and textual representations present at predicting different types of attributes, which suggests interesting commonalities between visual and textual representations. Further, this seems to indicate that some attribute types are genuinely more difficult to predict than others (e.g., *tactile*), conceivably because the nouns to which these attributes apply tend to have little in common in terms of both, visual resemblance and word co-occurrences in similar contexts. This can be further appreciated in Fig. 5 (bottom row) from the scattered pattern of the attribute *is_soft*, which proves to be a difficult target for both, vision and language. In turn, this suggests that neither vision nor language might be sufficiently informative about certain attribute types (e.g., *tactile* or *sound*).

From Fig. 2 (C) it can also be observed that our results align with Rubinstein et al. (2015)'s findings with DMs. That is, from text-only embeddings, *taxonomic* attributes can be generally more accurately predicted than most of the *attributive* properties (i.e., all attribute types from Tab. 1 except *taxonomic*). We additionally find a similar behavior for visual embeddings (Fig. 2 A and B).

4.2 Visual Vs. Text Performance

Fig. 3 provides an answer to our first research question, showing that, clearly, neither vision nor language absolutely dominates the other in grasping fine-grain semantic knowledge but they rather show preference for different attributes. In general, visual embeddings (especially VIS_{avg}) perform better than GloVe in three main attribute types: *motion*, *form_and_surface* and *color* (Fig. 3 and 4). On the other hand, GloVe clearly outperforms vision in *encyclopedic* and *function* attribute types (Fig. 3 and 4), which are seldom visual. For the *taxonomic* type, vision or language clearly dominate in different individual attributes (Fig. 3). The visual performance gains with respect to GloVe (in e.g., *is_a_bird*) are particularly interesting since previous research evidenced that *taxonomic* is the attribute type where text-only DMs are the strongest (Baroni and Lenci, 2008; Rubinstein et al., 2015). Hence, these results suggest that the representation of taxonomic knowledge can further benefit from visual grounding.

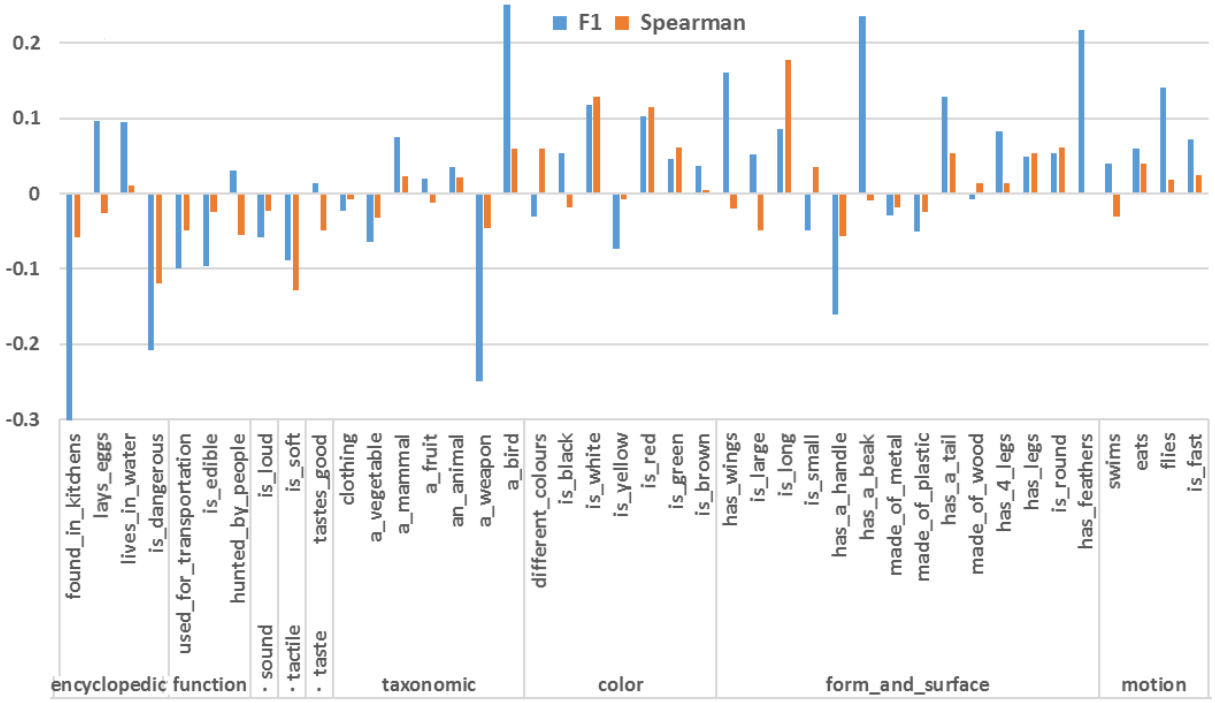

Figure 3: Difference of performance between VIS_{avg} minus GloVe. Attributes are shown on the horizontal axis and grouped by their type. Positive bars indicate better performance of visual embeddings and negative bars otherwise. Results with VIS_{max} are omitted as they exhibit almost identical patterns as VIS_{avg}, yet slightly worse.

Interestingly, even in the attribute types where either vision or language generally dominate, there are exceptions. For example, VIS_{avg} seems to outperform GloVe in classifying *lays_eggs* (i.e., an *encyclopedic* attribute), while GloVe seems to capture better *has_a_handle* (a *form_and_surface* attribute) which is predominantly visual. It is important to notice that visual attributes do not equal "less abstract" knowledge. For example, the visual attribute *has_a_handle* clearly requires more abstract semantic understanding than purely sensory visual attributes such as *is_green* since the definition of "handle" is clearly functionally-motivated rather than visual. For instance, the ball-shaped handle of a door has virtually no visual resemblance with the handle of a bag, yet they both have the same function. All this suggests that not only the attribute type is important but there are other factors to be taken into account. More concretely, the visual resemblance among objects to which the same attribute applies

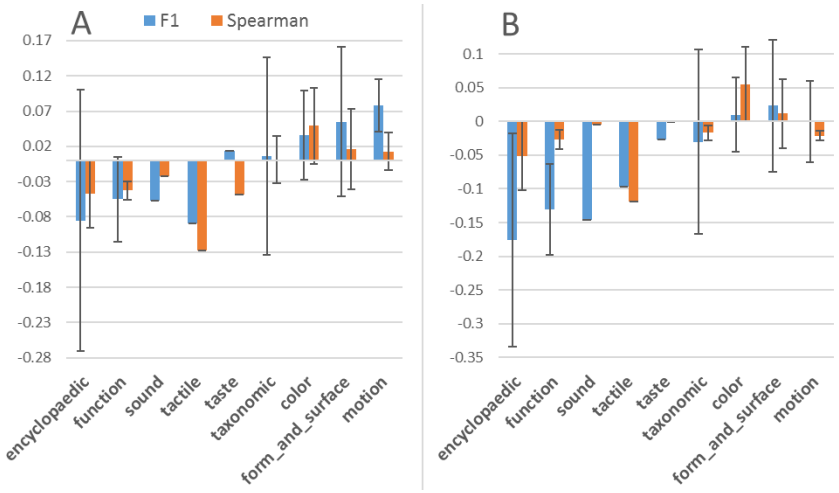

Figure 4: Averages of performance difference per attribute type. For each attribute type (e.g., taxonomic, taste, etc.), the bar indicates the average performance difference of its set of attributes. Plot A shows performance difference between VIS_{avg} and GloVe and B between VIS_{max} and GloVe. As in Fig. 3, positive bars indicate better performance of visual embeddings and negative bars otherwise. Error bars show standard error.

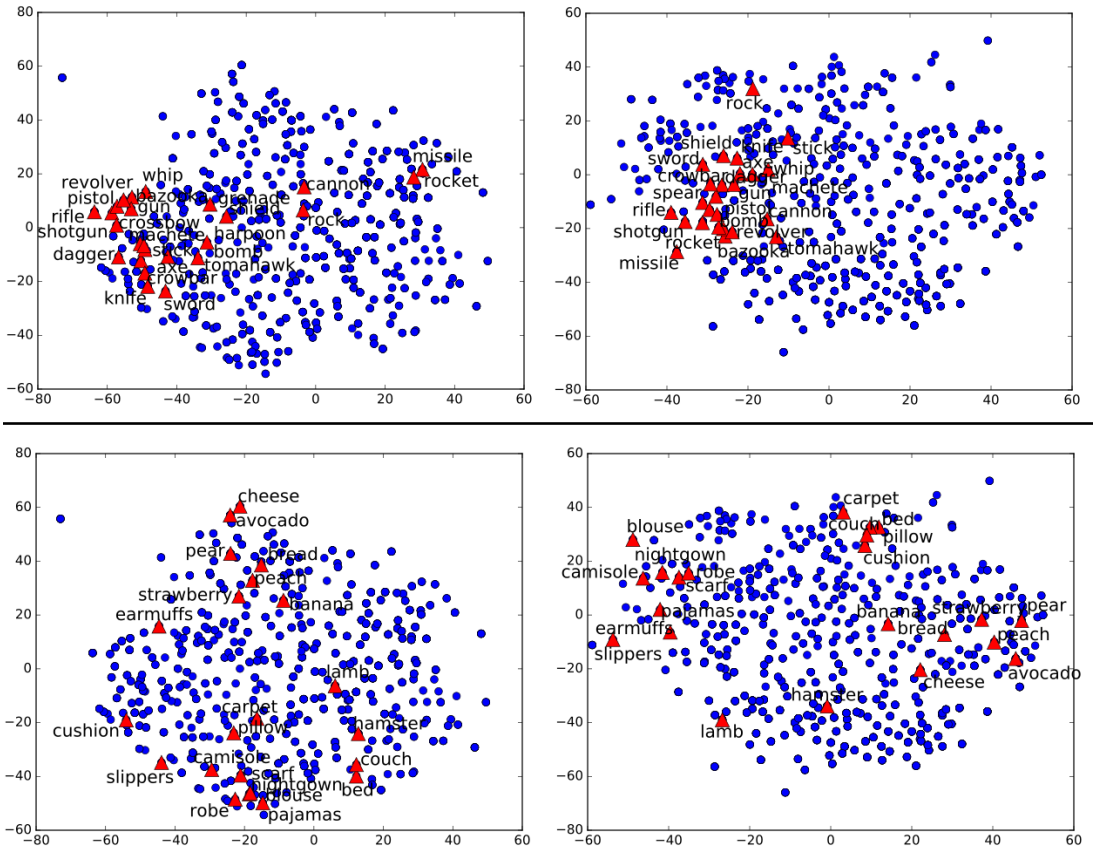

Figure 5: T-SNE visualization (Maaten and Hinton, 2008) of the VIS_{avg} embeddings (left column) and of the GloVe embeddings (right column). Red triangles show the positive class for the attribute *a_weapon* (top row) and *is_soft* (bottom row), while blue circles correspond to the negative class words.

seems to play a role. For example, *a_weapon* and *is_a_bird* are both *taxonomic* attributes although GloVe clearly dominates in the first and vision in the second one (Fig. 3). A closer inspection reveals that

the concepts from *is_a_bird* (e.g., "canary", "chicken", "eagle", "penguin") exhibit an important visual resemblance, whilst those from *a_weapon* (e.g., "rock", "bow", "rifle", "axe") do not. From Fig. 5 (top row) one can observe that the instances of *a_weapon* present a more scattered pattern in the visual embeddings (left) than in the linguistic ones (right). The same applies to *has_a_handle*, which one would perhaps—wrongly—expect that it might be better captured by vision. Contrarily, visual resemblance generally yields vectors that are closer in the visual space, making class boundaries easier to learn.

Even though the performances of classification and regression models (F1 and Spearman, respectively) are markedly correlated (Fig. 2, 3 and 4), there are a few exceptions. Small "contradictions" are plausible considering that classification and regression are two different problems—detection and estimation respectively—in which the learner is exposed to different (output) data. However, just a few bars show an opposite sign, none of them showing extreme opposite values.

5 Conclusions and Future Work

Overall, the present study adds evidence to the fact that visual and textual representations encode different semantic aspects of concepts. Crucially, we find that neither vision nor language are superior to the other in grasping every aspect of meaning, but they rather dominate in different attribute types. More concretely, vision proves generally better at capturing *form_and_surface*, *color* and *motion* attributes while language proves better at *encyclopedic* and *function* attributes. However, even within these general trends, we find that there are important exceptions in which visual resemblance among the concepts to which an attribute applies seems to play an important role. As an additional finding, we find that vision and language present a surprisingly similar pattern of predictive capacity for the different attributes types (Fig. 2), and that neither vision nor language succeed at capturing certain attribute types (e.g., *tactile* or *sound*). This suggests that other perceptual modalities can further improve the representations.

Taken together, we conclude that fine-grain attribute understanding can benefit from the integration of visual and textual representations. Thus, our results align with previous multimodal research that evaluates vision and language in coarse-grain tasks such as concept similarity and conclude that multimodal representations outperform the unimodal baselines (Lazaridou et al., 2015; Silberer and Lapata, 2014; Kiela and Bottou, 2014). Ultimately, our findings provide insights that can help building better multimodal representations by taking into account the types of semantic knowledge that vision and language selectively capture. In turn, better representations can improve automatic language understanding by providing a more human-like and perceptually grounded processing. Furthermore, we believe that the taxonomic knowledge encoded in visual representations can be further exploited towards building methods that automatically identify taxonomic relationships between concrete (perceptible) nouns, offering potential alternatives to WordNet (Fellbaum, 1998). Finally, recent work in computer vision showed that better fine-grain semantic understanding of objects can be achieved if images are segmented into the objects' individual parts (Vedaldi et al., 2014). We believe that this is an interesting direction to extend our work.

Abstract

Temporal relation classification is a challenging task, especially when there are no explicit markers to characterise the relation between temporal entities. This occurs frequently in inter-sentential relations, whose entities are not connected via direct syntactic relations making classification even more difficult. In these cases, resorting to features that focus on the semantic content of the event words may be very beneficial for inferring implicit relations. Specifically, while morpho-syntactic and context features are considered sufficient for classifying event-timex pairs, we believe that exploiting distributional semantic information about event words can benefit supervised classification of other types of pairs. In this work, we assess the impact of using word embeddings as features for event words in classifying temporal relations of event-event pairs and event-DCT (document creation time) pairs.

1 Introduction

The classification of temporal relations between events in text has been long studied and attacked from different perspectives in the NLP community. However, existing approaches heavily rely on information overtly expressed in text, such as explicit temporal markers (e.g. *before*, *during*), the tense, aspect and modality of event words, as well as specific syntactic constructions. In case overt indicators are missing, the task becomes significantly more challenging, as is often the case when two events take place in different sentences, or in anchoring an event to the document creation time (DCT). See for example the sentences in (i), where the label for the event pair (e_1, e_2) is BEFORE, and the sentence in (ii), where e INCLUDES the DCT.

(i) *When Wong Kwan* ***spent*** $_{e_1}$ *seventy million dollars for this house, he thought it was a great deal. He* ***sold*** $_{e_2}$ *the property to five buyers and said he'd double his money.*

(ii) *The U.N. Security Council on Aug. 6 ordered a global* ***embargo*** $_{e}$ *on trade with Iraq as punishment for seizing Kuwait.*

Inter-sentential event relations are quite frequent, covering for example 32.76% of the event pairs in the TempEval-3 evaluation corpus (UzZaman et al., 2013). Around 42.37% of pairs of an event and a time expression in the same corpus are actually pairs of an event and the DCT. Moreover, the TimeBank corpus contains 718 temporal relations which are co-ordinated by temporal signals, i.e., only 11.2% of all temporal links (Derczynski and Gaizauskas, 2013). These make research on implicit temporal ordering very relevant.

One common approach, first proposed in Marcu and Echihabi (2002), incorporates word-based information in the form of word pair feature vectors. Conventionally, a word is converted into a symbolic ID, which is then transformed into a feature vector using a *one-hot* representation: the feature vector has the same length as the size of the vocabulary, and only one dimension is on. From a machine learning point of view, this type of sparse representation makes parameter estimation extremely difficult and prone to

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2818–2828, Osaka, Japan, December 11-17 2016.

over-fitting. It is also very challenging to achieve any interesting semantic generalization with this representation. Consider for instance, (*attack*, *injured*) that would be at equal distance from a synonymic pair (*raid*, *hurt*) and an antonymic pair (*died*, *shooting*).

Other approaches make use of semantic features extracted from external knowledge bases such as WordNet synsets (Fellbaum, 1998) and VerbOcean semantic relations between verbs (Chklovski and Pantel, 2004), capturing for instance that *marriage* happens-before *divorce*. Mirza and Tonelli (2014) exploit the list of event duration distribution from Gusev et al. (2011) for temporal relation classification, showing that it gives no benefit to classifier performance. The problem with such knowledge bases is that they have limited coverage, while approaches based on distributional semantics require no supervision and have a much better coverage.

The main goal of this work is to assess the contribution of dense vector representations of words and word pairs to temporal relation type classification, as detailed in Section 3. Specifically, we want to establish (i) which vector combination schemes are more suitable for classifying pairs of events, (ii) how well word embeddings can be used for this particular task compared to traditional features (Section 4.2), and finally, (iii) whether the combination of traditional features and word embeddings yields a better performance than using the two components in isolation. To the latter purpose, we compare vector concatenation and stacked learning (Section 4.3).

Experiments and evaluations are performed on the TimeBank-Dense corpus (Chambers et al., 2014), which was designed to address the sparsity issue in existing corpora with temporal annotation. We also compare our approach with CAEVO, a CAscading EVent Ordering system evaluated on the same corpus (Section 5).

2 Related Work

Many natural language processing applications such as information extraction (IE), question answering (QA), topic detection and tracking require understanding about temporally located events, i.e., to anchor events in time and order them. This temporal information is often modelled as a graph, with *times* and *events/states* as the nodes and *temporal relations* holding between them as the arcs. The details of how these three primitives are expressed in English, as well as their conceptual background (Allen, 1984; Moens and Steedman, 1987) have been discussed in Setzer (2001), and formalized in the TimeML annotation standard (Pustejovsky et al., 2003). In this work we focus on the task of ordering temporal entities, i.e., the classification of temporal relation types.

Current state-of the-art systems for temporal ordering resort to data-driven approaches (Bethard, 2013; Laokulrat et al., 2013; Mirza and Tonelli, 2014) or hybrid approaches combining rules and supervised classifiers (D'Souza and Ng, 2013; Chambers et al., 2014; Mirza and Tonelli, 2016). In building the classification models, most approaches rely primarily on morpho-syntactic features as well as lexical semantic information derived from WordNet synsets (Chambers et al., 2007; Laokulrat et al., 2013; Chambers et al., 2014) and VerbOcean semantic relations between verbs (Mani et al., 2006; D'Souza and Ng, 2013).

Other approaches exploit sentence-level semantic information, i.e. predicate-argument structure, as features for the classifiers (Llorens et al., 2010; Laokulrat et al., 2013; D'Souza and Ng, 2013). However, the evaluation results of TempEval-3 (UzZaman et al., 2013) show that a system with basic morpho-syntactic and lexical semantic features, such as ClearTK (Bethard, 2013), is hard to beat even if using more sophisticated semantic features. Indeed, ClearTK indirectly uses distributed lexical semantic features in the form of context (tokens appearing) between events.

As far as we know, there is no work on the task of ordering/anchoring temporal entities which specifically addresses the issue of implicit relations often recurring when two events are in different sentences, or when an event is related to the DCT. Such implicit relations are probably covered by hand-crafted rules or features based on the tense, aspect and modality of event words (Chambers et al., 2014), but sometimes such an overt indicator is lacking, as exemplified in previous examples (Section 1).

Most works on implicit discourse relations focused on the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), in which relations are annotated at the discourse level and organized into a three-level hier-

archy. The top level relations, for example, include *Temporal*, *Contingency*, *Comparison* and *Expansion*. Braud and Denis (2015) presented a detailed comparative studies for assessing the benefit of unsupervised word representations, i.e. one-hot word pair representations against low-dimensional ones based on Brown cluster (Brown et al., 1992) and word embeddings, for identifying implicit discourse relations in PDTB. However, only the top level relations are considered, for instance, whether there exists a *Temporal* relation without investigating further into the more fine-grained temporal ordering.

3 Classifying Temporal Relations

Temporal relations, or temporal links, are annotations that connect markables bearing temporal information in a text, and express their temporal order. TimeML (Pustejovsky et al., 2003) is the widely known annotation framework for creating such representation that was used in the TempEval series, i.e., evaluation exercises focusing on temporal information processing. One of the main tasks in TempEval is temporal relation (TLINK) classification: given a pair of temporal entities (te_1 , te_2), namely events and time expressions (timex), determine their ordering relations (e.g. BEFORE, AFTER, INCLUDES, etc.).

Our goal is to compare classification performance on temporal relations using traditional features and word embeddings, which have recently shown to achieve good generalisation capabilities in several NLP tasks. Specifically, we want to evaluate whether, and in which configurations, they can contribute to advance state-of-the-art performance on temporal relation classification. To this purpose, we build and evaluate two different classifiers.

3.1 Temporal Relation Classification with Traditional Features

The first system is inspired by state-of-the-art approaches presented at TempEval-3 (UzZaman et al., 2013). Following UTTime (Laokulrat et al., 2013), we build three LIBLINEAR (Fan et al., 2008) classifiers (L2-regularized logistic regression): one for event-document creation time (E-D), one for event-timex (E-T) and one for event-event (E-E) edges. For timex-timex (T-T) relations, we implement a simple set of rules based on the values of time expressions, which proved to be effective for most T-T edges.

E-D, E-T and E-E Classifiers A set of features, listed in Table 1, is used for each type of edge, largely inspired by the best performing systems in TempEval-2 (Verhagen et al., 2010) and TempEval-3 (UzZaman et al., 2013) campaigns. We assume that pairs of temporal entities are given, and we rely on EVENT and TIMEX3 *attributes* in annotated TimeML documents, *morphosyntactic information* generated by MorphoPro (Pianta et al., 2008) and *dependency information* from the Mate tools (Bjorkelund et al., 2010).

Derczynski and Gaizauskas (2013) show the importance of *temporal signals* in temporal relation labelling, hence, we include also a similar set of features. However, we take the list of temporal signals from the TimeBank corpus, further expand it using the Paraphrase Database (Ganitkevitch et al., 2013), and manually cluster synonymous signals together, e.g. {*before*, *prior to*, *in advance of*}. The cluster ID is then included in the feature set instead of the signal text.

Note that the only *lexical semantic information* we include in the feature set is the Wordnet semantic similarity/relatedness (Lin, 1998) between event words. In order to have a feature vector of reasonable size, we simplify the possible values of some features during the one-hot encoding:

- *dependencyPath*. We only consider the existence of a dependency path between an E-E pair when it describes coordination, subordination, subject or object relation. For E-T pairs, we only consider the dependency path expressing temporal modification.
- *tempSignalCluster*. Given a temporal signal, we include the *clusterID* of the cluster containing synonymous signals, e.g. {*before*, *prior to*, *in advance of*} instead of the signal text.
- *wnSim*. The value of WordNet similarity measure is discretized as follows: $sim \leq 0.0$, $0.0 < sim \leq 0.5$, $0.5 < sim \leq 1.0$ and $sim > 1.0$.

T-T Rules Only temporal expressions of types DATE and TIME are considered in the hand-crafted set of rules, based on their *normalized values*. For example, *7 PM tonight* with `2015-12-12T19:00` as value IS_INCLUDED in *today* with `2015-12-12` as value.

Feature	TLINK E-D	TLINK E-T	TLINK E-E	Rep.	Description
EVENT attributes					
class	x	x	x	one-hot	EVENT attributes as specified in TimeML.
tense	x	x	x	one-hot	
aspect	x	x	x	one-hot	
polarity	x	x	x	one-hot	
sameClass			x	binary	Whether e_1 and e_2 have the same EVENT attributes.
sameTenseAspect			x	binary	
samePolarity			x	binary	
TIMEX3 attributes					
type	x	x		one-hot	TIMEX3 attributes as specified in TimeML.
Morphosyntactic information					
PoS	x	x	x	one-hot	Part-of-speech tags of e_1 and e_2.
phraseChunk	x	x	x	one-hot	Shallow phrase chunk of e_1 and e_2.
samePoS		x	x	binary	Whether e_1 and e_2 have the same PoS.
Textual context					
entityOrder		x		binary	Appearance order of e_1 and e_2 in the text.[1]
sentenceDistance		x	x	binary	0 if e_1 and e_2 are in the same sentence, 1 otherwise.
entityDistance		x	x	binary	0 if e_1 and e_2 are adjacent, 1 otherwise.
Dependency information					
dependencyPath			x	one-hot	Dependency path between e_1 and e_2.
isMainVerb	x	x	x	binary	Whether e_1/e_2 is the main verb of the sentence.
hasModalVerb	x	x	x	binary	Whether e_1/e_2 is governed by a modal verb.
Temporal signals					
tempSignalCluster		x	x	one-hot	Cluster ID of temporal signal existing around e_1 and e_2.
tempSignalPosition		x	x	one-hot	Temporal signal position w.r.t e_1/e_2 (BETWEEN, BEFORE, BEGIN, etc.)
tempSignalDependency		x	x	one-hot	Temporal signal dependency path between signal tokens and e_1/e_2.
lexical semantic information					
wnSim			x	one-hot	WordNet similarity computed between the lemmas of e_1 and e_2.

Table 1: Feature set for TLINK classification model for event-document creation time (E-D), event-timex (E-T) and event-event (E-E) pairs, along with representation type (Rep.) and brief description.

3.2 Temporal Relation Classification with Word Embeddings

Recently there has been an increasing interest in using word embeddings as an alternative source of information to traditional hand-crafted features. Word embeddings represent (embed) the semantics of a word in a continuous vector space, where semantically similar words are mapped to nearby points. The underlying principle is the *Distributional Hypothesis* (Harris, 1954), which states that words which are similar in meaning occur in similar contexts.

Baroni et al. (2014) divide approaches based on this principle into two categories: (i) *count-based* models and (ii) *predictive* models. They also provide a systematic comparison of word vectors from the two models, on a wide range of lexical semantic tasks, including semantic relatedness, synonym detection, concept categorization, selectional preferences and analogy. The main takeaway is that predictive models, such as Word2Vec (Mikolov et al., 2013), are shown to perform better than count-based ones.

Levy et al. (2015) reveal that much of the performance gains of word embeddings are due to hyperparameter optimizations rather than the embedding algorithms themselves, thus refuting the claim that prediction-based methods are superior to count-based approaches. However, they also state that the Skip-Gram model with Negative Sampling (SGNS), which is used to build Word2Vec pre-trained word vectors, can be a robust baseline since it does not significantly underperform in any scenario.

In this work, we explore how well word embeddings can be used—as lexical semantic features—to capture the temporal order of events (e.g. *attack* often happens BEFORE *injured*) and the temporal anchoring of an event to the document creation time (e.g. *embargo* usually spans longer than a day, hence, INCLUDES the DCT). Again, we build LIBLINEAR (Fan et al., 2008) classifiers (L2-regularized logistic regression), one for E-D and another for E-E pairs. Instead of the traditional feature sets explained in Section 3.1, word embeddings are used as feature vectors.

[1]The order of e_1 and e_2 in E-E pairs is always according to the appearance order in the text, while in E-T pairs, e_2 is always a timex regardless of the appearance order.

Pre-trained word vectors We take pre-trained word vectors from Word2Vec[2], which are 300-dimensional vectors for 3 million words and phrases trained on part of Google News dataset (about 100 billion words). Given an E-E pair (e_1, e_2), we retrieve the pair of word vectors $(\vec{w}_1, \vec{w}_2)$ based on vector look-up for the head words of e_1 and e_2 in the pre-trained word vectors. Meanwhile, for an E-D pair (e, t) we retrieve word vectors $\vec{w}$ according to the head word of e.

Vector combinations For E-E pairs, we test three different strategies in combining the word vectors of a pair of events: we consider (i) *concatenation* $(\vec{w}_1 \oplus \vec{w}_2)$, (ii) *addition* $(\vec{w}_1 + \vec{w}_2)$ and (iii) *subtraction* $(\vec{w}_2 - \vec{w}_1)$, as vector combination schemes. Note that in (i) the word ordering information is retained, which is not the case in (ii) and (iii).

We only consider word embeddings for events, specifically their head words, because the embeddings for all events annotated in the dataset, which are mostly verbs and nouns, are readily obtainable from the pre-trained word vectors. Meanwhile, representing time expressions with single word vectors is non-trivial, since most of them express dates (e.g. *Friday the 13th*) and times (e.g. *half past ten*), which are usually multi-word expressions.

4 Experimental Setup and Evaluation

We present two sets of experiments: first, we investigate how well word embeddings can be used for temporal relation classification compared with traditional features, and then we analyse whether the combination of these two types of features is beneficial.

4.1 Dataset: TimeBank-Dense

We evaluate the temporal classifiers using the TimeBank-Dense corpus (Chambers et al., 2014), which was created to address the sparsity issue in existing TimeML corpora. Using a specialized annotation tool, annotators were prompted to label all pairs of events and time expressions in the same sentence, all pairs of events and time expressions in two adjacent sentences, and all pairs of events and document creation time. This solution was introduced to solve the problem of sparse annotation of temporal relations in the TempEval-3 evaluation corpus, which made it difficult to evaluate and compare different systems.

The VAGUE relation introduced at the first TempEval task (Verhagen et al., 2007) was also adopted in TimeBank-Dense to cope with ambiguous temporal relations, or to indicate pairs for which no clear temporal relation exists. The resulting corpus contains 12,715 temporal relations under 6 labels, i.e. BEFORE, AFTER, INCLUDES, IS_INCLUDED, SIMULTANEOUS and VAGUE, over 36 documents taken from TimeBank. Annotation here is much denser than in the TimeBank corpus, which contains 6,418 temporal relations under 14 labels over 183 documents.

We follow the experimental setup in Chambers et al. (2014), in which the TimeBank-Dense corpus is split into a 22 document training set, a 5 document development set and a 9 document test set.[3] All the classification models are trained using the training set, as well as the rule set development for T-T edges. We evaluate our classification performances on (i) stratified 10-fold cross validation over the training set and (ii) on the test set.

4.2 Experiment 1: Comparing Traditional Features vs. Word Embeddings

In Table 2 we report the performances (micro-averaged F1-scores) of each classifier using word vectors $\vec{w}$ as features, compared with the classifier performance using traditional features $\vec{f}$, evaluated on stratified 10-fold cross-validation. For E-E pairs, we also report the F1-scores for each vector combination scheme. Since we classify all possible event pairs in the dataset, precision and recall are the same.

From the different vector combinations, concatenation $(\vec{w}_1 \oplus \vec{w}_2)$ is shown to be the best combination. Using the concatenated Word2Vec embeddings $(\vec{w}_1 \oplus \vec{w}_2)$ as features results in .605 F1-score, significantly better than using only traditional features (.529 F1-score). The fact that this representation retain the word order information may be the reason why it beats the other vector combinations.

VAGUE	**.474**	.424	**.612**	.592	.611	.313
Overall	.476	**.479**	.493	**.496**	.444	.338

Table 3: F1-scores per TLINK type with different feature vectors, evaluated on the test set.

With the exception of SIMULTANEOUS and VAGUE, all of the other TLINK types are asymmetric, e.g. BEFORE/AFTER, INCLUDES/IS_INCLUDED.

Note that the classifier with subtracted word vectors $(\vec{w}_2 - \vec{w}_1)$ as features is able to capture event pairs labelled as SIMULTANEOUS, which are failed to be detected by the classifier with concatenated word embeddings. In some cases, the SIMULTANEOUS event pairs are co-referring events that have similar meanings, e.g. (*attack*, *strike*). By subtracting the word vectors of such event headwords, we could get a feature vector close to the origin $(0, 0, ..., 0)$, which can be used by the classifier to capture the SIMULTANEOUS relation. This kind of information is not available if we use concatenated word vectors as features. However, the traditional feature set containing Wordnet semantic similarity/relatedness information still yields a better performance than subtracted word embeddings.

For E-D pairs, using word vectors $\vec{w}$ as features (.476 F1-score) is better than using traditional features $\vec{f}$ (.449 F1-score), in particular for INCLUDES and AFTER labels. Given that in a news text, the document creation time is usually of TIME or DATE types, this means that word embeddings are able to predict when events last longer than a day, hence the appropriate label, i.e. INCLUDES, is chosen.

The same phenomena are also observed in the evaluation on test data, shown in Table 3: (i) concatenation $(\vec{w}_1 \oplus \vec{w}_2)$ is the best vector combination scheme for E-E edges and (ii) using word embeddings increases the performance on INCLUDES and AFTER labelling of E-D pairs. Pairs labelled as SIMULTANEOUS are highly under-represented in the dataset for all types of edges, composing only around 1.1% of the training data and 1.3% of the test data. This explains the failure of the classification models in capturing this particular relation in the test data.

Overall, using word vectors is better than using carefully crafted traditional features, particularly on the 10-fold cross-validation evaluation over the training data. However, on the evaluation over the test set, the improvements on the overall F1-scores are not significant ($p > .05$), even though we observe statistically significant improvements on specific TLINK types (e.g., INCLUDES for E-D pairs and IS_INCLUDED for E-E pairs).

4.3 Experiment 2: Combining Traditional Features and Word Embeddings

To assess whether traditional features are still relevant in the presence of word vectors, two experimental settings are considered:

S1 We simply concatenate word vectors and traditional feature vectors together as the feature sets for the classifiers: $(\vec{w} \oplus \vec{f})$ is taken as the feature set for E-D and $((\vec{w_1} \oplus \vec{w_2}) \oplus \vec{f})$ for E-E pairs.

S2 We employ an ensemble learning technique, namely *stacking*, to combine both sets of features. First, the classifiers with word vectors as features, i.e., $\vec{w}$ for E-D and $(\vec{w_1} \oplus \vec{w_2})$ for E-E, are trained on the training data in a 10-fold cross-validation scheme, producing prediction vectors $\vec{p}$, i.e., one-hot representation of predicted labels, for the whole training data. Then, a combined classifier is trained to make a final prediction using $(\vec{p} \oplus \vec{f})$ as the feature set.

Again, LIBLINEAR (L2-regularized logistic regression) is used to build all the classifiers, which are then evaluated on the test data. Table 4 gives an overview of system performances on both settings, along with F1-scores when using the best feature vectors according to previous experiments, i.e., $\vec{w}$ for E-D and $(\vec{w_1} \oplus \vec{w_2})$ for E-E pairs.

For both E-D and E-E pairs, a super classifier trained using $\vec{p} \oplus \vec{f}$ as the feature vector performs better than a classifier trained with concatenated word vectors and traditional features. Furthermore, the super classifiers significantly outperform classifiers trained with the best single feature sets (word embeddings for E-D and E-E pairs), i.e., .534 vs. .479 F1-scores for E-D ($p < .05$) and .519 vs. .496 F1-scores for E-E pairs ($p < .01$).

5 Discussion

Our final system is composed of a rule set for T-T pairs, and three LIBLINEAR (L2-regularized logistic regression) classifiers for E-D, E-T and E-E pairs. Following the results from our experiments detailed in Section 4, we consider the best feature set for E-D and E-E pairs, i.e., the combination of word embeddings and traditional features via stacked learning $(\vec{p} \oplus \vec{f})$. Meanwhile, for E-T edges, we use the traditional feature vector $\vec{f}$ as the feature set.

Comparison of system performances We compare our system performance with two baseline systems. The first baseline labels all edges as VAGUE, which is the baseline system reported in Chambers et al. (2014). The second baseline system chooses the majority labels (non-VAGUE) for each type of edges, i.e., BEFORE for T-T, E-D and E-E, and AFTER for E-T pairs. As reported in Table 5, our system outperforms both baselines.

We also report in Table 5 our system performance in comparison with CAEVO (Chambers et al., 2014), the only existing temporal ordering system evaluated on the TimeBank-Dense corpus. Note that CAEVO is a hybrid system combining several rule-based and machine-learned classifiers in a sieve-based architecture, which includes transitive reasoning after each classifier labels the entity pairs. Our

System	T-T	E-D	E-T	E-E	Overall
Baseline: All VAGUE	.203	.277	.388	.447	.409
Baseline: Majority (non-VAGUE)	.508	.241	.305	.269	.278
Our system	**.780**	.534	.468	**.519**	**.518**
CAEVO	.712	**.553**	**.494**	.494	.507

Table 5: The comparison of system performances (F1-scores) for each edge type and the overall entity pairs.

Relation	**P**	**R**	**F1**	**P**	**R**	**F1**
BEFORE	.58	.46	**.51**	.52	.45	.49
AFTER	.59	.35	.44	.55	.38	**.45**
SIMULTANEOUS	.92	.28	**.43**	.71	.31	**.43**
INCLUDES	.15	.09	.11	.44	.21	**.28**
IS_INCLUDED	.51	.44	.47	.57	.43	**.49**
VAGUE	.49	.71	**.58**	.48	.66	.56

Table 6: The comparison of system performances on individual relation types.

system, composed of only one rule-set and three supervised-classifiers, is marginally better than CAEVO, particularly for T-T and E-E pairs, with the overall F1-scores of .518 vs. .507 (CAEVO).

CAEVO includes hand-crafted rules for E-D and E-T pairs, for instance rules to label edges between reporting events and DCTs (as IS_INCLUDED) and rules for edges between one verbal event and one timex based on temporal prepositions connecting the two (e.g. prepositions *for*, *at* and *throughout* signal a SIMULTANEOUS relation). It is very likely that our system based on general-purpose features cannot beat these very specific and carefully designed rules.

Finally, we present our system performance (in terms of precision, recall and F1-score) per-relation in Table 6, which is again compared to CAEVO. Overall, the two systems have comparable performances for all relation types, with the exception of the INCLUDES relation, in which CAEVO clearly outperforms our system.

Intra- vs. inter-sentential entity pairs Since we argue that embedding-based features may be particularly beneficial when no overt clues to express the temporal relation are present, as is often the case in inter-sentential relations, we compare the performance of the different feature vectors on inter- and intra-sentential relations in the test set. Results are reported in Table 7.

Feature vector	E-D		E-E	
	same	**diff**	**same**	**diff**
$\vec{f}$	-	.476	.466	.507
$\vec{w}$ or $(\vec{w_1} \oplus \vec{w_2})$	-	.479	.488	.501
S1: $(\vec{w} \oplus \vec{f})$ or $((\vec{w_1} \oplus \vec{w_1}) \oplus \vec{f})$	-	.524	**.516**	.509
S2: $(\vec{p} \oplus \vec{f})$	-	**.534**	.492	**.533**

Table 7: F1-scores for different feature vectors, evaluated on pairs in the test set belonging to the same sentence (same) and different sentences (diff).

Combining word embeddings and traditional features in *stacking* setting (S2) is shown to be beneficial for entity pairs occurring in different sentences. Interestingly, the combination of word embeddings and traditional features in the concatenated setting (S1) is quite beneficial to the classification of E-E pairs in the same sentence.

6 Conclusions

We have analysed the contribution of word embeddings to temporal relation type classification, specifically for E-D and E-E edges. The evaluation results shed some light on how word embeddings can potentially improve a classifier performance for this particular task, i.e., in combination with traditional features in the stacked learning scheme. These results confirm that word embeddings can become effective features when there are no overt markers of temporal relations.

Compared with the state-of-the-art system evaluated on the same corpus, CAEVO, our system achieves quite similar performances, even though it is based on a much simpler architecture. We believe that, integrating our rule set (for T-T pairs) and classifiers (for E-D, E-T and E-E pairs) in CAEVO's sieve-based architecture completed with transitive reasoning, may result in an improvement of the state-of-the-art on the task, which we plan to evaluate soon.

Several works have recently presented methods for building task-specific word embeddings (Hashimoto et al., 2015; Boros et al., 2014; Nguyen and Grishman, 2014; Tang et al., 2014). We believe that this may be beneficial also for temporal ordering, and we plan to build this kind of embeddings in the future, instead of using general-purpose vectors.

Abstract

This paper proposes a novel problem setting of selectional preference (SP) between a predicate and its arguments, called as *context-sensitive* SP (CSP). CSP models the narrative consistency between the predicate and preceding contexts of its arguments, in addition to the conventional SP based on semantic types. Furthermore, we present a novel CSP model that extends the neural SP model (Van de Cruys, 2014) to incorporate contextual information into the distributed representations of arguments. Experimental results demonstrate that the proposed CSP model successfully learns CSP and outperforms the conventional SP model in coreference cluster ranking.

1 Introduction

Selectional Preference (SP) of predicates is a term denoting a bias in co-occurrence of a predicate and its argument. Predicates tend to take a particular semantic type of phrase as an argument. For example, the object slot of *eat* is generally filled by a noun phrase denoting food such as *an apple*; it is rarely filled by a phrase that is not food such as *a watch*. As the knowledge of SP has been recognized as key for many natural language processing tasks, including semantic role labeling and anaphora resolution, automatic acquisition of SP knowledge has persisted as a popular research topic. In literature, a variety of computational models for SP have been proposed, ranging from thesaurus-based approaches (Resnik, 1996), to probabilistic latent variable models (Rooth et al., 1999; Séaghdha and Korhonen, 2014), and distributed approaches (Van de Cruys, 2014).

Conventionally, SP is defined as the context-independent acceptability of a word as a filler of a predicate *in the sense of a semantic type*. Suppose that we must identify the referent of $him_{(j)}$:

(1) $John_{(i)}$ *beat* $Bob_{(j)}$. *Mary comforted* $him_{(j)}$.

Henceforth, we call a predicate (e.g., *comfort*) and an argument (e.g., *John* and *Bob*) to be examined as a *query predicate* and *query argument*, respectively. Conventional SP models judge the appropriateness of $John_{(i)}$ and $Bob_{(j)}$ in terms of whether *comfort* can take each noun as its object. However, it ignores the information signified by the preceding context, namely $John_{(i)}$ *beat Bob* and $Bob_{(j)}$, *whom John beat*. Therefore, conventional approaches cannot determine the preference between *John* and *Bob*, both of whom can fill the object of *comfort*, with the same semantic type.

In this paper, we propose a *context-sensitive* version of SP (CSP), a novel task setting in which SP is considered in discourse. In text (1), for instance, $Bob_{(j)}$ is considered to be a more plausible filler than $John_{(i)}$ in terms of contextual relatedness: *one who was beaten* is more likely to be *comforted* than *one who beat someone*. In this paper, we want to discriminate (2a) from (2b) in addition to the conventional SP-based discrimination (e.g., *Mary comforted John* versus *Mary comforted a banana*):

(2) a. *Mary comforted John, who beat Bob.*
b. *Mary comforted Bob, whom John beat.*

*Present affiliation: FUJITSU FIP CORPORATION

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2829–2838, Osaka, Japan, December 11-17 2016.

The goal of this paper is to develop a CSP model that jointly considers the following aspects: (i) the conventional acceptability based on the semantic type of a query argument, and (ii) the narrative consistency between events denoted by a query predicate and preceding context of the query argument (as seen in (3a) with its counter example (3b)).

(3) a. *Mary comforted X who beat Bob.*

b. *Mary comforted X whom John beat.*

The joint modeling has an advantage in applications, such as predicate argument structure analysis and coreference resolution because the preceding context of a given query argument may not always be available in these tasks. For example, in pronoun resolution, some candidate antecedents may have preceding contexts relevant to narrative consistency but other candidates may not.

The challenges in modeling a CSP are as follows: (i) data sparseness caused by the incorporation of context words, and (ii) an effective means of incorporating context-sensitivity into SP. To address these issues, we propose to extend the state-of-the-art SP model by using a distributed representation (Van de Cruys, 2014). The distributed framework alleviates the data sparseness problem and naturally injects the contextual information of a query argument into its word vector based on compositional distributional semantics (Socher et al., 2012; Socher et al., 2013; Muraoka et al., 2014; Hashimoto et al., 2014, etc.).

We empirically evaluate the impacts of incorporating context-sensitivity into SP for two tasks: (i) context-sensitive pseudo-disambiguation, a novel benchmark tailored for evaluating CSP models, and (ii) coreference cluster ranking for pronominal anaphora resolution. The results demonstrate that our approach achieves considerable improvements. Moreover, the results suggest that CSP is a meaningful problem setting and that our model captures the context-sensitivity of SP.

2 Related Work

A fundamental approach to modeling SP is to count the co-occurrences of predicates and their arguments on a large corpus. As simply counting a predicate-argument pair causes data sparseness problem, previous SP models adopted methods for smoothing co-occurrence counts. Earlier efforts combined a manually crafted thesaurus with the acquired distribution (Resnik, 1996; Li and Abe, 1998). Another approach used a latent probabilistic model to obtain a semantically smoothed probability distribution (Rooth et al., 1999; Séaghdha and Korhonen, 2014). Other directions include example-based approaches (Erk, 2007). However, these studies differ from ours in that they do not consider the context-sensitivity.

Some previous studies (Ritter et al., 2010; Van de Cruys, 2014; Kawahara et al., 2014) estimate the plausibility of a subject–verb–object (SVO) tuple. These studies model a type of CSP: a subject or an object can be regarded as an additional context to restrict a set of possible fillers of a query predicate. However, the context captured in our study is not a local context of a query *predicate* but that of a query *argument*, working as a *validator* of the narrative consistency between a query predicate and events in which a query argument participates (see Section 4).

In addition, the modeling of a narrative consistency between events has been studied extensively (Chambers and Jurafsky, 2009; Modi and Titov, 2014; Granroth-wilding and Clark, 2016, etc.). Chambers and Jurafsky (2009) acquired sets of narratively related events sharing at least one entity (e.g., $\{X$ *commit a crime, police arrest* X*,* X *convict, ...*$\}$) by collecting a set of verbal mentions sharing coreferring arguments in a large corpus. The relatedness between two events was then estimated statistically through pointwise mutual information (Church and Hanks, 1990).

To address the data sparseness problem of Chambers and Jurafsky (2009), Granroth-wilding and Clark (2016) proposed an architecture based on distributed representation to judge the narrative coherence between two events. They trained a neural network (NN) model based on event chain instances acquired in the same strategy as that of Chambers and Jurafsky (2009) and reported that the NN model outperformed their approach. As argued in Section 4, our approach can be regarded as an integrated framework of the state-of-the-art approaches of conventional SP and narrative consistency.

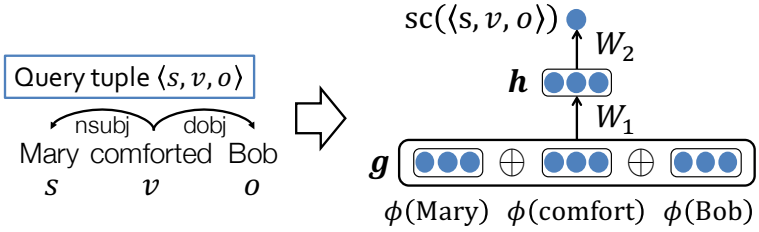

Figure 1: Van de Cruys' SVO model

3 Van de Cruys' SVO model

We adopted the SVO model by Van de Cruys (2014) as a baseline model and extended it to capture narrative consistency. Van de Cruys' SVO model, based on an NN architecture, estimates a preference score for a tuple of words $\langle s, v, o\rangle$ (referred to as a *query tuple*), in which s and o respectively correspond to the subject and object of a transitive verb v. Figure 1 presents the NN structure. The SP score $\mathrm{sc}(\cdot)$ of $\langle s, v, o\rangle$ is calculated using a two-layer NN:

$$\mathrm{sc}(\langle s, v, o\rangle) = W_2 \boldsymbol{h}_{s,v,o}, \tag{1}$$

$$\boldsymbol{h}_{s,v,o} = f(W_1 \boldsymbol{g}_{s,v,o} + \boldsymbol{b}), \tag{2}$$

$$\boldsymbol{g}_{s,v,o} = \phi(s) \oplus \phi(v) \oplus \phi(o) \tag{3}$$

where $\phi(w) \in \mathbb{R}^d$ is the vector representation[1] of word w, $\boldsymbol{g} \in \mathbb{R}^{3d}$ presents an input layer concatenating word vectors of $\langle s, v, o\rangle$ by using the operator $\oplus$, and $\boldsymbol{h} \in \mathbb{R}^h$ is a hidden layer. $W_1 \in \mathbb{R}^{h \times 3d}$ and $W_2 \in \mathbb{R}^{1 \times h}$ are respectively the weight matrices of the first and second layers, and $\boldsymbol{b} \in \mathbb{R}^h$ is a bias on the first layer. $f(\cdot)$ is an element-wise activation function using $\tanh$.

The model simultaneously learns word embedding and scoring function of SP based on the framework proposed by Collobert et al. (2011), who employed a ranking-type loss function that discriminates between positive and negative examples. Positive training examples include $\langle s, v, o\rangle$ tuples observed in a corpus. Negative examples are generated from the positive examples by replacing arguments in correct tuples with randomly selected words. This procedure generates the following three types of negative examples from a positive example $\langle s, v, o\rangle$: $\langle \tilde{s}, v, o\rangle$, $\langle s, v, \tilde{o}\rangle$, and $\langle \tilde{s}, v, \tilde{o}\rangle$. The loss function is then defined as:

$$\sum_{(s,v,o)} \big\{ \max(0, 1 - \mathrm{sc}(\langle s, v, o\rangle) + \mathrm{sc}(\langle \tilde{s}, v, o\rangle)) + \max(0, 1 - \mathrm{sc}(\langle s, v, o\rangle) + \mathrm{sc}(\langle s, v, \tilde{o}\rangle)) \\ + \max(0, 1 - \mathrm{sc}(\langle s, v, o\rangle) + \mathrm{sc}(\langle \tilde{s}, v, \tilde{o}\rangle)) \big\}. \tag{4}$$

Following Collobert et al. (2011), Van de Cruys (2014) calculates the gradient of the loss *online* by sampling a single corrupted subject $\tilde{s}$ and object $\tilde{o}$ for each correct tuple.

4 Context-sensitive SP Model

We propose a context-sensitive selectional preference (CSP) model by extending the SVO model. The advantage of using the model by Van de Cruys (2014) is that we can naturally represent the attachment of the contextual information into a query argument with compositional distribution semantics (Socher et al., 2012; Hashimoto et al., 2014, etc.). We incorporate both the conventional SP and narrative consistency described in Section 1 into a single model by learning the vector representation of *an argument with its context* in the same vector space as word vectors in the SVO model. To realize this, we inserted an additional layer for calculating a context-injected word vector under the input layer.

Figure 2 presents the network structure of our model with the following text as an input.

[1]The original paper differentiates vectors for a word w depending on whether it is used as a subject, object, or verb. However, we used the same vector for a word because we obtained higher performance than that setting.

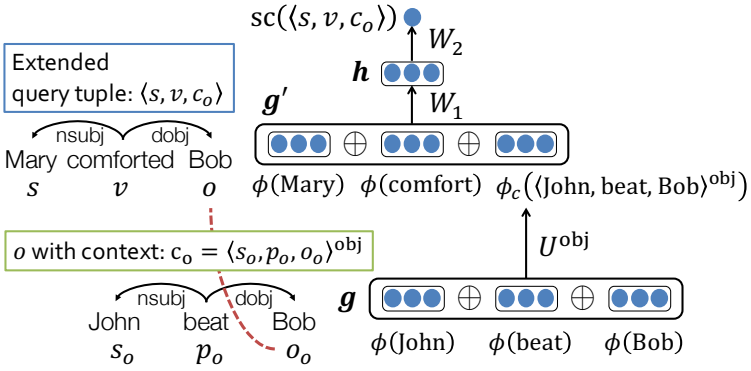

Figure 2: Network structure of proposed model

(4) *John beat Bob*$_{(i)}$. *Mary comforted Bob*$_{(i)}$.

Here, the query tuple $\langle s, v, o\rangle$ is $\langle$*Mary, comfort, Bob*$\rangle$ and the context for the query argument *Bob*$_{(i)}$ is "*John beat Bob*." From this context, we calculate a context-injected word vector representing "*Bob, whom John beat*" by combining the vectors of the words in its predicate-argument structure (PAS). We use the resulting vector as the input to the SVO model, instead of the vanilla word vector.

Formally, we extend the representation of query tuple $\langle s, v, o\rangle$ so that s and o can accompany their contexts. We represent such cases as $\langle c_s, v, o\rangle$, $\langle s, v, c_o\rangle$, and $\langle c_s, v, c_o\rangle$, where c_w denotes *a word w with its context*. Then, we extend Equations (1), (2), and (3) for $\langle s, v, c_o\rangle$ as

$$\mathrm{sc}(\langle s, v, c_o\rangle) = W_2 \boldsymbol{h}'_{s,v,c_o}, \tag{5}$$

$$\boldsymbol{h}'_{s,v,c_o} = f(W_1 \boldsymbol{g}'_{s,v,c_o} + \boldsymbol{b}), \tag{6}$$

$$\boldsymbol{g}'_{s,v,c_o} = f(\phi(s) \oplus \phi(v) \oplus \phi_c(c_o)), \tag{7}$$

where $\phi_c(c_w)$ is a context-injected word vector, which is explained in the rest of this section. Similarly, for $\langle c_s, v, o\rangle$ and $\langle c_s, v, c_o\rangle$, we extend Equation (3) as follows: $\boldsymbol{g}'_{c_s,v,o} = f(\phi_c(c_s) \oplus \phi(v) \oplus \phi(o))$, and $\boldsymbol{g}'_{c_s,v,c_o} = f(\phi_c(c_s) \oplus \phi(v) \oplus \phi_c(c_o))$.

As a context of w, we can potentially consider various types of modifiers, such as predicates, adverbs, appositives, and genitives, that affects the preference score of a query argument. In this study, as a first step, we restrict the context information to PASs along the lines of the previous studies that utilize event-to-event relations in an anaphora resolution (Inoue et al., 2012; Peng et al., 2015).

Specifically, we first assume a context of a query argument be a single PAS which takes the query argument as its argument (referred to as a *context-PAS*). Then we represent w *with its context-PAS* as $c_w = \langle s_w, p_w, o_w\rangle^r$, where s_w and o_w are respectively the subject and object of a predicate p_w that syntactically governs the word w (i.e., either s_w or o_w is w). r indicates the grammatical role of the query argument w in the context-PAS, whose value is either subj (when $w = s_w$) or obj (when $w = o_w$). For example, for text (4), the context for the query object *Bob*, modified by the PAS of the transitive verb *beat*, is represented as $c_o = \langle$*John, beat, Bob*$\rangle^{\mathrm{obj}}$. The grammatical role obj of the query argument *Bob* is indicated to discriminate "*Bob, whom John beat*" from "*John, who beat Bob*." Note that some context-PASs (e.g., intransitive verbs and adjectives) do not take an object argument. r and o_w for these ASs are thus ignored.

To compute a context-injected vector of a query argument, we composed a word vector in a context-PAS by using methods similar to those for building phrase vectors (Socher et al., 2012; Socher et al., 2013; Muraoka et al., 2014; Hashimoto et al., 2014). In this study, we adopted a simple compositional operation, keeping comparisons with other composition methods for future studies. We compute the context-injected word vector $\phi_c(c_w)$ as

$$\phi_c(\langle s_w, p_w, o_w\rangle^r) = U^r \boldsymbol{g}_{s_w,p_w,o_w}, \tag{8}$$

$$\boldsymbol{g}_{s_w,p_w,o_w} = f(\phi(s_w) \oplus \phi(p_w) \oplus \phi(o_w)), \tag{9}$$

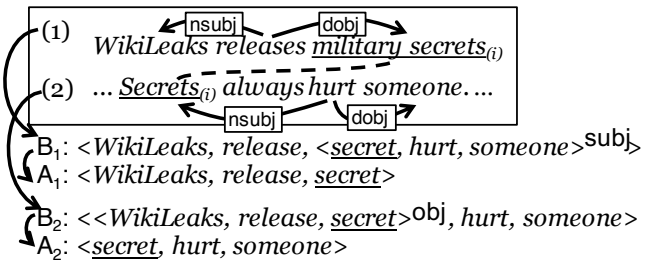

Figure 3: Generation of training instances.

where $U^r \in \mathbb{R}^{h \times 3d}$ is a weight matrix used for building the context-injected vector for the grammatical role r. We set a word vector $\phi(o_w) = \mathbf{0} \in \mathbb{R}^d$ if o_w does not exist (when the context-PAS does not have o_w).

5 Training

To model conventional SP and CSP jointly, we simultaneously train matrices U^r, W_1, and W_2, and vectors $\phi(\cdot)$. We minimize the same loss function introduced in Section 3, except that (i) we replace the score function $\mathrm{sc}(\cdot)$ with Equation (5); and (ii) we use two types of tuples (TYPE A and TYPE B) as training instances. TYPE A is a tuple whose subject and object are bare nouns (i.e., $\langle s, v, o \rangle$). TYPE B is a tuple with either its subject or object including a context-PAS (i.e., $\langle c_s, v, o \rangle$ and $\langle s, v, c_o \rangle$). Hereafter, we describe the method to obtain these instances from a corpus.

5.1 TYPE B instance generation

Positive instance. We assume that a corpus is parsed using a syntactic dependency parser and a coreference resolver. We extract a collection of TYPE B positive instances from the dependency and coreference relations, where we include only a head word for each predicate/argument slot. Figure 3 illustrates the extraction procedure. From sentence (1), we obtain $\langle$*WikiLeaks, release,* $\langle$*secret, hurt, someone*$\rangle^{\mathrm{subj}}\rangle$ (B_1), where "*hurt someone*", the context of *secret*, is attached via the coreference link between *military secrets* and *Secrets*. Similarly, from sentence (2), we obtain $\langle\langle$*WikiLeaks, release, secret*$\rangle^{\mathrm{obj}}$*, hurt, someone*$\rangle$ (B_2).

As context-PASs, we used a *non-negated* transitive verb, intransitive verb, adjective, and copula. Thus, we do *not* extract tuples including one or more negations (e.g., $\langle$John, *not* eat, apple$\rangle$). A nontrivial issue of managing negations in compositional semantics has not been explored much in distributional compositional semantics. Furthermore, we removed tuples where the predicates of coreferent mentions are connected via an *adversative* connective (e.g., *John beat Bob but Bob was happy*), which cannot be handled by the CSP model.

Negative instance. Next, negative training instances are generated by considering positive instances as counterparts. We generate $\langle \tilde{c_s}, v, o \rangle$, $\langle c_s, v, \tilde{o} \rangle$, and $\langle \tilde{c_s}, v, \tilde{o} \rangle$ for positive instance $\langle c_s, v, o \rangle$ and $\langle \tilde{s}, v, c_o \rangle$, $\langle s, v, \tilde{c_o} \rangle$, and $\langle \tilde{s}, v, \tilde{c_o} \rangle$ for positive instance $\langle s, v, c_o \rangle$. Here, $\tilde{s}$ and $\tilde{o}$ are sampled from all the bare subjects and objects in the positive instances, respectively. In addition, $\tilde{c_s}$ and $\tilde{c_o}$ are sampled from all the subjects and objects respectively, with contexts attached. For example, we generate $\tilde{c_s}$=$\langle$*John, eat, apple*$\rangle^{\mathrm{obj}}$ from c_s=$\langle$*WikiLeaks, release, secret*$\rangle^{\mathrm{obj}}$. We use the probabilistic negative sampling (Mikolov et al., 2013) based on the frequency of arguments in the positive instances[2].

5.2 TYPE A instance generation

We then created a TYPE A positive instance from each TYPE B positive instance by replacing the context-attached argument with the original bare argument. In Figure 3, we obtain $\langle$*WikiLeaks, release, secret*$\rangle$ and $\langle$*secret, hurt, someone*$\rangle$ from B_1 and B_2, respectively. To generate TYPE A negative instance, we follow the same procedure described in Section 3 but use probabilistic negative sampling instead.

[2]Although Van de Cruys (2014) used random sampling to generate negative instances, we used probabilistic sampling because our preliminary experiment shows a better performance.

5.3 Dataset

We identified syntactic dependency relations and coreference relations in 4.5 billion sentences extracted from the ClueWeb12 corpus[3], that is, a large collection of Web documents, by applying Stanford CoreNLP (Manning et al., 2014). To reduce noises from the obtained coreference relations, we applied the following heuristics to skim only highly plausible coreference relations off from the pool: (i) the coreference relation must be *intrasentential*, (ii) the head words of the coreferent mentions must be *identical* and *non*pronominal (e.g. *John–John* but not *John–boy*)[4]. Furthermore, we discarded TYPE A and TYPE B instances containing low-frequency words so that all our training instances include only the top 50k frequent verbs, 50k frequent nouns, and 50k frequent adjectives. We replaced all the rare words (occurring less than four times) with the special symbol `OOV` (implying out of vocabulary) to facilitate the calculation of the SP of unseen words appearing in the test set.

As a result, we obtained a collection of 4,824,394 TYPE B positive instances (2,912,624 unique tuples; $\mathcal{B}$ hereafter) and 4,824,394 TYPE A positive instances (1,500,990 unique tuples; $\mathcal{A}$ hereafter).

6 Evaluation

To check whether the CSP model can properly learn the conventional SP and narrative consistency, we first evaluated the CSP model against Van de Cruys' model by using a pseudo-disambiguation test, a binary classification task of discriminating a positive SVO tuple from its pseudo-negative counterpart. We then evaluated the effectiveness of the CSP model in a realistic problem setting, in which the disambiguation test is created from coreference annotations of the OntoNotes corpus (Hovy et al., 2006).

6.1 Parameters

We set the dimension of word embedding $d = 50$ and the dimension of hidden layer $h = 50$. The word embeddings are initialized with the publicly available word vectors trained through GloVe (Pennington et al., 2014)[5] and updated through back propagation. We updated weights by using Adam (Kingma and Ba, 2014) with a mini-batch size of 1,000 and 30 epochs[6].

To evaluate the effectiveness of the CSP model, we replicated the SVO model of Van de Cruys (2014) by training the CSP model only with TYPE A instances (henceforth, SP).

6.2 Pseudo-disambiguation test

Inspired by the conventional SP model (Erk, 2007; Van de Cruys, 2014, etc.), we set up three binary classification tasks. We performed hold-out validation on datasets $\mathcal{A}$ and $\mathcal{B}$.

6.2.1 Tasks

Pseudo-disambiguation (PD) discriminates a positive *non*-context-injected tuple (e.g., $\langle$*Mary, eat, banana*$\rangle$) from its pseudo-negative counterpart ($\langle$*Mary, eat, watch*$\rangle$) without any context information. This task setting has been employed in the previous SP models, including in Van de Cruys (2014).

Context-sensitive PD (CSPD) discriminates a positive context-attached tuple (e.g., $\langle$*Mary, eat,* $\langle$*banana, delicious*$\rangle^{\mathrm{subj}}\rangle$) from its pseudo-negative counterpart ($\langle$*Mary, eat,* $\langle$*watch, new*$\rangle^{\mathrm{subj}}\rangle$). This is a novel task setting designed to highlight the ability of modeling both conventional SP and narrative consistency.

CSPD-X is the same as CSPD except that the coreferent arguments are masked; namely, the task is to discriminate a masked context-attached tuple (e.g. $\langle$*Mary, eat,* $\langle$*X, delicious*$\rangle^{\mathrm{subj}}\rangle$, where *X* denotes the special symbol for masked arguments) from its masked pseudo-negative counterpart. In this task, we set the word vector for the masked argument $\phi(X) = \mathbf{0}$. Forcing the ignorance of the meaning of an argument, this task can assess how precisely the proposed models can predict a query argument through narrative consistency only (i.e., by relying only on the context information).

[3] `http://lemurproject.org/clueweb12/`

[4] A manual inspection revealed that the filtering improved the accuracy of the coreference relations from 71% to 87%.

[5] `http://nlp.stanford.edu/projects/glove/`

[6] All the parameters were determined through our preliminary experiments; we found that all the models were insensitive to the dimension parameters (25, 50, and 100 were explored). An initialization with GloVe performed better than random initialization, and the update of a word vector had a positive impact.

Model	PD	CSPD	CSPD-X
RANDOM	0.5000†	0.5000†	0.5000†
SP	**0.8635**	0.8635	0.5000†
CSP	0.8623	**0.8947***	**0.7856**

Table 1: Accuracy for pseudo-disambiguation tasks. '*' denotes a statistical significance against SP (McNemar test, $p < .05$). '†' indicates the accuracy on random guesses (no clue for discrimination).

Model	MQ	MQ_{no_pr}
SP	0.7420	0.7125
CSP	**0.8265***	0.7586*

Table 2: Model performance on entity ranking. '*' indicates statistical significance against SP (Wilcoxon signed-rank test, $p < .05$).

6.2.2 Dataset

To perform hold-out validation, we first randomly divided the dataset $\mathcal{B}$ into a training set (90%, $\mathcal{B}_{\text{train}}$) and a test set (10%, $\mathcal{B}_{\text{test}}$)[7]. For the PD task, we extracted $\mathcal{A}_{\text{train}}$ from $\mathcal{B}_{\text{train}}$ and $\mathcal{A}_{\text{test}}$ from $\mathcal{B}_{\text{test}}$ by using the procedure described in Section 5.1. For the CSPD and CSPD-X tasks, we used $\mathcal{B}_{\text{train}}$ and $\mathcal{B}_{\text{test}}$. Note that $\mathcal{A}_{\text{train}}$ includes all the SVO instances included in $\mathcal{B}_{\text{train}}$.

6.2.3 Results

Table 1 reports the accuracy of each model in this task. A subtle performance drop (≤ 0.0013 point) is observed in our CSP compared to SP; this was not statistically significant (the statistical significance test by McNemar (1947) showed $p < .05$). This indicates that our joint modeling does not degrade the ability for modeling a conventional SP. In contrast, the CSP model significantly outperformed SP (McNemar test, $p < .05$) in the CSPD task, capturing the context-sensitivity of SP successfully. The results of CSPD-X imply that our joint modeling can properly learn narrative consistency.

6.3 Ranking coreference clusters

In Section 6.2, we reported the results of a binary classification task in which negative instances were artificially generated. In contrast, this section describes a more realistic task setting: *ranking* coreference clusters in the OntoNotes corpus (Hovy et al., 2006).

6.3.1 Task

Given a target pronoun, our task is to determine the coreference cluster (*entity*) that is the most likely to be coreferent with the pronoun. Let us consider text (5) as an example.

(5) *In* his$_{(i)}$ *40-minute* speech$_{(j)}$, Chen$_{(i)}$ *declared the* determination$_{(k)}$ *of the* people$_{(l)}$ ... *against* Chen$_{(i)}$..., *and* he$_{(?)}$ *made a statement...*

Given a target pronoun *he*$_{(?)}$, four coreference clusters C_i, C_j, C_k, C_l are used as candidates for antecedents. As *he*$_{(?)}$ is a subject of the predicate *made a statement*, $\text{sc}(\langle c_s, v, o\rangle)$ gives the preference of c_s as an antecedent of the pronoun, where $v =$ *made* and $o =$ *statement*. In the example, c_s can be a preceding noun with its context attached (if any) or without its context: $\langle$*Chen*, *declare*, *determination*$\rangle^{\text{subj}}$, $\langle$*Chen*, *declare*, *determination*$\rangle^{\text{obj}}$, *speech*, or *people*. We expect that an SP model prefers the correct antecedent $\langle$*Chen*, *declare*, *determination*$\rangle^{\text{subj}}$ over the others.

We measure the ability of a model for selecting the correct cluster by using a *mean quantile* (MQ) (Guu et al., 2015). Let p be the target pronoun, C_p^+ the correct cluster for the pronoun, and $\mathcal{N}_p$ the set of negative (incorrect) clusters. MQ for the pronoun p is defined as:

$$\text{MQ}(p) = \frac{|\{C^- \in \mathcal{N}_p | \text{sp}(C^-, p) < \text{sp}(C_p^+, p)\}|}{|\mathcal{N}_p|}. \tag{10}$$

Intuitively, $\text{MQ}(p)$ represents the ratio where a correct cluster C_p^+ is preferred to incorrect clusters $C^- \in \mathcal{N}_p$ by the model. In general, a cluster contains multiple mentions; thus, we simply consider the maximal of the scores in a cluster C: for example, $\text{sp}(C, p) = \max_{m \in C} \text{sc}(m, v, o)$.

[7]To ensure that the two subsets are strictly disjoint, we prohibited a test instance from being an inverse of any instance in the training set; more concretely, the instance $\langle$*WikiLeaks, release,* $\langle$*secret, hurt, someone*$\rangle^{\text{subj}}\rangle$ must not exist in the test set when the training set includes its inverse $\langle\langle$*WikiLeaks, release, secret*$\rangle^{\text{obj}}$*, hurt, someone*$\rangle$.

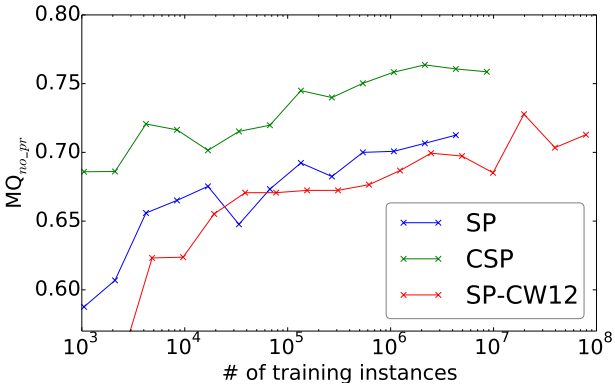

Figure 4: Learning curves of SP and CSP.

When a target pronoun appears at an object position, we use $\mathrm{sc}(\langle s, v, c_o \rangle)$ instead of $\mathrm{sc}(\langle c_s, v, o \rangle)$. In this experiment, we targeted only pronouns filling the subject or object slot of a *non-negated* transitive verb (see Section 5.3); we extracted *he*$_{(i)}$ but not *his*$_{(i)}$ in text (5).

6.3.2 Test set

We used the coreference annotations in OntoNotes Corpus 5.0 (Hovy et al., 2006). The corpus includes 625k newswire and 400k broadcast articles annotated with several layers of syntactic and semantic annotations. We obtained 16,414 test pronouns (16.6% of the total pronouns) with the average number of candidate coreference clusters of 75.9. Further, we used semantic roles to extract PASs.

Although pronouns are not informative to SP and CSP, CSP is expected to benefit from context-attached tuples. To test this, we enhanced the training dataset described in Section 5.1 by allowing pronominal coreferent mentions to be extracted because pronouns might appear in coreference clusters. Thus, we obtained a collection of 8,603,782 TYPE B positive instances (4,952,462 unique tuples; $\mathcal{B}_{pro}$ hereafter) and 8,603,782 TYPE A positive instances (2,178,540 unique tuples; $\mathcal{A}_{pro}$ hereafter). We trained SP with $\mathcal{A}_{pro}$, and CSP with $\mathcal{A}_{pro}$ and $\mathcal{B}_{pro}$.

6.3.3 Results

The MQ column of Table 2 shows the mean of the MQ scores for all target pronouns. The proposed model (CSP) outperformed the baseline model (SP) (Van de Cruys, 2014) (Wilcoxon signed-rank test, $p < .05$). The results indicate that the CSP model captures the SPs of predicates more precisely by exploiting the context information of coreference clusters. In addition, our joint models are demonstrated to be capable of comparing query arguments regardless of the existence of context information.

It may be presumed that this improvement is due to the task setting: pronominal coreferent clusters are relatively difficult for SP to discriminate because SP cannot exploit contextual information. Thus, we also report MQ$_{no_pr}$ in Table 2, which is the MQ of the coreference cluster ranking task including only nonpronominal nouns as candidate coreference clusters. This evaluation also shows that our CSP model outperformed the model by Van de Cruys (2014) (Wilcoxon signed-rank test, $p < .05$). The margin in MQ was found to be larger than in MQ$_{no_pr}$. This indicates that the CSP model successfully captures the narrative consistency-based SP of a pronoun that is difficult to be captured by SP. We leave the effectiveness of context-sensitivity on other (non-neural) types of conventional SP models (e.g., probabilistic latent models (Séaghdha and Korhonen, 2014, etc.)) as an open question. The primary goal of this study is to check the effectiveness of context information; this is proven by the aforementioned results.

6.3.4 Analysis

Although CSP outperformed SP for two tasks, the superiority of CSP may be argued to be due to the larger number of training instances; SP is trained on $\mathcal{A}_{pro}$ but CSP is trained on both $\mathcal{A}_{pro}$ and $\mathcal{B}_{pro}$. Therefore, we plotted the learning curves (`SP` and `CSP` in Figure 4), trained SP and CSP on subsets of

$\mathcal{A}_{pro}$ and $\mathcal{B}_{pro}$ sampled randomly, and measured MQs on the models. As we can generate much a larger size of TYPE A training instance from dependency parses, we also plot the learning curve of the SP model trained using extra SVO tuples extracted from the dependency parse of ClueWeb12 (SP-CW12). We extracted 316,063,648 SVO instances and trained the SP model by using up to 25% of all the extracted SVO tuples (77,011,125 instances) because of the computational cost of training. For fair comparison, we used MQ_{no_pr} as an evaluation measure.

The results show that the MQs of SP (SP, SP-CW12), and CSP (CSP) increase with the size of training data, and both models grow together, keeping a large margin. Based on the growth rate of SP and SP-CW12, we conjectured that we needed 10^3 times more instances of TYPE A for SP to reach the same performance as that of CSP. However, it is inefficient and unrealistic to increase the number of training instances of TYPE A in terms of the training time and availability of training data. In contrast, the CSP model leverages narrative consistency to SP, which is never addressed in previous studies.

To deeply analyze the CSP model, we investigated how the ranks of correct coreference cluster changed from SP to CSP. We found that MQ changed by 0.5 or more in 768 test instances, including 538 improvements and 230 degradations. For 75.7% of the improvements, a context was found to be attached to the candidate antecedent, which is maximally scored among a correct coreference cluster. For example, for the test pronoun *it* in $\langle$*you, own,* $\underline{it}\rangle$, the CSP model can rank the correct antecedent $\langle$*you, buy, something*$\rangle^{\text{obj}}$ at the top by capturing the narrative consistency between *buy X–own X*. In contrast, the context is attached to a correct coreference cluster in only 31.5% of the degradations. This indicates that the CSP model improves the conventional SP via narrative consistency.

7 Conclusion

We addressed the problem of CSP, the novel problem setting of SP. By extending the state-of-the-art SP model (Van de Cruys, 2014), we proposed the novel model that jointly learns both the conventional SP and narrative consistency between a query predicate and its context predicate. The experiments on the PD task demonstrated that the CSP model could leverage narrative consistency for predicting preferences of predicates. Furthermore, the CSP model is effective in a more realistic task setting, ranking coreference clusters.

In the immediate future, we will explore broader contextual information (e.g., prepositional attachment), which can be implemented in our framework naturally. We are interested in applying recent advances in NN, for example, Long Short-Term Memory, Gated Recurrent Unit, and attention mechanism, to compute the vector representation integrating multiple pieces of contextual information. In the experiments, we reserved a downstream application-oriented evaluation for future study so as to exclude various factors specific to a downstream application from the modeling of the CSP. We will explore how to integrate the CSP model with a neural coreference resolver (e.g., Wiseman et al. (2016)) together with conventional coreference features (e.g., distance between a candidate antecedent and a query predicate).

Abstract

The paper presents an iterative bidirectional clustering of adjectives and nouns based on a co-occurrence matrix. The clustering method combines a Vector Space Models (VSM) and the results of a Latent Dirichlet Allocation (LDA), whose results are merged in each iterative step. The aim is to derive a clustering of German adjectives that reflects latent semantic classes of adjectives, and that can be used to induce frame-based representations of nouns in a later step. We are able to show that the method induces meaningful groups of adjectives, and that it outperforms a baseline k-means algorithm.

1 Introduction

The research presented in this paper is part of a larger project which aims at the semantic analysis of adjectival modification of nouns in German in a frame-based approach. Its approach is to model the conceptual mechanisms underlying adjectival modification by decomposing the meanings of adjectives (A) and nouns (N) in frames, i.e. in recursive attribute-value structures. The most common modification process is that the noun concept bears an attribute whose value is restricted by the adjective. The examples in (1) show that some adjectives are strongly associated with an attribute like the color attributes or the attributes of size or age. Some of these adjectives do not only require a special attribute but also a special noun concept (like the color adjective 'blond' that only applies to 'hair'). For other adjectives like *städtisch* 'urban' it is less clear the value of which attribute they specify.

(1) a. schwarzer Ball / Stift
black ball / pen
b. blondes Haar
blond hair
c. fröhlicher Junge / Abend
happy boy / evening
d. städtische Schule
city$_{adj}$ school
e. kindlicher Organismus
child$_{adj}$ organism
f. schneller Fahrer
fast driver

As adjectives often merely restrict the value of an attribute that is associated with the adjective, as 'black' modifying the attribute color in (1-a) such that $\text{COLOR}(ball) = black$, attribute-value structures are well-suited for the task of modeling adjectival modification (cf. Pustejovsky, 1995). However, flat attribute-value lists are not sufficient, because 'black pen' can denote a pen that is black, or a pen that writes in black, $\text{COLOR}(\textit{writing of the pen}) = black$. Similarly in (1-c), it cannot be the

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2839–2848, Osaka, Japan, December 11-17 2016.

same HAPPINESS-attribute applying to both 'boy' and 'evening' in the same way. Relational adjectives like 'städtisch' in (1-d) express a relation between the denotation of N and of the root of A, although the kind of relation is rather vague, a.o. OWNER(*school*) = *city*, OPERATOR(*school*) = *city*, LOCATION(*school*) = *city*. In cases like (1-e) where the noun is relational (cf. de Bruin and Scha, 1988; Löbner, 2011), the adjective fills in the argument slot, POSSESSOR(*organism*) = *child*. Finally, in an event-related A+N phrase as in (1-f) an event frame is activated and modified by A, SPEED(*driving event*) = *fast*.[1]

The examples in (1) show that the compositional mechanisms active in A+N phrases are based on an interplay of the adjective and the noun meaning. Our aim is to cluster adjectives and nouns by these mechanisms, that means by the attributes they exhibit or modify and by the structural position of the modified attribute in the A+N frame.

2 Related research

Distributional approaches to compositionality have been the subject of several recent publications (Blacoe and Lapata, 2012). Regarding A+N phrases, research concentrates on modeling their compositional meaning (Baroni and Zamparelli, 2010; Guevara, 2010), predicting the acceptability rates of novel A+N phrases (Vecchi et al., in press), and on connecting linguistic theory with computational models (Boleda et al., 2013). As an alternative to classical Vector Space Models (VSM) (Turney and Pantel, 2010; Erk, 2012), Latent Dirichlet Allocation (LDA) and related Dirichlet process mixture models are increasingly applied to questions in lexical semantics. Séaghdha and Korhonen (2014) model selectional preferences of verbs in a Bayesian framework, and learn semantic classes of arguments from the latent variables of the model.

Our approach is closely related to recent work in distributional semantics by Hartung and Frank (2010, 2011) on selecting attributes in A+N phrases. However, their task differs from ours in that they explicitly restrict themselves to property-denoting adjectives for which an associated attribute is explicitly assigned in WordNet (Fellbaum, 1998). Hartung and Frank (2011) apply supervised variants of LDA to the problem of attribute prediction for A+N phrases. The authors filter candidate phrases from synsets in WordNet, construct separate pseudo-documents for As and Ns, and compose the output vectors of the LDA with different arithmetic operations following Baroni and Zamparelli (2010), Guevara (2010), and Hartung and Frank (2010).

Unsupervised detection of semantic classes of adjectives has been the topic of several studies. Boleda et al. (2004) annotate Catalan adjectives with two types of coarse semantic labels (unary/binary, basic/object/event), and cluster morpho-syntactic sentence patterns in which the adjectives typically occur. When setting the number of expected clusters to 2 (unary/binary) and 3 (basic/object/event), the authors observe a high correlation between their semantic labelings and the detected clusters. Furthermore, our task is related to detecting synsets and gradability of adjectives using a corpus based approach (Schulam and Fellbaum, 2010). We are interested in detecting groups of adjectives that describe the full range of a (latent) attribute for a group of nouns. So, a group of nouns that denote motorized vehicles may be characterized by the adjectives *geparkt* 'parked', *gestartet* 'started', and *fahrend* 'driving', all of which describe an attribute 'motion state' in a vehicle frame, but don't necessarily belong to a single synset, or are part of a scale of values in a traditional definition.

3 Method

We aim at deriving an adjective and noun clustering that reflects all modificational mechanisms possible in A+N phrases. Due to the explorative nature of our approach, we need a full picture of the combinatorial possibilities of As and Ns, so that we need to investigate a huge corpus. Moreover, we cannot apply supervised methods, because we do not want to restrict ourselves to a subclass of adjectives. The basic idea is to extract as many attested A+N phrases as possible and to apply an iterative bidirectional clustering algorithm based on the co-occurrences of adjectives and nouns. First, the adjectives are clustered on the basis of co-occurring nouns, then the nouns are clustered on the basis of co-occurrences with

[1] For a recent overview on adjectival modification refer to Morzycki (2015).

	distinct A+N pairs	A types	N types	density
Google n-grams	894,743	4,460	10,996	0.0182
Wikipedia	82,022	12,616	19,849	0.0003
newspaper	261,327	4,507	7,955	0,0073

Table 1: Number of A+N pairs and A and N types extracted from the corpora

adjectives from the just gained clusters. The process is iterated, until it reaches a stable clustering or a point at which new clusters would become too diverse.

As detected clusters are reinserted into the vector space matrix, our clustering produces hierarchically structured representations of As and Ns. An example will be discussed in Section 4.

3.1 Data

3.1.1 Co-occurrence data

Data for the A+N co-occurrences are extracted from the Google n-gram corpus (Michel et al., 2011), from a corpus of German newspaper texts, and from a dump of the German Wikipedia, including the Wikisources.[2] The Google and Wikipedia corpora are chosen for their sizes, but also because they contain texts from literary domains that may display other patterns of A+N usage than newspapers. Note that our focus is on the binary question of whether an adjective can modify a noun or not. Thus, throughout the A+N pair extraction process, we prioritize precision above recall. Furthermore, we are not interested in the co-occurrence frequencies (as long as each A+N pair occurs at least 5 times in the corpus), which allows us to merge the data received from the two text corpora ('newspaper' and 'wikipedia') with the Google n-gram corpus.

German marks most A+N pairs in singular number and all definite A+N pairs in plural by using articles. In addition, all nouns are capitalized, while adjectives start with lowercase letters, such that A+N pairs can be extracted from the Google n-grams by applying a regular expression (remember that we do not aim at the extraction of all A+N pairs). Raw A+N pairs detected in this way are grouped, counted, lemmatized with a full form lexicon and normalized[3], resulting in a total of 894,743 distinct A+N pairs with 4,460 A and 10,996 N types. We process the Wikipedia data by removing Wiki specific formatting, and splitting the resulting text into sentences. After POS-tagging each sentence with MATE (Bohnet and Nivre, 2012), A+N pairs are extracted by searching for the POS tag sequence ADJA + [NN|NE]. After removing AN pairs that occur less than 5 times and applying the spelling normalization, this corpus contains 82,022 distinct A+N pairs with 12,616 A and 19,849 N types. The newspaper corpus is lemmatized and POS tagged in the same way as the Wikipedia corpus. This corpus yields 261,327 distinct lemmatized and counted A+N combinations with 4,507 A and 7,955 N types.

Table 1 summarizes the results of the A+N pair extraction process for the three corpora. The small number of distinct A+N pairs found in the Wikipedia corpus compared to the large number of A and N types can be explained by the characteristics of the texts in this corpus. Many Wikipedia entries deal with highly specified topics and introduce a professional terminology; especially the introduced adjectives are mainly used in fixed expressions. Furthermore, the table shows the relevance of the Google n-gram corpus, although it is built from slightly outdated texts and contains many OCR errors (Pechenick et al., 2015). Compared to the newspaper corpus the number of A and N types in the Google corpus is similar, while the number of distinct A+N combinations is much higher. This is due to the fact that the Google corpus is extracted from a huge corpus exhibiting more of the combinatorial possibilities of As and Ns. The density values illustrate the differences between the corpora (number of A+N pairs divided by the product of the number of noun types and number of adjective types).

[2]We use Version 20120701 of the German Google n-grams, the 2013 collection from `http://www.statmt.org/wmt14/training-monolingual-news-crawl/` and the Wikipedia dump from 1st of June 2016.

[3]Because the Google and Wikipedia corpora contain several texts in old German orthography, we apply a spelling normalization that transforms, for example, *th* into *t* (*Alterthum* 'antiquity' → *Altertum*), and corrects a few obvious OCR errors (*Iahr* 'year' → *Jahr*).

3.1.2 Gold data

A gold clustering is required for the evaluation of our clustering solutions. We tested the adjective classification given in GermaNet (Hamp and Feldweg, 1997; Henrich and Hinrichs, 2010) as a gold standard for our purpose. It turned out that the data was not ideal for our task for two reasons: First, GermaNet is hierarchically structured by the hyperonymy relation. That makes it difficult to automatically detect the appropriate granularity level which corresponds to the level of attribute value specifications. Second, GermaNet is constructed on the basis of binary semantic relations like 'synonymy', 'antinonymy' and 'hyperonymy' and not on the basis of attributes. For our purpose, a classification based on attributes and their potential values and bearers would be more suitable.

As an alternative, we used a dataset consisting of all simple adjectives from a German dictionary (Duden, 2004) that are neither loanwords nor derived from other words.[4] The 278 extracted adjectives have been manually classified by 45 attributes. Attributes that take characteristic values if applied to special noun classes are separated from each other. Hence, the attribute *Haarfarbe* 'hair color' is separated from the general attribute *Farbe* 'color' as it allows for hair specific values like *blond* 'blond'. Similarly, *Körpergestalt* 'shape of a human body' is separated from *Gestalt* 'shape', because it takes values like *hager* 'lean' or *mager* 'skinny' that cannot be used for non-human bodies. The main drawback of this data set is its restriction on non-derived adjectives, which are relatively rare in German. As a result, the data set is fairly small, and it contains several outdated and rarely used adjectives.

3.2 Algorithm

The proposed clustering is run in two configurations. The configuration **bin** operates with Jaccard distances calculated from the binarized vector space matrix (VSM) only. The configuration **lda** reweights these Jaccard distances with the output of an LDA topic model.

Both configurations start by constructing a vector space matrix V in which each A is described by the frequencies of the nouns with which it occurs in the corpus, such that rows represent adjectives, and columns represent nouns. This matrix is a structured distributional semantic model in the sense of Baroni and Lenci (2010), because the context words are defined by the syntactic relation between A and N. Sparsely populated rows (A) and columns (N) are removed by an iterative thinning step. After desparsification, a binary matrix V_B is derived from V by setting all non-zero values in V to 1.[5]

In the following, we describe the first iteration step in which the rows correspond to nouns and the columns to adjectives. Note, that after each iteration the matrix V_B is transposed, such that rows correspond to adjectives in even iterations and to nouns in odd iterations. Let $\vec{r_i}$ denote a logical row vector of V_B.

In the configuration **bin**, pairwise distance measures d_{ij} between all rows in V_B are calculated based on the Jaccard distances of the rows.

$$d_{ij} = 1 - \frac{|\vec{r_i} \wedge \vec{r_j}|}{|\vec{r_i} \vee \vec{r_j}|}$$

In order to avoid the clustering of nouns that share only a few adjectives, we set the distance measure to zero if the number of shared nouns is less than a given parameter t_J:

$$d_{ij}^{\text{bin}} = \begin{cases} d_{ij} & \text{if } |\vec{r_i} \wedge \vec{r_j}| \geq t_J \\ 0 & \text{else} \end{cases}$$

In the current configuration the parameter t_J is set to 3 to avoid the clustering of nouns sharing only two or less adjectives and vice versa.

In the configuration **lda**, LDA[6] is applied to the V_B, and another list of pairwise distance tuples

[4] These adjectives were collected and annotated by Sebastian Löbner and Thomas Gamerschlag in the project B02 "Dimensional Verbs", SFB 991, HHU Düsseldorf. Our special thanks to Thomas Gamerschlag for providing the data.

[5] The binarization step is performed, because we are only interested in whether a noun can be modified by an adjective, thus whether it bears an attribute the value of which can be restricted by the adjective. We could not rely on the frequency counts, as our corpus of A+N pairs results from an unbalanced merge of different corpora.

[6] LDA is performed with Gibbs Sampling using the library `GibbsLDA++`, `https://sourceforge.net/projects/gibbslda/`.

$(\vec{r_i}, \vec{r_j}, \theta_{ij})$ is created from the Θ values obtained from the LDA. For row vectors $\vec{r_i}$ and $\vec{r_j}$, θ_{ij} is given as

$$\theta_{ij} = \left(\sum_{k=1}^{K=15} (\Theta_{ik} - \Theta_{jk})^2 \right)^{\frac{1}{2}}$$

The number of latent topics $K = 15$ is intentionally kept low, because we don't derive semantic classes from the topic model of the LDA, but rather use the similarities between the Θ distributions for reweighting the Jaccard distances. In configuration **lda**, the Jaccard distances d_{ij} are reweighted with the distances from the LDA topic model, resulting in the final score d_{ij}^{lda} for each pair of words:

$$d_{ij}^{\text{lda}} = d_{ij}^{\text{bin}} \cdot \theta_{ij}$$

When the pairs of candidates $(\vec{r_i}, \vec{r_j})$ are reordered using this score, the top scoring pairs have high similarities in the binary vector space and in the topic model induced by the LDA.

Depending on the configuration mode, new word clusters are created either from the top 5% of the top scoring pairs with respect to the d^{bin} or to the d^{lda} distance measure. Clusters are built by constructing the transitive closures. Thus, if d_{ij} and d_{ik} belong to the 5% lowest distances measured, the words belonging to the rows $\vec{r_i}$, $\vec{r_j}$ and $\vec{r_k}$ are clustered together. Let R denote all rows that belong to one transitive closure and should thus be clustered together. The distributional representation of the new cluster, i.e. of the new row vector $\vec{R}$, is built by merging R with a majority based binary operator:

$$\vec{R_k} = \begin{cases} 1 & \text{if } \sum_{\vec{r} \in R} r_k \geq \frac{|R|}{2} \\ 0 & \text{else} \end{cases}$$

The rows in V which belong to R are deleted and the new row $\vec{R}$ is added, shrinking the matrix dimension in this way by $|R| - 1$.

The algorithm terminates, when no new classes are detected, because no pair of rows has more than t_J non-zero columns in common. Else, V_B is transposed, and the clustering method is applied to the other word class.

4 Evaluation and Results

We will restrict the evaluation of the obtained clusters to the adjective clusters, as we do not have access to an attribute based clustering of nouns that could be used as our gold data. We evaluate the results of the bidirectional clustering against the gold data described in Section 3.1, and against the results of k-means as a baseline clustering algorithm. As the adjective noun co-occurrence matrix is too sparse to run k-means successfully on it, we use information from context windows of the adjectives instead. For running the baseline k-means, we create neural embeddings of all words that occur at least 20 times in the merged corpus (newspaper, Wikipedia) using the `word2vec` tool (Mikolov et al., 2011),[7] and extract the embeddings of the adjectives that are processed in the bidirectional clustering. Remember that one of the main challenges in this task consists in determining the number of semantic classes from the raw data. In order to find this number, we calculate the gap statistic (Tibshirani et al., 2001) for cluster sizes between 40 (and thus just below the number of semantic classes in the gold data) and an – arbitrarily chosen – upper limit of 300, advancing in steps of 10 classes. Figure 1 shows that $\hat{k}$ as defined in Tibshirani et al. (2001, 415) changes from negative to positive values, when k-means is performed with approximately 160 classes, so that we use $k = 160$ for the baseline k-means clustering.

Since k-means and the gold standard provide hard non-hierarchical clusterings, we need to extract a hard non-hierarchical clustering from our bidirectional clustering as well, in order to compare them by standard measures as the Rand index (RI; Rand, 1971). The bidirectional clustering can produce deeply nested hierarchical clusterings, when later iterations of the method merge detected clusters and adjectives

[7] We cannot use the Google corpus for `word2vec` as it does not provide us with the necessary context of the A+N pairs. The settings for the `word2vec` tools are as follows: window size: 6 words, embedding size: 300, bow. All other parameters are set to their default values.

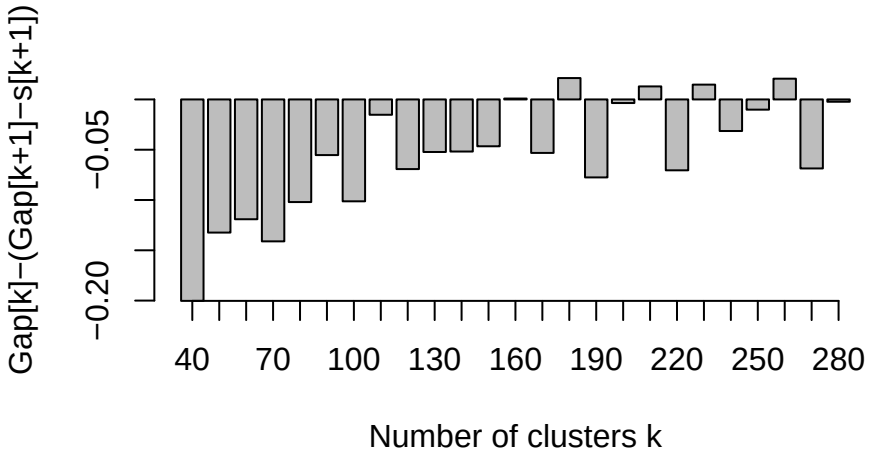

Figure 1: Gap statistic ($\hat{k}$) for neural embeddings of adjectives, showing a switch from negative to positive values at about 160 classes.

213 wunderschön wunderbar

Figure 2: Example demonstrating the effect of the two configurations 'leaf' and 'topmost'. Indentation indicates at which iteration a word cluster has been created. The configuration 'jaccard' cannot be displayed as its cannot be computed locally

into new classes. As such hierarchical representations provide no unambiguous hard clusters, we present three different modes of deriving hard clusterings from our representation. The following rules apply only to those adjectives that belong to at least one singleton cluster: In the configuration 'leaf' each such adjective is assigned to the smallest non-singleton cluster it belongs to; in the configuration 'topmost' it is assigned to the largest cluster it belongs to. Figure 2 illustrates the difference between these two configurations. The adjective *ausgezeichnet* 'excellent' is labeled with ID 196 in the 'leaf' and with ID 268 in the 'topmost' configuration. In addition, we derive a third hard clustering 'jaccard' that takes the homogeneity of the clusters into account. For this sake, we obtain pairwise Jaccard indexes between all adjectives that are subsumed under each node of the hierarchical output, and calculate their means for each node. To make this evaluation comparable with the result of k-means, the 160 nodes with the highest average Jaccard indexes are taken as hard cluster labels. All leaves that are not subsumed under one of these nodes are assigned to singleton clusters.

For the evaluation of the clustering we compute the Rand index (RI; Rand, 1971) and the Adjusted Rand index (Hubert and Arabie, 1985, ARI;). The Rand index of two clusterings C and C' is defined by

$$\mathcal{R}(C, C') = \frac{n_{11} + n_{00}}{\binom{n}{2}}$$

where n_{11} is the number of adjective pairs which belong to the same cluster in both clusterings, n_{00} is the number of adjective pairs that are assigned to different clusters in both clusterings, and n is the number of adjectives. Thus RI measures the proportion of the pairs which are clustered in the same

Table 3: (Adjusted) Rand index for the bidirectional clustering

way in both clusterings. The adjusted Rand index corrects the Rand index by agreements that are solely due to chance. Note that while RI takes values between 0 and 1, ARI can take negative values as well (Meila, 2007). Table 2 shows the RI and ARI values for the k-means clusterings. Table 3 compares the clusterings resulting from the bidirectional clustering in different configurations and for different corpora.

While the RI values are high, ARI values are very low. This outcome is typical for sparse data and a large number of clusters. Remember that we have put each adjective that was not clustered by the algorithm into a singleton cluster. No clear favorite emerges when comparing the clusterings with and without LDA (Table 3, **bin** and **lda**). Only for the merged corpus which contains the data of all three corpora (newspaper, Google and Wikipedia), there is a tendency that **lda** outperforms **bin**. The different granularity levels ('topmost', 'jaccard' and 'leaf') by which the hierarchy is cut into a non-hierarchical clustering influence the RI and the ARI values as expected: a coarser clustering leads to higher ARI but slightly lower RI values. The most obvious result is that the bidirectional clustering outperforms the k-means clustering with respect to the more relevant ARI (independent of the chosen configuration). This result is remarkable, as the k-means clustering is based on textual context windows, while the bidirectional clustering only considers isolated A+N combinations. Thus, while for many tasks which aim at a semantic clustering it is better to look at the distribution of words in a larger context, the task of clustering adjectives by attributes seems to benefit from using a structured VSM.

To conclude this section, we will discuss some of the received clusters to give an impression of what kind of clusters can be expected. Many property-denoting adjectives turn out to be clustered very well, especially those which are derived from a numeral like *X-stellig* 'X place', *X-geschossig / X-stöckig* 'X floor', *X-malig* 'X times', *X-spurig* 'X lane', *X-jährig* 'X year', *X-tägig* 'X day' .... Although these clusters could have been easily identified by using morphological features, they are good candidates for a first proof of concept of our approach. Furthermore, we have gained satisfactory clusters of relational adjectives derived from concepts such as countries, languages, religions, cities, or territories.

A final example will be discussed in order to show the strengths and weaknesses of the approach. We get a cluster consisting of twenty adjectives describing properties of curves of some measure (temperature, price, ...), namely

5911 [*gleichbleibend* 'stable', *nachlassend* 'decreasing', *verringert* 'reduced', *gesunken* 'fallen']

5297 [*abnehmend* 'decreasing']

3163 [*vermindert* 'reduced', *vermehrt* 'increased']

2662 [*gesteigert* 'increased', *erhöht* 'raised']

1939 [*steigend* 'climbing']

1168 [*zunehmend* 'increasing / more and more', *wachsend* 'growing']

4541 [*höchstmöglich* 'highest possible']

3980 [*maximal* 'maximal', *größtmöglich* 'biggest possible']

5347 [*rückläufig* 'declining']

4687 [*sinkend* 'sinking', *gestiegen* 'climbed']

3331 [*stagnierend* 'stagnating', *schrumpfend* 'shrinking']

Most of the adjectives in this cluster denote some form of 'increasing', 'decreasing' or 'staying stable', thus a dynamic progression along a curve, and can be interpreted as values of the attribute 'progression' applied to curves. Others like *vermindert* 'decreased' or *vermehrt* 'increased' describe the general height of the curve. Only in subcluster 4541 one finds adjectives denoting extreme points of a curve like 'maximum' or 'highest possible'. Although the whole cluster 5911 is quite satisfactory, it could be improved in two respects. First, it obviously lacks many antinomies like *minimal* 'minimal' (to *maximal* 'maximal') or *fallend* 'decreasing' (to *steigend* 'increasing') which have been clustered elsewhere. Other adjectives describing the curve progression like *schwankend* 'floating' are missing as well. Second, from our frame-based perspective it would be desirable to receive clusters that reflect the different attributes by which a curve can be described like 'progression' and 'height' and which strictly separates adjectives that specify curves from others that specify points on a curve.

5 Conclusion

We have presented an iterative bidirectional clustering of adjectives and nouns by co-occurrences. The aim has been to derive adjective clusters which correspond to the value spaces of attributes. It has turned out that only some of the received clusters are perfect in that respect. Most miss some adjectives or mix adjectives belonging to different by familiar attributes. However, it has turned out that the clusters are a useful starting point for a manual analysis of the attribute value space.

In the quantitative evaluation the presented iterative bidirectional clustering outperformed the k-means clustering on word vectors. That indicates that for our task, the approach of only looking at individual adjective noun pairs instead of adjectives in bigger contexts is promising. By iteratively clustering adjectives on the basis of co-occurring nouns and vice versa, the hidden attributes connecting both can be crystallized out. However, bigger gold clusterings and more reliable evaluation measures are still missing.

The next steps to be taken are the following: The algorithm should be adapted to allow for overlapping clusters in order to account for polysemy. Better evaluation measures and more gold clusters which are specific to the task are needed. Ideally one would develop a frame-specific evaluation measure. One way could be to automatically induce frames from the derived adjective and noun clusters and to evaluate the resulting frames.

Abstract

According to the distributional inclusion hypothesis, entailment between words can be measured via the feature inclusions of their distributional vectors. In recent work, we showed how this hypothesis can be extended from words to phrases and sentences in the setting of compositional distributional semantics. This paper focuses on inclusion properties of tensors; its main contribution is a theoretical and experimental analysis of how feature inclusion works in different concrete models of verb tensors. We present results for relational, Frobenius, projective, and holistic methods and compare them to the simple vector addition, multiplication, min, and max models. The degrees of entailment thus obtained are evaluated via a variety of existing word-based measures, such as Weed's and Clarke's, KL-divergence, APinc, balAPinc, and two of our previously proposed metrics at the phrase/sentence level. We perform experiments on three entailment datasets, investigating which version of tensor-based composition achieves the highest performance when combined with the sentence-level measures.

1 Introduction

Distributional hypothesis asserts that words that often occur in the same contexts have similar meanings (Firth, 1957). Naturally these models are used extensively to measure the semantic similarity of words (Turney and Pantel, 2010). Similarity is an a-directional relationship and computational linguists are also interested in measuring degrees of directional relationships between words. Distributional inclusion hypothesis is exactly about such relationships, and particularly, about entailment (Dagan et al., 1999; Geffet and Dagan, 2005; Herbelot and Ganesalingam, 2013). It states that a word u entails a word v if in any context that word u is used so can be word v. For example, in a corpus of sentences 'a boy runs', 'a person runs', 'a person sleeps', according to this hypothesis, *boy* $\vdash$ *person*, since wherever 'boy' is used, so is 'person'. Formally, we have that u entails v if features of u are included in features of v, where features are non-zero contexts. In this example, *boy* $\vdash$ *person*, since $\{\text{run}\} \subset \{\text{run, sleep}\}$.

For the same reasons that the distributional hypothesis is not directly applicable to phrases and sentences, the distributional inclusion hypothesis does not scale up from words to larger language constituents. In a nutshell, this is because the majority of phrases and sentences of language do not frequently occur in corpora of text, thus reliable statistics cannot be collected for them. In distributional models, this problem is addressed with the provision of composition operators, the purpose of which is to combine the statistics of words and obtain statistics for phrases and sentences. In recent work, we have applied the same compositionality principles to lift the entailment relation from word level to phrase/sentence level (Kartsaklis and Sadrzadeh, 2016; Balkır et al., 2016a; Balkır et al., 2016b; Balkır, 2014). The work in (Balkır, 2014; Balkır et al., 2016b) was focused on the use of entropic measures on density matrices and compositional operators thereof, but no experimental results were considered; similarly, Bankova et al. (2016) use a specific form of density matrices to represent words for entailment purposes, focusing only on theory. In (Balkır et al., 2016a), we showed how entropic and other measures can be used on vectors as well as on density matrices and supported this claim with experimental results. In (Kartsaklis and Sadrzadeh, 2016), we focused on making the distributional inclusion hypothesis compositional, worked

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2849–2860, Osaka, Japan, December 11-17 2016.

out how feature inclusion lifts from words to compositional operators on them, and based on experimental results showed that intersective composition operators result in more reliable entailments. This paper takes a more concrete perspective and focuses on the feature inclusion properties of tensors constructed in different ways and composition operators applied to the tensors and vectors.

One can broadly classify the compositional distributional models to three categories: ones that are based on simple element-wise operations between vectors, such as addition and multiplication (Mitchell and Lapata, 2010); tensor-based models in which relational words such as verbs and adjectives are tensors and matrices contracting and multiplying with noun (and noun-phrase) vectors (Coecke et al., 2010; Grefenstette and Sadrzadeh, 2011; Baroni and Zamparelli, 2010); and models in which the compositional operator is part of a neural network (Socher et al., 2012; Kalchbrenner et al., 2014) and is usually optimized against a specific objective.

Tensor-based models stand in between the two extremes of element-wise vector mixing and neural net-based methods, offering a sufficiently powerful alternative that allows for theoretical reasoning at a level deeper than it is usually possible with black-box statistical approaches. Models of this form have been used in the past with success in a number of NLP tasks, such as head-verb disambiguation (Grefenstette and Sadrzadeh, 2011), term-definition classification (Kartsaklis et al., 2012), and generic sentence similarity (Kartsaklis and Sadrzadeh, 2014). In this paper we extend this work to entailment, by investigating (theoretically and experimentally) the properties of feature inclusion on the phrase and sentence vectors produced in four different tensor-based compositional distributional models: the relational models of (Grefenstette and Sadrzadeh, 2011), the Frobenius models of (Kartsaklis et al., 2012; Milajevs et al., 2014), the projective models of (Kartsaklis and Sadrzadeh, 2016), and the holistic linear regression model of (Baroni and Zamparelli, 2010).

Contrary to formal semantic models, and customary to distributional models, our entailments are non-boolean and come equipped with degrees. We review a number of measures that have been developed for evaluating degrees of entailment at the lexical level, such as the *APinc* measure and its newer version, *balAPinc* of Kotlerman et al. (2010), which is considered as state-of-the-art for word-level entailment. A newly proposed adaptation of these metrics, recently introduced by the authors in (Kartsaklis and Sadrzadeh, 2016), is also detailed. This measure takes into account the specificities introduced by the use of a compositional operator and lifts the measures from words to phrase/sentence level.

We experiment with these models and evaluate them on entailment relations between simple intransitive sentences, verb phrases, and transitive sentences on the datasets of (Kartsaklis and Sadrzadeh, 2016). Our findings suggest that the Frobenius models provide the highest performance, especially when combined with our sentence-level measures. On a more general note, the experimental results of this paper support that of previous work (Kartsaklis and Sadrzadeh, 2016) and strongly indicate that compositional models employing some form of intersective feature selection, i.e. point-wise vector multiplication or tensor-based models with an element of element-wise mixing (such as the Frobenius constructions), are more appropriate for entailment tasks in distributional settings.

2 Compositional distributional semantics

The purpose of a compositional distributional model is to produce a vector representing the meaning of a phrase or a sentence by combining the vectors of its words. In the simplest case, this is done by element-wise operations on the vectors of the words (Mitchell and Lapata, 2010). Specifically, the vector representation $\overrightarrow{w}$ of a sequence of words $w_1, \ldots, w_n$ is defined to be:

$$\overrightarrow{w} := \overrightarrow{w_1} + \overrightarrow{w_2} + \cdots + \overrightarrow{w_n} \qquad\qquad \overrightarrow{w} := \overrightarrow{w_1} \odot \overrightarrow{w_2} \odot \cdots \odot \overrightarrow{w_n}$$

In a more linguistically motivated approach, relational words such as verbs and adjectives are treated as linear or multi-linear maps. These are then applied to the vectors of their arguments by following the rules of the grammar (Coecke et al., 2010; Grefenstette and Sadrzadeh, 2011; Baroni and Zamparelli, 2010). For example, an adjective is a map $N \to N$, for N a basic noun space of the model. Equivalently, this map can be represented as a matrix living in the space $N \otimes N$. In a similar way, a transitive verb is a map $N \times N \to S$, or equivalently, a "cube" or a tensor of order 3 in the space $N \otimes N \otimes S$, for S a basic sentence space of the model. Composition takes place by tensor contraction, which is a generalization of

matrix multiplication to higher order tensors. For the case of an adjective-noun compound, this simplifies to matrix multiplication between the adjective matrix and the vector of its noun, while for a transitive sentence it takes the following form, where $\overline{\text{verb}}$ is a tensor of order 3 and $\times$ is tensor contraction:

$$\overrightarrow{svo} = (\overline{\text{verb}} \times \overrightarrow{\text{obj}}) \times \overrightarrow{\text{subj}}$$

Finally, phrase and sentence vectors have been also produced by the application of neural architectures, such as recursive or recurrent neural networks (Socher et al., 2012; Cheng and Kartsaklis, 2015) and convolutional neural networks (Kalchbrenner et al., 2014). These models have been shown to perform well on large scale entailment tasks such as the ones introduced by the RTE challenge.

3 Distributional inclusion hypothesis

The distributional inclusion hypothesis (DIH) (Dagan et al., 1999; Geffet and Dagan, 2005; Herbelot and Ganesalingam, 2013) is based on the fact that whenever a word u entails a word v, then it makes sense to replace instances of u with v. For example, 'cat' entails 'animal', hence in the sentence 'a cat is asleep', it makes sense to replace 'cat' with 'animal' and obtain 'an animal is asleep'. On the other hand, 'cat' does not entail 'butterfly', and indeed it does not make sense to do a similar substitution and obtain the sentence 'a butterfly is asleep'. This hypothesis has limitations, the main one being that it only makes sense in upward monotone contexts. For instance, the substitution of u for v would not work for sentences that have negations or quantifiers such as 'all' and 'none'. As a result, one cannot replace 'cat' with 'animal' in sentences such as 'all cats are asleep' or 'a cat is not asleep'. Despite this and other limitations, the DIH has been subject to a good amount of study in the distributional semantics community and its predictions have been validated (Geffet and Dagan, 2005; Kotlerman et al., 2010).

Formally, the DIH says that if word u entails word v, then the set of features of u are included in the set of features of v. In the context of a distributional model of meaning, the term *feature* refers to a non-zero dimension of the distributional vector of a word. By denoting the features of a distributional vector $\overrightarrow{v}$ by $\mathcal{F}(\overrightarrow{v})$, one can symbolically express the DIH as follows:

$$u \vdash v \quad \text{whenever} \quad \mathcal{F}(\overrightarrow{u}) \subseteq \mathcal{F}(\overrightarrow{v}) \tag{1}$$

The research on the DIH can be categorised into two classes. In the first class, the degree of entailment between two words is based on the distance between the vector representations of the words. This distance must be measured by asymmetric means, since entailment is directional. Examples of measures used here are entropy-based measures such as KL-divergence (Chen and Goodman, 1996). KL-divergence is only defined when the support of $\overrightarrow{v}$ is included in the support of $\overrightarrow{u}$. To overcome this restriction, a variant referred to by α-skew (Lee, 1999) has been proposed (for $\alpha \in (0, 1]$ a smoothing parameter). *Representativeness* provides another way of smoothing the KL-divergence. The formulae for these are as follows, where abusing the notation we take $\overrightarrow{u}$ and $\overrightarrow{v}$ to also denote the probability distributions of u and v:

$$D_{\text{KL}}(\overrightarrow{v} \| \overrightarrow{u}) = \sum_i v_i(\ln v_i - \ln u_i) \qquad s_\alpha(\overrightarrow{u}, \overrightarrow{v}) = D_{\text{KL}}(\overrightarrow{v} \| \alpha\overrightarrow{u} + (1-\alpha)\overrightarrow{v})$$

$$R_{\text{D}}(\overrightarrow{v} \| \overrightarrow{u}) = \frac{1}{1 + D_{\text{KL}}(\overrightarrow{v} || \overrightarrow{u})}$$

Representativeness turns KL-divergence into a number in the unit interval $[0, 1]$. As a result we obtain $0 \leq R_{\text{D}}(\overrightarrow{v} \| \overrightarrow{u}) \leq 1$, with $R_{\text{D}}(\overrightarrow{v} \| \overrightarrow{u}) = 0$ when the support of $\overrightarrow{v}$ is not included in the support of $\overrightarrow{u}$ and $R_{\text{D}}(\overrightarrow{v} \| \overrightarrow{u}) = 1$, when $\overrightarrow{u}$ and $\overrightarrow{v}$ represent the same distribution.

The research done in the second class attempts a more direct measurement of the inclusion of features, with the simplest possible case returning a binary value for inclusion or lack thereof. Measures developed by Weeds et al. (2004) and Clarke (2009) advance this simple methods by arguing that not all features play an equal role in representing words and hence they should not be treated equally when it comes to measuring entailment. Some features are more "pertinent" than others and these features have to be given a higher weight when computing inclusion. For example, 'cat' can have a non-zero coordinate on

all of the features 'mammal, miaow, eat, drink, sleep'. But the amount of these coordinates differ, and one can say that, for example, the higher the coordinate the more pertinent the feature. Pertinence is computed by various different measures, the most recent of which is *balAPinc* (Kotlerman et al., 2010), where *LIN* is Lin's similarity (Lin, 1998) and *APinc* is an asymmetric measure:

$$\mathit{balAPinc}(u,v) = \sqrt{\mathit{LIN}(u,v) \cdot \mathit{APinc}(u,v)} \qquad \mathit{APinc}(u,v) = \frac{\sum_r [P(r) \cdot \mathit{rel}'(f_r)]}{|\mathcal{F}(\overrightarrow{u})|}$$

APinc applies the DIH via the idea that features with high values in $\mathcal{F}(\overrightarrow{u})$ must also have high values in $\mathcal{F}(\overrightarrow{v})$. In the above formula, f_r is the feature in $\mathcal{F}(\overrightarrow{u})$ with rank r; $P(r)$ is the precision at rank r; and $\mathit{rel}'(f_r)$ is a weight computed as follows:

$$rel'(f) = \begin{cases} 1 - \frac{\mathit{rank}(f, \mathcal{F}(\overrightarrow{v}))}{|\mathcal{F}(\overrightarrow{v})|+1} & f \in \mathcal{F}(\overrightarrow{v}) \\ 0 & o.w. \end{cases} \tag{2}$$

where $\mathit{rank}(f, \mathcal{F}(\overrightarrow{v}))$ shows the rank of feature f within the entailed vector. In general, *APinc* can be seen as a version of average precision that reflects lexical inclusion.

4 Measuring feature inclusion at the phrase/sentence level

In recent work, the authors of this paper introduced a variation of the *APinc* and *balAPinc* measures aiming to address the extra complications imposed when evaluating entailment at the phrase/sentence level (Kartsaklis and Sadrzadeh, 2016). The modified measures differ from the original ones in two aspects. Firstly, in a compositional distributional model, the practice of considering only non-zero elements of the vectors as features becomes too restrictive and thus suboptimal for evaluating entailment; indeed, depending on the form of the vector space and the applied compositional operator (especially in intersective models, see Sections 5 and 6), an element can get very low values without however ever reaching zero. The new measures exploit this blurring of the notion of "featureness" to the limit, by letting $\mathcal{F}(\overrightarrow{w})$ to include all the dimensions of $\overrightarrow{w}$.

Secondly, the continuous nature of distributional models is further exploited by providing a stronger realization of the idea that $u \vdash v$ whenever v occurs in all the contexts of u. Let $f_r^{(u)}$ be a feature in $\mathcal{F}(\overrightarrow{u})$ with rank r and $f_r^{(v)}$ the corresponding feature in $\mathcal{F}(\overrightarrow{v})$, we remind that Kotlerman et al. consider that feature inclusion holds at rank r whenever $f_r^{(u)} > 0$ and $f_r^{(v)} > 0$; the new measures strengthen this assumption by requiring that $f_r^{(u)} \leq f_r^{(v)}$. Incorporating these modifications in the *APinc* measure, $P(r)$ and $rel'(f_r)$ are redefined as follows:

$$P(r) = \frac{\left|\{f_r^{(u)} | f_r^{(u)} \leq f_r^{(v)}, 0 < r \leq |\overrightarrow{u}|\}\right|}{r} \qquad rel'(f_r) = \begin{cases} 1 & f_r^{(u)} \leq f_r^{(v)} \\ 0 & o.w. \end{cases} \tag{3}$$

The new relevance function subsumes the old one, as by definition high-valued features in $\mathcal{F}(\overrightarrow{u})$ must be even higher in $\mathcal{F}(\overrightarrow{v})$. The new *APinc* at the phrase/sentence level thus becomes as follows:

$$\mathit{SAPinc}(u,v) = \frac{\sum_r [P(r) \cdot \mathit{rel}'(f_r)]}{|\overrightarrow{u}|} \tag{4}$$

where $|\overrightarrow{u}|$ is the number of dimensions of $\overrightarrow{u}$. Further, we notice that *balAPinc* is the geometric average of *APinc* with Lin's similarity measure, which is symmetric. According to (Kotlerman et al., 2010), the rationale of including a symmetric measure was that *APinc* tends to return unjustifyingly high scores when the entailing word is infrequent, that is, when the feature vector of the entailing word is very short; the purpose of the symmetric measure was to penalize the result, since in this case the similarity of the narrower term with the broader one is usually low. However, now that all feature vectors have the same length, such a balancing action is unnecessary; more importantly, it introduces a strong element of symmetry in a measure that is intended to be strongly asymmetric. We cope with this issue by replacing Lin's measure with representativeness on KL-divergence,[1] obtaining the following new version of *balAPinc*:

[1]Using other asymmetric measures is also possible; the choice of representativeness on KL-divergence was based on informal experimentation which showed that this combination works better than other options in practice.

$$\textit{SBalAPinc}(u,v) = \sqrt{R_{\mathrm{D}}(\overrightarrow{u}\,\|\,\overrightarrow{v}) \cdot \textit{SAPinc}(\overrightarrow{u},\overrightarrow{v})} \tag{5}$$

Recall that $R_{\mathrm{D}}(p\|q)$ is asymmetric, measuring the extent to which q represents (i.e. is similar to) p. So the term $R_{\mathrm{D}}(\overrightarrow{u}\,\|\,\overrightarrow{v})$ in the above formula measures how well the *broader* term v represents the narrower one u; as an example, we can think that the term 'animal' is representative of 'cat', while the reverse is not true. The new measure aims at: (i) retaining a strongly asymmetric nature; and (ii) providing a more fine-grained element of entailment evaluation.

5 Generic feature inclusion in compositional models

In the presence of a compositional operator, features of phrases or sentences adhere to set-theoretic properties. For simple additive and multiplicative models, the set of features of a phrase/sentence is derived from the set of features of their words using union and intersection. It is slightly less apparent (and for reasons of space we will not give details here) that the features of point-wise minimum and maximum of vectors are also derived from the intersection and union of their features, respectively. That is:

$$\mathcal{F}(\overrightarrow{v_1} + \cdots + \overrightarrow{v_n}) = \mathcal{F}(\max(\overrightarrow{v_1},\cdots,\overrightarrow{v_n})) = \mathcal{F}(\overrightarrow{v_1}) \cup \cdots \cup \mathcal{F}(\overrightarrow{v_n})$$
$$\mathcal{F}(\overrightarrow{v_1} \odot \cdots \odot \overrightarrow{v_n}) = \mathcal{F}(\min(\overrightarrow{v_1},\cdots,\overrightarrow{v_n})) = \mathcal{F}(\overrightarrow{v_1}) \cap \cdots \cap \mathcal{F}(\overrightarrow{v_n})$$

As shown in (Kartsaklis and Sadrzadeh, 2016), element-wise composition of this form lifts naturally from the word level to phrase/sentence level; specifically, for two sentences $s_1 = u_1 \dots u_n$ and $s_2 = v_1 \dots v_n$ for which $u_i \vdash v_i\ \forall i \in [1,n]$, it is always the case that $s_1 \vdash s_2$. This kind of lifting of the entailment relationship from words to the phrase/sentence level also holds for tensor-based models (Balkır et al., 2016a).

In general, feature inclusion is a more complicated process for tensor-based settings, since in this case the composition operation is matrix multiplication and tensor contraction. As an example, consider the simple case of a matrix multiplication between a $m \times n$ matrix $\mathbf{M}$ and a $n \times 1$ vector $\overrightarrow{v}$. Matrix $\mathbf{M}$ can be seen as a list of column vectors $(\overrightarrow{w_1},\overrightarrow{w_2},\cdots,\overrightarrow{w_n})$, where $\overrightarrow{w_i} = (w_{1i},\cdots,w_{mi})^{\mathsf{T}}$. The result of the matrix multiplication is a combination of scalar multiplications of each element v_i of the vector $\overrightarrow{v}$ with the corresponding column vector $\overrightarrow{w_i}$ of the matrix $\mathbf{M}$. That is, we have:

$$\begin{pmatrix} w_{11} & \cdots & w_{1n} \\ w_{21} & \cdots & w_{2n} \\ \vdots & & \vdots \\ w_{m1} & \cdots & w_{mn} \end{pmatrix} \times \begin{pmatrix} v_1 \\ \vdots \\ v_n \end{pmatrix} = v_1\overrightarrow{w_1} + v_2\overrightarrow{w_2} + \cdots + v_n\overrightarrow{w_n}$$

Looking at $\mathbf{M} \times \overrightarrow{v}$ in this way enables us to describe $\mathcal{F}(\mathbf{M} \times \overrightarrow{v})$ in terms of the union of $\mathcal{F}(\overrightarrow{w_i})$'s where v_i is non zero, that is, we have:

$$\mathcal{F}(\mathbf{M} \times \overrightarrow{v}) = \bigcup_{v_i \neq 0} \mathcal{F}(\overrightarrow{w_i})$$

By denoting v_i a feature whenever it is non-zero, we obtain an equivalent form as follows:

$$\bigcup_i \mathcal{F}(\overrightarrow{w_i})\ |_{\mathcal{F}(v_i)} \tag{6}$$

The above notation says that we collect features of each $\overrightarrow{w_i}$ vector but only up to "featureness" of v_i, that is up to v_i being non-zero. This can be extended to tensors of higher order; a tensor of order 3, for example, can be seen as a list of matrices, a tensor of order 4 as a list of "cubes" and so on. For the case of this paper, we will not go beyond matrix multiplication and cube contraction.

6 Feature inclusion in concrete constructions of tensor-based models

While the previous section provided a generic analysis of the feature inclusion behaviour of tensor-based models, the exact feature inclusion properties of these models depend on the specific concrete constructions, and in principle get a form more refined than that of simple intersective or union-based composition. In this section we investigate a number of tensor-based models with regard to feature inclusion, and derive their properties.

6.1 Relational model

As a starting point we will use the model of Grefenstette and Sadrzadeh (2011), which adopts an extensional approach and builds the tensor of a relational word from the vectors of its arguments. More specifically, the tensors for adjectives, intransitive verbs, and transitive verbs are defined as below, respectively:

$$\overline{adj} = \sum_i \overrightarrow{Noun_i} \qquad \overline{verb}_{\text{IN}} = \sum_i \overrightarrow{Sbj}_i \qquad \overline{verb}_{\text{TR}} = \sum_i \overrightarrow{Sbj}_i \otimes \overrightarrow{Obj}_i \tag{7}$$

where $\overrightarrow{Noun_i}$, $\overrightarrow{Sbj}_i$ and $\overrightarrow{Obj}_i$ refer to the distributional vectors of the nouns, subjects and objects that occurred as arguments for the adjective and the verb across the training corpus. For the case of a subject-verb sentence and a verb-object phrase, composition reduces to element-wise multiplication of the two vectors, and the features of the resulting sentence/phrase vector get the following form (with $\overrightarrow{s}$ and $\overrightarrow{o}$ to denote the vectors of the subject/verb of the phrase/sentence):

$$\mathcal{F}(\overrightarrow{sv}) = \bigcup_i \mathcal{F}(\overrightarrow{Sbj}_i) \cap \mathcal{F}(\overrightarrow{s}) \qquad \mathcal{F}(\overrightarrow{vo}) = \bigcup_i \mathcal{F}(\overrightarrow{Obj}_i) \cap \mathcal{F}(\overrightarrow{o}) \tag{8}$$

For a transitive sentence, the model of Grefenstette and Sadrzadeh (2011) returns a matrix, computed in the following way:

$$\overline{svo}_{\text{Rel}} = \overline{verb} \odot (\overrightarrow{s} \otimes \overrightarrow{o})$$

where $\overline{verb}$ is defined as in Equation 7. By noticing that $\mathcal{F}(\overrightarrow{u} \otimes \overrightarrow{v}) = \mathcal{F}(\overrightarrow{u}) \times \mathcal{F}(\overrightarrow{v})$, with symbol $\times$ to denote in this case the *cartesian product* of the two feature sets, we define the feature set of a transitive sentence as follows:

$$\mathcal{F}(\overline{svo}_{\text{Rel}}) = \bigcup_i \mathcal{F}(\overrightarrow{Sbj}_i) \times \mathcal{F}(\overrightarrow{Obj}_i) \cap \mathcal{F}(\overrightarrow{s}) \times \mathcal{F}(\overrightarrow{o}) \tag{9}$$

Equation 9 shows that the features of this model are pairs (f_{sbj}, f_{obj}), with f_{sbj} a subject-related feature and f_{obj} an object-related feature, providing a fine-grained representation of the sentence. Throughout this paper, we refer to this model as *relational*.

6.2 Frobenius models

As pointed out in (Kartsaklis et al., 2012), the disadvantage of the relational model is that their resulting representations of verbs have one dimension less than what their types dictate. According to the type assignments, an intransitive verb has to be a matrix and a transitive verb a cube, where as in the above we have a vector and a matrix. A solution presented in (Kartsaklis et al., 2012) suggested the use of *Frobenius* operators in order to expand vectors and matrices into higher order tensors by embedding them into the the diagonals. For example, a vector is embedded into a matrix by putting it in the diagonal of a matrix and padding the off-diagonal elements with zeros. Similarly, one can embed a matrix into a cube by putting it into the main diagonal and pad the rest with zeros. Using this method, for example, one could transform a simple intersective model in tensor form by embedding the context vector of a verb $\overrightarrow{v}$ first into a matrix and then into a cube. For a transitive sentence, one could use the matrix defined in Equation 7 and derive a vector for the meaning of the sentence in two ways, each one corresponding to a different embedding of the matrix into a tensor of order 3:

$$\overrightarrow{svo}_{\text{CpSbj}} = \overrightarrow{s} \odot (\overline{verb} \times \overrightarrow{o}) \qquad \overrightarrow{svo}_{\text{CpObj}} = (\overrightarrow{s}^{\mathsf{T}} \times \overline{verb}) \odot \overrightarrow{o} \tag{10}$$

We refer to these models as Copy-Subject and Copy-Object, correspondingly. In order to derive their feature inclusion properties, we first examine the form of the sentence vector produced when the verb is composed with a new subject/object pair:

$$\overrightarrow{svo}_{\text{CpSbj}} = \overrightarrow{s} \odot (\overline{verb} \times \overrightarrow{o}) = \overrightarrow{s} \odot \sum_i \overrightarrow{Sbj_i} \langle \overrightarrow{Obj_i} | \overrightarrow{o} \rangle$$
$$\overrightarrow{svo}_{\text{CpObj}} = (\overrightarrow{s}^{\mathsf{T}} \times \overline{verb}) \odot \overrightarrow{o} = \overrightarrow{o} \odot \sum_i \overrightarrow{Obj_i} \langle \overrightarrow{s} | \overrightarrow{Sbj_i} \rangle$$

We can now define the feature sets of the two models using notation similar to that of Equation 6:

$$\begin{aligned} \mathcal{F}(\overrightarrow{svo}_{\text{CpSbj}}) &= \mathcal{F}(\overrightarrow{s}) \cap \bigcup_i \mathcal{F}(\overrightarrow{Sbj_i}) \mid_{\mathcal{F}\left(\langle \overrightarrow{Obj_i} | \overrightarrow{o} \rangle\right)} \\ \mathcal{F}(\overrightarrow{svo}_{\text{CpObj}}) &= \mathcal{F}(\overrightarrow{o}) \cap \bigcup_i \mathcal{F}(\overrightarrow{Obj_i}) \mid_{\mathcal{F}\left(\langle \overrightarrow{s} | \overrightarrow{Sbj_i} \rangle\right)} \end{aligned} \tag{11}$$

The symbol | defines a restriction on feature inclusion based on how well the arguments of the sentence fit to the arguments of the verb. For a subject-object pair (Sbj, Obj) that has occured with the verb in the corpus, this translates to the following:

- *Copy-Subject:* Include the features of Sbj up to similarity of Obj with the sentence object
- *Copy-Object:* Include the features of Obj up to similarity of Sbj with the sentence subject

Note that each of the Frobenius models puts emphasis on a different argument of a sentence; the Copy-Subject model collects features of the subjects that occured with the verb, while the Copy-Object model collects features from the verb objects. It is reasonable then to further combine the two models in order to get a more complete representation of the sentence meaning, and hence its feature inclusion properties. Below we define the feature sets of two variations, where this combination is achieved via addition (we refer to this model as *Frobenius additive*) and element-wise multiplication (*Frobenius multiplicative*) of the vectors produced by the individual models (Kartsaklis and Sadrzadeh, 2014):

$$\begin{aligned} \mathcal{F}(\overrightarrow{svo}_{\text{FrAdd}}) &= \mathcal{F}(\overrightarrow{svo}_{\text{CpSbj}}) \cup \mathcal{F}(\overrightarrow{svo}_{\text{CpObj}}) \\ \mathcal{F}(\overrightarrow{svo}_{\text{FrMul}}) &= \mathcal{F}(\overrightarrow{svo}_{\text{CpSbj}}) \cap \mathcal{F}(\overrightarrow{svo}_{\text{CpObj}}) \end{aligned} \tag{12}$$

where $\mathcal{F}(\overrightarrow{svo}_{\text{CpSbj}})$ and $\mathcal{F}(\overrightarrow{svo}_{\text{CpObj}})$ are defined as in Equation 11.

6.3 Projective models

In this section we provide an alternative solution and remedy the problem of having lower dimensions than the required by arguing that the sentence/phrase space should be spanned by the vectors of the arguments of the verb across the corpus. Thus we create verb matrices for intransitive sentences and verb phrases by summing up *projectors* of the argument vectors, in the following way:

$$\overline{v}_{itv} := \sum_i \overrightarrow{Sbj_i} \otimes \overrightarrow{Sbj_i} \qquad \overline{v}_{vp} := \sum_i \overrightarrow{Obj_i} \otimes \overrightarrow{Obj_i} \tag{13}$$

When these verbs are composed with some subject/object to form a phrase/sentence, each vector in the spanning space is weighted by its similarity (assuming normalized vectors) with the vector of that subject/object, that is:

$$\overrightarrow{sv}_{\text{Prj}} = \overrightarrow{s}^{\mathsf{T}} \times \overline{v}_{itv} = \sum_i \langle \overrightarrow{Sbj_i} | \overrightarrow{s} \rangle \overrightarrow{Sbj_i} \qquad \overrightarrow{vo}_{\text{Prj}} = \overline{v}_{vp} \times \overrightarrow{o} = \sum_i \langle \overrightarrow{Obj_i} | \overrightarrow{o} \rangle \overrightarrow{Obj_i} \tag{14}$$

Translating the above equations to feature inclusion representations will give:

$$\mathcal{F}(\overrightarrow{s\bar{v}}_{\mathrm{Prj}}) = \bigcup_i \mathcal{F}(\overrightarrow{Sbj}_i) \mid_{\mathcal{F}\left(\langle \overrightarrow{Sbj}_i | \overrightarrow{s} \rangle\right)} \qquad \mathcal{F}(\overrightarrow{v\bar{o}}_{\mathrm{Prj}}) = \bigcup_i \mathcal{F}(\overrightarrow{Obj}_i) \mid_{\mathcal{F}\left(\langle \overrightarrow{Obj}_i | \overrightarrow{o} \rangle\right)} \tag{15}$$

with symbol | to define again a restriction on feature inclusion based on the similarity of the arguments with the subject or object of the sentence/phrase. For the subject-verb case, this reads: "include a subject that occured with the verb, up to its similarity with the subject of the sentence". For the case of a transitive verb (a function of two arguments), we define the sentence space to be spanned by the average of the argument vectors, obtaining:

$$\overline{v}_{trv} := \sum_i \overrightarrow{Sbj}_i \otimes \left(\frac{\overrightarrow{Sbj}_i + \overrightarrow{Obj}_i}{2} \right) \otimes \overrightarrow{Obj}_i$$

The meaning of a transitive sentence then is computed as:

$$\overrightarrow{s\bar{v}o}_{\mathrm{Prj}} = \overrightarrow{s}^{\mathsf{T}} \times \overline{v}_{trv} \times \overrightarrow{o} = \sum_i \left[\langle \overrightarrow{s} \mid \overrightarrow{Sbj}_i \rangle \langle \overrightarrow{Obj}_i \mid \overrightarrow{o} \rangle \left(\frac{\overrightarrow{Sbj}_i + \overrightarrow{Obj}_i}{2} \right) \right] \tag{16}$$

Feature-wise, the above translates to the following:

$$\mathcal{F}(\overrightarrow{s\bar{v}o}_{\mathrm{Prj}}) = \bigcup_i \left(\mathcal{F}(\overrightarrow{Sbj}_i) \cup \mathcal{F}(\overrightarrow{Obj}_i) \right) \mid_{\mathcal{F}\left(\langle \overrightarrow{s} | \overrightarrow{Sbj}_i \rangle\right) \mathcal{F}\left(\langle \overrightarrow{Obj}_i | \overrightarrow{o} \rangle\right)} \tag{17}$$

Note that in contrast with the relational and Frobenius models, which all employ an element of intersective feature selection, the projective models presented in this section are purely union-based.

6.4 Inclusion of verb vectors

The models of the previous sections provide a variety of options for representing the meaning of a verb from its arguments. However, none of these constructions takes into account the distributional vector of the verb itself, which includes valuable information that could further help in entailment tasks. We remedy this problem by embedding the missing information into the existing tensors; for example, we can amend the tensors of the projective model as follows:

$$\overline{v}_{itv} = \sum_i \overrightarrow{Sbj}_i \otimes \left(\overrightarrow{Sbj}_i \odot \overrightarrow{v} \right) \qquad \overline{v}_{vp} = \sum_i \left(\overrightarrow{Obj}_i \odot \overrightarrow{v} \right) \otimes \overrightarrow{Obj}_i \tag{18}$$

with $\overrightarrow{v}$ denoting the distributional vector of the verb. In the context of an intransitive sentence, now we have the following interaction:

$$\overrightarrow{s\bar{v}} = \overrightarrow{s}^{\mathsf{T}} \times \overline{v}_{itv} = \overrightarrow{s}^{\mathsf{T}} \times \sum_i \overrightarrow{Sbj}_i \otimes \left(\overrightarrow{Sbj}_i \odot \overrightarrow{v} \right) = \overrightarrow{v} \odot \sum_i \langle \overrightarrow{s} | \overrightarrow{Sbj}_i \rangle \overrightarrow{Sbj}_i \tag{19}$$

We see that the result of the standard projective model (Equation 14) is now enchanced with an additional step of interesective feature selection. In feature inclusion terms, we get:

$$\mathcal{F}(\overrightarrow{s\bar{v}}) = \mathcal{F}(\overrightarrow{v}) \cap \mathcal{F}(\overrightarrow{s\bar{v}}_{\mathrm{Prj}}) \qquad \mathcal{F}(\overrightarrow{v\bar{o}}) = \mathcal{F}(\overrightarrow{v}) \cap \mathcal{F}(\overrightarrow{v\bar{o}}_{\mathrm{Prj}}) \tag{20}$$

It is easy to show that similar formulae hold for the relational and Frobenius models.

7 Experimental setting

We evaluate the feature inclusion behaviour of the tensor-based models of Section 6 in three different tasks; specifically, we measure upward-monotone entailment between (a) intransitive sentences; (b) verb phrases; and (c) transitive sentences. We use the entailment datasets introduced in (Kartsaklis and Sadrzadeh, 2016), which consist of 135 subject-verb pairs, 218 verb-object pairs, and 70 subject-verb-object pairs, the phrases/sentences of which stand in a fairly clear entailment relationship. Each dataset has been created using hypernym-hyponym relationships from WordNet, and it was extended with the reverse direction of the entailments as negative examples, creating three strictly directional entailment

datasets of 270 (subject-verb), 436 (verb-object) and 140 (subject-verb-object) entries. Some examples of positive entailments from all three categories include:[2]

Subject-verb	Verb-object	Subject-verb-object
evidence suggests ⊢ information expresses	sign contract ⊢ write agreement	book presents account ⊢ work shows evidence
survey reveals ⊢ work shows	publish book ⊢ produce publication	woman marries man ⊢ female joins male
player plays ⊢ contestant compete	sing song ⊢ perform music	author retains house ⊢ person holds property
study demonstrates ⊢ examination shows	reduce number ⊢ decrease amount	study demonstrates importance ⊢ work shows value
summer finishes ⊢ season ends	promote development ⊢ support event	experiment tests hypothesis ⊢ research evaluates proposal

In all cases, we first apply a compositional model to the phrases/sentences of each pair in order to create vectors representing their meaning, and then we evaluate the entailment relation between the phrases/sentences by using these composite vectors as input to a number of entailment measures. The goal is to see which combination of compositional model/entailment measure is capable of better recognizing strictly directional entailment relationships between phrases and sentences.

We experimented with a variety of entailment measures, including *SAPinc* and *SBalAPinc* as in (Kartsaklis and Sadrzadeh, 2016), their word-level counterparts (Kotlerman et al., 2010), KL-divergence (applied to smoothed vectors as in Chen and Goodman (1996)), α-skew with $\alpha = 0.99$ as in Kotlerman et al. (2010), *WeedsPrec* as in Weeds et al. (2004), and *ClarkeDE* as in Clarke (2009). We use strict feature inclusion as a baseline; in this case, entailment holds only when $\mathcal{F}(\overrightarrow{phrase_1}) \subseteq \mathcal{F}(\overrightarrow{phrase_2})$. For compositional operators, we experimented with element-wise vector multiplication and MIN, vector addition and MAX, and the tensor models presented in Section 6. Informal experimentation showed that directly embedding distributional information from verb vectors in the tensors (Section 6.4) works considerably better than the simple versions, so the results we report here are based on this approach. We also present results for a least squares fitting model, which approximates the distributional behaviour of holistic phrase/sentence vectors along the lines of (Baroni and Zamparelli, 2010). Specifically, for each verb, we compute an estimator that predicts the ith element of the resulting vector as follows:

$$\overrightarrow{w_i} = (\mathbf{X}^\mathsf{T}\mathbf{X})^{-1}\mathbf{X}^\mathsf{T}\overrightarrow{y_i}$$

Here, the rows of matrix $\mathbf{X}$ are the vectors of the subjects (or objects) that occur with our verb, and $\overrightarrow{y_i}$ is a vector containing the ith elements of the holistic phrase vectors across all training instances; the resulting $\overrightarrow{w_i}$'s form the rows of our verb matrix. This model could be only implemented for verb-object and subject-verb phrases due to data sparsity problems. As our focus is on analytic properties of features, we did not experiment with any neural model.

Regarding evaluation, since the tasks follow a binary classification objective and our models return a continuous value, we report *area under curve* (AUC). This reflects the generic discriminating power of a binary classifier by evaluating the task at every possible threshold. In all the experiments, we used a 300-dimensional PPMI vector space trained on the concatenation of UKWAC and Wikipedia corpora. The context was defined as a 5-word window around the target word.

8 Results and discussion

The results are presented in Table 1 (subject-verb and verb-object task) and Table 2 (subject-verb-object task). In all cases, a combination of a Frobenius tensor model with one of the sentence-level measures (*SAPinc*) gives the highest performance. In general, *SAPinc* and *SBalAPinc* work very well with all the tested compositional models, achieving a cross-model performance higher than that of any other metric, for all three tasks. From a feature inclusion perspective, we see that models employing an element of interesective composition (vector multiplication, MIN, relational and Frobenius tensor models) have consistent high performances across all the tested measures. The reason may be that the intersective filtering avoids generation of very dense vectors and thus facilitates entailment judgements based on the DIH. On the other hand, union-based compositional models, such as vector addition, MAX, and the projective tensor models, produce dense vectors for even very short sentences, which affects negatively the evaluation of entailment. The non-compositional verb-only baseline was worse than any compositional model other than the least-squares model, which is the only tensor model that did not perform well; this indicates that our algebraic tensor-based constructions are more robust against data sparsity problems than statistical models based on holistic vectors of phrases and sentences.

[2]The datasets are available at `http://compling.eecs.qmul.ac.uk/resources/`.

$\otimes_{\mathrm{FrMul}}$	0.55	0.62	0.76	0.81	0.68	0.78	0.73	**0.86**	**0.83**

Table 2: AUC results for the subject-verb-object task. $\otimes_{\mathrm{Rel}}$ refers to the relational tensor model of Section 6.1, while $\otimes_{\mathrm{CpSbj}}$, $\otimes_{\mathrm{CpObj}}$, $\otimes_{\mathrm{FrAdd}}$, and $\otimes_{\mathrm{FrMul}}$ to the Frobenius models of Section 6.2. As in the other tasks, the distributional vector of the verb has been taken into account in all tensor-based models except Least-Sqr.

9 Conclusion and future work

In this paper we investigated the application of the distributional inclusion hypothesis on evaluating entailment between phrase and sentence vectors produced by compositional operators with a focus on tensor-based models. Our results showed that intersective composition in general, and the Frobenius tensor models in particular, achieve the best performance when evaluating upward monotone entailment, especially when combined with the sentence-level measures of (Kartsaklis and Sadrzadeh, 2016). Experimenting with different versions of tensor models for entailment is an interesting topic that we plan to pursue further in a future paper. Furthermore, the extension of word-level entailment to phrases and sentences provides connections with natural logic (MacCartney and Manning, 2007), a topic that is worth a separate treatment and constitutes a future direction.

Parameter estimation of Japanese predicate argument structure analysis model using eye gaze information

Abstract

In this paper, we propose utilising eye gaze information for estimating parameters of a Japanese predicate argument structure (PAS) analysis model. We employ not only linguistic information in the text, but also the information of annotator eye gaze during their annotation process. We hypothesise that annotator's frequent looks at certain candidates imply their plausibility of being the argument of the predicate. Based on this hypothesis, we consider annotator eye gaze for estimating the model parameters of the PAS analysis. The evaluation experiment showed that introducing eye gaze information increased the accuracy of the PAS analysis by 0.05 compared with the conventional methods.

1 Introduction

In recent years, there have been many attempts of annotating corpora with various kinds of information, as supervised machine learning (ML) techniques had been a significant device for natural language processing (NLP) (Pustejovsky and Stubbs, 2012). The annotated corpus is used as training data for constructing a task model, considering the annotated information as expected output of the model. In the current framework, however, only annotated information in the corpus is used for training. In this paper, we propose utilising the information of annotator behaviour during the annotation process as well as resulting annotated information for training the task model (Tokunaga et al., 2013).

We take the predicate argument structure (PAS) analysis of Japanese texts as the target task in the present work. Predicate argument relations are usually marked by case particles denoting grammatical cases in Japanese, therefore identifying dependencies marked by the major obligatory cases, *ga* (nominative), *wo* (accusative) and *ni* (dative) is the main task. However, since ellipses are ubiquitous in Japanese texts, arguments might be identified beyond the sentence including the target predicates (inter-sentence arguments) as well as within the sentence (intra-sentence arguments). This feature is different from the PAS analysis in English in which arguments can be found in the same sentence of the target predicate in most cases. Another complication is the case alternation caused by certain types of auxiliary verbs such as causative and passivisation verbs. In such cases, the original case should be recovered in the PAS analysis. In this respect, the Japanese PAS analysis shares the similarity with semantic role labelling in English (Gildea and Jurafsky, 2002). Furthermore, treating "event nouns" (Komachi et al., 2007) as predicates, we identify their arguments as well as the arguments of verbs and adjectives. Currently, several PAS annotated Japanese corpora such as NAIST Text Corpus (NTC) (Iida et al., 2007b) and BCCWJ-DepParaPAS (Ueda et al., 2015; Maekawa et al., 2014) are available. We use the latter in this study.

In order to improve the PAS analysis performance, we propose to utilise the information of annotator behaviour, particularly eye gaze information, during their annotating predicate argument relations in texts. In the past PAS analysis, a model has been constructed by utilising a certain ML technique regarding the human annotated argument as the correct argument for a given predicate, i.e. it is considered the positive example for the predicate and all other argument candidates are negative examples. Observing

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2861–2869, Osaka, Japan, December 11-17 2016.

the annotator eye movement during their annotation, however, they look at other argument candidates as well until their final decision. Although the not-selected candidates are not the argument of the target predicate in the text, frequently-looked candidates could be an argument of the predicate in similar but different texts. Our idea is to utilise the information gained from those "near miss" candidates in the training phase of the model.

Consider the following two example texts.

(1) *watasi-wa kinou tomodati-to ranti-wo tabeni ikimasita.*
I-TOPIC yesterday friend-with lunch-ACC to eat went

nedan-ni mo azi-ni mo manzokusimasita.
price-DAT also taste-DAT also was satisfied

'Yesterday, I went to have lunch with my friend. I was satisfied with its price and taste.'

(2) *watasi-wa kinou tomodati-to ranti-wo tabeni ikimasita.*
I-TOPIC yesterday friend-with lunch-ACC to eat went

nedan-ni mo azi-ni mo manzokusita youdesu.
price-DAT also taste-DAT also was satisfied seem

'Yesterday, I went to have lunch with my friend. He seemed to be satisfied with its price and taste.'

Although these texts are almost the same on the surface except for the verb ending in the second sentences, the *ga* (nominative) arguments of the predicate '*manzokusuru* (be satisfied)' are different; the *ga* argument in (1) is '*watasi* (I)' in the first sentence while that in (2) is '*tomodati* (friend)'. This difference is caused by the modality auxiliary '*youdesu* (seem)' in the second sentence of (2). Treating these texts as a part of the training examples for binary classification, '*watasi* (I)' is regarded as a positive example, and other candidates including '*tomodati* (friend)' as negative examples in the text (1). However, '*tomodati* (friend)' looks a better negative example than others in (1). This is also the case for (2) but in the opposite way. Our proposal treats '*tomodati* (friend)' in (1) and '*watasi* (I)' in (2) as "near miss" candidates, i.e. better negative examples than others in each text, and takes them into account in the training. To salvage the "near miss" candidates that were merely discarded in the existing PAS analysis based on binary classification, we build our PAS analyser with a learning-to-rank framework; we make a ranking of candidates instead of their binary positive-negative distinction.

It has been reported that the eye gaze information contributes to detecting annotation disagreement between annotators (Mitsuda et al., 2013), but there has been no study on the Japanese PAS analysis using eye gaze information. We hypothesise that frequent looks at argument candidates imply their plausibility of being the argument of the predicate. In this study, we make a candidate ranking based on the frequency of the annotator gaze at the candidates for training a model with the ranking SVM (Joachims, 2002)

This paper is organised as follows. Section 2 overviews the related work, and in Section 3, we define the task setting and propose a method for Japanese PAS analysis. Section 4 discusses the evaluation results and Section 5 concludes the paper.

2 Related work

Basic features for the PAS analysis were proposed in the studies in English (Gildea and Jurafsky, 2002). Unlike English, subject ellipses frequently occur in Japanese. Thus dealing with ellipses, i.e. zero anaphora resolution, is fundamental in processing Japanese texts, and linguistic features for Japanese zero anaphora resolution have been proposed in the past research (Iida et al., 2007a; Sasano and Kurohashi, 2011; Komachi et al., 2007).

The past Japanese PAS analysis methods can be categorised into two classes: one constructs an individual model for predicting each case (*ga* , *wo* , and *ni*) (Taira et al., 2008; Imamura et al., 2009; Hayashibe et al., 2011) and another constructs a single model for predicting all three cases at the same time. The

latter is further divided into two types: (i) identifying all the three cases of one predicate (Sasano and Kurohashi, 2011; Yoshikawa et al., 2011; Hangyo et al., 2013), and (ii) identifying all the three cases of all predicates in the same sentence (Ouchi et al., 2015; Shibata et al., 2016). Since *ga* arguments tend to be omitted more than other cases, we focus on identifying the *ga* case in the present study, thus our proposing method belongs to the former class.

Table 1: Features for PAS analysis

category	ID	feature name	description
predicate	1	lemma	a lemma of the predicate
	2	word origin	originated in Japanese, Chinese, other language or compound
	3	parts of speech	POS of the predicate
	4	conjugation form	a conjugation form of the predicate
	5	conjugation type	a conjugation type of the predicate
	6	surface form	a surface form of the predicate
argument	7	lemma	a lemma of the argument candidate
	8	word origin	originated in Japanese, Chinese, other language or compound
	9	parts of speech	POS of the argument candidate
	10	surface form	a surface form of the argument candidate
	11	case marker	a case particle following the argument candidate
	12	semantic category	a semantic category of the argument candidate
predicate and argument	13	lemma pair	a pair of lemmas of the predicate and the argument candidate
	14	distance	distance between the predicate and the argument candidate
	15	intra/inter	a binary value indicating if the predicate and the argument candidate are in the same sentence or not
	16	intra/inter+case marker	combination of the feature 11 and 15
	17	semantic category pair	a pair of semantic categories of the predicate and the argument candidate
	18	dependency	dependency type: direct dependency, indirect dependency and no dependency

3 Introducing eye gaze information into PAS analysis

3.1 Task setting

The task in this study is identifying the *ga* argument of a specified predicate in a text. We particularly focus on the *ga* case since it tends to be omitted more than other cases in Japanese. Given a target predicate and argument candidates preceding the predicate in a text as an input, the learnt model is expected to select a candidate as the correct *ga* argument as the output. The goal of this study is to show that eye gaze information is useful for training the PAS analysis model.

3.2 Detecting fixations

As detailed below, we detect fixations from the recorded gaze sequence by using the Dispersion-Threshold Identification Algorithm (Salvucci and Goldberg, 2000). A fixation on a word in texts is widely believed to have some relation with the cognitive process on that word (Just and Carpenter, 1980). The overview of the algorithm is described below.

1. A gaze point is added to a set one by one as far as the following conditions hold.
   - All gaze points in the set resides within the distance threshold D from the centre-of-gravity of the set.
   - No tracking error was flagged in the set.

   Just before violating the above conditions, the centre-of-gravity of the set is identified as a fixation candidate.
2. Repeat Step 1. to the rest of the gaze sequence.
3. For each fixation candidate, if its duration time is T or longer, we identify the candidate as a fixation.

Following Mitsuda et al. (2013), we set the space and time threshold D and T as 16 pixels and 100 msec respectively. By making the correspondence between the fixation points and the bounding boxes of argument candidates, we obtain the data indicating what argument candidates the annotators looked at at a certain duration at a certain time point.

3.3 Features

We use the features proposed in the past studies (Taira et al., 2008; Imamura et al., 2009) to represent each argument candidate as shown in Table 1. The distance feature d is calculated by the number of words between the predicate and the candidate, which is normalised to $d \in [0, 1]$. The semantic category feature adopts the categories defined in the Japanese thesaurus 'Nihongo Goi Taikei' (Ikehara et al., 1997).

3.4 Ranking argument candidates

We make the ranking of argument candidates for each training instance represented in terms of the features in Table 1 by using the fixations in the following way.

1. The correct candidate is placed at the top of the ranking.
2. The most frequently fixated candidate other than the correct one follows the correct candidate in the ranking.
3. The candidates with no fixation are placed at the bottom of the ranking with equal rank.
4. Any other candidates are excluded from the ranking.

Using these rankings of argument candidates as training data for the ranking SVM (Joachims, 2002), we estimate the model parameter. In the test phase, the most highly ranked candidate by the model is considered as the model output. Note that we do not require any eye gaze information in the test phase. The eye gaze information is required only for estimating the model parameters.

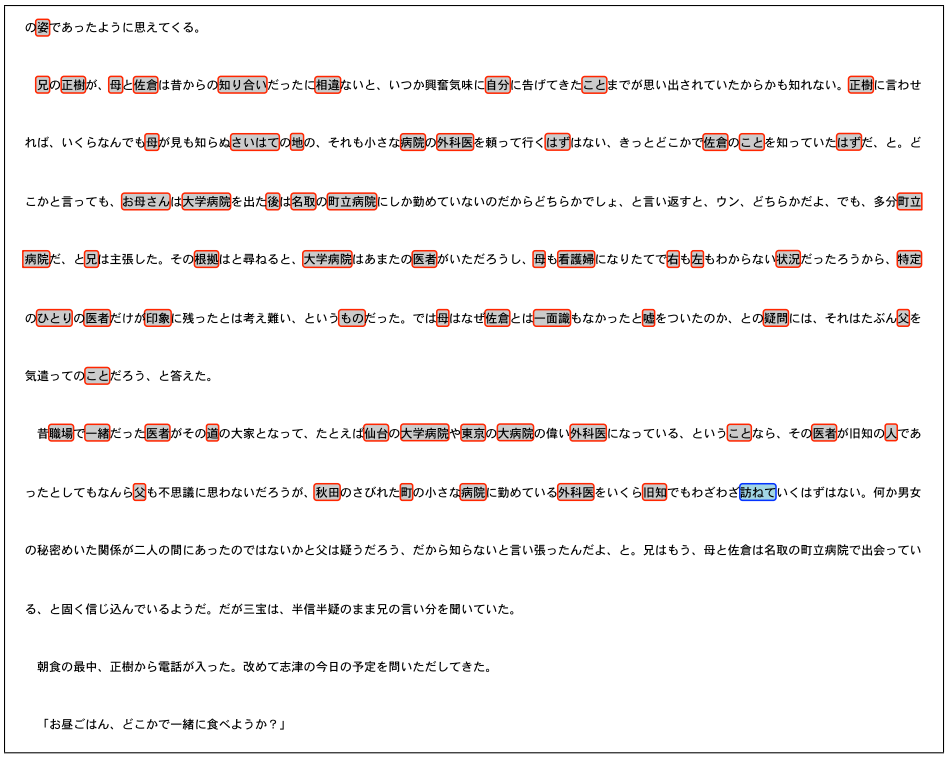

Figure 1: Screenshot of annotation interface

4 Evaluation

4.1 Data

We use the data collected by Mitsuda et al. (2014) for evaluation. Mitsuda et al. (2014) conducted an experiment for collecting annotator's behavioural data during the PAS annotation in Japanese texts. Given a single predicate in a text in which its argument candidates were marked on the screen, the annotators were instructed to identify the *ga* (nominative) argument of the target predicate by clicking it with a mouse. Figure 1 shows a screenshot of the annotation interface, in which a single target predicate in the text is highlighted in blue and *ga* argument candidates are highlighted in gray.

The texts used in their experiment were sampled from Balanced Corpus of Contemporary Written Japanese (BCCWJ) (Maekawa et al., 2014). BCCWJ contains approximate 100 million words collected from around 170 thousand texts of various domains. The texts are annotated with various kinds of information at bibliographic and morphological levels. BCCWJ has two types of schema for dividing a sentence into words: Long Unit Word (LUW) and Short Unit Word (SUW). Roughly speaking, an LUW corresponds to a compound noun, whereas an SUW corresponds to a component word of the compound. The LUW were used as argument candidates in their experiment.

BCCWJ consists of three sub-corpora (Publication, Library, and Special-purpose) and each sub-corpus has several registers. For example, PB register, whose texts are sampled from books, is a part of the publication sub-corpus.

About one percent of BCCWJ is defined as the "core data", and the core data is manually annotated with richer linguistic information. The core data annotated with dependency structures, coordinate structures, coreference relations and predicate argument structures is particularly called BCCWJ-DepParaPAS (Ueda et al., 2015; Maekawa et al., 2014). BCCWJ-DepParaPAS adopts the annotation schema of NAIST Text Corpus (Iida et al., 2007b) where three obligatory arguments, *ga* (nominative), *wo* (accusative) and *ni* (dative) are annotated at the SUW level.

The 221 texts used in their experiment were sampled from the PB register of BCCWJ-DepParaPAS, thus they have rich linguistic information including the PAS information. Among these 221 texts we discarded 37 texts because of the discrepancy in the annotation schema between BCCWJ-DepParaPAS and the experiment conducted by Mitsuda et al. (2014). The remaining 184 texts comprise 107 texts with intra-sentence *ga* arguments and 77 texts with inter-sentence ones. The number of candidates including the correct one in a text ranges from 12 to 109, with the median being 60.

In the experiment by Mitsuda et al. (2014), the texts were independently annotated by 20 annotators. During the annotation, annotator eye gaze was captured by the eye tracker Tobii T60 at intervals of 1/60 second. Although recent development of the eye-tracking technology enables us to capture eye gaze handily and precisely, we have still errors in the eye tracking data due to various factors such as the ambient lighting conditions, the annotator's glasses, and the characteristics of annotator's eyes. Among data from 20 annotators, we discarded the data from 13 annotators because their data included a session the tracking error rate of which exceeded 30%. Here "a session" stands for a single annotation session in which an annotator chooses a *ga* argument of the specified predicate in a single text. In summary, we utilise the data consisting of the 184 texts annotated by seven annotators.

Training data We prepare the following three types of models for evaluation and construct the training data for each model from the data explained above.

- **Binary Regression (BiReg) model**:
  This model chooses the argument candidate with the highest regression value as the correct *ga* argument. In the training examples, only the correct argument, i.e. the manually annotated *ga* argument, is considered a positive example, and all other candidates in the text are negative examples.

- **Distance Ranking (DRank) model**:
  This model ranks the argument candidates according to their plausibility of being the *ga* argument of the specified predicate. The distance between the predicate and the candidate is used for calculating the rank. The training examples are created as follows. For each annotation instance, the correct

argument is placed at the top of the ranking, and the other candidates are ranked in the ascending order of their distance feature, i.e. the normalised number of LUWs between the predicate and the candidate. We prepare this model for verifying the effectiveness of the ranking model based on the other metric than the fixation frequency.

- **Fixation Ranking (FixRank) model**:
  This model also ranks the argument candidates according to their plausibility of being the *ga* argument of the specified predicate. Training examples are created based on the number of fixations on the candidates as described in 3.4.

Test data We sampled 29,519 predicate instances from the PB register in the BCCWJ core data: 21,816 intra-sentence instances and 7,703 inter-sentence instances. We kept the range of the number of candidates in a text of the test data as the same as that of the training data, ranging from 12 to 109 with the median being 48.

4.2 Results and discussion

For the training of the BiReg model, we utilised Classias (Okazaki, 2009). As a learning algorithm, L2 regularised logistic regression was adopted. For the training of the DRank and FixRank models, we utilised SVM$^{\text{rank}}$ (Joachims, 2006). As a slack variable, L1-norm was adopted. We prepared four variations of the feature set for model training: a base set (F_{base}), the base set with semantic category features (F_{sem}), the base set with syntactic dependency features (F_{syn}), and the base set with both semantic and syntactic features (F_{synsem}). These feature sets are summarised in Table 2.

Table 2: Variations of feature set

feature set	feature ID defined in Table 1
F_{base}	1–11, 13–16
F_{sem}	1–17
F_{syn}	1–11, 13–16, 18
F_{synsem}	1–18

The all models estimated *ga* likeliness of each candidate, and then selected the candidate with the maximum score as the *ga* argument. If the selected candidate agreed with the answer, it was judged to be correct. Even though the selected candidates were in the same coreference chain as the answer argument, we judged it as wrong selection. We adopted a strict criterion in correctness.

Table 3: Evaluation result (Accuracy)

model	feature set	intra	inter	total
BiReg	F_{base}	0.56	0.04	0.42
	F_{sem}	0.48	**0.06**	0.37
	F_{syn}	0.58	0.03	0.44
	F_{synsem}	0.52	0.05	0.40
DRank	F_{base}	0.47	0.01	0.35
	F_{sem}	0.47	0.01	0.35
	F_{syn}	0.50	0.01	0.37
	F_{synsem}	0.51	0.01	0.38
FixRank	F_{base}	0.55	0.02	0.41
	F_{sem}	0.49	0.02	0.37
	F_{syn}	**0.63**	0.02	**0.47**
	F_{synsem}	0.58	0.02	0.43

Table 3 shows the accuracy of each model and feature set combination. We calculated the accuracy for two groups: intra-sentence cases, i.e. a predicate and its *ga* argument are in the same sentence, and inter-sentence cases, i.e. they are not in the same sentence. Table 3 shows that FixRank+F_{syn} shows the

highest accuracy in the 'intra-sentence' and 'total' columns, while the BiReg model, particularly with F_{sem}, shows the better accuracy in the 'inter-sentence' column.

As far as this result is concerned, the FixRank+F_{syn} model predicts intra *ga* arguments the best of all the models. This supports our hypothesis that frequent looks at argument candidates imply their plausibility of being the argument of the predicate, and utilising eye gaze information contributes to the improvement in parameter estimation of the PAS analysis model.

The table also showed that the semantic feature set F_{sem} does not work well except for the inter-sentence cases with the BiReg model. We automatically assigned the semantic categories to the arguments. As Taira et al. (2008) did, it is worthwhile to see if manual assignment of the semantic categories would improve the effectiveness of F_{sem}.

We need to mention that the DRank model showed the worst performance among three models. The training examples for the DRank model would contain more superfluous information than the FixRank model because the candidates were rigidly ordered in the ascending order of the distance feature, thus there was no candidate of equal rank. This rigid ranking could make the DRank model fail to capture better negative examples.

Table 4: Comparison between BiReg+F_{syn} model and FixRank+F_{syn} model

(15) intra/inter	(18) dependency	(11) case marker	BiReg+F_{syn} P	BiReg+F_{syn} R	BiReg+F_{syn} F	FixRank+F_{syn} P	FixRank+F_{syn} R	FixRank+F_{syn} F
intra	direct	*ga*	0.949	0.884	0.915	0.948	0.975	0.962
		others	0.513	0.463	0.487	0.403	0.693	0.509
	indirect	*ga*	0.227	0.602	0.330	0.242	0.561	0.338
		others	0.184	0.166	0.175	0.156	0.103	0.124
	no	*ga*	0.294	0.892	0.442	0.352	0.741	0.477
		others	0.239	0.469	0.316	0.306	0.290	0.297
inter	no	*ga*	0.232	0.050	0.082	0.284	0.025	0.046
		others	0.247	0.031	0.055	0.172	0.014	0.025

"others" in the case marker column includes arguments without case markers.
P, R, and F denote precision, recall, and F-measure, respectively.

For further analysis, we focused on the specific three features: (11) case marker, (15) intra/inter, and (18) dependency, and calculated precision (P), recall (R), and F-measure (F) for the test cases with each combination of these features. Table 4 shows the comparison between the BiReg+F_{syn} model and the FixRank+F_{syn} model that show the highest accuracy in total in Table 3.

The notable difference between these two model is that the FixRank model shows the better F-measures for directly dependent arguments, particularly in *ga* arguments. Concerning the directly dependent *ga* argument cases, the FixRank shows the better recall value with the similar precision value. In contrast, in the cases of directly dependent 'other' case markers, the BiReg shows the better precision value. We investigated the number of directly dependent arguments that each model selected as the answer. The FixRank model selected 19,612 directly dependent arguments, and 13,751 *ga* argument among them, while the BiReg model selected 12,520 directly dependent arguments with 7,208 *ga* arguments. These numbers suggest that the FixRank model tends to choose directly dependent arguments regardless of their case markers.

Concerning the FixRank model, we further investigated the number of the second rank training candidates that directly depend on the target predicate, i.e. the directly dependent "better negative examples", to obtain 428 candidates out of 1,288 candidates ($= 184$ texts $\times$ 7 annotators) that make 33% of the total training examples. On the other hand, the number of the correct arguments that directly depend on the target predicate is 35 out of 184 examples, making 19% of the texts. These numbers suggest that the annotators tend to look at directly dependent arguments more during the annotation, the FixRank model tends to select directly dependent arguments as our method proposes frequently fixated arguments as "better negative candidates". This tendency would explain the poor performance of the FixRank model in the inter-sentence cases.

5 Conclusion

We proposed utilising the information of annotator eye gaze during their annotation for estimating the parameters of the Japanese PAS analysis model. Through the evaluation in which the *ga* argument of a specified predicate was identified, we confirmed the effectiveness of the eye gaze information for the PAS analysis. We gained 0.05 point increase in accuracy by introducing the eye gaze information into the parameter estimation. The accuracy for the inter-sentence arguments, however, still remains very low. Moreover, the eye gaze information does not work well on the inter-sentence arguments. We need to refine the usage of the eye gaze information for further improvement of the PAS analysis. Currently we use only the fixation frequency, but the fixation duration might provide the information from different aspects. Also instead of utilising all fixations, their selective usage would be another exploring direction.

In the current evaluation, we used the DRank model as the baseline of the ranking model, but its performance is too poor to be a fair baseline. It would be necessary to adopt a state-of-the-art ranking model such as Hangyo et al. (2013) for further evaluation.

The eye gaze information has attracted much attention in various NLP tasks in recent years such as dialogue systems (Prasov et al., 2007; Qu and Chai, 2007), reference resolution (Prasov and Chai, 2008), dependency parsing (Barrett and Søgaard, 2015), coreference resolution (Ross et al., 2016), named entity recognition (Tomanek et al., 2010). Exploring the effectiveness of eye gaze information during annotation in other NLP tasks would be another important research direction.

Abstract

Recognizing Textual Entailment (RTE) is a fundamentally important task in natural language processing that has many applications. The recently released Stanford Natural Language Inference (SNLI[1]) corpus has made it possible to develop and evaluate deep neural network methods for the RTE task. Previous neural network based methods usually try to encode the two sentences and send them together into multi-layer perceptron, or use LSTM-RNN to link two sentence together while using attention mechanic to enhance the model's ability. In this paper, we propose to use the intensive reading mechanic, which means to re-read the sentence (read the sentence again) according to the memory of the other sentence for a better understanding of the sentence pair. The re-read process can be applied alternatively between the two sentences. Experiments show that we achieve results better than current state-of-art equivalents.

1 Introduction

For the natural language, a common phenomenon is that there exist a lot of ways to express the same or similar meaning. To discover such different expressions, the Recognizing Textual Entailment (RTE) task is proposed to judge whether the meaning of one text (denoted as *hypothesis*) can be inferred (entailed) from the other one (*premise*) (Dagan et al., 2006). A simple example is shown in Table 1. For many natural language processing applications like question answering, information retrieval which need to deal with the diversity of natural language, recognizing textual entailments is a critical step.

Most previous neural network based methods are sentence encoding-based models. They applied a large variety of methods to encode the two sentences (premise and hypothesis), such as LSTM encoder, GRU encoder and tree-based CNN encoder. Then combine them as the feature of this sentence pair and send into a deep neural network for classification. However, in the sentence encoding process, the premise and the hypothesis cannot affect each other. It is well known that the encoding procedure is just automatically learning useful features. Without the impact between the two sentences, it is difficult for the encoder to extract the sentence-relationship-specific features. Other methods mainly make use of attention mechanism to capture the word-by word alignment information while training (Rocktäschel et al., 2015) or just integrate memory network into LSTM to make the model remember more information (Cheng et al., 2016). Among them, only the attention mechanism can make the two sentences contact with each other. However, the word-by-word attention does not represent a better understanding of the sentences.

When deciding the entailment relationship between a pair of sentences, what is really matters? Unlike paraphrasing and machine translation, entailment relationship does not force the two sentences have the same meaning. Instead, as long as the premise can cover the meaning of the hypothesis, the entailment stands. Therefore, if the premise entails the hypothesis, that doesn't really mean that the words in hypothesis can be totally entailed by the words in premise. For example, "these girls are having a great

[1] http://nlp.stanford.edu/projects/snli/

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2870–2879, Osaka, Japan, December 11-17 2016.

Relationship	Premise & Hypothesis	
Entailment	Premise:	This church choir sings to the masses as they sing joyous songs from the book at a church.
	Hypothesis:	The church is filled with song.
Neutral	Premise:	This church choir sings to the masses as they sing joyous songs from the book at a church.
	Hypothesis:	The church has cracks in the ceiling.
Contradict	Premise:	This church choir sings to the masses as they sing joyous songs from the book at a church.
	Hypothesis:	A choir singing at a baseball game.

Table 1: Example of entailment / neutral / contradict eases.

time looking for seashells" can entail "the girls are outside". These entailment cases certainly cannot be solved by word-by-word alignment based methods since "outside" cannot be aligned to any of the words in the premise. Intuitively, when a human is judging the relationship of the two sentences, he/she would first read the premise, and then read the hypothesis while considering whether it can be entailed by the premise. Therefore, we intend to make the model more like human, namely, we require the model be capable of reading and thinking.

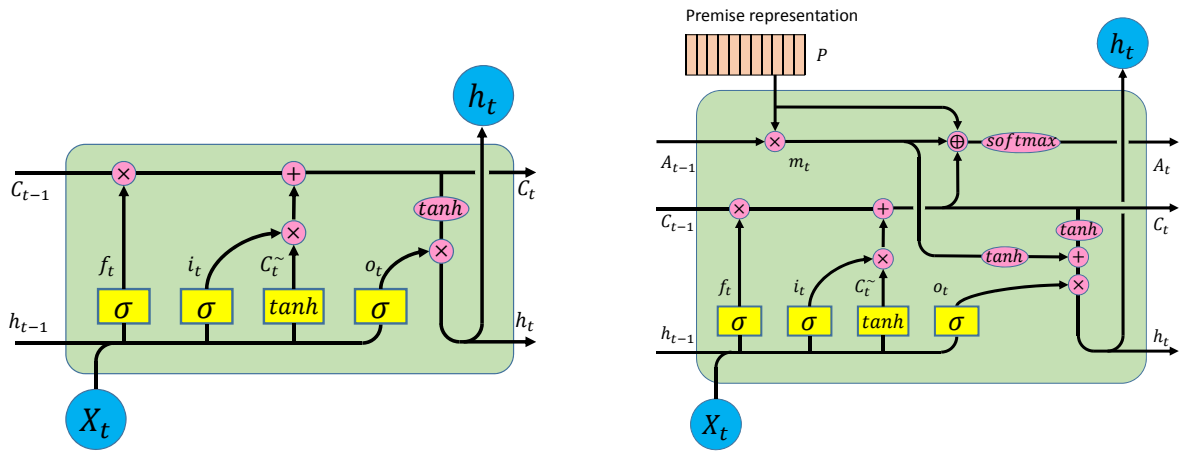
In this paper, we propose a new LSTM variant called re-read LSTM unit (rLSTM), which also take the attention vector of one sentence as an inner state while reading the other sentence. Therefore, this kind of unit is specially designed for dual sentence modeling. Then we use a standard bidirectional LSTM to read the premise, and use a bidirectional rLSTM to read the hypothesis. The output of the standard BiLSTM is taken as the general input of the bidirectional rLSTM. Experiments show that our method has outperformed the state-of-the-art approaches.

2 Related Work

Textual Entailment Recognizing (RTE) task has been widely studied by many previous work. Firstly, the methods use statistical classifiers which leverage a wide variety of features, including hand-engineered features derived from complex NLP pipelines and similarity between sentences (T and H) and sentence pairs ((T', H') and (T'', H''))(Malakasiotis and Androutsopoulos, 2007; Jijkoun and de Rijke, 2005; Wan et al., 2006; Zanzotto and Moschitti, 2006; Wang and Neumann, 2007; Dinu and Wang, 2009; Nielsen et al., 2009; Malakasiotis, 2011). This kind of methods are hard to generalize due to the complexity of feature engineering. Moreover, the hand-engineered features usually cannot represent implicit meanings of sentences.

Secondly, (Hickl, 2008; Sha et al., 2015; Shnarch et al., 2011b; Shnarch et al., 2011a; Beltagy et al., 2013; Rios et al., 2014) extract the structured information (discourse commitments or predicate-argument representations) in T-H pair and check if the information in T contains or can infer the information in H. Probabilistic methods are used for recognizing the entailment. However, these work are still based on hand-engineered features which is not easy to generalize.

Recently, neural network based methods start to show its effectiveness. Based on (Bowman et al., 2015), Rocktäschel et al. (2015) uses the attention-based technique to improve the performance of LSTM-based recurrent neural network. Then, Yin et al. (2015) applied attention mechanic to convolution neural network, Liu et al. (2016a) proposed coupled-LSTM, Vendrov et al. (2015) proposed ordered embedding, Mou et al. (2016) applied Tree-based CNN, Wang and Jiang (2015) proposed matching LSTM, Liu et al. (2016b) applied inner-attention, Cheng et al. (2016) proposed Long Short-Term Memory-Networks to improve the performance. To free the model from traditional parsing process, Bowman et al. (2016) combines parsing and interpretation within a single tree sequence hybrid model by integrating tree structured sentence interpretation into the linear sequential structure of a shift-reduce parser. Parikh et al. (2016) uses attention to decompose the problem into subproblems that can be solved separately, thus making it trivially parallelizable.



(a) LSTM Unit (b) rLSTM Unit

Figure 1: The inner architecture of the traditional LSTM unit and the re-read LSTM unit.

3 Model

3.1 Background

The LSTM architecture (Hochreiter and Schmidhuber, 1997) addresses this problem of learning long-term dependencies by introducing a memory cell that is able to preserve state over long periods of time. While numerous LSTM variants have been described, here we describe the most widely-used version.

Long short-term memory (LSTM) based recurrent neural networks (RNNs) have long been tried to apply to a wide range of NLP tasks, including RTE (Bowman et al., 2015). We define the LSTM unit at each time step t to be a collection of vectors in $\mathbb{R}^d$: an input gate i_t, a forget gate f_t, an output gate o_t, a memory cell c_t, candidate memory cell state $\widetilde{C}_t$ and a hidden state h_t. The entries of the gating vectors i_t, f_t and o_t are in $[0, 1]$. We refer to d as the memory dimension of the LSTM. The LSTM transition equations are listed in Eq 1.

$$
\begin{aligned}
i_t &= \sigma(W_i x_t + U_i h_{t-1} + b_i) & \widetilde{C}_t &= \tanh(W_c x_t + U_c h_{t-1} + b_c) \\
f_t &= \sigma(W_f x_t + U_f h_{t-1} + b_f) & c_t &= i_t \odot \widetilde{C}_t + f_t \odot c_{t-1} \\
o_t &= \sigma(W_o x_t + U_o h_{t-1} + b_o) & h_t &= o_t \odot \tanh(c_t)
\end{aligned} \tag{1}
$$

where x_t is the input at the current time step, σ denotes the logistic sigmoid function and $\odot$ denotes element-wise multiplication. Intuitively, the forget gate controls the extent to which the previous memory cell is forgotten, the input gate controls how much information is input to each unit, and the output gate controls the exposure of the internal memory state. The hidden state vector in an LSTM unit is therefore a gated, partial view of the state of the unit's internal memory cell. Since the value of the gating variables vary for each vector element, the model can learn to represent information over multiple time scales.

3.2 Re-read LSTM (rLSTM)

In the textual entailment recognition problem, we need to model the relationship of two sentences and judge whether the premise can entail the hypothesis. As for human beings, maybe the most nature way for the judging process is first read the premise, remember it, and then read the hypothesis while thinking whether the premise can entail the hypothesis. Intuitively, we can improve the performance of RTE by adding some human nature to deep neural network models. In this paper, we intend to make the LSTM unit capable of thinking the relation between premise and hypothesis while reading them. Our proposed LSTM architecture is shown in Figure 1b, we call it re-read LSTM (rLSTM). The rLSTM unit is specially designed for dual sentence modeling, it is applied only when dealing with the second sentence. Therefore, in Figure 1b, there is a general input to rLSTM: the premise representation. This representation is composed of each word's representation in the premise. The word's representation can

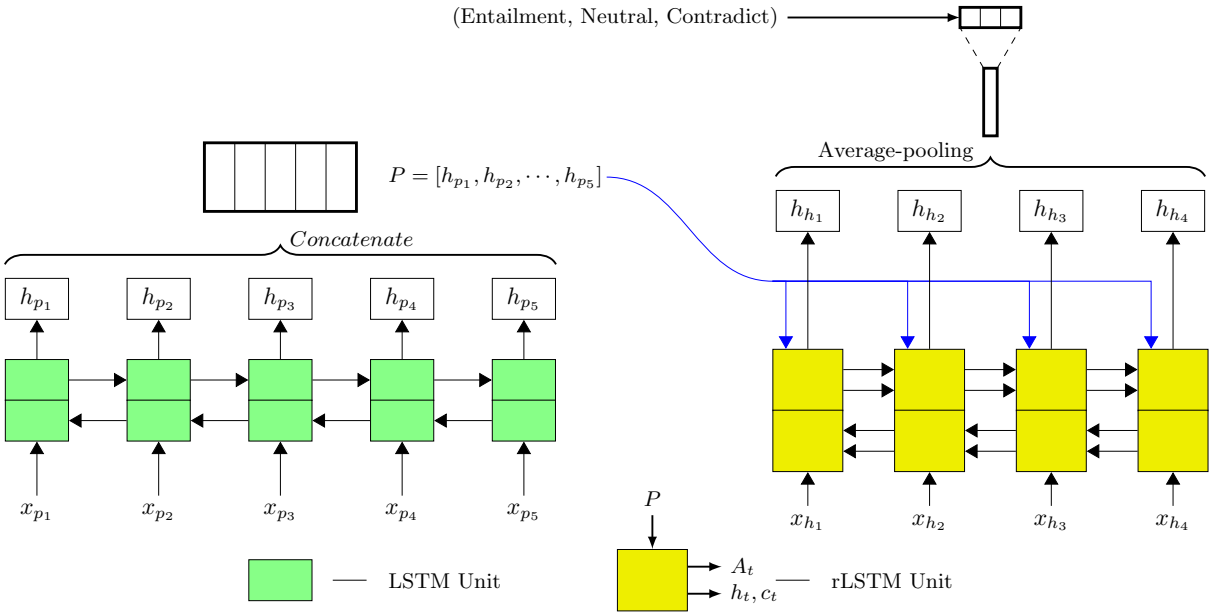


Figure 2: The architecture of our model.

be the word embedding or another plain LSTM's output. We add an input and an output to rLSTM unit which represents the attention over the words in the premise at time step $t-1$ (A_{t-1}) and $t(A_t)$. Given the attention at time $t-1$ and the premise representation P, we can get the current understanding of the premise, or the memory m_t:

$$m_t = A_{t-1}P \tag{2}$$

where $A_{t-1} \in \mathbb{R}^L$, $P \in \mathbb{R}^{d \times L}$, L represents the number of words in the premise.

The model needs to consider the entailment relationship. Therefore, the memory of the premise should also affect the hidden state of the hypothesis. With the information of premise, the hidden state of the hypothesis can learn more specific information for their relationship. So we add the memory of the premise and the memory cell to affect the hidden state vector as follows:

$$h_t = o_t \odot \Big(\tanh(c_t) + \tanh(m_t) \Big) \tag{3}$$

Intuitively, each time the model reads one more word in the hypothesis, it should be clearer about what information in the premise is more important respected to the hypothesis. So the A_{t-1} is the premise's attention in time step $t-1$, after read one word, it became A_t, the information represented by which is more focus on the relationship between the premise and the hypothesis. Therefore, the origin LSTM's memory cell can affect the attention in time step t:

$$\begin{aligned} \alpha &= W_p P + W_m m_t + W_c C_{t-1} \\ A_t &= softmax(w\alpha) \end{aligned} \tag{4}$$

where $W_p \in \mathbb{R}^{d \times d}$, $W_m \in \mathbb{R}^{d \times d}$, $W_c \in \mathbb{R}^{d \times d}$, $w \in \mathbb{R}^d$ are weight matrices or vectors.

3.3 Our Model

Our model is shown in Figure 2. We use the standard LSTM to deal with the premise. The output of the standard LSTM $h_{p_1}, h_{p_2}, \cdots, h_{p_n}$ are concatenated as a matrix P:

$$P = [h_{p_1}, h_{p_2}, \cdots, h_{p_L}] \tag{5}$$

where $P \in \mathbb{R}^{d \times n}$, L represents the number of words in the premise.

	Train	Dev	Test
Entailment	183416	3329	3368
Neutral	182764	3235	3219
Contradict	183187	3278	3237
Total	549367	9842	9824

Table 2: Distribution of Entailment Classes in SNLI

And then, we take P as the general input of re-read LSTM (rLSTM), which is used to deal with the hypothesis as is shown in Formula 6.

$$\begin{aligned} h_{h_i}^{\rightarrow} &= rLSTM(P, A_{t-1}, h_{h_{i-1}}, c_{t-1}) \\ h_{h_i}^{\leftarrow} &= rLSTM(P, A_{t+1}, h_{h_{i+1}}, c_{t+1}) \\ h_{h_i} &= [h_{h_i}^{\rightarrow}, h_{h_i}^{\leftarrow}] \end{aligned} \tag{6}$$

where the forward output $h_{h_i}^{\rightarrow}$ and the backward output $h_{h_i}^{\leftarrow}$ are all calculated by re-read LSTM unit. We concatenate the forward output $h_{h_i}^{\rightarrow}$ and the backward output $h_{h_i}^{\leftarrow}$ as the final output of the bidirectional rLSTM: h_{h_i}.

Then, we average the outputs of rLSTM as the final representation of the premise-hypothesis sentence pair:

$$S = \frac{1}{n}\sum_{i=1}^{n} h_{h_i} \tag{7}$$

where $S \in \mathbb{R}^d$ is the final representation. Then S is fed into a logistic classifier:

$$O = WS + b \tag{8}$$

where $W \in \mathbb{R}^{3\times d}$, $b \in \mathbb{R}^3$ are the parameters, $O \in \mathbb{R}^3$ is the final output of this premise-hypothesis pair, each entry contains the score of an entailment class (entailment, neutral, contradiction).

3.4 Training

We define the ground-truth label vector y for each premise-hypothesis pair as a binary vector. If this premise-hypothesis pair belongs to class i, only the i-th dimension $y(i)$ is 1 and the other dimensions are set to 0. In our model, the RTE task is classification problem and we adopt cross entropy loss as the objective function. Given the parameters set $\theta = \{\theta_{LSTM}, \theta_{rLSTM}, W, b\}$, where θ_{LSTM} represents the LSTM neural network parameters, θ_{rLSTM} represents the rLSTM neural network parameters. the objective function for a premise-hypothesis pair can be written as,

$$J(\theta) = -\sum_{i} y(i)\log(O(i)) + \frac{\lambda}{2}\|\theta\|^2 \tag{9}$$

To compute the network parameter θ, we maximize the log likelihood $J(\theta)$ through stochastic gradient descent over shuffled mini-batches with the Adadelta (Zeiler, 2012) update rule.

4 Experiment

In this section, we present the evaluation of our model. We first perform quantitative evaluation, comparing our model with previous works. We then conduct some qualitative analyses to understand how our rLSTM model works in matching the premise and the hypothesis.

4.1 Datasets and Model Configuration

We conduct experiments on the Stanford Natural Language Inference corpus (SNLI) (Bowman et al., 2015). The original data set contains 570,152 sentence pairs, each labeled with one of the following relationships: entailment, contradiction, neutral and $-$, where $-$ indicates a lack of consensus from the

human annotators. We discard the sentence pairs labeled with $-$ and keep the remaining ones for our experiments. Table 2 summarizes the statistics of the three entailment classes in SNLI.

We use 300 dimensional GloVe embeddings (Pennington et al., 2014) to represent words, which is trained on the Wikipedia+Gigaword dataset. The embeddings of unknown tokens are initialized by random vectors.

4.2 Methods for Comparison

Although we list all of the approaches designed for recognizing textural entailment task on the SNLI dataset in Table 3, we mainly want to compare our model with the word-by-word attention model by Rocktäschel et al. (2015), long short term memory network model by Cheng et al. (2016) and the decomposable attention model by Parikh et al. (2016) since they are either related to our work or achieved the state-of-the-art performance on the SNLI corpus.

We did the following ablation experiments:

- rLSTM: our final model.
- rLSTM - C info: in this model, in the rLSTM unit, the origin memory cell C_{t-1} cannot affect the next attention A_t. Then the Formula 4 is changed into Formula 10. We intend to see whether the origin memory cell's information can help the model to focus on more important information in the premise.

$$\begin{aligned} \alpha &= W_p P + W_m m_t \\ A_t &= softmax(w\alpha) \end{aligned} \tag{10}$$

- rLSTM - A info: in this model, in the rLSTM unit, the premise's memory m_t cannot affect the next hidden state h_t. Then the Formula 3 is changed into Formula 11, which is the origin formula of LSTM. We intend to see whether the current understanding of the premise can help the model to make better decision of the relation between the premise and the hypothesis.

$$h_t = o_t \odot \tanh(c_t) \tag{11}$$

- rLSTM - A&C info: in this model, in the rLSTM unit, the origin memory cell C_{t-1} cannot affect the next attention A_t and the premise's memory m_t cannot affect the next hidden state h_t. Then the LSTM part in the rLSTM is the same as the origin LSTM, and the attention part is updated each step only based on the model's understanding of the premise itself.

4.3 Quantitative Results

The experiment results are listed in Table 3. The experiment results are listed in Table 3. We can see that when we set d to 300 our final model (rLSTM) achieves an accuracy of 87.5% on the test data, which to the best of our knowledge is the highest on this data set. When we remove the effect of the origin memory cell C_{t-1} on the next attention A_t (rLSTM $-$ C info), we found that the performance has dropped 2.7 percent. This phenomenon shows that the memory of the hypothesis can indeed contribute to a better understanding of the premise. When we remove the effect of the premise's memory m_t on the next hidden state h_t, the performance dropped again. That means the premise's memory can indeed help understand the hypothesis.

When comparing our rLSTM model with Rocktäschel et al. (2015)'s LSTM word-by-word attention model under the same setting with $d = 100$, we can see that our performance on the test dataset is still higher than that of Rocktäschel et al. (2015)'s (**student t-test,** $p < 0.05$). One advantage of our model compared to Rocktäschel et al. (2015)'s model is that our attention is inside the LSTM unit, so that it can be affected by the inner memory of LSTM and can also affect the LSTM's inner state. This mechanic can provide our model more flexibility to achieve a better result.

Our result has also outperformed Cheng et al. (2016)'s 300d LSTMN model (**student t-test,** $p < 0.05$). LSTMN tends to use memory network to remember the sentence while making intra-attention (within a sentence) and inter-attention (between two sentences) complement each other to get good results.

This paper	300D rLSTM - A&C info	1.9m	88.6	84.7

Table 3: Train/test accuracies on the SNLI dataset and number of parameters (excluding embeddings) for each approach.

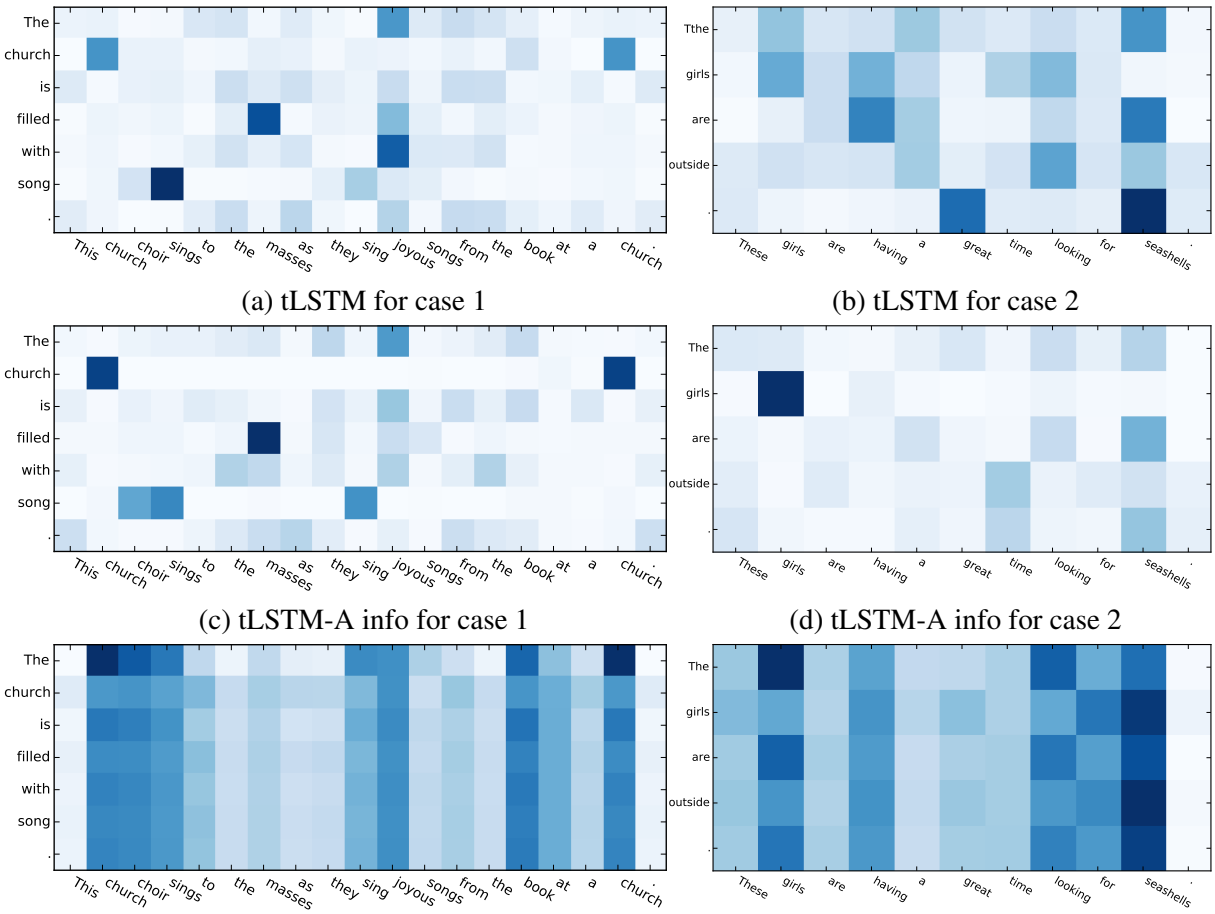
However, the intra-attention is generated just according to the information of the current sentence itself and the inter-attention focus on generating a better alignment of the two sentences without considering a better understanding of the sentence relationship. Our model intends to better understand the relation between two sentences by making the two sentence's information affect each other, which helps our model achieves good result.

4.4 Qualitative Analyses

Figure 3 listed the visualizations of the attention changing process. Figure 3a, Figure 3c, Figure 3e are the visualization of the entailment case in Table 1. Figure 3b, Figure 3d, Figure 3f are the visualization of the case in Section 1.

In Figure 3a, we can see that as the tLSTM is dealing with the hypothesis, the model pays more attention on the real meaning of the two sentences instead of simple word alignment. For example, when dealing with the word "song" in the hypothesis, the model focus more on the word "sing" in the main clause instead of the word "sing" in the subordinate clause (Figure 3c). Figure 3b has the similar phenomenon. After dealing with "outside", the model tend to focus on the words related to "outside" such as "seashells". Instead, in Figure 3d, after remove the "A info", the model cannot focus on useful information any more.

In addition, when we stop allowing the hypothesis's memory to affect the attention of the premise,



(a) tLSTM for case 1

(b) tLSTM for case 2

(c) tLSTM-A info for case 1

(d) tLSTM-A info for case 2

(e) tLSTM-C info for case 1

(f) tLSTM-C info for case 2

Figure 3: The attention visualization analysis of tLSTM, tLSTM-A info and tLSTM-C info. The premise is on the x axis, the hypothesis is on the y axis.

in Figure 3e and Figure 3f, the model's attention performs very poor. Therefore, the test accuracy of tLSTM−C info is much lower than tLSTM.

5 Conclusion

In this paper, we proposed a special LSTM architecture for the task of textural entailment recognizing. Inspired by the process of human reading, we bring re-read mechanic into the LSTM unit and call it re-read LSTM (rLSTM). Re-read LSTM is specially designed for dual sentence modeling and it takes the representation of the premise as general input when dealing with the hypothesis. There are two main differences between rLSTM and LSTM. First, in rLSTM, the memory of the hypothesis can affect the attention of the premise, which means the hypothesis can help the model better understanding the premise. Second, the premise's memory can affect the hidden state of the hypothesis, which means the premise can provide useful information to help the model make better decision of the relation between the premise and the hypothesis. And then, we designed an architecture for the RTE task, we use a traditional bidirectional LSTM to deal with the premise and use bidirectional rLSTM to deal with the hypothesis. Finally, the average of the bidirectional rLSTM's outputs can be used for predicting the relationship between the premise and the hypothesis.

Experiments on the SNLI corpus showed that the rLSTM model outperformed the state-of-the-art performance reported so far on this data set. Moreover, closer analyses on the attention vectors revealed that our rLSTM mechanics indeed provide and generate better attention on the premise, which represents a better understanding of the sentences.

Abstract

Existing systems deliver high accuracy and F1-scores for detecting paraphrase and semantic similarity on traditional clean-text corpus. For instance, on the clean-text Microsoft Paraphrase benchmark database, the existing systems attain an accuracy as high as 0.8596. However, existing systems for detecting paraphrases and semantic similarity on user-generated short-text content on microblogs such as Twitter, comprising of noisy and ad hoc short-text, needs significant research attention. In this paper, we propose a machine learning based approach towards this. We propose a set of features that, although well-known in the NLP literature for solving other problems, have not been explored for detecting paraphrase or semantic similarity, on noisy user-generated short-text data such as Twitter. We apply support vector machine (SVM) based learning. We use the benchmark Twitter paraphrase data, released as a part of SemEval 2015, for experiments. Our system delivers a paraphrase detection F1-score of 0.717 and semantic similarity detection F1-score of 0.741, thereby significantly outperforming the existing systems, that deliver F1-scores of 0.696 and 0.724 for the two problems respectively. Our features also allow us to obtain a rank among the top-10, when trained on the Microsoft Paraphrase corpus and tested on the corresponding test data, thereby empirically establishing our approach as ubiquitous across the different paraphrase detection databases.

1 Introduction

Detecting paraphrase, and more specifically, given a pair of input natural language texts identifying whether one is a paraphrase of the other, has been a challenging research problem. Over a number of years and volumes of research, the paraphrase detection systems have emerged as robust and well-performing ones, especially for "clean text corpus", such as the Microsoft Paraphrase Corpus (Dolan et al., 2004). Semantic similarity detection has been another related problem of interest, where the objective is to identify how similar is one text with respect to another (Harispe et al., 2015). Since, paraphrases are expected to have significant semantic similarity (Corley and Mihalcea, 2005) (Mihalcea et al., 2006), systems performing well for paraphrase detection can also be intuitively expected to perform well for semantic similarity detection of a pair of text inputs. It is worth noting that, for benchmark "clean text corpus" data such as the Microsoft Paraphrase Corpus database, the paraphrase detection systems deliver an impressive performance, with a high F-score of 0.8596.

While the literature around paraphrase and semantic similarity detection has matured along the directions of clean text corpus, much work remains to be done to attain commendable performances in the paradigm of noisy short-text inputs, such as user-generated short-text content found on Twitter. Some initial work has been recently carried out on the benchmark SemEval 2015 data (Xu, 2014) (Xu et al., 2015); however, the performance of the systems developed till date leave much desired. Detecting paraphrases and semantic similarity on such text is inherently difficult; however, we believe there is scope for improvement over the current 0.724 performance, that the current state of the art delivers (Xu et al., 2014). Given the well-understood importance of paraphrase detection in multiple fields of NLP, such as

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2880–2890, Osaka, Japan, December 11-17 2016.

review summarization, opinion mining and information matching, to name a few, and practical applications such as first-story detection (Petrović et al., 2012), it is of paramount importance to develop highly accurate paraphrase detectors for such user-generated noisy short-text corpus.

This motivates us to attempt to improve the performance of detecting paraphrases and semantic similarity on user-generated short-text on noisy platforms such as Twitter. We propose a feature-set driven approach, and use support vector machine (SVM) based machine learning. We rely upon lexical, syntactic, semantic and pragmatic features of a given pair of tweets, to label whether these two tweets are paraphrases of each other. We further obtain the semantic similarity scores of the pairs, and thereby assign semantic similarity labels. We validate our work against the benchmark SemEval 2015 data, and find our system (F1-score 0.741) to outperform the known state of the art (best known F1-score 0.724), that includes all of the feature-based approaches as well as deep-learning based approaches.

The main contributions of our work are the following.

- We provide a machine learning based model, and a set of lexical, syntactic, semantic and pragmatic features, for detecting paraphrases on user-generated noisy Twitter short-text content data.
- We empirically show the goodness of the proposed features, on a benchmark Twitter paraphrase corpus. Our system outperforms all the systems that exist in the state of the art.
- We further demonstrate the effectiveness of our feature set on benchmark clean-corpus text data, namely Microsoft Paraphrase dataset, and obtain a rank within the top 10 existing systems, by training our system (our features) on their dataset, and testing on their dataset as well. This empirically establishes the goodness of our proposition across different types of text.

2 Related Work

The importance of detecting paraphrases for different information processing applications, has been well-accepted by researchers. Over the long-standing history of research on paraphrase detection, a volume of significant work has been carried out.

Substantial work has been carried out in the space of detecting paraphrases on traditional clean-text corpus, by several researchers. The Microsoft Paraphrase corpus (Dolan et al., 2004), that presents sentence pairs from newswire text, serves as the long-standing baseline for such text. As observed by (Ji and Eisenstein, 2013), there are three high-level approaches. (1) String similarity metrics, comprising of n-gram overlaps and BLEU features, that have been proposed by (Wan et al., 2006), and (Madnani et al., 2012). (2) Parse structure based syntactic operations, such as by (Wu, 2005), and (Das and Smith, 2009). (3) Distributional methods, such as latent semantic analysis (LSA), by (Landauer et al., 1998). (Kauchak and Barzilay, 2006) propose a distributionally similar alternative based approach. (Socher et al., 2011) propose a feature auto-encoder based approach, combining word representations, building upon recursive auto-encoding. (Blacoe and Lapata, 2012) demonstrate the effectiveness of combining latent representations with simple element-wise operations, for the purpose of identifying semantic similarity amongst larger text units. (Ji and Eisenstein, 2013) propose a discriminative term weighting metric, namely TF-KL_D to outperform TF-IDF, and show that "using the latent representation from matrix factorization as features in a classification algorithm substantially improves accuracy". They combine the latent features with fine-grained n-gram overlap features, improving the state of the art significantly.

Recently, a few initial works have been carried out for detecting paraphrases and semantic similarities on user-generated noisy social network and microblog short-text, such as Twitter. In a recent seminal paper, (Xu et al., 2014) proposed a joint word-sentence approach based model, and applied a multi-instance learning assumption (Dietterich et al., 1997) that "two sentences under the same topic are paraphrases if they contain at least one word pair that is indicative of sentential paraphrase". They observe that the "at least one anchor" overlap works well for short text situations, such as on Twitter, though they are not necessarily effective for traditional long texts, and thereby design a graphical model to discriminatively determine whether a given pair of words are paraphrases. They create a dataset (the collection of which is found in further detail in (Xu, 2014)), and empirically demonstrate their system. They obtain an F1-score

for semantic similarity of 0.724 by their system, and claim the human upper bound to have an F1-score of 0.823. While they do not report their paraphrase detection score, our experimentations using the data[1] and the corresponding released code[2] finds their system to yield an F1-score of 0.696.

Subsequently, a number of researchers attempted to solve the problem of paraphrase detection, as part of the task proposed by (Xu et al., 2015). The model by (Eyecioglu and Keller, 2015) proposes to have unigram and bigram features for characters and words, and explores the overlap (and non-overlap) of these features for determining whether one tweet is a paraphrase of the other. While the authors do not address the semantic similarity detection problem, the paraphrase detection problem yields an F1-score of 0.674. In another work applied on the same data, (Zarrella et al., 2015) obtain a paraphrase detection F1-score of 0.667, and a semantic similarity score of 0.724. They use "mixtures of string-matching metrics, tweet-specific distributed word representation alignments, recurrent neural networks to model similarity between those alignments, and distance measurements on pooled latent semantic features", and tie these systems together using logistic regression. In addition to using string based, corpus based and syntactic features, (Zhao and Lan, 2015) propose "novel features based on distributed word representations, learned using deep learning paradigms". They attained an F1-score of 0.662 for paraphrase detection on the given dataset.

As apparent from the above discussion, the state of the art for paraphrase detection on noisy short-text can potentially be significantly improved. Different classes of features, with different implications, need to be applied for making such improvement. Our work addresses this, and also attempts to explore the applicability of the proposed model across other, clean-text corpus. Our system, with its feature set that have not been used on noisy Twitter data before, outperforms the state of the art systems for both paraphrase detection as well as semantic similarity identification.

3 Methodology

We choose a machine-learning based approach to solve the problem at hand. We identify several features of different types, and apply Support Vector Machine (SVM) based learning.

3.1 Preprocessing

While by itself we do not use any *preprocessing feature* per se, we carry out preprocessing steps that impact the performance of our overall system. The preprocessing steps include the following.

- **Topic phrase removal:** We remove the topic phrase from the tweet pairs, as this does not provide any information to distinguish given tweet pairs, but causes unnecessary gram overlaps. To illustrate with an example, in the test dataset, a given pair of texts are: *"Which Star Wars episode should I watch"* and *"I have so much of a life that Im at home watching Star Wars"*. The topic given here, explicitly noted as part of the dataset, is *Star Wars*.

- **Tweet normalization using net slang and Han-Baldwin dictionary:** We normalize the tweets, using net slang and Han-Baldwin normalization dictionary knowledge (Han and Baldwin, 2011). This would help resolve non-dictionary colloquial expressions. E.g.: *aaf* maps to *as a friend*. We use an online version of one of the many net slang dictionaries that are available today. For experiments, we use an online net slang dictionary.

- **Named Entity (NE) boundary correction:** We align NE boundaries across tweets, for appropriate matching. For example, for a given pair of tweets having the same topic, words like *Colorado Ravens* and *Ravens* probably convey the same concept, but would create different gram features. For experimentation, we use the NE tags provided in the dataset, in the CoNLL IOB format.

- **NE tag cleaning:** Inconsistent capitalization of tweets lead to named entity recognition (NER) errors, jeopardizing system performance. For example, if within a given pair of tweets with the

[1] https://github.com/cocoxu/SemEval-PIT2015, crawled on July 10, 2016
[2] https://github.com/cocoxu/multip, crawled on July 10, 2016

same topic, one tweet consists of a named entity *Colorado Ravens* and the other one has the word *ravens* with a NE-tag **O**, they are likely to be discussing the same Raven, with the inconsistency of capitalization confusing the named entity recognizer. We clean NE tags by cross-checking the given pair of tweets, and matching unigrams and bigrams in a case-insensitive manner.

- **Synonym and hypernym replacement using Wordnet:** We use Wordnet (Miller, 1995) to carry out a synonym and hypernym replacement process. For a pair of given tweets, we aim to unify the diverse words appearing in the pair of input texts (tweets), by replacing a word with its synonym (or hypernym). For instance, if *Tweet 1* contains the text *"He made a fast move"* and if *Tweet 2* contains the text *"He performed a quick move"*, then the content of the second tweet (*tweet 2*) gets updated to *"He performed a fast move"*, as long as "fast" and "quick" appear as synonyms in Wordnet. This in turn is fed to the main processing stream for feature selection. This replacement process proves to be useful for adjectives and verbs, so the synonym replacement process considers all the words having adjective and verb POS tags.

3.2 Feature Selection

The challenges to perform the task of paraphrase and semantic similarity detection, exist at different layers of NLP. These include several challenges at (a) lexical, (b) syntactic, (c) semantic and (d) pragmatic levels. We observe that the existing systems, that have specifically attempted to solve the paraphrase and/or semantic similarity detection problem for noisy short-text user generated content platform as Twitter, such as (Xu et al., 2014) and (Eyecioglu and Keller, 2015) *etc.*, have opportunities to be improved, by enhancing the features to solve for all these levels. With this observation, we attempt to explore features across these dimensions, as described below.

3.2.1 Lexical Features

Character-level gram features: We create character-level gram features, notionally borrowing from the features described by (Eyecioglu and Keller, 2015), and thereby include the number of overlaps of character trigrams as features. We further include the number of character trigrams in each of the two input texts (tweets), the size of union of character trigrams over the pair of input texts, the size of intersection, and the size of difference of number of character trigrams - in the form of (a) the number of trigrams that occur in the first text but not the second, and (b) those which occur in the second text but not the first - as features.
Word-level gram features: Apart from character-grams, we also construct word-level gram features, again borrowing in principle from (Eyecioglu and Keller, 2015). We construct features for word-level unigrams, bigrams and trigrams, that are similar in nature with the character gram features, in that, we consider the number of grams in each of the two input texts, and the union, intersection and difference sizes. Further, we also consider **unordered gram overlap** features for word grams, rewarding the system for unordered match in word bigrams and trigrams. This significantly helps the system performance.
Stemming: We repeat the use of the word-level gram features, after having stemmed the text (tweet content). We use the Porter stemmer (Porter, 2001) for performing the stemming in our experimentation.
Stopword removal: We perform stopword removal, using a list of well-accepted set of stopwords. We repeat the use of the word-level gram features after stopword removal.
String-level features: Stemming and Han-Baldwin normalization, done as part of the earlier steps, are two of the string-level features used by our methodology. Further, motivated by (Xu et al., 2014), we use the Jaro-Winkler string similarity (Winkler, 1999) of each given pair of input texts, as a feature.

3.2.2 Syntactic Features

Part-of-Speech (POS) agreement features: We construct two features under this subcategory, that attempt to capture the POS agreement features across the pair of input texts (tweets).

- **Number of matching words with matching POS:** We count the number of word unigrams across the pair of texts, where both the actual word as well as the POS tags of the pair of words, match with each other. We use this count as a feature. We empirically observe that the preprocessing step

of performing synonym replacement with Wordnet, significantly improves the system performance, when deployed along with this feature.

- **Verb similarity:** We count the number of verbs in each of the two texts, where the verb tag (such as VB, VBP, VBZ, VBN *etc.*) match with each other, and use this count as a feature.

Named entity (NE) features: Using the preprocessed named entities, we explore the degree of overlap of NEs across the tweet pairs, over and beyond the core topic phrase. Note that the core topic words are often named entities in our case, and hence they are removed earlier in the preprocessing phase.

3.2.3 Semantic Features

We extensively use Wordnet (Miller, 1995), to enable the construction of our semantic features.
Word overlap features: We compute the degree of overlap between words that appear across the pair of input texts, considering their semantics. Note that, this is inherently different from the word gram features computed as part of the lexical features, as the lexical features are agnostic of semantic attributes of words. Using Wordnet, we construct two features under this subcategory, as given below.

- **Best word overlap:** For each pair of words of a given POS that appear in each of the input texts (tweets), we compute the overlap (intersection) of the sets of Wordnet synonyms and hypernyms of each word of the pair, as well as the union of the synonym and hypernym set. We repeat the above for the stemmed words. If one word is a part of the synonym or hypernym set of the other word, then we count the word as a whole (with $weight = 1$), and the value of this feature becomes unity (1). Otherwise, if none of the two words is included in any of the synonym or hypernym sets of the other, then we use the sum of Jaccard coefficients of the above-computed overlap, of the combination of the given words and stemmed words, as the value of the best word overlap feature. Thus, for the four different POS tags we consider, namely noun, verb, adjective and adverb, this gives us a set of four different features.

- **Adjective overlap:** For each pair of words tagged as adjectives by the POS tagging process, we compute the overlap (intersection) of the sets of Wordnet synonyms and hypernyms of each word of the pair, as well as the union of the synonym and hypernym set. Just like in the case of finding the best word overlap feature, we repeat the above for the stemmed words. We use the sum of Jaccard coefficients of the above-computed overlap, of the combination of the given words and stemmed words, as a feature. Note that, in this feature, even if an adjective from one text appears directly as a synonym or hypernym of the other adjective from the other text, we never consider the feature value to be unity (which is captured by the best word overlap feature separately). While intuitively this feature is extremely "close" to the best word overlap feature, we still retain this feature as during the feature construction (development) process, we observe this feature to be beneficial.

Phrase overlap features: We compute the degree of direct overlap of (a) noun phrases (b) and verb phrases across tweet pairs. We also use the stemmed versions to compute stemmed phrase overlaps. Treating each input text (tweet) as a disconnected graph and each phrase as a vertex in the graph, we connect the pairs of graphs (one graph for each tweet) using the best matching phrase. The matching of a pair of phrases is carried out, by computing the overlap (intersection) of the sets of Wordnet synonyms and hypernyms of the individual words that appear in the phrase pair. Similar to the case of the best word overlap feature, we set the value of this feature of unity if, any one word belonging to one phrase, is directly included in the set union of synonyms and hypernyms of any one word belonging to the other phrase. Otherwise, we compute the sum of Jaccard coefficients of the above-computed overlap for all the word pairs across the text (tweet) pairs, and use this sum as the value of the feature. This is constructed for noun and verb phrase types, thereby adding two features to the overall set of features. Effectively, this is a manifestation of MAXSIM (Chan and Ng, 2008), that is used in the machine translation paradigm.

3.2.4 Pragmatic Features

Subjectivity/objectivity agreement feature: In one implementation, we include the agreement of the nature of the tweet pair with respect to subjectivity/objectivity, as a boolean feature. We make use of the MPQA dictionary, that indicates strong and weak subjectivity and objectivity of words, to construct this feature. The final experimental results we present for the Twitter, does not include this feature, when we attain an F1-score of 0.741; however, if we compromise our F1-score on the Twitter noisy short-text data to 0.740, we obtain a marginal lift from 0.824 to 0.825 on the Microsoft Paraphrase data, helping our system outperform other systems that also yield an F1-score of 0.824 on the Microsoft Paraphrase data.
Close attachment of negations: We also perform close attachment of negations, by attaching the semantic sense of a negation (not *etc.*) with an appropriate term, using well-known techniques from the literature. This in turn assigns appropriate polarity to the subjectivity features.

4 Experiments

In this section, we provide the details of the experiments we conducted.

4.1 Data Description and Tools Used

For experimentation, we select the benchmark dataset by (Xu, 2014) provided as part of the SemEval 2015 task (Xu et al., 2015). This dataset has been used by all the recent works in this space, and further, existing paraphrase detection algorithms, developed optimizing for clean corpus and tested with other clean-text datasets such as the Microsoft Paraphrase database, have also been tested on this dataset. Thus, it provides a well-tested foundation for empirically observing the performance of our system, and benchmarking the performance of our system against the other existing systems.

The original dataset of (Xu et al., 2014) is shown on Table 1. Note that, the dataset based on which the final scores are reported by (Xu et al., 2014), which is also released as part of SemEval 2015 (Xu et al., 2015), consists of 838 tweets in the test set, as opposed to the 972 that were present in the original dataset. This is arrived at, by ignoring the 134 "debatable" entries, that were marked in (Xu et al., 2015), All the systems that use this dataset to report their scores, are against the modified test dataset with 838 test entries ignoring the "debatable" ones, and our reports are also based upon this modified dataset. We used Weka (Hall et al., 2009) for machine learning, and used the POS and NE tags already provided by the SemEval 2015 (Xu et al., 2015) dataset.

	Num. Unique Sentences	**Num. Pair of Sentences**	**Num. Paraphrases**	**Num. Non-Paraphrases**	**Num. Debatable**
Train	$13,231$	$13,063$	$3,996$ (30.6%)	$7,534$ (57.7%)	$1,533$ (11.7%)
Dev	$4,772$	$4,727$	$1,470$ (31.1%)	$2,672$ (56.5%)	585 (12.4%)
Test	$1,295$	972	175 (18.0%)	663 (68.2%)	134 (13.8%)

Table 1: The benchmark dataset released by SemEval 2015 (Xu et al., 2015).

4.2 Performance of Our System

As detailed in Section 3, we train our SVM model on the training data provided, using the identified features. After identifying the effective features, we train our final model on the combination of training and development data provided, and subsequently execute the model to benchmark our system on the given test data. The baseline features comprise of word unigrams and bigrams, and Jaro-Winkler string similarity features. The performance, as well as the impact of each feature (as observed by feature ablation tests) of our system, are provided in Table 2.

Some example cases have been illustrated in Table 3, including cases of correct and incorrect detections by our system. One glance at the examples make it obvious that, in most cases, it is challenging to label the text pairs as paraphrases versus otherwise. Thus, these examples not only illustrate instances of successes and failures of our system, but also provides an instinctive view of the magnitude of challenge, that a solution to the current problem needs to overcome.

Features Used in Model	Semantic Similarity			Paraphrase		
	F1	P	R	F1	P	R
Baseline	0.641	0.667	0.617	0.523	0.67	0.429
+Trigrams	0.663	0.701	0.629	0.533	0.675	0.44
+Topic Removal	0.708	0.739	0.68	0.705	0.707	0.703
+WordNet Synonym Replacement	0.718	0.747	0.691	0.709	0.683	0.737
+POS features	0.721	0.734	0.709	0.709	0.683	0.737
+Phrase Overlap features	0.735	0.758	0.714	0.717	0.697	0.737
+NE features (Final Model)	**0.741**	0.756	0.726	**0.717**	0.697	0.737

Table 2: Performance of our system and impact of features (based upon feature ablation tests). F1 ← F1-score. P ← Precision. R ← Recall.

4.3 Comparing with existing systems

We compare the performance of our system with the existing systems. (Xu et al., 2014) summarize the performances of prior existing paraphrase and semantic similarity detection systems, trained on clean-text corpus, when tested on noisy user-generated short-text data on Twitter. We further compare our results with the existing systems in the literature that are specifically trained on the Twitter paraphrase corpus, and benchmark our performance. Table 4 provides a summary of the results that are attained by the existing systems, trained and tested on the same (SemEval 2015) dataset as ours, as well as our by our methodology. Clearly, our system outperforms all the others in terms of the F1-score it achieves. Although (Zhao and Lan, 2015) obtain a higher precision and (Zarrella et al., 2015) obtain a higher recall compared to ours, our system ranks #2 in terms of precision as well as in terms of recall, and #1 when the precision and recall are combined to obtain an F1-score.

4.4 Applying our feature set on clean-corpus paraphrase detection text

In order to obtain empirical insights about the goodness of the proposed feature set, for the task of paraphrase detection on clean-corpus data, we port the features to the Microsoft Paraphrase dataset (Dolan et al., 2004). Performing training on the Microsoft Paraphrase dataset with our features, and testing on the corresponding test dataset, we obtain an F1-score of 0.824. We further note that, including the subjectivity feature described in Section 3.2.4, lifts the score to 0.825 on this dataset. According to the ACL wiki for paraphrase identification [3], and also factoring for (Eyecioglu and Keller, 2015) that delivers a higher performance on the Microsoft Paraphrase database[4] compared to our system, this gives us the 10^{th} rank overall for the clean-corpus text, using no additional feature. We note the following.

- The best known system, designed by (Ji and Eisenstein, 2013), currently delivers an F1-score of 0.8596 on the Microsoft Paraphrase dataset, while ours delivers 0.825, without any adaptation. On the other hand, our system at an F1-score of 0.741, delivers a significantly better performance compared to their system with an F1-score of 0.641 on the Twitter data, also without any adaptation. Clearly, our system performs (adapts) "better" when observed in a cross-data-type (clean and noisy text) scenario, compared to theirs. This argument holds for all the other existing systems as well, including (Eyecioglu and Keller, 2015), that delivers an F1-score of 0.674 on the noisy Twitter data and an F1-score of 0.828 on the clean Microsoft Paraphrase data.

- Topic removal, which plays a major in helping our system deliver its high performance (as clear from Table 2), cannot be performed on the Microsoft Paraphrase corpus, since, unlike the Twitter corpus, the topics are not explicitly given, and topic-detection is not a focus of the current work. Detecting and removing topics from the Microsoft Paraphrase dataset, would completely unify the

feature set across the two types of data (clean and noisy), and also might potentially improve the system performance (open for exploration). We propose to explore this in future.

5 Discussion

Choice of Approach: Why not Deep Learning?
We use the traditional methodology of identifying features, and a traditional SVM classifier. The choice of modeling in the given manner is, in the known state of the art, traditional feature-based systems, such as (Xu et al., 2014) and (Eyecioglu and Keller, 2015), have so far outperformed deep learning systems, such as the recurrent neural network based approaches by (Zarrella et al., 2015) and (Zhao and Lan, 2015), for paraphrase detection. A deeper subsequent study by (Sanborn and Skryzalin, 2015) also models deep neural learning systems, and observes a similar shortcoming of such systems. A likely cause of this anomaly is the simple absence of a sufficiently large paraphrase dataset in the domain of user-generated noisy texts on microblogs such as Twitter. As and when a much-larger noisy short-text paraphrase corpus for user generated content on microblogs, such as Twitter, becomes available, a deep-learning model will be likely to deliver stronger performances, and will require a revisit.

The Human Upper Bound and the Practical Improvement Delivered by Our System
We further note that, (Xu et al., 2014) observe the human upper bound for detecting paraphrases (computed as semantic similarity, as per the numerical values they report and the corresponding program code they make available) on noisy short-text of Twitter to be limited to 0.823. Given this human upper bound, improving the F1-score for semantic similarity from the reported 0.724 to the current

Method	F1	P	R	Rank		
				F1-Based	P-Based	R-Based

MultiP (Xu et al., 2014)	0.724	0.722	0.726	2	3	2
Our Methodology	**0.741**	0.756	0.726	**1**	2	2

Table 4: A comparison of the performance of different systems on the given Twitter data. F1 ← F1-score. P ← Precision. R ← Recall. Note: a part of the table has been reprinted from (Xu et al., 2014).

0.741 delivers an effective improvement of not $(0.741 - 0.724) * 100\% = 1.7\%$, but a much-higher $((0.741 - 0.724)/0.823) * 100\% = 2.066\%$. This enhances the significance of our work.

6 Conclusion

In this work, we proposed a rich feature set, and performed simplistic SVM-based learning, for performing paraphrase and semantic similarity detection on user generated noisy short-text on social microblogs such as Twitter. We demonstrated the goodness of our system on the benchmark SemEval 2015 database, obtaining an F1-score of 0.717 for paraphrase detection where the known state of the art attains 0.696, and an F1-score of 0.741 for semantic similarity detection where the known state of the art attains 0.724, thus outperforming all the known systems. We show our system to also work well on the benchmark Microsoft Paraphrase database for clean text, and thereby empirically establish our approach as the most ubiquitous system available today, across the different types of paraphrase detection datasets (noisy and clean-text). Our system can be used on applications that need to identify paraphrases and semantic similarities, such as social information spread modeling.

Abstract

Sentence intersection captures the semantic overlap of two texts, generalizing over paradigms such as textual entailment and semantic text similarity. Despite its modeling power, it has received little attention because it is difficult for non-experts to annotate. We analyze 200 pairs of similar sentences and identify several underlying properties of sentence intersection. We leverage these insights to design an algorithm that decomposes the sentence intersection task into several simpler annotation tasks, facilitating the construction of a high quality dataset via crowdsourcing. We implement this approach and provide an annotated dataset of 1,764 sentence intersections.

1 Introduction

Various paradigms exist for comparing the meanings of two texts and modeling their semantic overlap. Paraphrase detection (Dolan et al., 2004), for example, tries to identify whether two texts express the same information. It cannot, however, capture cases where there is only partial information overlap. One paradigm that addresses this issue is textual entailment (Dagan et al., 2006), which asks whether one text can be inferred from another. While textual entailment models when the information of one text is subsumed by another, it falls short when neither text strictly subsumes the other, yet a significant amount of information is common to both. A more recent paradigm, semantic text similarity (Agirre et al., 2012), allows for these cases by measuring "how much" similar two sentences are.

In this paper, we consider an additional paradigm for modeling the semantic overlap between two texts. The task of *sentence intersection*, as defined in several variants (Marsi and Krahmer, 2005; McKeown et al., 2010; Thadani and McKeown, 2011), is to construct a sentence containing all the information shared by the two input sentences (Figure 1). While sentence intersection was originally proposed for abstractive summarization, we argue that it is an interesting generic paradigm for modeling information overlap, which generalizes over several previous approaches. In particular, it is expressive enough to capture partial semantic overlaps that are not modeled by textual entailment or even partial textual entailment (Nielsen et al., 2009; Levy et al., 2013). Furthermore, rather than quantifying the *amount* of shared information as in semantic text similarity, sentence intersection captures *what* this shared information is.

Although sentence intersection has existed for over a decade, it has received little attention due to a lack of annotated data. Previous annotation attempts have either used experts, which did not scale, or crowdsourcing, which yielded unreliable annotations (McKeown et al., 2010). We also observe that annotating sentence intersection is difficult for non-experts. We hypothesize that this difficulty stems from the task's requirement that the annotator indicate *all* the shared information when constructing the intersection, necessitating a high level of attention to fine details in two different sentences simultaneously.

This paper addresses the issue of annotating sentence intersection. We clarify some ambiguous aspects of sentence intersection by defining *extractive sentence intersection* (§3): the *set* of all intersections that can be composed only from words in the input sentences. Though less ambiguous, this task is still challenging for non-experts to annotate correctly (§4). Our main observation is that extractive intersections have a common underlying structure – *an aligned partition* (§6). In a nutshell, the dependency tree of

Figure 2: Extractive intersection is a combinatorial problem, because the common information between two sentences can often be expressed in various equivalent ways.

an intersection sentence can be partitioned into subtrees, each one originating from one of the input sentences. The interesting property is that for every subtree originating from one input sentence, there exists another subtree in the other input sentence, which entails the first. For this purpose, we define *subtree entailment* (§5), an extension of the well-studied inference rules paradigm (Lin and Pantel, 2001).

We then design a semi-automatic algorithm that helps the annotator construct an aligned partition and eventually the extractive intersection set (§7). Our process decomposes the complex task of extractive sentence intersection into a collection of simpler local subtree entailment queries. The entailment queries (which are easy for humans but hard for machines) are annotated manually, while the combinatorial aspect of generating intersections is completely automated. Finally, we apply our process and annotate 1,764 examples via crowdsourcing (§8). These annotations are superior to direct manual crowdsourced annotations.[1]

2 Background: Sentence Intersection

The ability to combine two (or more) semantically-similar sentences into one is a core requirement of abstractive summarization. Various flavors of this combination task, dubbed *sentence fusion*, have been studied. Barzilay et al. (1999; 2003; 2005) focused on generating a single sentence from the most important parts of the input sentences. The importance criterion was argued to be too vague for consistent human annotation (Daume III and Marcu, 2004), giving rise to the more accurately-defined notions of sentence *union* and *intersection* (Marsi and Krahmer, 2005). Sentence union aspires to create a single sentence containing *all* the information in the input sentences, while sentence intersection tries to isolate all the information that they have *in common* – i.e. the consensus. Figure 1 demonstrates this difference.

Annotation Efforts Perhaps the most pressing issue in making sentence intersection an appealing semantic task is creating enough high-quality annotated data. However, prior art appears to lack a method for annotating sentence intersection that is both efficient (scalable) and accurate. The previous attempt to annotate sentence intersection via crowdsourcing (McKeown et al., 2010) resulted in unreliable annotations. Annotators were presented with two similar sentences, and asked to combine them "into a single sentence conveying only the information they have in common". Each pair of input sentences was given to 5 different workers, and the most agreed-upon (centroid) annotation was selected. Results showed that only 54% of the annotation were indeed valid intersections. On the other hand, sentence *union* annotations over the same sentence pairs had 95% accuracy. Krahmer et al. (2008) also observed intersection annotations to be less consistent than unions while studying query-based sentence fusion.

More recently, Thadani and McKeown (2013) proposed a different dataset, which relied on pre-existing pyramid annotated data (Nenkova and Passonneau, 2004). This dataset is more consistent, but does not comply with the definition of sentence intersection. In practice, it models a simpler task: generating a sentence that contains only shared information, not necessarily *all* of the shared information. It seems that this distinction – the need to identify *every* piece of common information at once – is what makes sentence intersection a combinatorial problem, explaining why it is so difficult for humans to perform this task consistently.

Algorithms The sentence fusion literature typically takes an alignment-based algorithmic approach (Barzilay and McKeown, 2005; Filippova and Strube, 2008), which was also adopted by Thadani and

McKeown (2011) for sentence intersection. In general, they (lexically) align the input sentences, and then select a subset of the aligned components when generating the fused sentence. Our annotation method is inspired by this approach, though it differs in various ways, such as the kind of alignments it creates (subtree entailments), the output it generates (a *set* of sentences), and the fact that it is interactive.

3 Extractive Sentence Intersection

We define a new variant of sentence intersection, *extractive sentence intersection*, which departs from the original task in two aspects: specifying a set of intersection sentences, while limiting their scope to be based on the lexical elements in the input sentences.

First, we observe that several different output sentences may satisfy the original definition of sentence intersection. In Figure 2, we see two input sentences conveying very similar information that are expressed by completely different words. Since many of the terms are synonymous, choosing one over another is arbitrary (e.g. "Bernie" = "Sanders" in this context). Combining different words from the input sentences creates several intersections – each one as valid as the other. Therefore, instead of defining sentence intersection as a single sentence that contains all the information shared by the input sentences, we define it as the *set* of all such sentences.

Second, we observe that, according to its original definition, an intersection sentence might include words that do not appear in any of the two input sentences. This may happen in two situations: (a) lexical variability – when introducing an unmentioned synonym (e.g. using "Clinton" instead of "HRC" or "Hillary"); (b) lexical abstraction – where creating an intersection requires introducing a new word that subsumes two terms from the input sentences (Figure 3). Intersections that require lexical abstraction are difficult to define and annotate consistently because the desired level of abstraction is often unclear. We avoid the issues of lexical variability and abstraction by focusing on intersections that are *extractive*, i.e. intersections that *only contain lexical elements from the input sentences*.

To maintain grammaticality, we make an exception to this rule. Placeholders, such as *[something]*, *[somewhere]*, and *[sometime]*, can be used when the input sentences provide different information on an entity that cannot be omitted for syntactic reasons (e.g. subjects). In many cases, there is a specific word that could fit instead of a placeholder, but this word does not appear in the input sentences (Figure 4). The task of finding such words requires lexical abstraction, which is beyond our current scope.

Combining both these criteria – output set and extractiveness – we define *extractive sentence intersection* as the set of all sentences that each contains all the information common to the input sentences, while being composed only of words that appeared in the input sentences and placeholders.[2]

The entire set of extractive intersections allows for more accurate automatic evaluation, since the evaluation mechanism does not need to overcome issues in lexical variability; instead, it can simply select the most similar expert-crafted sentence from the set using simple metrics such as BLEU (Papineni et al., 2002) or ROUGE (Lin, 2004). Having multiple possible solutions is not a foreign concept to NLP, and is widely used in translation and summarization.

[2]While this paper discusses intersections between two input sentences, one can theoretically extend this setting to multiple input sentences by consecutively applying the intersection operation. For example, if we have three sentences s_1, s_2, s_3, we could first find the intersection between s_1 and s_2, and then for each sentence s' in $s_1 \cap s_2$, intersect that with s_3. We would essentially take the union of the latter set of intersection sets, i.e. $s_1 \cap s_2 \cap s_3 = (s_1 \cap s_2) \cap s_3 = \bigcup\{s' \cap s_3 | s' \in s_1 \cap s_2\}$.

s_1	It was Rehnquist who presided over the swearing-in ceremony when Roberts took his seat on the U.S. Court of Appeals for the District of Columbia.

$\cap$	Roberts won senate confirmation to the U.S. Court of Appeals for the District of Columbia.

Figure 5: An example pair of sentences from our dataset and their (expert-annotated) intersection.

4 Annotation Feasibility

We wish to create a large gold-standard annotated dataset of extractive intersection via crowdsourcing. Since the previous crowdsourced intersection dataset was of mixed quality (McKeown et al., 2010), we annotate the same data with both experts and crowdsourcing to determine the annotation's feasibility.

Evaluation Metrics We present two complementary methods for evaluating extractive sentence intersection: a strict method based on sentence equality, and a softer measure similar to ROUGE (Lin, 2004). The methods essentially compare a candidate set of sentences C to a gold-standard set G, yielding precision and recall scores that are averaged across the dataset.

The sentence equality method follows directly from the task's definition: $Precision = |C \cap G|/|C|$, $Recall = |C \cap G|/|G|$. Note that the underlying sentence equality measure is simple string equality.

Sentence equality can sometimes be too harsh for measuring intersection. For example, if an intersection sentence contains exactly all the shared information except for one minor detail, we would want to partially penalize it rather than completely rejecting it. We therefore adopted a more lenient evaluation measure, based on ROUGE (Lin, 2004). In automatic summarization, ROUGE measures the n-gram overlap between a single candidate summary and a set of several gold-standard summaries. Whereas ROUGE tries to maximize agreement with *all* gold summaries, we are satisfied if there exists even one gold intersection sentence that is sufficiently similar to the given candidate sentence. Therefore, to calculate the precision of a given candidate intersection sentence $c \in C$, we take the best-matching gold sentence g, and calculate the portion of n-grams in c that are covered by g. Similarly, a gold sentence's recall is measured versus the best-matching $c \in C$. We define an intersection set's precision and recall by taking the averages. Formally: $Precision = \frac{1}{|C|}\sum_{c \in C} \max_{g \in G}(Cover(c, g))$, $Recall = \frac{1}{|G|}\sum_{g \in G} \max_{c \in C}(Cover(g, c))$, where the portion of n-grams covered is $Cover(a, b) = |ngrams(a) \cap ngrams(b)|\,/|ngrams(a)|$. To avoid deviating too much from the sentence equality measure, we select a conservative definition of n-grams ($n = 4$). Note that replacing $Cover$ with equality in the equations above is exactly the sentence equality method.

Annotation We annotated a random sample of 200 sentence pairs, half from Columbia's sentence fusion dataset (McKeown et al., 2010) and half from MSR's paraphrase dataset (Dolan et al., 2004). Columbia's dataset contains 297 pairs of related sentences, annotated for sentence intersection and union. MSR's dataset contains 1,500 pairs of related sentences, originally annotated for a paraphrase detection task, and later with semantic text similarity scores (Agirre et al., 2012). Existing annotations are ignored, and replaced by our new annotations (see Figure 5).

The first author annotated the data (as an expert), and Mechanical Turk workers were hired to annotate the same sentence pairs. Workers were told to "extract" a new sentence by selecting words from the input sentences or a bank of placeholders, and encouraged to create as many intersections as possible. Each sentence pair was given to 5 workers, of which the most consistent 3 were selected to reduce the effect of poor annotations (agreement between two workers was measured using the ROUGE-like F_1). We also used the set of both input sentences as a simple annotation baseline (the "input" baseline), which captures (with some error) the cases in which one sentence is completely entailed by another.

Results Table 1 shows very poor crowd-expert agreement rates when measured using sentence equality. The crowdsourced annotation is slightly better than the input baseline (precision-wise), and does not seem to improve coverage. Even using the softer ROUGE-like metric, the crowdsourced data does not seem to provide enough added value beyond the simple input baseline (its F_1 is only 0.014 higher).

	Sentence Equality			ROUGE-like		
	P	R	F_1	P	R	F_1
Input	0.080	0.124	0.097	0.611	0.952	0.744
Direct	0.130	0.124	0.127	0.735	0.781	0.758

$\sigma(s, \text{killed}, \text{assassinated})$	Oswald assassinated JFK.
$\sigma(s, \text{killed}, \text{was shot by})$	JFK was shot by Oswald.
$\sigma(s, \text{killed}, \text{died})$	JFK died.

Figure 6: Four examples of the substitution function.

Extractive intersection is clearly a difficult task for non-expert annotators. We suggest that this stems from the many nuanced pieces of information in each sentence (precision) and the many possible combinations that reflect valid extractive intersections (recall). From our own annotation effort, we noticed that these two difficulties pertain to an underlying structure that consistently appears in extractive intersections. In the following sections, we describe this structure (§6) and propose a way of exploiting it to generate high-quality annotations (§7).

5 Subtree Entailment in Context

In this section, we describe a new textual relation, *subtree entailment in context*, which will assist in defining the underlying structure of extractive intersection. Subtree entailment in context models inference between rich lexical-syntactic patterns (subtrees of syntactic dependency trees), while considering internal context (instantiated arguments) and external context (substitution in a complete sentence). As such, it generalizes over previous ideas presented separately in prior art; subtrees were used in TEASE (Szpektor et al., 2015) and PPDB (Pavlick et al., 2015), internal context was considered in context-sensitive relation inference (Zeichner et al., 2012; Melamud et al., 2013; Levy and Dagan, 2016), and external context is studied in the lexical substitution task (McCarthy and Navigli, 2007; Biemann, 2013; Kremer et al., 2014). Subtree entailment in context is the first notion that combines all these traits. In addition to these advantages, we also introduce a new mechanism for handling changes in arity, in case one subtree contains more/less arguments than another.

The Substitution Function To define subtree entailment in context, we must first define an auxiliary operation – subtree substitution. The substitution function σ is given a sentence tree s, a subtree within that sentence t, and another subtree t', which is not necessarily part of s. It creates a new sentence s' by replacing t with t' (see Figure 6): $s' = \sigma(s, t, t')$.

Slot Assignments The substitution function does not specify how the child nodes of t connect to t'. This is not always trivial; e.g. in the third example in Figure 6, the *subject* of "killed" is attached as the *object* of "was shot by". Moreover, the arity of t (the number of expected child nodes) might be different from that of t', as in the fourth example.

The missing piece of the puzzle is *slot assignments*. A *slot* is a dangling edge whose head is part of a subtree (either t or t') but its modifier is not. Slot assignments match these outgoing edges, and are especially useful when going from passive to active and when there is a change in arity. We denote slot assignment as a function α from the slots of t' to those of t, and extend the definition of the substitution function to include it: $s' = \sigma(s, t, t', \alpha)$.

The fact that α is a function means that not all of t's child nodes will necessarily appear in the new sentence s'. In addition, the slots of t' can be assigned a null value ($\emptyset$), which means that none of t's child nodes will fill this slot, leaving it empty. When generating a natural language expression with an empty slot, it is often the case that a placeholder will fill it (see §3). For example, let us invert the fourth example in Figure 6: $s' = \sigma(\text{"JFK died."}, \text{died}, \text{killed}, \alpha)$. If $\alpha(subject) = \emptyset$, then s' will be "[someone] killed JFK", where "[someone]" is a placeholder.

Definition Given a sentence s, we can say that t_p (p for premise), a subtree of s, *entails* some other subtree t_h (h for hypothesis) in the context of s, if: $s \vDash \sigma(s, t_p, t_h, \alpha)$, where α assigns the slots of t_h, and $\vDash$ is textual entailment. In other words, if s is true, then replacing t_p with t_h in s should create a new sentence that is also true. Considering the second example from Figure 6, "killed" entails "assassinated"

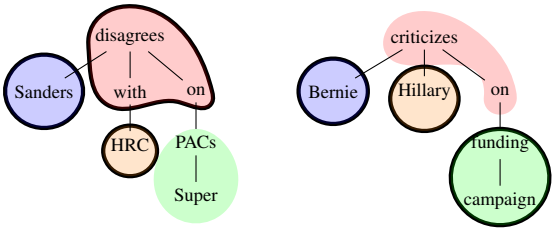

Figure 7: The aligned partition of the example in Figure 2. Subtrees marked by the same color are aligned, and those surrounded by dark borders are entailed by their counterpart.

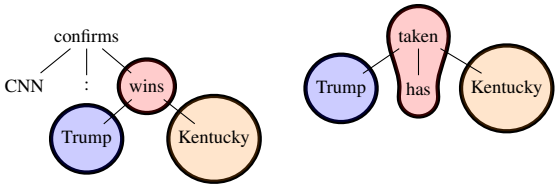

Figure 8: Two input sentences whose aligned partition does not include s_1's root.

(in the context of s) if given that "Oswald killed JFK", it is also true that "Oswald assassinated JFK". Subtree entailment is always in the context of a full premise s; we therefore use the shorthand notation $t_p \models_s t_h$.

Notice that, in fact, we are reducing the subtree entailment question to a textual entailment question, where both premise and hypothesis are full sentences (instantiated predicates). This is essential, since one cannot ask "given that 'killed' is true, is 'assassinated' true too?"; an uninstantiated predicate (or worse, a noun) does not yield a truth value.

6 Properties of Extractive Intersections

When examining the dependency trees of sentences created by extractive intersection, we observe that almost all of them (93%–99.5%, see footnote 5 in §8) exhibit three particular properties, which we define using subtree entailment in context.

Aligned Partition The dependency tree of a sentence created by extractive intersection can be partitioned into subtrees, each one originating from one of the input sentences. Interestingly, for every subtree t_1 originating from s_1 (without loss of generality), there exists another subtree t_2 in the other input sentence s_2, which entails t_1 ($t_2 \models_{s_2} t_1$). The entailment relation between t_1 and t_2 can be mutual or asymmetric, but it is always one-to-one, i.e. no other subtree within s_2 entails t_1, and vice versa. This induces a partition of the input sentences' dependency trees (seen in Figure 7), where each subtree t_1 is either unaligned or in an entailment relation with exactly one subtree from s_2. This also means that each aligned subtree (except for the root) has exactly one parent, which we denote as $\pi(t, s)$ (t being a subtree in sentence s).

We observe that the vast majority of output sentences can be easily created from such an aligned partition of the input sentences. This is not surprising, because every intersection sentence is entailed by both input sentences (Marsi and Krahmer, 2005). It makes sense that the same quality exists at the subtree level, which we model with aligned partitions.

Inverse Inheritance of Alignment The second property, *inverse inheritance of alignment*, describes how subtrees in the output sentence connect. Given a subtree t_1, its parent in the output sentence's tree is either its original parent $\pi(t_1, s_1)$ or its "parent-in-law" $\pi(t_2, s_2)$ (the parent of its aligned subtree). Looking back at the input sentences, this means that every pair of aligned subtrees also has aligned parents, i.e. the parents "inherit" the alignment from their children. However, this does not mean that the direction of entailment needs to be the same; in Figure 7, "Super PACs" entails "campaign funding" ($t_1 \models_{s_1} t_2$), while "X criticizes Y on Z" entails "X disagrees with Y over Z" ($\pi(t_2, s_2) \models_{s_2} \pi(t_1, s_1)$).

Entailed Embedded Clauses Figure 8 shows that the input sentences are not necessarily aligned at the root, and that the common information might be contained in an embedded clause. In such cases, if there is a valid (non-empty) intersection, we typically observe that the embedded clause is entailed by the original sentence. In terms of subtree entailment, this means that the subtree wrapping the embedded clause entails the empty subtree (a single slot with no nodes); e.g. if "CNN confirms: X", then "X" is typically true. Conversely, if the embedded clause is not entailed by the original sentence (e.g. s_3 ="Carson will

quit if Trump wins Kentucky") then there is no intersection ($s_1 \cap s_3 = s_2 \cap s_3 = \emptyset$, assuming s_1 and s_2 from Figure 8).

7 A Semi-Automatic Algorithm

Based on the properties discussed in §6, we describe a semi-automatic algorithm for annotating extractive intersection. It requires relatively simple human interaction throughout the process, while automating the combinatorial aspect, which is difficult for humans. Our algorithm also masks the underlying syntactic tree from the annotator, making the entire process crowdsourcable. The core of our algorithm is creating an aligned partition of the input sentences. Once the aligned partition is obtained, we can deterministically create the set of output dependency trees, from which natural language sentences are generated. Some minor technical details are omitted from this description, and will be made available with our code and its documentation upon publication.

7.1 Creating the Aligned Partition

Given the dependency trees[3] of two sentences, we create their aligned partition over 4 steps. We first elicit lexical alignments from the annotators; these are used to detect the aligned partition's root in each sentence, and then as a seed for automatically deriving subtree alignments. The final step validates that the subtrees are indeed in an entailment relation, and also annotates the entailment's direction.

Step 1: Lexical Alignment We present both sentences in natural language, and ask the annotators to mark words (or phrases) that appear in different sentences yet have similar meanings. This phase is recall-oriented, and its goal is to capture as many potential entailments by annotating a slightly looser notion. We limit the number of alignments to one per token; this constraint is essential for inducing an aligned *partition*. Despite detailed guidelines and examples, non-expert annotators mainly mark nouns, typically ignoring verbs and other predicates unless they are identical. We address this issue in Step 3.

Step 2: Root Detection As discussed in §6, the root of an aligned partition does not always contain the roots of both input sentences. We therefore apply a heuristic, on each sentence separately, which finds the root of the embedded clause participating in the aligned partition: the lowest common ancestor of nodes that have a lexical alignment. This technique is motivated by our observation that, for intersection purposes, the original sentence can be replaced with the embedded clause since it contains all the aligned components. In Figure 8, for example, if an annotator were to only align "Trump" and "Kentucky" with themselves, the heuristic would detect "wins" and "taken" as the roots of s_1 and s_2, respectively.

Step 3: Subtree Alignment Since annotators rarely align predicates, we introduce a heuristic method for automatically deriving subtree alignments from the lexical ones provided manually (Step 1). Figure 9 shows a typical lexical alignment. Our heuristic makes greedy local changes until the following four constraints are satisfied:

Inverse Inheritance of Alignment: In §6 we saw that if two subtrees are aligned, then so are their parents. To enforce this property, we create new alignments between parents of already-aligned subtrees. In our example (Figure 9), this yields two new alignments: "primary" – "wins" and "to" – "wins".

Include Function Modifiers: Annotators also tend to ignore function words. We observe that for certain dependency types[4] that connect function words to content words as modifiers, the modifiers should always be part of the same alignment as their heads. Therefore, if the head participates in an alignment, the modifier is added as well; e.g. "the" modifies "primary" and is therefore added to its alignment.

No Overlapping Alignments: Since aligned partitions induce a *partition* of each input sentence, each node take part in one alignment at most. Therefore, if a node participates in more than one alignment, those two alignments are merged. In our example, "wins" participates in two alignments. After merging, we are left with a single alignment (excluding the initial ones): "the", "primary", "to" – "wins".

[3] We used the Stanford converter on top of the Berkeley parser (Petrov and Klein, 2007), which produced correct dependency trees for most of our data.

[4] The following Stanford dependencies: `det`, `aux`, `auxpass`, `neg`, `prt`, `attr`.

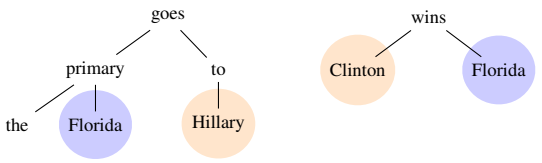

Figure 9: The information provided by a typical annotator in the lexical alignment phase is usually limited to nouns.

	Sentence Equality			ROUGE-like		
	P	R	F_1	P	R	F_1
Input	0.080	0.124	0.097	0.611	0.952	0.744
Direct	0.130	0.124	0.127	0.735	0.781	0.758
Semi-Auto	0.360	0.305	0.330	0.820	0.902	0.859

Table 2: The agreement between crowd and expert annotations. "Semi-Auto" is the semi-automatic annotation process, "Direct" is the direct annotation process described in §4, and "Input" is a baseline where the two input sentences are also the output.

Subtrees Only: Subtree entailment in context (§5) requires every alignment to be between two subtrees. If an aligned component is not a subtree, (i.e. is non-contiguous in the dependency tree) that subgraph will be turned into a subtree by adding the nodes all the way up to the lowest common ancestor. In our case, ("the", "primary", "to") is non-contiguous; adding the lowest common ancestor to this alignment ("goes") yields the subtree alignment: "the", "primary", "goes", "to" – "wins".

Step 4: Entailment Questions The previous step yields a *potential* aligned partition, where aligned subtrees have not yet been tested for entailment. Based on this structure, we generate a set of yes/no subtree entailment questions. Starting at the root, we traverse the aligned partition, and for each alignment (t_1, t_2), two subtree entailment questions are generated: $t_1 \vDash_{s_1} t_2$ and $t_2 \vDash_{s_2} t_1$.

Reusing the example from Figure 9, let t_1 = "the", "primary", "goes", "to" and t_2 = "wins". In the entailment question $t_1 \vDash_{s_1} t_2$, the premise is the original sentence in which t_1 appeared ("The Florida primary goes to Hillary."). The hypothesis is created by substituting t_1 with t_2: $\sigma(s_1, t_1, t_2, \alpha)$. The slot assignment α is deduced directly from the existing subtree alignments; if a child node of t_2 is aligned to a child node of t_1, their slots will be assigned accordingly. If no such alignment exists for a given slot, it will be assigned $\emptyset$ and manifest as a placeholder. In our example, this yields the assignment: "the X primary goes to Y" – "Y wins X", because (X) "Florida" is aligned to itself, and (Y) "Hillary" is aligned to "Clinton". Therefore, the hypothesis we generate is: "Hillary wins Florida."

Annotators are asked if given that the premise is true, the hypothesis is true too. This step determines both the validity and direction of each alignment, creating the final aligned partition.

7.2 Creating the Intersection Set

The aligned partition contains all the information necessary for constructing the intersection set. We create this set by traversing the aligned partition and generating every combination of subtrees, in which only one subtree from each alignment is chosen. Given an alignment between two subtrees, if only subtree is entailed, this subtree is always chosen. If the subtrees are mutually entailing, the number of generated trees is doubled, each one containing a different subtree. If there is no entailment, the subtrees are not aligned, and will not participate in any of the generated sentences.

Overall, this process creates 2^n sentences, where n is the number of mutually entailing subtrees in the aligned partition. For example, the aligned partition in Figure 7 contains 2 mutually-entailing subtrees ("Bernie" = "Sanders", "Hillary" = "HRC"), resulting in 4 intersection sentences (Figure 2). Finally, we generate natural language sentences from the intersection sentences' trees.

8 Annotated Dataset

We hired Mechanical Turk workers to annotate the entire set of 1,800 examples from the sentence fusion (McKeown et al., 2010) and paraphrase (Dolan et al., 2004) datasets presented in §4 using our semi-automatic algorithm. After removing spam annotations, we had an annotated dataset of 1,764 extractive sentence intersections. Again, we retained the 3 most consistent annotations out of 5, per example. For evaluation, we compared the same 200 examples we analyzed in §4. We call this annotation "Semi-Auto", the expert annotation "Expert", and the manual annotation in §4 "Direct".

In terms of measured agreement with Expert, Table 2 shows that Semi-Auto substantially improves over Direct in both the sentence equality and ROUGE-like metrics. Semi-Auto has much higher precision

than both Direct and the input baseline. We hypothesize that explicitly decomposing the intersection task into several local subtree entailment queries allows the annotators to focus on the finer details and nuances of each sentence. Semi-Auto's recall is also better than Direct's because the combinatorial component of creating the entire intersection set is automated.

Although Semi-Auto significantly increases agreement with experts, the agreement is still not perfect. To determine whether these errors stem from annotator quality or algorithmic issues, we sampled 25 input sentence pairs and examined the intersection sentences constructed by Semi-Auto that were not produced by Expert. From this sample of false-positives, 42.2% were actually valid intersections, which were not covered by Expert because of the task's subjective nature. While we used only a single expert, multiple expert annotators could potentially reduce the subjectivity factor. An additional 51.1% stem from real annotation errors by Mechanical Turk workers. A deeper look reveals that these errors result from low-quality annotators who did not follow our instructions. Having said that, the vast majority of these errors manifest as a single missing or superfluous word (in some cases, it is even a function word), while getting the core aspects of the intersection correct. Only 6.7% of the cases were traced to algorithmic errors, most of which are caused by the way English dependency parsers represent coordinations.[5] Overall, it appears that the major cause of error is a portion of Mechanical Turk annotators who failed to follow our instructions accurately. Our semi-automatic algorithm, on the other hand, seems relatively robust.

9 Conclusions

This work resurrects the task of sentence intersection, and addresses the main reason it has remained dormant: lack of annotated data. We show that our new variant of the task, extractive sentence intersection, can be decomposed into several simpler tasks, allowing for high-quality annotation via crowdsourcing. We hope our insights, data, and algorithmic framework provide a foundation for future work on sentence intersection and semantic overlap.

[5] A word on coordinations: English dependency parsers typically represent coordinations ("Bill and Ted") with the first conjunct ("Bill") as the head, and the other conjuncts ("Ted") and coordinators ("and") as its modifiers. This prevents us from modeling entailments between reflexive verbs, such as "X met Y"="X and Y met", using subtrees. To correctly capture the pattern "X and Y met", we need to use Prague-style coordinations (Popel et al., 2013), which place the coordinator ("and") at the head of the structure. This modification, which we did not apply to Semi-Auto, fixes 13 out of 14 cases in which we did not observe a perfect aligned partition during our expert annotation, leaving only 1 exception in 200 examples.

Context-Sensitive Inference Rule Discovery: A Graph-Based Method

Xianpei Han Le Sun

{xianpei, sunle}@nfs.iscas.ac.cn

Abstract

Inference rule discovery aims to identify entailment relations between predicates, e.g., '*X acquire Y → X purchase Y*' and '*X is author of Y → X write Y*'. Traditional methods discover inference rules by computing distributional similarities between predicates, with each predicate is represented as one or more feature vectors of its instantiations. These methods, however, have two main drawbacks. Firstly, these methods are mostly *context-insensitive*, cannot accurately measure the similarity between two predicates in a specific context. Secondly, traditional methods usually model predicates *independently*, ignore the rich inter-dependencies between predicates. To address the above two issues, this paper proposes a graph-based method, which can discover inference rules by effectively modelling and exploiting both the context and the inter-dependencies between predicates. Specifically, we propose a graph-based representation—*Predicate Graph*, which can capture the semantic relevance between predicates using both the predicate-feature co-occurrence statistics and the inter-dependencies between predicates. Based on the predicate graph, we propose a context-sensitive random walk algorithm, which can learn context-specific predicate representations by distinguishing context-relevant information from context-irrelevant information. Experimental results show that our method significantly outperforms traditional inference rule discovery methods.

1 Introduction

Inference rule discovery aims to identify entailment relations between predicates, such as '*X acquire Y → X purchase Y*' and '*X is author of Y → X write Y*', with each predicate is a textual pattern with (two) variable slots (*X* and *Y* in above). Inference rules are important in many fields such as Question Answering (Ravichandran and Hovy, 2002), Textual Entailment (Dagan et al., 2006) and Information Extraction (Hearst, 1992). For example, given the problem "*Which company purchases WhatsApp?*", a QA system can extract the answer "*Facebook*" from the sentence "*Facebook acquires WhatsApp for $19 billion*" based on the inference rule '*X acquire Y → X purchase Y*'.

Given a set of predicates and their instantiations in a large corpus, most traditional methods identify inference rules by computing distributional similarities between predicates, where each predicate is represented as one or more feature vectors of its variable instantiations. For example, given the predicates and their instantiations in Figure 1, we can represent '*X acquire Y*' as {*X='Google', Y='YouTube', X='children', Y='skill'*} and measure the similarity between '*X acquire Y*' and '*X purchase Y*' based on their common features {*X='Google', Y='YouTube'*}. To achieve the above goal, many similarity measures have been proposed for inference rule discovery, such as *DIRT* Similarity (Lin and Pantel, 2001), *Balanced-Inclusion* similarity (Szpektor and Dagan, 2008) and *Soft Set Inclusion* similarity (Nakashole et al., 2012), etc.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2902–2911, Osaka, Japan, December 11-17 2016.

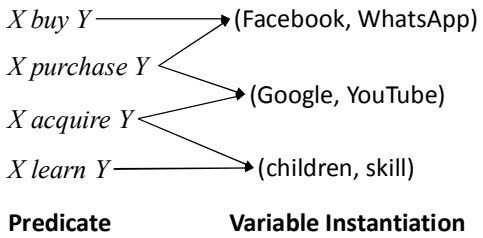

Figure 1. Some predicates and their variable instantiations

These distributional similarity based methods, however, have two main drawbacks:

Firstly, these methods are mostly *context-insensitive*, cannot accurately measure the similarity between two predicates in a specific context. Due to the ambiguity of predicates, a predicate may have different meanings under different contexts (In this paper, as the same as Melamud et al. (2013), the context of a predicate is specified by the predicate's given arguments). For example, the predicate '*X acquire Y*' should have different meanings under context (*Google, YouTube*) and context (*children, skill*), because it corresponds to two different senses of *acquire* in these two contexts. Unfortunately, traditional methods mostly use the same representation to represent a predicate in different contexts, therefore may learn invalid inference rules. For example, given two predicates '*X acquire Y*' and '*X purchase Y*', traditional context-insensitive methods will return the same similarity between them in contexts (*Google, YouTube*) and (*children, skill*). However, '*X acquire Y* → *X purchase Y*' is not a valid rule in context (*children, skill*). Based on the above discussion, we believe that context-specific predicate representation is critical to the success of inference rule discovery.

Secondly, traditional methods usually model predicates *independently*, ignore the rich inter-dependencies between predicates. It is clear though, that there are rich inter-dependencies between predicates. For example, '*X buy Y*' is a synonym of '*X purchase Y*', and '*Y be acquired by X*' is the passive form of '*X acquire Y*'. These dependencies can be exploited to enhance inference rule discovery in many ways. For instance, we can collect richer instantiation co-occurrence statistics per predicate by combining the statistics of semantically similar predicates, or enforce global coherence between the representations of semantically similar predicates. Ignoring these useful inter-dependencies, traditional methods often suffer from the data sparsity problem. For example, if we represent predicates using only their instantiations, we cannot identify the inference rule '*X acquire Y* → *X buy Y*' in Figure 1, because '*X acquire Y*' and '*X buy Y*' don't share any common features.

To address the above two problems, this paper proposes a graph-based method, which can effectively exploit both the context of a predicate and the inter-dependencies between predicates for accurate inference rule discovery. Specifically, we propose a graph-based representation, called *Predicate Graph*, which can capture the semantic relevance between predicates and features by encoding both the predicate-feature co-occurrence statistics and the rich inter-dependencies between predicates. For example, the predicate graph will model the semantic relevance between the predicate '*X buy Y*' and the feature *X*='*Google*' in Figure 1 by taking advantage of the synonym relation between '*X buy Y*' and '*X purchase Y*'. Based on the predicate graph, we propose a context-sensitive random walk algorithm, which can learn context-specific predicate representations by distinguishing context-relevant information from context-irrelevant information. For example, to learn the representation of '*X acquire Y*' under context (*people, language*), our method will identify (*Google, YouTube*) and (*Facebook, WhatsApp*) in Figure 1 as context-irrelevant and will identify (*children, skill*) as context-relevant.

We have evaluated our method on a publicly available dataset. The experimental results show that, using context-specific predicate representations and taking advantage of inter-dependencies between predicates, our method can significantly outperform traditional inference rule discovery methods.

This paper is structured as follows. Section 2 briefly reviews related work. Section 3 describes the proposed method. Section 4 presents and discusses experimental results. Finally we conclude this paper in Section 5.

2 Related Work

Many approaches have been proposed for inference rule discovery, and most of them are distributional similarity based methods. Based on the distributional hypothesis, traditional methods differ in their feature representations and their similarity measures. For predicate representation, some methods represent predicates using one feature vector, where each feature is a pair of argument instantiations such as *X*='*children*'-*Y*='*skill*'(Szpektor et al., 2004; Sekine, 2005; Nakashole et al., 2012; Dutta et al., 2015); some methods represent predicates using two or more feature vectors, one for each argument slot (Lin and Pantel, 2001; Bhagat et al., 2007), e.g., one feature vector for slot *X* and one for slot *Y*. To compute the similarity between predicates, many similarity measures have been proposed, such as *DIRT* Similarity (Lin and Pantel, 2001), *Balanced-Inclusion* similarity (Szpektor and Dagan, 2008) and *Soften Set Inclusion* similarity (Nakashole et al., 2012), etc. Hashimoto et al. (2009) proposed a conditional probability based directional similarity measure to acquire verb entailment pairs on a large scale corpus. As discussed in above, the main drawbacks of these methods are that they are *context-insensitive* and model predicates *independently*.

Having observed that the meaning of a predicate is context-sensitive, several recent methods try to model the context of a predicate using class-based model or latent topic model. The class-based models represent the context of a predicate using ontological type signatures (Pantel et al., 2007; Nakashole et al., 2012), e.g., <*singer, song*> for '*X sing Y*', based on the assumption that two predicates in a rule must have the same type signature. The shortcomings of the class-based context models are that they need a fine-grained ontology and it is often very challenging to determine the fine-grained types of arguments. The latent topic based model represents the context of a predicate as a vector in a low dimensional space, such as the LSA-based model (Szpektor et al., 2008) and the LDA based model (Ritter et al., 2010; Dinu and Lapata, 2010). Based on the context vector, the similarity between two predicates are computed by combining both the context vector similarity and the feature vector similarity (Szpektor et al., 2008), or by first learning predicate similarity per topic, then combining the per-topic similarities using context vector (Melamud et al., 2013). Currently, most of the context-sensitive methods focus on developing an extra context model, by contrast our method focuses on the learning of context-specific predicate representations, without the need of an extra context model.

Recent research has also investigated the jointly learning of inference rules. Kok and Domingos (2008) and Yates and Etzioni (2009) learned inference rules by clustering predicates using relational clustering algorithms. Berant et al.(2010) and Berant et al.(2011) proposed two global learning methods, which first classify each pair of predicates using a local classifier, then these local results are globally rescored using *Integer Linear Programming(ILP)* algorithm. Nakashole et al. (2012) proposed a prefix-tree mining algorithm, which can arrange predicates into a semantic taxonomy. The current joint learning methods mostly employ a meta-classification schema, i.e., the inter-dependencies between predicates are used to adjust the pair-wise predicate similarities, therefore their predicate representations still suffer from the data sparsity problem. In contrast our method exploits the inter-dependencies for better predicate representation, which can effectively resolve the data sparsity problem.

3 Graph-Based Context-Sensitive Inference Rule Discovery

This section describes our graph-based method for context-sensitive inference rule discovery. We first construct a graph, which can effectively capture the semantic relevance between predicates and features. Then we propose a context-sensitive random walk algorithm, which can learn accurate, context-sensitive predicate representations. Finally, we discover inference rules by computing similarities between context-sensitive predicate representations.

3.1 The Predicate Graph Representation

Generally, there are two kinds of information which can be exploited to represent a predicate: 1) its variable instantiations in a corpus, such as the instantiations (*Google, YouTube*) and (*children, skill*) in Figure 1 for representing predicate '*X acquire Y*'; 2) the information from semantically similar predicates, for example, the instantiation (*Google, YouTube*) of '*X purchase Y*' can be used to enrich the representation of '*X buy Y*'. In this paper, we uniformly encode the above two kinds of information using a graph representation, named *Predicate Graph*, which is defined as follows:

*A **Predicate Graph** is a weighted graph **G=(V, E)**, where the node set **V** contains all predicates and all features of these predicates; each edge between a predicate and a feature represents a co-occurrence relation between them; each edge between two predicates represents a semantic-dependent relation between them.*

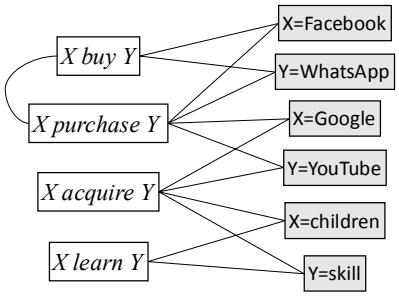

Figure 2. A predicate graph demo

Figure 2 demonstrates a predicate graph, which is constructed using the information in Figure 1. We can see that, the instantiation information of predicates is modelled by co-occurrence edges between (*predicate, feature*), such as the edges between (‘*X buy Y*’, *Y*=‘*WhatsApp*’) and between (‘*X buy Y*’, *X*=‘*Facebook*’). The inter-dependencies between predicates are modelled by semantic-dependent edges between predicates, e.g., the edge between (‘*X buy Y*’, ‘*X purchase Y*’). Based on the co-occurrence and the semantic-dependent edges, both the explicit and the implicit semantic relevance between predicates and features can be captured using the paths between them. For example, the implicit semantic relevance between the feature *X*=‘*Google*’ and the predicate ‘*X buy Y*’ can be modelled through the path *X*=‘*Google*’–‘*X purchase Y*’–‘*X buy Y*’.

The Construction of Predicate Graph. Given a set of predicates and their instantiations in a large corpus, we construct predicate graph by first adding all predicates and all features as nodes, then we link these nodes using the following two types of edges:

- *Co-occurrence Edge*. We take each argument instantiation of a predicate *p* as a feature *f* of *p* and add a co-occurrence edge between them, the pointwise mutual information (PMI) between *p* and *f* is used as the edge’s weight;
- *Semantic-Dependent Edge*. To encode inter-dependencies between predicates, we add a semantic-dependent edge between a predicate *p* and each of its semantically similar predicates. We use the same edge weight α for all semantic-dependent edges, and which will be empirically tuned. Specifically, given a predicate *p*, we find its semantically similar predicates as follows: 1) we identify its active/passive verb form as its semantically similar predicate, e.g., ‘*Y be acquired by X*’ will be identified as a semantically similar predicate of ‘*X acquire Y*’; 2) we generate semantically similar predicate candidates by replacing each verb/noun in the predicate *p* with its synonyms/hypernyms in WordNet 3.0. If a predicate candidate is a valid predicate (i.e., it is one of the given predicates), we take it as a semantically similar predicate of *p*. For example, (‘*X buy Y*’, ‘*X purchase Y*’) and (‘*X be maker of Y*’, ‘*X be creator of Y*’) will be identified semantically similar using the synonym relations between (*buy*, *purchase*) and between (*maker*, *creator*).

3.2 Context-Sensitive Random Walk Algorithm

In this section, we describe how to accurately represent a predicate in a specific context. Specifically, given a predicate *p*, its context *c* and all features $\{f_1, f_2, \ldots, f_n\}$, we represent predicate *p* as a vector:

$$\vec{v}_p^c = (w_{p1}^c, w_{p2}^c, \ldots, w_{pn}^c)$$

where w_{pi}^c is the relevance score between predicate *p* and feature f_i under context *c*. In following we first develop a context-insensitive random walk algorithm which can estimate context-insensitive relevance score between a predicate *p* and a feature *f*, then we extend the algorithm by taking context into consideration. For simplicity, we assign each node in predicate graph *G=(V, E)* an integer index from 1 to $|V|$, and use it to represent the node.

Context-Insensitive Random Walk. Given a predicate graph *G=(V, E)*, the relevance score between a predicate *p* and a feature *f* can be naturally modelled as the relevance score between the two nodes in *G* corresponding to *p* and *f*. Estimating relevance score between two nodes in a graph is one of the

fundamental tasks in graph mining, and many algorithms have been developed. In this paper we estimate the context-insensitive relevance score between two nodes using one of the most widely used algorithm – *Random Walk with Restart (RWR)* (Tong et al., 2006), which can be fast computed and has been successfully used in many applications, like personalized PageRank (Haveliwala, 2003), image retrieval (He et al., 2004), etc.

Specifically, *RWR* models the relevance score between node *i* and node *j* in a graph *G* as the steady-state probability $r_{i,j}$, i.e., the probability of a random walk starts from node *i* will end at node *j*. For example, the relevance between ('*X acquire Y*', *X*='*Facebook*') in Figure 2 will be computed by starting random walks from the predicate node '*X acquire Y*', then estimate the probability of these random walks ending at the feature node *X*='*Facebook*'.

The random walk used in *RWR* is specified as follows: consider a random particle that starts from node *s* that indicates predicate *p*, at each step the particle iteratively transmits to its neighbourhood with probability that is proportional to their edge weights, and it also has a restart probability $\lambda \in [0, 1]$ to return to the start node *s*:

$$\mathrm{P}(\mathrm{i} \rightarrow \mathrm{j}) = \begin{cases} (1-\lambda)\dfrac{w_{ij}}{\sum_k w_{ik}} & \text{transmit to neighorhood } j \\ \lambda & \text{restart to start node } s \end{cases}$$

where $\mathrm{P}(\mathrm{i} \rightarrow \mathrm{j})$ is the probability of transmit from node *i* to node *j* at each step, and w_{ij} is the edge weight between node *i* and node *j*. *RWR* can also be written in matrix form:

$$\vec{r}_s = (1-\lambda)\mathbf{M}\vec{r}_s + \lambda\vec{e}_s$$

where $\vec{r}_s$ is the n×1 relevance score vector, with $r_{s,j}$ is the relevance score of node *j* with respect to start node *s*, and $\vec{e}_s$ is n×1 starting vector with the s^{th} element 1 and 0 for others; **M** is the neighbourhood transition matrix with $\mathrm{M_{ij}} = w_{ji}/\sum_k w_{jk}$.

Using *RWR*, the relevance score between a predicate *p* and a feature *f* can effectively summarize the semantic relevance information between them by exploiting the global structure of predicate graph. For example, in Figure 2 all the paths between '*X buy Y*' and *X*='*Facebook*' will be used to estimate the relevance score between them, such as the direct edge '*X buy Y*'—*X*='*Facebook*' and the indirect path '*X buy Y*'—'*X purchase Y*'—*X*='*Facebook*'. To demonstrate the effect of *RWR*, Table 1 shows the state-steady probability of the random walk starting from '*X acquire Y*'. We can see that *RWR* can effectively exploit both the inter-dependencies between predicates and the predicate-feature co-occurrence information. For example, although '*X acquire Y*' doesn't co-occur with *X*='*Facebook*' in Figure 2, *RWR* can still estimate the relevance score between them as *0.045*.

Context / Feature	No Context	X=Microsoft Y=Nokia	X=people Y=language
X=Facebook	*0.045*	*0.055*	*0.003*
Y=WhatsApp	*0.045*	*0.055*	*0.003*
X=Google	*0.064*	*0.092*	*0.073*
Y=YouTube	*0.064*	*0.092*	*0.073*
X=children	*0.119*	*0.080*	*0.163*
Y=skill	*0.119*	*0.080*	*0.163*

Table 1. The representations of 'X acquire Y' in different contexts (λ=0.1 and semantic-dependent edge weight = 0.5)

Context-Sensitive Random Walk. The main problem of the above random walk algorithm is that it is context-insensitive, cannot accurately represent a predicate in different contexts. For example, the above algorithm will return the same representation for '*X acquire Y*' in contexts (*Microsoft, Nokia*) and (*people, language*), although it corresponds to different senses of *acquire*.

To learn context-specific predicate representations, we extend *RWR* algorithm by also taking context into consideration. Specifically, the start point of our algorithm is to distinguish context relevant information from context irrelevant information. For example, to represent '*X acquire Y*' in the context (*peo-*

ple, language), the features *X*='*Facebook*', *X*='*Google*', *Y*='*WhatsApp*' and *Y*='*YouTube*' will be identified as context-irrelevant and their relevance scores will be reduced, meanwhile the features *X*='*children*' and *Y*='*skill*' will be identified as context-relevant and their relevance scores will be increased. To achieve the above goal, we revise the transition probability of *RWR* using a context-sensitive node-dependent restart probability:

$$\mathrm{P}(\mathrm{i} \rightarrow \mathrm{j}|\mathrm{c}) = \begin{cases} (1-\lambda_{c,i})\dfrac{w_{ij}}{\sum_i w_{ik}} & \text{transmit to neighorhood } j \\ \lambda_{c,i} & \text{restart to start node } s \end{cases}$$

where $\lambda_{c,i}$ is the restart probability at node *i* in context *c*, which depends on the context relevance between node *i* and context *c*. For instance, in Figure 1, to learn the representation of '*X acquire Y*' in context (*people, language*), our method will set a high restart probability to context-irrelevant nodes *X='Facebook', X='Google', Y='WhatsApp'* and *Y='YouTube'*, in contrast our method will set a low restart probability to context-relevant nodes *X='children'* and *Y='skill'*. Based on the context-sensitive random walk, we can easily identify context-relevant information: once a random walk hits a context-irrelevant node, it will jump to the start node, then the relevance scores of all nodes which are semantically similar to the context-irrelevant node will be reduced. The context-sensitive random walk algorithm can also be written in matrix form:

$$\vec{r}_s^{\,c} = \mathbf{M}(\mathbf{I}-\mathbf{\Lambda})\vec{r}_s^{\,c} + (\vec{1}\,\mathbf{\Lambda}\,\vec{r}_s^{\,c})\vec{e}_s$$

where $\mathbf{\Lambda} = \mathrm{diag}(\lambda_{c,1}, \lambda_{c,2}, \ldots, \lambda_{c,n})$ is the diagonal matrix of node-dependent restart probabilities, **I** is the identity matrix and $\vec{1}$ is a 1×n vector with all entries 1.

To compute the context-sensitive node-dependent restart probability $\lambda_{c,i}$, we first measure the context relevance between a feature *f* and context *c*. In this paper, the context of a predicate *p* is its variable instantiation (*X=x, Y=y*), such as (*X*='*Microsoft*', *Y*='*Nokia*') for '*X acquire Y*'. Then we measure the context relevance using the word similarity between feature *f* and the corresponding argument of context *c*:

$$\mathrm{CR}(\mathrm{f},\mathrm{c}) = \mathrm{Sim}(\mathrm{f_w}, \mathrm{c_{fs}})$$

where f_w is the word content of feature *f* (e.g., *people* for *X*='*people*'), *fs* is the slot signature of feature *f* (e.g., *X* for *X*='*people*'), and c_{fs} is the word in the slot *fs* of context *c*. In this paper, the similarity between two words is the cosine similarity between their word vectors (Pennington et al., 2014), using a publicly available pre-trained word vectors[1].

Finally, the context-sensitive node-dependent restart probability of node *i* is computed as:

$$\lambda_{\mathrm{i,c}} = \begin{cases} \lambda + \beta\,(1-\lambda)\big(1.0 - \mathrm{CR}(\mathrm{i},\mathrm{c})\big) & \text{if i is a feature} \\ \lambda & \text{if i is a predicate} \end{cases}$$

where λ is the global restart probability used for smoothing, β is used to control the impact of context relevance in context-sensitive random walk, which will be empirically tuned.

Table 2 shows the learned context-specific representations of '*X acquire Y*' in different contexts. We can see that our algorithm can effectively learn context-specific representations: the most important features are *X='Google'* and *Y='Youtube'* in context (*X*='*Microsoft, Y*='*Nokia*'), by contrast the most important features are *X='children'* and *Y='skill'* in context (*X*='*people*', *Y*='*language*').

3.3 Context-Sensitive Inference Rule Discovery

Based on the above algorithm, each predicate in a specific context is represented as the context-specific steady-state probability vector $\vec{r}_s^{\,c}$. To discover inference rules, we first compute similarities between predicates, then two predicates *p* and *q* in context *c* will form an inference rule if their similarity is above a threshold. Specifically, because each representation $\vec{r}_s^{\,c}$ can be viewed as a distribution over nodes, we measure the similarity between two predicates using the Kullback–Leibler divergence between $\vec{r}_p^{\,c}$ and $\vec{r}_q^{\,c}$ (Kullback & Leibler, 1951):

[1] http://www-nlp.stanford.edu/data/glove.840B.300d.txt.gz

$$\mathrm{KL}(\vec{r}_p^c|\vec{r}_q^c) = \sum_i r_{p,i}^c \times \ln(\frac{r_{p,i}^c}{r_{q,i}^c})$$

Notice that KL divergence is a distance measure: the smaller the KL divergence between $\vec{r}_p^c$ and $\vec{r}_q^c$, the more similar the two predicates p and q.

4 Experiments

In this section, we evaluate the performance of our method and compare it with traditional methods.

4.1 Experimental Settings

Corpus. In this paper, we use the ReVerb corpus (Fader et al., 2011) as the inference rule discovery corpus, which contains about 15 million publicly available unique open extractions. Each extraction in ReVerb is an instantiation of a predicate in the form (x, predicate, y), such as (*Facebook, acquire, Instagram*) and (*Paris, is capital of, France*). Before inference rule discovery, we apply some clean-up preprocessing to the ReVerb extractions: we remove all predicates occurring in less than 50 times and all arguments occurring in less than 10 times.

Evaluation. For evaluation, we use the publicly available dataset constructed by Zeichner et al. (2015)[2]. The dataset contains 6567 instantiated inference rules, where each one is manually labeled as correct or incorrect. For example, '*X be crucial to Y → X be important in Y*' is labeled as correct with instantiation (*oil prices, decisions*), and '*X own Y → X purchase Y*' is labeled as incorrect with instantiation (*we, these items*). For evaluation, we remove all inference rules whose predicates are not within the *ReVerb* corpus. Finally the evaluation dataset contains 5688 inference rules (2213 are correct and 3475 are incorrect). We split the dataset randomly in 2 subsets: 80% for testing and 20% for validating.

To assess the performance of different methods, we compute similarity scores for all annotated testing inference rules using different methods, and outputted the ranked inference rules of different methods using their similarity scores.

As the same as Melamud et al. (2013), we compare different methods by measuring Mean Average Precision (MAP) (Manning et al., 2008) of the inference rule ranking outputted by different methods. To compute MAP values and corresponding statistical significance, we randomly split test set into 30 subsets and computed Average Precision on every subset, the average over all subsets are used as the final MAP value.

Baselines. We compare our method with three types of inference rule discovery methods:

1) We evaluate two distributional similarity based context-insensitive baselines. One follows the DIRT similarity in (Lin and Pantel, 2001), we denote it as *DIRT*. The other uses the *Balanced-Inclusion* similarity in (Szpektor and Dagan, 2008), we denote it as *BINC*.
2) We evaluate a latent topic model based context-sensitive method. We follow the method described in Melamud et al. (2013), a two level model which computes context-sensitive similarity using two predicates' word-level vectors biased by topic-level context representations. We apply their method on two base word-level similarities, the *LIN* similarity and the *BINC* similarity, correspondingly denoted as *WT-LIN* and *WT-BINC*.
3) We evaluate the global learning method proposed in Berant et al. (2011), which use ILP solvers to performance global optimization over local classification results—We denote it as *ILP*. For comparison, we directly use the inference rule resource[3] released by Berant et al. (2011), which was also learned from the *ReVerb* corpus.

For our graph-based method, we tune its parameters on the validating dataset, and the final parameters used in our method are as follows: the global restart probability λ=0.1, the weight of the semantic dependent edge α = 4.0, and the context relevance restart weight β=0.7.

4.2 Experimental Results and Discussions

We conduct experiments on the test dataset using all baselines. For our method, we use two different settings: one uses context-insensitive random walk – we denote it as *RWR-CI*, and the other uses context-sensitive random walk—we denote it as *RWR-CS*. The overall results are presented in Table 2.

System	MAP
DIRT	0.401
BINC	0.424
WT-LIN	0.482
WT-BINC	0.500
ILP	0.513
RWR-CI	0.511
RWR-CS	**0.576**

Table 2. The overall results of different methods

From Table 2, we can see that:

1) By taking both the context and the inter-dependencies between predicates into consideration, our method can achieve significant performance improvement over traditional methods. Compared with the distributional similarity based baselines *DIRT* and *BINC*, *RWR-CS* achieved 44% and 36% MAP improvements. Compared with the latent topic model based context-sensitive baselines *WT-LIN* and *WT-BINC*, *RWR-CS* achieved 20% and 15% MAP improvements. Compared with the global learning baseline *ILP*, *RWR-CS* achieved 12% MAP improvement.
2) Context-sensitive similarity is critical for inference rule discovery. By taking the context into consideration, *WT-LIN*, *WT-BINC* and *RWR-CS* correspondingly achieved 20%, 18% and 13% MAP improvements over their context-insensitive counterparts—*DIRT*, *BINC* and *RWR-CI*.
3) The predicate inter-dependency can enhance the performance of inference rule discovery. By taking advantage of the rich inter-dependencies, both *ILP* and *RWR-CI* achieve performance improvements over the two baselines which model predicates independently: *DIRT* and *BINC*.

To better understand the reasons why and how the graph-based method works well, we evaluate our method using different settings. The results are presented in Table 3.

	Context-Insensitive Random Walk	Context-Sensitive Random Walk
Co-occurrence Edges	0.506	0.547
+ Semantic-Dependent Edges	0.511	0.576

Table 3. The results of the different settings of our method

From Table 3, we can see that:

1) The context-sensitive random walk algorithm can effectively capture the semantics of a predicate in a specific context: Using context-sensitive random walk algorithm, our method achieves MAP improvements on both predicate graph settings (co-occurrence edges only and all edges).
2) The predicate inter-dependency and the context-sensitive random walk can reinforce each other: our method can achieve a 14% MAP improvement by both adding semantic-dependent edges and performing context-sensitive random walk, which is larger than the sum of the performance improvements by only adding semantic-dependent edges (1% improvement) and by only performing context-sensitive random walk (8% improvement). We believe this is because although the inter-dependencies between predicates can enrich predicate representation with more information, it may also introduce some irrelevant information. As a complement, the context-sensitive random walk can filter out irrelevant information and retain only relevant information.

5 Conclusions and Future Work

This paper proposes a graph-based method for context-sensitive inference rule discovery. The advantages of our method are: 1) our method is context-sensitive, it can accurately represent the semantics of a predicate in a specific context; 2) our method can take advantage of the inter-dependencies between predicates for better predicate representation. Experiments verified the effectiveness of our method.

In future work, we aim to jointly model inference rule discovery and knowledge base completion, so that inference rules can be exploited to complete a knowledge base and the semantic knowledge in the given knowledge base can be used to enhance inference rule discovery. Furthermore, we also want to learn the distributed representations of predicates using deep neural networks.

Abstract

We describe an attentive encoder that combines tree-structured recursive neural networks and sequential recurrent neural networks for modelling sentence pairs. Since existing attentive models exert attention on the sequential structure, we propose a way to incorporate attention into the tree topology. Specially, given a pair of sentences, our attentive encoder uses the representation of one sentence, which generated via an RNN, to guide the structural encoding of the other sentence on the dependency parse tree. We evaluate the proposed attentive encoder on three tasks: semantic similarity, paraphrase identification and true-false question selection. Experimental results show that our encoder outperforms all baselines and achieves state-of-the-art results on two tasks.

1 Introduction

Modelling a sentence pair is to score two pieces of sentences in terms of their semantic relationship. The applications include measuring the semantic relatedness of two sentences (Marelli et al., 2014), recognizing the textual entailment (Bowman et al., 2015) between the premise and hypothesis sentences, paraphrase identification (He et al., 2015), answer selection and query ranking (Yin et al., 2015) etc.

The approach of modelling a sentence pair based on neural networks usually consist of two steps. First, a sentence encoder transforms each sentence into a vector representation. Second, a classifier receives two sentence representations as features to make the classification. The sentence encoder can be regarded as a semantic compositional function which maps a sequence of word vectors to a sentence vector. This compositional function takes a range of different forms, including (but not limited to) sequential recurrent neural networks (Seq-RNNs) (Mikolov, 2012), tree-structured recursive neural networks (Tree-RNNs) (Socher et al., 2014; Tai et al., 2015) and convolutional neural networks (CNNs) (Kim, 2014).

We introduce an approach that combines recursive neural networks and recurrent neural networks with the attention mechanism, which has been widely used in the sequence to sequence learning (*seq2seq*) framework whose applications ranges from machine translation (Bahdanau et al., 2015; Luong et al., 2015), text summarization (Rush et al., 2015) to natural language conversation (Shang et al., 2015) and other NLP tasks such as question answering (Sukhbaatar et al., 2015; Hermann et al., 2015), classification (Rocktäschel et al., 2016; Shimaoka et al., 2016). In the machine translation, the attention mechanism is used to learn the alignments between source words and target words in the decoding phase. More generally, we consider that the motivation of attention mechanism is to allow the model to attend over a set of elements with the intention of attaching different emphases to each element. We argue that the attention mechanism used in a tree-structured model is different from a sequential model. Our idea is inspired by Rocktäschel et al. (2016) and Hermann et al. (2015). In this paper, we utilise the attention mechanism to select semantically more relevant child by the representation of one sentence learned by a Seq-RNNs, when constructing the head representation of the other sentence in the pair on a dependency tree. Since our model adopts the attention in the sentence encoding phase, we refer to it as an attentive

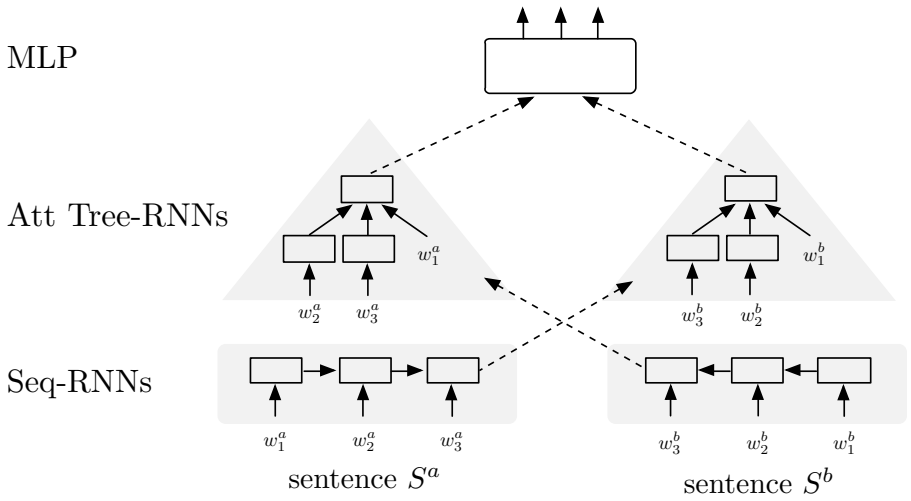

Figure 1: An overview of our tree-structured attentive encoder.

encoder. In this work, we implement this attentive encoder with two architectures: tree-structured LSTM and tree-structured GRU.

We evaluate the proposed encoder on three sentence pair modelling tasks: semantic similarity on the SICK dataset, paraphrase identification on the MSRP dataset and true-false question selection on the AI2-8grade science questions dataset. Experimental results demonstrate that our attentive encoder is able to outperform all non-attentional counterparts and achieves the state-of-the-art performance on the SICK dataset and AI2-8grade dataset.

2 Models

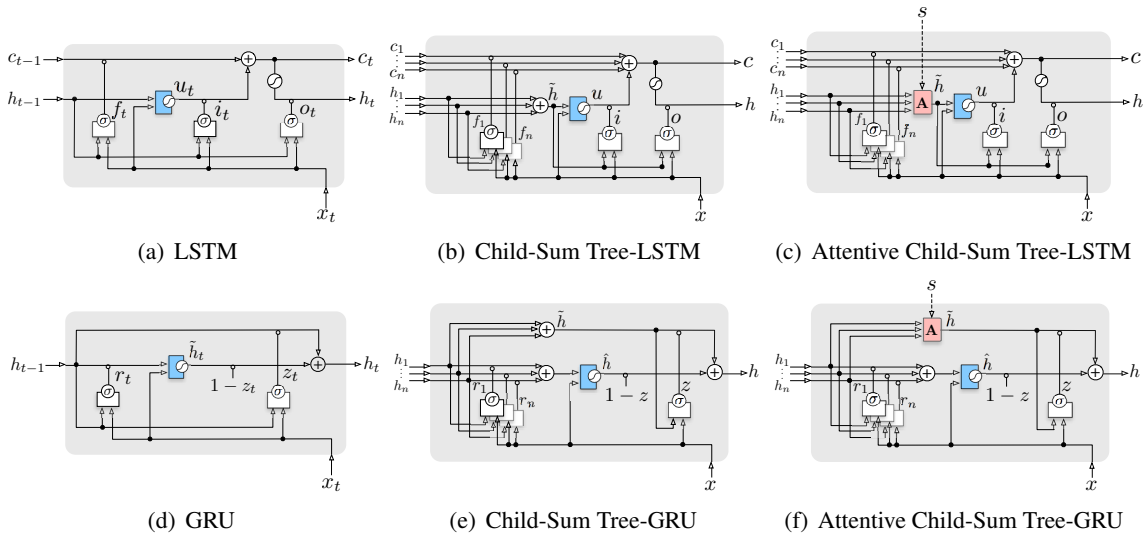
Let's begin with a high-level discussion of our tree-structured attentive encoder. As shown in Figure 1An overview of our tree-structured attentive encoderfigure.1, given a sentence pair (S^a, S^b), our goal is to score this sentence pair. Our tree-structured attentive model has two components. In the first component, a pair of sentences is fed to a Seq-RNNs, which encodes each sentence and results in a pair of sentence representations. In second component, the Attentive Tree-RNNs encodes a sentence again, aimed by the representation of the other sentence generated by the first component. Compared with the existing approaches of modelling sentence pairs, our attentive encoder consider not only the sentence itself but also the other sentence in the pair. Finally, the two sentence vectors produced by the second component are fed to the multilayer perceptron network to produce a distribution over possible values. These components will be detailed in the following sections.

2.1 Seq-RNNs

We first describe the RNN composer, which is the basic unit of Seq-RNNs. Given an input sequence of arbitrary length, an RNN composer iteratively computes a hidden state h_t using the input vector x_t and its previous hidden state h_{t-1}. In this paper, the input vector x_t is a word vector of the t-th word in a sentence. The hidden state h_t can be interpreted as a distributed representation of the sequence of tokens observed up to time t. Commonly, the RNN transition function is the following:

$$h_t = \tanh(Wx_t + Uh_{t-1} + b) \tag{1}$$

We refer to the model that recursively apply the RNN composer to a sequence as the Seq-RNNs. Unfortunately, standard Seq-RNNs suffers from the problem that the gradients of the hidden states of earlier part of the sequence vanishes in long sequences (Hochreiter, 1998). Long Short-term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (GRU) (Chung et al., 2014) are two powerful and popular architectures that address this problem by introducing gates and memory. In this paper, we only show the illustrations of LSTM (Figure 2(a)Subfigure 2(a)subfigure.2.1) and



(a) LSTM (b) Child-Sum Tree-LSTM (c) Attentive Child-Sum Tree-LSTM

(d) GRU (e) Child-Sum Tree-GRU (f) Attentive Child-Sum Tree-GRU

Figure 2: Illustrations of different recurrent architectures.

GRU (Figure 2(d)Subfigure 2(d)subfigure.2.4). The implementations of standard LSTM and GRU in this paper are same as (Luong et al., 2015) and (Chung et al., 2014). When we replace the standard RNN composer with LSTM or GRU, the Seq-RNNs becomes Seq-LSTMs or Seq-GRUs.

2.2 Standard Tree-RNNs

Compared with standard RNN composer, which computes its hidden state from the input at the current time step and the hidden state of previous time step, the Tree-RNN composer computes its hidden state from an input and the hidden states of arbitrarily many child units. We now describe the *Child-Sum Tree-LSTM* and *Child-Sum Tree-GRU* architectures which are formed by applying the *Child-Sum* algorithm to LSTM and GRU respectively.

Child-Sum Tree-LSTM. In this paper, the implementation of Child-Sum Tree-LSTM is same as (Tai et al., 2015). We consider that a Child-Sum Tree-LSTM composer contains two parts: the external part and internal part. The external part consists of the inputs and outputs, and the internal part is the controllers and memory of the composer. As shown in Figure 2(b)Subfigure 2(b)subfigure.2.2, the inputs of the composer are: a input vector x, multiple hidden states $h_1, h_2, \ldots, h_n$ and multiple memory cells $c_1, c_2, \ldots, c_n$, where n is the number of child units. The outputs consist of a memory cell c and a hidden state h which can be interpreted as the representation of a phrase. The internal part aims at controlling the flow of information by an input gate i, an output gate o and multiple forget gates $f_1, f_2, \ldots, f_n$. The gating mechanisms used in the Child-Sum Tree-LSTM are similar to sequential LSTM. Intuitively, the sum of children's hidden states $\tilde{h}$ is the previous hidden state, the forget gate f_k controls the degree of memory kept from that of the child k, the input gate i controls how much the internal input u is updated and the output gate controls the exposure of internal memory c. We define the transition equations as follows:

$$
\begin{aligned}
&\tilde{h} = \textstyle\sum_{1 \le k \le n} h_k, && i = \sigma(W^{(i)}x + U^{(i)}\tilde{h} + b^{(i)}),\\
&o = \sigma(W^{(o)}x + U^{(o)}\tilde{h} + b^{(o)}), && u = \tanh(W^{(u)}x + U^{(u)}\tilde{h} + b^{(u)}),\\
&f_k = \sigma(W^{(f)}x + U^{(f)}h_k + b^{(f)}), && c = i \odot u + \textstyle\sum_{1 \le k \le n} f_k \odot c_k,\\
&h = o \odot \tanh(c), &&
\end{aligned}
\tag{2}
$$

Child-Sum Tree-GRU. The way of Child-Sum Tree-GRU extending to the standard GRU is similar to the way of Child-Sum Tree-LSTM extending to the standard LSTM. Since we only introduce the Child-Sum algorithm applied to the LSTM and GRU, in the following, we omit the "Child-Sum" prefix of Child-Sum Tree-LSTM and Child-Sum Tree-GRU for simplicity. Compared with the Tree-LSTM,

the Tree-GRU removes the memory cell c and introduces an update gate z and multiple reset gates $r_1, r_2, \ldots, r_n$ that allow the composer to reset the hidden states of the child units. The candidate hidden state $\hat{h}$ is computed similarly to the standard RNN (Equation 1Seq-RNNsequation.2.1) and the update gate z is used to control how much the previous hidden state $\tilde{h}$ and the candidate $\hat{h}$ should be passed. The transition equations of Tree-GRU are in the following:

$$\begin{array}{ll} \tilde{h} = \sum_{1 \leq k \leq n} h_k, & r_k = \sigma(W^{(r)}x + U^{(r)}h_k + b^{(r)}), \\ \hat{h} = \tanh(W^{(h)}x + U^{(h)} \sum_{k=1}^{n} r_k \odot h_k), & z = \sigma(W^{(z)}x + U^{(z)}\tilde{h} + b^{(z)}) \\ h = z \odot \tilde{h} + (1 - z) \odot \hat{h}, & \end{array} \tag{3}$$

where σ denotes the sigmoid function and $\odot$ denotes element-wise multiplication.

We can easily apply the Child-Sum Tree-RNN to the dependency trees that have branching factors of arbitrary number and order-insensitive nodes. We refer to the model adopting the Tree-LSTM and Tree-GRU composer to the dependency tree as the *Dependency Tree-LSTMs* and *Dependency Tree-GRUs*. For simplicity, we also omit the prefix "Dependency" in the following sections.

2.3 Attentive Tree-RNNs

We now details how we extend the standard Tree-RNN. The idea that we incorporate the attention into the standard Tree-RNN comes from: (1) there will be semantic relevance between two sentences in the sentence pair modelling tasks; (2) the effect of semantic relevance could be implemented in the process of constructing the sentence representation by Tree-RNN where each child should be assigned a different weight; and (3) the attention mechanism is well suited for learning weights on a contextual collection where a guided vector is attending over.

Soft Attention Layer In this work, the attention mechanism is implemented by a *soft attention layer* A. Given a collection of hidden states $h_1, h_2, \ldots, h_n$ and an external vector s, the soft attention layer produce a weight α_k for each hidden state as well as a weighted vector g via the Equations 4Soft Attention Layerequation.2.4:

$$\begin{array}{ll} m_k = \tanh(W^{(m)}h_k + U^{(m)}s), & \alpha_k = \frac{\exp(w^\intercal m_k)}{\sum_{j=1}^{n} \exp(w^\intercal m_j)}, \\ g = \sum_{1 \leq k \leq n} \alpha_k h_k, & \end{array} \tag{4}$$

Attentive Tree-LSTM and -GRU As illustrated in Figure 2(c)Subfigure 2(c)subfigure.2.3 and Figure 2(f)Subfigure 2(f)subfigure.2.6, when the attention layer is embedded to the standard Tree-LSTM and Tree-GRU composer, these composers become the Attentive Tree-LSTM and Attentive Tree-GRU. The attention layer (notated with A) receives the children's hidden states and an external vector s, producing a weighted representation g (Equation 4Soft Attention Layerequation.2.4). In our implementation, the external vector s is a vector representation of sentence learned by a Seq-RNNs. Specifically, if the tree composer is Attentive Tree-LSTM, then the Seq-RNNs is Seq-LSTMs. Instead of taking the sum of children's hidden states as the previous hidden state $\tilde{h}$ in the standard Tree-RNN, we compute a new hidden state by a transformation $\tilde{h} = \tanh(W^{(a)}g + b^{(a)})$. Similar to the standard Tree-RNN, the attentive composers can also be easily applied to dependency trees. We refer to the model which applies the Attentive Tree-RNN composer to the dependency tree as the Attentive (Dependency) Tree-RNNs.

2.4 MLP

The multilayer perceptron network (MLP) receives a pair of vectors produced by the sentence encoder to compute a multinomial distribution over possible values. Given two sentence representations h_L and h_R, we compute their componentwise product $h_L \odot h_R$ and their absolute difference $|h_L - h_R|$. These features are also used by Tai et al.(2015). We then compress these features into a low dimensional vector

h_s, which is used to compute the probability distribution $\hat{p}_\theta$. The equations are the following:

$$
\begin{aligned}
h_\times &= h_L \odot h_R, \quad h_+ = |h_L - h_R|, \\
h_s &= \sigma(W^{(\times)} h_\times + W^{(+)} h_+ + b^{(h)}), \\
\hat{p}_\theta &= \text{softmax}(W^{(p)} h_s + b^{(p)}),
\end{aligned} \tag{5}
$$

3 Experiments and Results

Config	Value	Config	Value
Word vectors	Glove (Pennington et al., 2014)	Dims of word vectors	300
OOV word vectors	uniform(-0.05, 0.05)	Dims of hidden state	150
Learning rate	0.05	Batch size	25
Regularization	L2 with $\lambda = 10^{-4}$	Dropout rate	0.5
Optim method	Adagrad (Duchi et al., 2011)	Num of epoch	10

Table 1: The training configs. We use the 300D Glove vectors as the initial word vectors. Out-of-vocabulary words are initialized with a uniform distribution. The model parameters are regularized with a per-minibatch L2 regularization strength of 10^{-4}. The dropout is used at the classifier with a dropout rate 0.5. All models are trained using Adagrad with a learning rate of 0.05. We train our models for 10 epochs, and pick the model that has the best results on the devlopment set to evaluate on the test set.

Our baselines In order to make a meaningful comparison between the sequential models, tree-structured models and attentive models, we present four baselines. They are: (i) **Seq-LSTMs**, learning two sentence representations by the sequential LSTMs; (ii) **Seq-GRUs**, like Seq-LSTMs but using GRU composer; (iii) **Tree-LSTMs**, learning two sentence representations by the Dependency Tree-LSTMs; and (iv) **Tree-GRUs**, like Tree-LSTMs but using Child-Sum Tree-GRU composer. The two sentence representations are fed to the MLP to produce a probability distribution.

3.1 Task 1: Semantic Similarity

First we conduct our semantic similarity experiment on the Sentences Involving Compositional Knowledge(SICK) dataset (Marelli et al., 2014)[12]. This task is to predict a similarity score of a pair of sentences, based on human generated scores. The SICK dataset consists of 9927 sentence pairs with the split of 4500 training pairs, 500 development pairs and 4927 testing pairs. Each sentence pair is annotated with a similarity score ranging from 1 to 5. A high score indicates that the sentence pair is highly related. All sentences are derived from existing image and video annotation dataset. The evaluation metrics are Pearson's r, Spearman's ρ and mean squared error (MSE).

Recall that the output of MLP (Section 2.4MLPsubsection.2.4) is a probability distribution $\hat{p}_\theta$. Our goal in this task is to predict a similarity score of two sentences. Let $r^\intercal = [1, \ldots, 5]$ be an integer vector, the similarity score $\hat{y}$ is computed by $\hat{y} = r^\intercal \hat{p}_\theta$. We take the same setup as (Tai et al., 2015) that computes a target distribution p as a function of prediction score y given by:

$$
p_i = \begin{cases} y - \lfloor y \rfloor, & i = \lfloor y \rfloor + 1 \\ \lfloor y \rfloor - y + 1, & i = \lfloor y \rfloor \\ 0 & \text{otherwise} \end{cases}
$$

The loss function of semantic similarity is the KL-divergence that measures the continuous distance between the predicted distribution $\hat{p}_\theta$ and the distribution of the ground truth p:

$$
J(\theta) = \frac{1}{N} \sum_{k=1}^{N} \text{KL}(p^{(k)} \Big|\Big| \hat{p}_\theta^{(k)}) + \frac{\lambda}{2} ||\theta||_2^2 \tag{6}
$$

Method	r	ρ	MSE
ECNU (Zhao et al., 2014)	0.8414	-	-
Dependency Tree-LSTMs (Tai et al., 2015)	0.8676	0.8083	0.2532
combine-skip+COCO (Kiros et al., 2015)	0.8655	0.7995	0.2561
ConvNet (He et al., 2015)	0.8686	0.8047	0.2606
Seq-GRUs	0.8595	0.7974	0.2689
Seq-LSTMs	0.8528	0.7911	0.2831
(Dependency) Tree-GRUs	0.8672	0.8116	0.2573
(Dependency) Tree-LSTMs(ours)	0.8664	0.8068	0.2610
+Attention			
Attentive (Dependency) Tree-GRUs	0.8701	0.8085	0.2524
Attentive (Dependency) Tree-LSTMs	**0.8730**	**0.8117**	**0.2426**

Table 2: Test set results on the SICK dataset. The first group is previous results, and remaining is ours.

The results are summarized in Table 2Test set results on the SICK dataset. The first group is previous results, and remaining is ourstable.2. We first compare our results against the previous results. ECNU (Zhao et al., 2014), the best result of SemEval 2014 submissions, achieves a 0.8414 r score by a heavily feature-engineered approach. Kiros et al. (2015) presents an unsupervised approach to learn the universal sentence vectors without depending on a specific task. Their Combine–skip+COCO model improve the Pearson's r to 0.8655, but a weakness is that their sentence vectors are high-dimensional vectors (2400D). Training the skip-thoughts vectors needs a lot of time and space. He et al. (2015) show the effectiveness of convolutional nets with the similarity measurement layer for modelling sentence similarity. Their ConvNet outperforms ECNU with +0.027 Pearson's r. We can observe that dependency Tree-LSTM, combine-skip+COCO and ConvNet almost achieve the same performance and our Attentive Tree-LSTMs outperforms these three methods around +0.005 points. Comparison to ECNU, our Attentive Tree-LSTMs gains an improvement of +0.032 and achieves the state-of-the-art performance. We find a phenomenon also appeared in (Tai et al., 2015) that tree-structured models can outperform sequential counterparts. Comparison to the non-attentional baselines (such as Tree-LSTMs), the attention mechanism (such as Attentive Tree-LSTMs) gives us a boost of around +0.007. All results highlight that our attentive Tree-RNNs are well suited for the semantic similarity task.

3.2 Task 2: Paraphrase Identification

The next task we evaluate is paraphrase identification on the Microsoft Research Paraphrase Corpus (MSRP) (Dolan et al., 2004). Given two sentences, this task is to predict whether or not they are paraphrases. The dataset is collected from news sources and contains 5801 pairs of sentences, with 4076 for training and the remaining 1725 for testing. We randomly select 10% of training set and use them as our dev set. This task is a binary classification task, therefore we report the accuracy and F1 score.

Since that the $\hat{p}_\theta$ indicates the distribution over the possible labels, we take $argmax(\hat{p}_\theta)$ as the predicted label in the testing phase. The loss function for the binary classification is the *binary cross-entropy*:

$$J(\theta) = -\frac{1}{N}\sum_{k=1}^{N}(y^{(k)}\log\hat{p}_\theta^{(k)} + (1-y^{(k)})\log(1-\hat{p}_\theta^{(k)})) + \frac{\lambda}{2}||\theta||_2^2 \quad (7)$$

Table 3The test results of paraphrase identification on the Microsoft Paraphrase Corpus (**Left**) and true-false selection on the AI2-8grade dataset (**Right**)table.3 (**left**) presents our results on the MSRP dataset. The previous approaches are: (1) Baseline, cosine similarity with tf-idf weighting; (2) RAE,

recursive autoencoder with dynamic pooling; (3) combine-skip+feats, skip-thought vectors with features; (4) ABCNN-3, attention-based convolutional nets; and (5) TF-KLD, matrix factorization with supervised reweighting. First, all our models are able to outperform the baseline. We only compare our models with the neural networks-based approaches, including RAE and ABCNN-3 for a fair comparison. We find that our models do not prove to be very competitive. After a careful analysis, we conclude that the reasons are (1) our models are pure neural networks-based, we don't add any features to identify paraphrases while the other methods have used additional features; (2) The MLP is not very suitable in this task. We attempt to replace the MLP with the cosine distance and euclidean distance in our future work. Although our models have not yet matched the SOTA performance, we obtain an improvement of +2.3 accuracy by Attentive Tree-LSTMs when we incorporate the attention into the standard Tree-LSTM.

3.3 Task 3: True-False Question Selection

We last consider a challenging task: selecting true or false given a scientific question and its evidence. In this task, we use the AI2-8grade dataset built by (Baudis et al., 2016). This dataset is derived from the *AI2 Elementary School Science Questions* released by Allen Institute. Each sentence pair consists of a hypothesis sentence processed by substituting the wh-word in the question by answer and its evidence sentence extracted from a collection of CK12 textbooks. The number of sample pairs in the training, development, and test set are 12689, 2483 and 11359 respectively. This dataset contains 626 words not appearing in *Glove vectors*, most of which are named entities and scientific jargons.

The loss function is the same as the paraphrase identification since this task is also a binary classification task. We reports the accuracy on development set and test set shown in Table 3The test results of paraphrase identification on the Microsoft Paraphrase Corpus (**Left**) and true-false selection on the AI2-8grade dataset (**Right**)table.3 (**right**). Since this dataset is a fresh and uncompleted dataset, we only compare our models with Baudis et al. (2016) who have evaluated several models on it. Comparison to (Baudis et al., 2016), all of our models gain a significant improvement. Specially, our best result achieved by the Attentive Tree-LSTMs is higher than the best of (Baudis et al., 2016) by +28 percents. It is observed that tree-structured models are more competitive than the sequential counterparts. As we expected, the attentive models can outperform all non-attentional counterparts.

4 Quantitative Analysis

Example Analysis Table 4Example predictions from the test set. **GT**: ground truth, **Pred**: predicted scoretable.4 presents example predictions that are produced by our Attentive Tree-LSTMs. The first group shows that our model is able to predict semantic similarity score nearly perfectly on the SICK dataset. We argue the reason is that the sentences of SICK dataset are image and video descriptions whose sentence structure is relatively simple and there are less uncommon words and named entities in the vocabulary. The second group gives us three examples on the MSRP test set. We find that our model can identify whether two fact statements are paraphrases, but fails to recognize the numbers (in group 2, line 3). We presents the examples on AI2-8grade dataset in the last group. We can observe that our model is efficient to select the false questions, while our model is difficult to select the true answers,

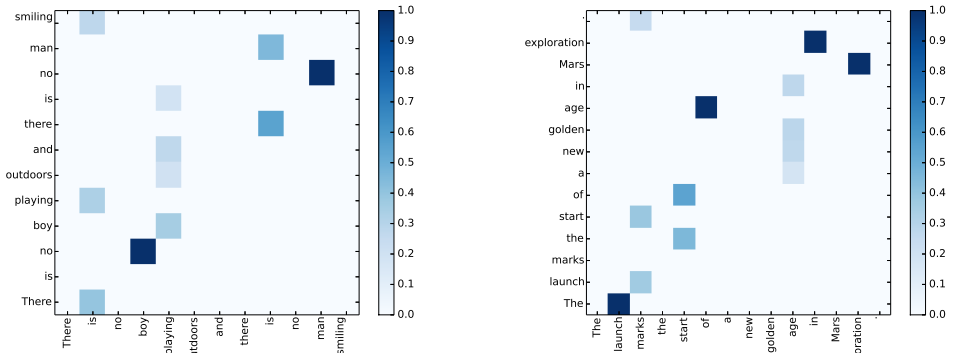
unless the evidence of question is very strong.

Effect of Sentence Length In order to analyse the effect of mean sentence length on the SICK dataset, we draw the Figure 3(a)Subfigure 3(a)subfigure.3.1. We observe that the Pearson score become lower as sentence become longer. Compared with the Seq-RNNs, the Tree-RNNs obtain a little improvements. Specially, the Attentive Tree-GRUs proves to be more effective than Tree-GRUs when the mean sentence length reaches to 20.

Effect of N-grams In the MSR paraphrase corpus, a hypothesis is that two sentence tend to be paraphrases when the value of their n-gram overlap is high. As a result we present the Figure 3(b)Subfigure 3(b)subfigure.3.2, x-axis is the normalized n-grams overlap whose value is computed by $c* \frac{(unigram+bigram+trigram)}{mean\_sent\_length}$, where c equals to 50, and y-axis is the accuracy. We can observe that the Attentive Tree-GRUs are more effective than Tree-GRUs when the value of normalized n-grams overalp is less than 40. The results suggest that our attentive models are more general.

Attention Visualization It is instructive to analyse which child the attentive model is attending over when constructing the head representation. We visualize the heatmaps of attention weights shown in Figure 4Heatmap of attention weightsfigure.4. The words at x-axis are modified by the words at y-axis with a weight (greater than *zero*). For example in Figure 4(a)Subfigure 4(a)subfigure.4.1, the 5th word at x-axis is "playing" whose children are "boy", "outdoors", "and" and "is". We can observe that the word "boy" holds a higher weight among all the modifiers. It means that the branch rooted with "boy" contributes more when constructing the representation of subtree whose root node is "playing". This phenomenon is very reasonable because the sentence is describing a image of "a **boy** is **playing**



(a) (b)

Figure 4: Heatmap of attention weights.

something".

5 Conclusion

In this paper, we introduced a way of incorporating attention into the Child-Sum Tree-LSTM and Tree-GRU that can be applied to the dependency tree. We evaluate the proposed models on three sentence pair modelling tasks and achieve state-of-the-art performance on two of them. Experiment results show that our attentive models are effective for modelling sentence pairs and can outperform all non-attentional counterparts. In the future, we will evaluate our models on the other sentence pair modelling tasks (such as RTE) and extend them to the $seq2seq$ learning framework.

Abstract

In this paper, we propose a novel neural approach for paraphrase generation. Conventional paraphrase generation methods either leverage hand-written rules and thesauri-based alignments, or use statistical machine learning principles. To the best of our knowledge, this work is the first to explore deep learning models for paraphrase generation. Our primary contribution is a stacked residual LSTM network, where we add residual connections between LSTM layers. This allows for efficient training of deep LSTMs. We evaluate our model and other state-of-the-art deep learning models on three different datasets: PPDB, WikiAnswers, and MSCOCO. Evaluation results demonstrate that our model outperforms sequence to sequence, attention-based, and bidirectional LSTM models on BLEU, METEOR, TER, and an *embedding*-based sentence similarity metric.

1 Introduction

Paraphrasing, the act to express the same meaning in different possible ways, is an important subtask in various Natural Language Processing (NLP) applications such as question answering, information extraction, information retrieval, summarization and natural language generation. Research on paraphrasing methods typically aims at solving three related problems: (1) recognition (i.e. to identify if two textual units are paraphrases of each other), (2) extraction (i.e. to extract paraphrase instances from a thesaurus or a corpus), and (3) generation (i.e. to generate a reference paraphrase given a source text) (Madnani and Dorr, 2010). In this paper, we focus on the paraphrase generation problem.

Paraphrase generation has been used to gain performance improvements in several NLP applications, for example, by generating query variants or pattern alternatives for information retrieval, information extraction or question answering systems, by creating reference paraphrases for automatic evaluation of machine translation and document summarization systems, and by generating concise or simplified information for sentence compression or sentence simplification systems (Madnani and Dorr, 2010). Traditional paraphrase generation methods exploit hand-crafted rules (McKeown, 1983) or automatically learned complex paraphrase patterns (Zhao et al., 2009), use thesaurus-based (Hassan et al., 2007) or semantic analysis driven natural language generation approaches (Kozlowski et al., 2003), or leverage statistical machine learning theory (Quirk et al., 2004; Wubben et al., 2010). In this paper, we propose to use deep learning principles to address the paraphrase generation problem.

Recently, techniques like sequence to sequence learning (Sutskever et al., 2014) have been applied to various NLP tasks with promising results, for example, in the areas of machine translation (Cho et al., 2014; Bahdanau et al., 2015), speech recognition (Li and Wu, 2015), language modeling (Vinyals et al., 2015), and dialogue systems (Serban et al., 2016). Although paraphrase generation can be formulated as a sequence to sequence learning task, not much work has been done in this area with regard to applications of state-of-the-art deep neural networks. There are several works on paraphrase recognition (Socher et al., 2011; Yin and Schütze, 2015; Kiros et al., 2015), but those employ classification techniques and do not attempt to generate paraphrases. More recently, attention-based Long Short-Term Memory (LSTM) networks have been used for textual entailment generation (Kolesnyk et al., 2016); however, paraphrase

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 2923–2934, Osaka, Japan, December 11-17 2016.

generation is a type of bi-directional textual entailment generation and no prior work has proposed a deep learning-based formulation of this task.

To address this gap in the literature, we explore various types of sequence to sequence models for paraphrase generation. We test these models on three different datasets and evaluate them using well recognized metrics. Along with the application of various existing sequence to sequence models for the paraphrase generation task, in this paper we also propose a new model that allows for training multiple stacked LSTM networks by introducing a residual connection between the layers. This is inspired by the recent success of such connections in a deep Convolutional Neural Network (CNN) for the image recognition task (He et al., 2015). Our experiments demonstrate that the proposed model can outperform other techniques we have explored.

Most of the deep learning models for NLP use Recurrent Neural Networks (RNNs). RNNs differ from normal perceptrons as they allow gradient propagation in time to model sequential data with variable-length input and output (Sutskever et al., 2011). In practice, RNNs often suffer from the vanishing/exploding gradient problems while learning long-range dependencies (Bengio et al., 1994). LSTM (Hochreiter and Schmidhuber, 1997) and GRU (Cho et al., 2014) are known to be successful remedies to these problems.

It has been observed that increasing the depth of a deep neural network can improve the performance of the model (Simonyan and Zisserman, 2014; He et al., 2015) as deeper networks learn better representations of features (Farabet et al., 2013). In the vision-related tasks where CNNs are more widely used, adding many layers of neurons is a common practice. For tasks like speech recognition (Li and Wu, 2015) and also in machine translation, it is useful to stack layers of LSTM or other variants of RNN. So far this has been limited to only a few layers due to the difficulty in training deep RNN networks. We propose to add residual connections between multiple stacked LSTM networks and show that this allows us to stack more layers of LSTM successfully.

The rest of the paper is organized as follows: Section 2 presents a brief overview of the sequence to sequence models followed by a description of our proposed residual deep LSTM model, Section 3 describes the datasets used in this work, Section 4 explains the experimental setup, Section 5 presents the evaluation results and analyses, Section 6 discusses the related work, and in Section 7 we conclude and discuss future work.

2 Model Description

2.1 Encoder-Decoder Model

A neural approach to sequence to sequence modeling proposed by Sutskever et al. (2014) is a two-component model, where a source sequence is first encoded into some low dimensional representation (Figure 1) that is later used to reproduce the sequence back to a high dimensional target sequence (i.e. decoding). In machine translation, an encoder operates on a sentence written in the source language and encodes its meaning to a vector representation before the decoder can take that vector (which represents the meaning) and generate a sentence in the target language. These encoder-decoder blocks can be either a vanilla RNN or its variants. While producing the target sequence, the generation of each new word depends on the model and the preceding generated word. Generation of the first word in the target sequence depends on the special '`EOS`' (end-of-sentence) token appended to the source sequence.

The training objective is to maximize the log probability of the target sequence given the source sequence. Therefore, the best possible decoded target is the one that has the maximum score over the length of the sequence. To find this, a small set of hypotheses (candidate set) called *beam size* is used and the total score for all these hypotheses are computed. In the original work by Sutskever et al. (2014), they observe that although a beam size of 1 achieves good results, a higher beam size is always better. This is because for some of the hypotheses, the first word may not always have the highest score.

2.2 Deep LSTM

LSTM (Figure 2) is a variant of RNN, which computes the hidden state h_t using a different approach by adding an internal memory cell $c_t \in \mathbb{R}^n$ at every time step t. In particular, an LSTM unit considers the input state x_t at time step t, the hidden state h_{t-1}, and the internal memory state c_{t-1} at time step

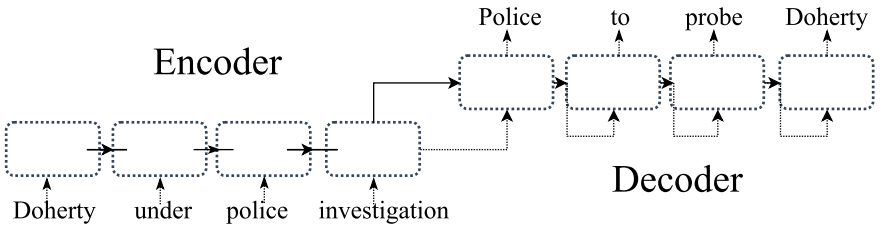

Figure 1: Encoder-Decoder framework for sequence to sequence learning.

1. Gates

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i)$$
$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f)$$
$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o)$$

2. Input transform

$$c\_in_t = \tanh(W_{xc}x_t + W_{hc}h_{t-1} + b_{c\_in})$$

3. State Update

$$c_t = f_t \odot c_{t-1} + i_t \odot c\_in_t$$
$$h_t = o_t \odot \tanh(c_t)$$

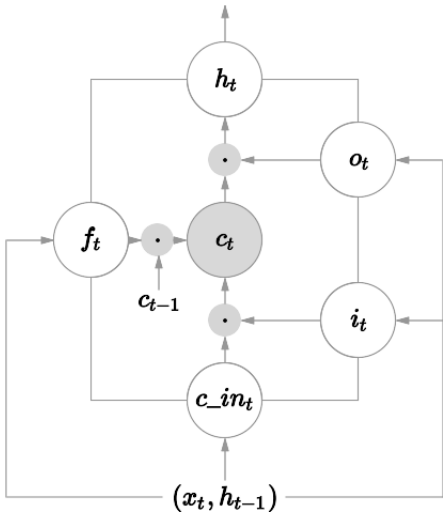

Figure 2: LSTM cell (Paszke, 2015).

$t-1$ to produce the hidden state h_t and the internal memory state c_t at time step t. The memory cell is controlled via three learned gates: input i, forget f, and output o. These memory cells use the addition of gradient with respect to time and thus minimize the gradient explosion. In most NLP tasks, LSTM outperforms vanilla RNN (Sundermeyer et al., 2012). Therefore, for our model we only explore LSTM as a basic unit in the encoder and decoder. Here, we describe the basic computations in an LSTM unit, which will provide the grounding to understand the residual connections between stacked LSTM layers later.

In the equations above, $W_{x\_}$, $W_{h\_}$ are the learned parameters for x and h respectively. $\sigma(.)$ and $\tanh(.)$ denote element-wise sigmoid and hyperbolic tangent functions respectively. $\odot$ is the element-wise multiplication operator and b denotes the added bias.

Graves (2013) explored the advantages of deep LSTMs for handwriting recognition and text generation. There are multiple ways of combining one layer of LSTM with another. For example, Pascanu et al. (2013) explored multiple ways of combining them and discussed various difficulties in training deep LSTMs. In this work, we employ vertical stacking where only the output of the previous layer of LSTM is fed to the input, as compared to the stacking technique used by Sutskever et al. (2014), where hidden states of all LSTM layers are fully connected. In our model, all but the first layer input at time step t is passed from the hidden state of the previous layer h_t^l, where l denotes the layer. This is similar to stacked RNN proposed by Bengio et al. (1994) but with LSTM units. Thus, for a layer l the activation is described by:

$$\boldsymbol{h}_t^{(l)} = f_h^l(\boldsymbol{h}_t^{(l-1)}, \boldsymbol{h}_{t-1}^{(l)})$$

where hidden states $\boldsymbol{h}$ are recursively computed and $\boldsymbol{h}_t^{(l)}$ at $t = 0$ and $l = 0$ is given by the LSTM equation of h_t.

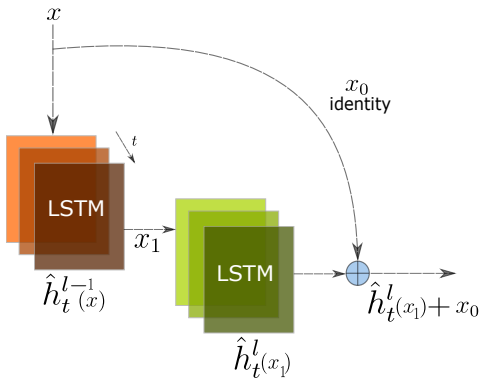

Figure 3: A unit of stacked residual LSTM.

2.3 Stacked Residual LSTM

We take inspiration from a very successful deep learning network *ResNet* (He et al., 2015) with regard to adding residue for the purpose of learning. With theoretical and empirical reasoning, He et al. (2015) have shown that the explicit addition of the residue x to the function being learned allows for deeper network training without overfitting the data.

When stacking multiple layers of neurons, the network often suffers through a *degradation* problem (He et al., 2015). The degradation problem arises due to the low convergence rate of training error and is different from the vanishing gradient problem. Residual connections can help overcome this issue. We experimented with four-layers of stacked LSTM for each of the model. Residual connections are added at layer two as the pointwise addition (see Figure 3), and thus it requires the input to be in the same dimension as the output of h_t. Principally because of this reason, we use a simple last hidden unit stacking of LSTM instead of a more intricate way as shown by Sutskever et al. (2014). This allowed us to clip the h_t to match the dimension of x_{t-2} where they were not the same. Similar results could be achieved by padding x to match the dimension instead. The function $\hat{\boldsymbol{h}}$ that is being learned for the layer with residual connection is therefore:

$$\hat{\boldsymbol{h}}_t^{(l)} = f_h^l(\boldsymbol{h}_t^{(l-1)}, \boldsymbol{h}_{t-1}^{(l)}) + x_{l-n}$$

where $\hat{h}$ for layer l is updated with residual value x_{l-n} and x_i represents the input to layer $i+1$. Residual connection is added after every n layers. However, for stacked LSTM, $n > 3$ is very expensive in terms of computation. In this paper we experimented with $n = 2$. Note that, when $n = 1$, the resulting function learned is a standard LSTM with bias that depends on the input x. That is why, it is not necessary to add the residual connection after every stacked layer of LSTM. The addition of residual connection does not add any learnable parameters. Therefore, this does not increase the complexity of the model unlike bi-directional models which double the number of LSTM units.

3 Datasets

We present the performance of our model on three datasets, which are significantly different in their characteristics. So, evaluating our paraphrase generation approach on these datasets demonstrates the versatility and robustness of our model.

PPDB (Pavlick et al., 2015) is a well known paraphrase dataset used for various NLP tasks. It comes in different sizes and the precision of the paraphrases degrades with the size of the dataset. We use the size L dataset from PPDB 2.0, which comes with over $18M$ paraphrases including lexical, phrasal and syntactic types. We have omitted the syntactic paraphrases and the instances which contain numbers, as they increase the vocabulary size significantly without giving any advantage of a larger dataset. This dataset contains relatively short paraphrases (86% of the data is less than four words), which makes it suitable for synonym generation and phrase substitution to address lexical and phrasal paraphrasing (Madnani and Dorr, 2010). For some phrases, PPDB has one-to-many paraphrases. We collect all such phrases to make a set of paraphrases and sampling without replacement was used to obtain the source

and reference phrases.

WikiAnswers (Fader et al., 2013) is a large question paraphrase corpus created by crawling the WikiAnswers website[1], where users can post questions and answers about any topic. The paraphrases are different questions, which were tagged by the users as similar questions. The dataset contains approximately 18M word-aligned question pairs. Sometimes, there occurs a loss of specialization between a given source question and its corresponding reference question when a paraphrase is tagged as similar to a reference question. For example, "prepare a *three month* cash budget" is tagged to "how to prepare a cash budget". This happens because general questions are typically more popular and get answered. So, specific questions are redirected to the general ones due to a comparative lack of interest in the very specific questions. It should be noted that this dataset comes preprocessed and lemmatized. We refer the reader to the original paper for more details.

MSCOCO (Lin et al., 2014) dataset contains human annotated captions of over $120K$ images. Each image contains five captions from five different annotators. While there is no guarantee that the human annotations are paraphrases, the nature of the images (which tends to focus on only a few objects and in most cases one prominent object or action) allows most annotators describe the most obvious things in an image. In fact, this is the main reason why neural networks for generating captions obtain better `BLEU` scores (Vinyals et al., 2014), which confirms the suitability of using this dataset for the paraphrase generation task.

4 Experimental Settings

4.1 Data Selection

For `PPDB` we remove the phrases that contain numbers including all syntactic phrases. This gives us a total of $5.3M$ paraphrases from which we randomly select 90% instances for training. For testing, we randomly select $20K$ pairs of paraphrases from the remaining 10% data. Although `WikiAnswers` comes with over $29M$ instances, we randomly select $4.8M$ for training to keep the training size similar to `PPDB` (see Table 1). $20K$ instances were randomly selected from the remaining data for testing. Note that, for the `WikiAnswers` dataset, we clip the vocabulary size[2] to $50K$ and use the special *UNK* symbol for the words outside the vocabulary. `MSCOCO` dataset has five captions for every image. This dataset comes with separate subsets for training and validation: *Train 2014* contains over $82K$ images and *Val 2014* contains over $40K$ images. From the five captions accompanying each image, we randomly omit one caption and use the other four as training instances (by creating two source-reference pairs). Thus, we obtain a collection of over $330K$ instances for training and $20K$ instances for testing. Because of the free form nature of the caption generation task (Vinyals et al., 2014), some captions were very long. We reduced those captions to the size of 15 words (by removing the words beyond the first 15) in order to reduce the training complexity of the models.

Dataset	Training	Test	Vocabulary Size
`PPDB`	4,826,492	20,000	38,279
`WikiAnswers`	4,826,492	20,000	50,000
`MSCOCO`	331,163	20,000	30,332

Table 1: Dataset details.

Bi-directional LSTM	(Graves et al., 2013)
Residual LSTM	Our proposed model

Table 2: Models.

4.2 Models

We experimented with four different models (see Table 2). For each model, we experimented with two- and four-layers of stacked LSTMs. This was motivated by the state-of-the-art speech recognition systems that also use three to four layers of stacked LSTMs (Li and Wu, 2015). In encoder-decoder models, the size of the beam search used during inference is very important. Larger beam size always gives higher

[1] http://wiki.answers.com

[2] `WikiAnswers` dataset had many spelling errors yielding a very large vocabulary size (approximately $250K$). Hence, we selected the most frequent $50K$ words in the vocabulary to reduce the computational complexity.

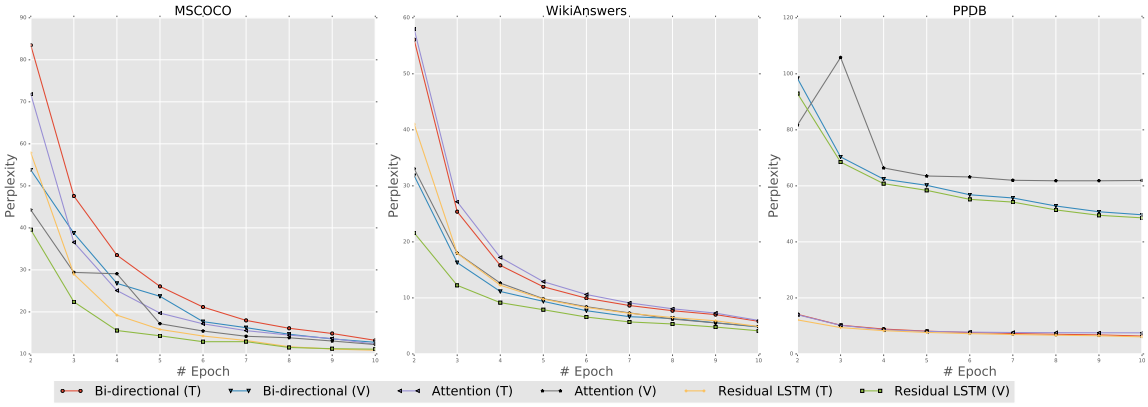

Figure 4: Perplexity during training (T) and validation (V) for various models [shared legend]. A lower perplexity represents a better model.

accuracy but is associated with a computational cost. We experimented with beam sizes of 5 and 10 to compare the models, as these are the most common beam sizes used in the literature (Sutskever et al., 2014). The bi-directional model used half of the number of layers shown for other models. This was done to ensure similar parameter sizes across the models.

4.3 Training

We used a one-hot vector approach to represent the words in all models. Models were trained with a stochastic gradient descent (SGD) algorithm. The learning rate began at 1.0, and was halved after every third training epoch. Each network was trained for ten epochs. In order to allow exploration of a wide variety of models, training was restricted to a limited number of epochs, and no hyper-parameter search was performed. A standard dropout (Srivastava et al., 2014) of 50% was applied after every LSTM layer. The number of LSTM units in each layer was fixed to 512 across all models. Training time ranged from 36 hours for `WikiAnswers` and `PPDB` to 14 hours for `MSCOCO` on a *Titan X* with *CuDNN 5* using Theano version $0.9.0dev1$ (Theano Development Team, 2016).

A beam search algorithm was used to generate optimal paraphrases by exploiting the trained models in the testing phase (Sutskever et al., 2014). We used perplexity as the loss function during training. Perplexity measures the uncertainty of the language model, corresponding to how many bits on average would be needed to encode each word given the language model. A lower perplexity indicates a better score. While `WikiAnswers` and `MSCOCO` had a very good correlation between training and validation perplexity, overfitting was observed with `PPDB` that yielded a worse validation perplexity (see Figure 4).

5 Evaluation

5.1 Metrics

To quantitatively evaluate the performance of our paraphrase generation models, we use the well-known automatic evaluation metrics[3] for comparing parallel corpora: `BLEU` (Papineni et al., 2002), `METEOR` (Lavie and Agarwal, 2007), and Translation Error Rate (`TER`) (Snover et al., 2006). Even though these metrics were designed for machine translation, previous works have shown that they can perform well for the paraphrase recognition task (Madnani et al., 2012) and correlate well with human judgments in evaluating generated paraphrases (Wubben et al., 2010).

Although there exists a few automatic evaluation metrics that are specifically designed for paraphrase generation, such as `PEM` (Paraphrase Evaluation Metric) (Liu et al., 2010) and `PINC` (Paraphrase In N-gram Changes) (Chen and Dolan, 2011), they have certain limitations. `PEM` relies on large in-domain bilingual parallel corpora along with sample human ratings for training while it can only model paraphrasing up to the phrase-level granularity. `PINC` attempts to solve these limitations by proposing a method that is essentially the inverse of `BLEU`, as it calculates the n-gram difference between the source

[3]We used the software available at `https://github.com/jhclark/multeval`

and the reference sentences. Although PINC correlates well with human judgments in lexical dissimilarity assessment, BLEU has been shown to correlate better for semantic equivalence agreements at the sentence-level when a sufficiently large number of reference sentences are available for each source sentence (Chen and Dolan, 2011).

BLEU considers exact matching between reference paraphrases and system generated paraphrases by considering n-gram overlaps while METEOR improves upon this measure via stemming and synonymy using WordNet. TER measures the number of edits required to change a system generated paraphrase into one of the reference paraphrases. As suggested in Clark et al. (2011), we used a stratified approximate randomization (AR) test. AR calculates the probability of a metric score providing the same reference sentence by chance. We report our *p*-values at 95% Confidence Intervals (CI).

The major limitation of these evaluation metrics is that they do not consider the meaning of the paraphrases, and hence, are not able to capture paraphrases of entities. For example, these metrics do not reward the paraphrasing of *"London"* to *"Capital of UK"*. Therefore, we also evaluate our models on a sentence similarity metric[4] proposed by Rus et al. (2012). This metric uses word embeddings to compare the phrases. In our experiments, we used Word2Vec embeddings pre-trained on the Google News Corpus (Mikolov et al., 2014). This is referred to as *'Emb Greedy'* in our results table.

5.2 Results

Table 3 presents the results from various models across different datasets. ↑ denotes that higher scores represent better models while ↓ means that a lower score yields a better model. Although our focus is on stacked residual LSTM, which is applicable only when there are more than two layers, we still present the scores from two-layer LSTM as a baseline. This provides a good comparison against deeper models. The results demonstrate that our proposed model outperforms other models on BLEU and TER for all datasets. On *Emb Greedy*, our model outperforms other models in all datasets except the Attention model when beam size is 10. On METEOR, our model outperforms other models on MSCOCO and WikiAnswers; however, for PPDB, the simple sequence to sequence model performs better. Note that these results were obtained by using single models and no ensemble of the models was used.

To calculate BLEU and METEOR, four references were used for MSCOCO, and five for PPDB and WikiAnswers. In some instances, WikiAnswers did not have up to five reference paraphrases for every source, hence, those were calculated on reduced references. In Table 4, we present the variance due to the test set selection. This is calculated using bootstrap re-sampling for each optimizer run (Clark et al., 2011). Variance due to optimizer instability was less than 0.1 in all cases. *p*-value of these tests are less than 0.05 in all cases. Thus, comparison between two models is significant at 95% CI if the difference in their score is more than the variance due to test set selection (Table 4).

5.3 Analysis

Scores on various metrics vary a lot across the datasets, which is understandable due to their inherent differences. PPDB contains very small phrases and thus does not score well with metrics like BLEU and METEOR which penalize shorter phrases. As shown in Figure 5, more than 50% of PPDB contains one or two words. This leads to a substantial difference between training and validation errors, as shown in Figure 4. The results demonstrate that deeper LSTMs consistently improve performance over shallow models. For beam size of 5 our model outperforms other models in all datasets. For beam size of 10, the attention-based model has a marginally better *Emb Greedy* score than our model. When we look at the qualitative results, we notice that the bias in the dataset is exploited by the system which is a side effect of any form of learning on a limited dataset. We can see this effect in Table 5. For example, *an OBJECT* is mostly paraphrased with *an OBJECT* (e.g. *bowl*, *motorcycle*). Shorter sentences mostly generate shorter paraphrases and the same is true for longer sequences. Based on our results, the embedding-based metric correlates well with statistical metrics. Figure 4 and the results from Table 5 suggest that perplexity is a good loss function for training paraphrase generation models. However, a more ideal metric to fully encode the fundamental objective of paraphrasing should also reward novelty and penalize redundancy during paraphrase generation, which is a notable limitation of the existing paraphrase evaluation metrics.

6 Related Work

Prior approaches to paraphrase generation have applied relatively different methodologies, typically using knowledge-driven approaches or statistical machine translation (SMT) principles. Knowledge-driven methods for paraphrase generation (Madnani and Dorr, 2010) utilize hand-crafted rules (McKeown, 1983) or automatically learned complex paraphrase patterns (Zhao et al., 2009). Other paraphrase generation methods use thesaurus-based (Hassan et al., 2007) or semantic analysis-driven natural language generation approaches (Kozlowski et al., 2003) to generate paraphrases. In contrast, Quirk et al., (2004)

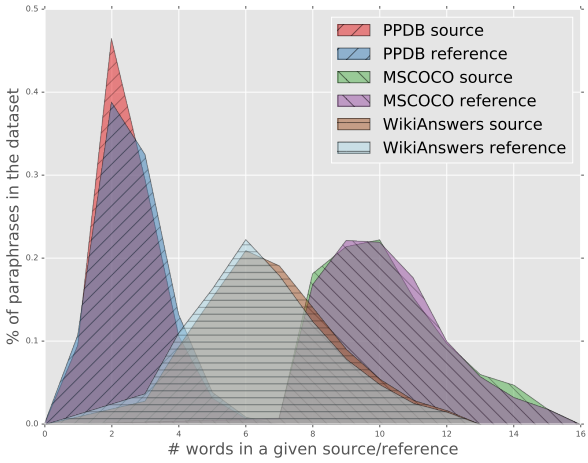

Figure 5: Distribution of sequence length (in number of words) across datasets.

show the effectiveness of SMT techniques for paraphrase generation given adequate monolingual parallel corpus extracted from comparable news articles. Wubben et al., (2010) propose a phrase-based SMT framework for sentential paraphrase generation by using a large aligned monolingual corpus of news headlines. Zhao et al., (2008) propose a combination of multiple resources to learn phrase-based paraphrase tables and corresponding feature functions to devise a log-linear SMT model. Other models generate application-specific paraphrases (Zhao et al., 2009), leverage bilingual parallel corpora (Bannard and Callison-Burch, 2005) or apply a multi-pivot approach to output candidate paraphrases (Zhao et al., 2010).

Applications of deep learning for paraphrase generation tasks have not been rigorously explored. We utilized several sources as potential large datasets. Recently, Weiting et al. (2015) took the PPDB dataset (size XL) and annotated phrases based on their paraphrasability. This dataset is called *Annotated*-PPDB and contains 3000 pairs in total. They also introduced another dataset called *ML-Paraphrase* for the purpose of evaluating bigram paraphrases. This dataset contains 327 instances. Microsoft Research Paraphrase Corpus (MSRP) (Dolan et al., 2005) is another widely used dataset for paraphrase detection. MSRP contains 5800 pairs of sentences (obtained from various news sources) accompanied with human annotations. These datasets are too small and therefore, we did not use them for training our deep learning models.

To the best of our knowledge, this is the first work on using residual connections with recurrent neural networks. Very recently, we found that Toderici et al. (2016) used residual GRU to show an improvement in image compression rates for a given quality over JPEG. Another variant of residual network called *DenseNet* (Huang et al., 2016), which uses dense connections over every layer, has been shown to be effective for image recognition tasks achieving state-of-the-art results in CIFAR and SVHN datasets. Such works further validate the efficacy of adding residual connections for training deep networks.

7 Conclusion and Future Work

In this paper, we described a novel technique to train stacked LSTM networks for paraphrase generation. This is an extension to sequence to sequence learning, which has been shown to be effective for various NLP tasks. Our model outperforms state-of-the-art models for sequence to sequence learning. We have shown that stacking of residual LSTM layers is useful for paraphrase generation, but it may not perform equally well for machine translation because not every word in a source sequence needs to be substituted for paraphrasing. Residual connections help retain important words in the generated paraphrases.

We experimented on three different large scale datasets and reported results using various automatic evaluation metrics. We showed the use of the well-known MSCOCO dataset for paraphrase generation and demonstrated that the models can be trained effectively without leveraging the images. The presented experiments should set strong baselines for neural paraphrase generation on these datasets, enabling future researchers to easily compare and evaluate subsequent works in paraphrase generation.

Recent advances in neural networks with regard to learnable memory (Sukhbaatar et al., 2015; Graves et al., 2014) have enabled models to get one step closer to learning comprehension. It may be helpful to explore such networks for the paraphrase generation task. Also, it remains to be explored how unsupervised deep learning could be harnessed for paraphrase generation. It would be interesting to see if researchers working on image-captioning can employ neural paraphrase generation to augment their dataset.

English-Chinese Knowledge Base Translation with Neural Network

Xiaocheng Feng, Duyu Tang, Bing Qin, Ting Liu
Harbin Institute of Technology, Harbin, China
{*xcfeng, dytang, qinb, tliu*}@ir.hit.edu.cn

Abstract

Knowledge base (KB) such as Freebase plays an important role for many natural language processing tasks. English knowledge base is obviously larger and of higher quality than low resource language like Chinese. To expand Chinese KB by leveraging English KB resources, an effective way is to translate English KB (source) into Chinese (target). In this direction, two major challenges are to model triple semantics and to build a robust KB translator. We address these challenges by presenting a neural network approach, which learns continuous triple representation with a gated neural network. Accordingly, source triples and target triples are mapped in the same semantic vector space. We build a new dataset for English-Chinese KB translation from Freebase, and compare with several baselines on it. Experimental results show that the proposed method improves translation accuracy compared with baseline methods. We show that adaptive composition model improves standard solution such as neural tensor network in terms of translation accuracy.

1 Introduction

Knowledge base (KB) like Freebase[1] and Yago[2] has attracted a lot of attention in both research and industry communities. Knowledge Base contains massive triples (entries), each of which is a fact consisting of two arguments and one predicate, such as (*Una White, profession, Nurse*). A large, high-quality KB is valuable and can be applied to many natural language processing and information retrieval tasks (Graupmann et al., 2005; Hotho et al., 2006; Ferrández et al., 2009; Bouma et al., 2009; Shi et al., 2016; Feng et al., 2016). Let us take Freebase as an example, English KB contains 2.7 billion entries and the accuracy is higher than 80%. This is obviously larger and better than a KB with less amount of entries such as Chinese.

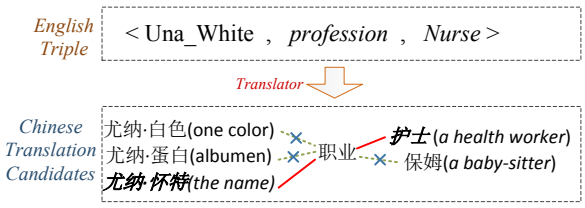

Figure 1: An example of translation ambiguity in English-Chinese KB translation.

A straightforward way to enrich Chinese KB is to directly translate English KB (source) to Chinese (target) based on the surface texts of a triple with existing machine translation system. However, we find that they suffer from the problem of ambiguity. An example is given in Figure 1. The argument "*nurse*" has two translation candidates namely "护士" (a person taking care of sick people in hospital) and "保姆" (baby sitter). "*Una White*" have three translation candidates, so that there are totally six ambiguous

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2935–2944, Osaka, Japan, December 11-17 2016.

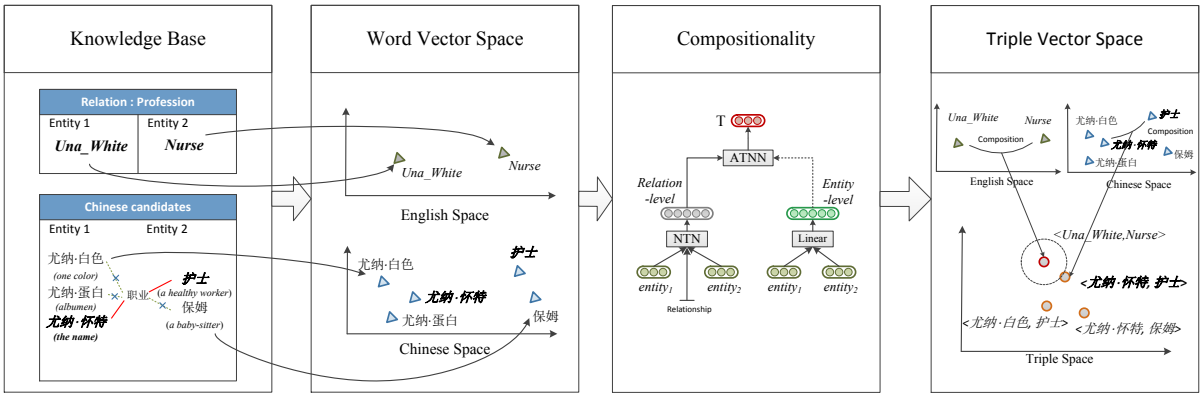

Figure 2: An illustration of the neural network approach for English-Chinese KB translation. It corresponds to the translation example as given in Figure 1.

candidates according to Cartesian product. A preliminary statistical analysis shows that more than half of Freebase translations (English→Chinese) are ambiguous.

There are two main challenges to effectively disambiguate these translated triples. The first challenge is how to effectively model the semantics of English triple and Chinese triple in a unified space. It is preferable to learn a projection function, which maps both English triples and Chinese triples in the same semantic space. The second challenge is how to build a robust KB translator without labor-intensive feature engineering.

In this paper, we address these two challenges by presenting an adaptive neural network to translate English KB into Chinese. Given an English triple and a list of translated Chinese triple candidates, the method assigns a scalar to each translation pair to represent their semantic relatedness. Specifically, we represent each KB triple from the embeddings of words it contains, and introduce an adaptive composition model to effectively capture the semantic composition between arguments of a triple. Compared to previous triple composition methods, the adaptive policy is inspired by highway network (Srivastava et al., 2015b), which is a dynamic calculating process based on different triples rather than a fixed model. In this way, source triple and target triple are naturally encoded in the same semantic vector space. We design a ranking-type hinge loss function to effectively train the parameters of neural networks.

We evaluate the effectiveness of our method on a manually created corpus. We conduct experiments in two settings. Empirical results show that the proposed method consistently outperforms baseline methods. We also show that the use of gated neural network improves strong composition models such as neural tensor network (Socher et al., 2013b) in terms of translation accuracy. The main contributions of this work are as follows:

- We introduce an approach based on representation learning for English-Chinese KB translation in this paper.
- We present a gated neural network to adaptively integrate entity and relational level evidences in triple representation.
- We build a dataset for English-Chinese KB translation, and report the superior performance of our method over baseline methods on it.

2 The Approach

In this section, we present our neural network method for KB Translation in detail. Figure 2 displays a high-level overview of the approach. Given an English triple as input, we first get the candidate Chinese triples (Section 2.1). Afterwards, the semantic representations of English triples and Chinese triples are modeled with neural network (Section 2.2), which are further used for triple ranking (Section 2.3).

2.1 Candidate Generation

In general, a triple in KB is composed of two entities and a relation. In this work, we use English triples from Freebase as the input source, which contains a small number of pre-defined relations. Therefore, we only translate the entities of a triple, while regarding the relation as given. To this end, it is intuitive to use existing text translator to directly translate entities for obtaining candidates. We try to feed English entities to Bing translator, however, a large portion of them can not be translated directly. This stems from the fact that majority of entities are names, proper nouns and named entities which are not well covered in existing translator. Therefore, we use a heuristic method to handle the entities not covered by Bing translator. We split an entity as individual words, and compose the translation results of words as its translation candidate. For example, "*Una White*" in Figure 2.

2.2 Semantic Composition for KB Triple

This section introduces a neural network approach to learn continuous representation for English and Chinese KB triple. We extend this principle in this paper and state that the meaning of a triple is composed from the meanings of entities, relations as well as their correlations.

We find that directly translating entity literally is not effective enough for English-Chinese triple translation. Let us take (Una White, Profession, Nurse) in Figure 1 as an example. The argument "*nurse*" has two translation candidates namely "护士" (a person taking care of sick people in hospital) and "保姆" (baby sitter). "*Una White*" has three translation candidates, so that there are totally six ambiguous candidates according to Cartesian product. To effectively handle this ambiguity problem, we develop an adaptive neural network approach to produce triple representations by effectively capturing entity semantics and the relations between them.

We first describe entity and relational representation. After that, an adaptive composition model is introduced to produce triple representations by automatically combining entity and relational semantics.

2.2.1 Entity Representation

We describe the method to learn continuous representation for each entity. Since an entity is typically a phrase consisting of 2 or 3 words, we average the continuous word representation as the entity representation (Socher et al., 2013b).

Formally, we represent each word as a distributed, continuous and dense vector, which is also known as word embedding (Bengio et al., 2003; Mikolov et al., 2013). These word vectors are stacked in an embedding matrix $L \in \mathbb{R}^{d \times |V|}$, where $|V|$ is word vocabulary size and d is the dimension of each word vector. These word vectors can be randomly initialized from a uniform distribution $U(-0.001, 0.001)$, regarded as parameters of neural networks, and jointly learned with task-specific objectives. Alternatively, the embedding of a word can be trained based on its context information in large-scale text corpus. We use the latter approach since it can make better use of the semantics of words. We learn word embeddings with word2vec[3], which is one of state-of-the-art embedding learning algorithms and widely used for many natural language processing tasks. We learn English word embedding from Wikipedia dump[4], and learn Chinese word embedding from Baike texts[5].

To compose the entity representation from the embedding of words it contains, we follow Socher et al. (2013b) and average the continuous word representation as entity representation. Recursive Neural Network is not suitable to represent entity because entities are typically people names which do not contain explicit compositional structure.

Since the English word vectors and Chinese word vectors are separately trained without using bilingual parallel corpus, these word vectors are mapped into different semantic spaces. This is not desirable for comparing the semantic relatedness between English triple and Chinese triple. We use linear layers to transform English and Chinese word vectors in a same semantic vector space. A simple linear layer is calculated as $v_e = We + b$, where W and b are the parameters. One could also learn bilingual

[3] code.google.com/p/word2vec/

[4] https://dumps.wikimedia.org/

[5] http://baike.baidu.com/

word vectors simultaneously from bilingual parallel corpus with tailored learning algorithm (Zou et al., 2013). We leave this as a future work and we believe our method could benefit from the bilingual word embeddings.

2.2.2 Relational Representation

We model the semantic relatedness between entities in this part. The basic idea is that the semantic relatedness between entities is determined by the semantics of entities and their relations. Based on this, we utilize neural tensor network, which is one of state-of-the-art semantic composition approach for natural language processing tasks (Mitchell and Lapata, 2010; Socher et al., 2013a; Jenatton et al., 2012).

A standard neural tensor with rank 3 is essentially a list of bilinear neural layers, each of which takes two vectors as inputs and outputs a real-valued scalar with element wise multiplication. Furthermore, relation-specific neural tensor can be exploited to make better use of the relation between entities, which is calculated as follows.

$$v_r = e_1^T W_R^{[1:k]} e_2 \tag{1}$$

where k is the length of output vector, e_1 and e_2 are the d-dimensional embeddings of two entities in a given triple, $W_R^{[1:k]} \in \mathbb{R}^{d \times d \times k}$ stands for the parameters of tensor. Each element in v_r is computed by one slice $i \in \{1, ..., k\}$ of tensor.

2.2.3 Adaptive Neural Network

We have previously obtained entity representation and relational representation, both of which play important roles for representing the meaning of a triple. Furthermore, a better approach should benefit from both aspects, and integrate them in triple semantic with an automatic method. To this end, we introduce a gated neural network in this part. It takes entity and relational vectors of a triple as input, and adaptively produces the composed continuous representation of them.

Given v_e and v_r as inputs, a traditional compositional function is to concatenate v_e and v_r and feed them to a linear layer (Socher et al., 2011), which is calculated as Equation 2. Despite its computational efficiency, tied parameters cannot easily capture the complex linguistic phenomena in natural language expressions.

$$\tilde{v} = tanh(W_e v_e + W_r v_r + b) \tag{2}$$

$$\alpha = \sigma(W_{eg} v_e + W_{rg} v_r + b_g) \tag{3}$$

$$v(t) = \alpha \cdot v_r + (1 - \alpha) \cdot \tilde{v} \tag{4}$$

Therefore, we add a neural gate to change parameter values for different input vectors v_e and v_r, which is partly inspired by the recent success of gated recurrent neural network (Cho et al., 2014; Chung et al., 2015) and Long Short-Term Memory (Hochreiter and Schmidhuber, 1997; Tai et al., 2015). And our gated neural network is inspired by highway network, which allow the model to suffer less from the vanishing gradient problem (Srivastava et al., 2015a; Srivastava et al., 2015b). The gate takes v_e and v_r as inputs, and outputs as a weight $\alpha \in [0, 1]$, which linearly weights the two parts. Specifically, the gate is calculated as Equation 3, where σ is standard sigmoid function, W_{eg}, W_{rg} and b_g are parameters. Triple representation $v(t)$ is calculated as given in Equation 4, which linearly weights the candidate composed representation $\tilde{v}$ and relational representation v_r. In this way, entity representation and relational representation are adaptively encoded in the semantic representation of a triple.

2.3 English-Chinese Triple Translation

Given an English triple t_e and a list of candidate Chinese triples $\{t_{c1}, ...t_{cj}, ... \ t_{ck}\}$, we select the most relevant Chinese candidate in terms of semantic as the translation answer. To this end, we need to formalize a scoring function $f(t_e, t_{cj})$, which is capable of measuring the semantic relatedness between an English triple t_e and a Chinese candidate triple t_{cj}. Specifically, we apply the continuous triple vector

learned in Section 2.2.3 as English and Chinese triple representations without any feature engineering. We use standard L1 and L2 norms as the dissimilarity measure f, namely:

$$f(t_e, t_{cj}) = ||v(t_e) - v(t_{cj})||_p \tag{5}$$

where $p = 1$ means L1 norm, and $p = 2$ stands for L2 norm.

To effectively estimate the parameters of the neural networks, we use a ranking type loss function based on the intuition of noise contrastive estimation (Gutmann and Hyvärinen, 2010), which has been exploited as an effective training objective in deep learning community (Socher et al., 2013b).

In this paper, the basic idea of the optimizing objective is that: the distance between an English triple and its correct translation candidate $f(t_e, t_c)$ should get a lower score than the distance between the source triple and a *corrupted* incorrect candidate triple $f(t_e, t'_c)$ by a margin of 1.

$$Loss = \sum_{i=1}^{N} max(0, 1 - f(t_e, t'_c) + f(t_e, t_c)) \tag{6}$$

where N is the number of training instances. Given a correct Chinese triple (e_1, r, e_2), we generate two corrupted triples by randomly replacing one entity at one time, resulting in (e_1, r, e'_2) and (e'_1, r, e_2). We train the neural networks with supervised learning using stochastic gradient descent. We take the derivative of the loss regarding the parameters with standard back-propagation. We learn 50-dimensional English and Chinese word embeddings using word2vec with default setting. The vocabulary size of English and Chinese word embeddings are 32K and 30K, respectively. For each relation type, we use relation untied parameters, randomly initialize the values of $W_e, W_r, W_{eg}, W_{rg}, W_R^1, W_R^2, u'$, b and b_g from a uniform distribution $U(-0.01/L, 0.01/L)$ where L is the input length of a neural layer, set the hidden length as 30, set the learning rate as 0.03 and tune the training round on development set.

3 Experiment

We apply the proposed method for English-Chinese KB translation to evaluate its effectiveness. We describe the data statistics, experimental settings and empirical results.

3.1 Experiment Settings

For the task of English-Chinese KB translation, since there is no publicly available benchmark dataset, we manually annotate a dataset by ourselves. We use Freebase as the English source, which is widely used in the field of KB population and KB completion. There are several relation types in Freebase, we only select "Profession" and "Cause of Death" in this work because they are representative relation types with large number of instances. We leave other relation types as future work. We use Bing translator to get the translation candidates, and employ two experts to annotate the best result among candidate list. The disagreements during annotation are fixed by detailed discussion.We randomly split the dataset as training, development and testing sets. The statistical information of the datasets are given in Table 1.

Relation Type	#Train	# Dev	# Test
Profession	3,000	500	500
Cause of death	2,000	500	500

Table 1: The statistics for Freebase including two different relations.

We conduct experiments in a supervised learning framework. For each relation type, we train the model on training set, tune parameters on dev set and evaluate on test set. We use $P@1$ (Manning and Schütze, 1999) as the evaluation metric, which indicates whether the first ranked translation results is the correct answer.

- Surface Matching. Given an English triple (e_1, r, e_2), we first get the translation candidates of e_1 and e_2. After that, we select the top-ranked entity in each set, and merge them as the best translate result.

Model	L1 Norm			L2 Norm		
	Profession	C-death	Avg	Profession	C-death	Avg
Surface Matching	52.4	51.6	52.0	52.4	51.6	52.0
Hints Similarity	58.2	56.4	57.3	58.2	56.4	57.3
Entity Model	70.4	64.6	67.5	72.2	67.4	69.9
Relational (Tensor) Model	71.8	65.2	68.5	72.4	68.6	70.5
Relational (Tensor*) Model	72.4	67.2	69.8	72.8	69.8	71.3
Average (Entity + Relational)	72.8	67.6	70.2	73.0	70.2	71.6
Linear (Entity + Relational)	73.2	68.0	70.6	73.6	70.6	72.1
Full Model	75.0	70.4	72.7	75.6	71.8	73.7

Table 2: Comparison of accuracy of the different models for English-Chinese KB translation. We run experiments in L1 Norm and L2 Norm. Evaluation metric is P@1.

- Hints Similarity. After obtaining the list of candidates with Cartesian product, we measure the similarity between entities in a candidate triple with web search. We concatenate two entities as a query and put them in a Chinese search engine. We count the co-occurrence frequency in snippets, and select the top ranked candidate as the answer.

Our model has several variations, which are detailed as below.

- Entity Model. We represent a triple by only using entity representation, without leveraging relational representation (Bordes et al., 2012) .

- Relational Model. We represent a triple by only using relational representation, without using entity representation. In Relational (Tensor) Model, the neural calculator only uses multiplicative composition function as described in Section 2.2.2. In Relational (Tensor*) Model, the neural calculator includes an additional linear layer, which is exploited in Socher et al. (2013b) and calculated as below.

$$v_t = [e_1^T W_R^{[1:k]} e_2 + V_R \begin{bmatrix} e_1 \\ e_2 \end{bmatrix} + b_R] \tag{7}$$

- Average (Entity + Relational). In this setting, we represent a triple by averaging its entity vector and relational vector, without using gated neural network.

$$v_t = \frac{v_e + v_r}{2} \tag{8}$$

- Linear (Entity + Relational). In this setting, we represent a triple by concatenating its entity vector and relational vector, and composing them with standard linear layer. This is a special case of the gated neural network, where α is always set to zero.

3.2 Results and Analysis

Table 2 shows the empirical results of the baseline methods and our method on two relations. We can find that the performances of these methods are consistent on two relations. Among all these algorithms, *Surface Matching* is the worst performer. The reason lies in that it does not capture the interaction between two entities in a triple, which is very important for KB translation. *Hints Similarity* outperforms *Surface Matching* by taking into account the relatedness of entities by web search results. However, its improvement over *Surface Matching* is not significant enough because it ignores the relation type. That is to say, the semantic similarities between two entities in a triple remain the same for different relation types (e.g. Profession, Cause of Death). This is problematic as the relation plays an important role in discovering entity similarity. Let us take "Barack Obama （奥巴马）" and "Honolulu（火奴鲁鲁）" as an example. Their similarity in terms of "born in" relation is high, but the similarity regarding "working place" should be extremely lower.

Table 2 shows that neural network models outperform *Surface Matching* and *Hints Similarity* method, which shows the powerfulness of neural network based representation learning methods. This is because that neural network methods map English triples and Chinese triples into a unified semantic vector space, which shares some characteristics with the human who is assigned to do this task.

Among all these neural network methods, *Entity Model* is the worst method because it captures the semantics of entities separately while ignoring the semantic interaction between them. On the other hand, *Relational (Tensor) Model* only use the relational information of a triple. We can find that it shows slight improvements over *Entity Model*, which indicates the importance of relation of triple for KB translation.

Relational (Tensor) Model* is an enhanced *Relational (Tensor) Model*, and can also be viewed as a tensor composition function added by a standard linear composition function (Socher et al., 2013b). We can find that Relational (Tensor*) Model yields better performances than previous two neural models. The full model yields the best performances among all baseline methods by simultaneously leveraging entity representation, relational representation and their interaction in an adaptive method.

Average (Entity + Relational) is a straight-forward method to compose entity- and relational- representations. From Table 2, we can find that *Average* does not yield obvious improvements over previous neural models. The main reason is that average function fails to model the interaction between entity vector and relational vector, which is important to effectively capture the complex linguistic phenomena in KB triple. In *Linear (Entity + Relational)*, we concatenate v_e and v_r, and calculate their semantic composition with a simple linear layer (Socher et al., 2011). It shows some improvements over *Average (Entity + Relational)*, which demonstrates the importance of semantic composition algorithm for obtaining semantic representation of a triple.

3.3 The Effect of Gated Neural Network

We explore the effectiveness of the gated neural model for English-Chinese KB translation on our datasets. We set the gated α as a fixed value from 0.1 to 1.0, increased by 0.1. This corresponds to a special case of gated neural network with a fixed weighted ratio between v_r and $\tilde{v}$. The model with α = 1.0 means that the representation of a triple only comes from relational representation, without using any entity representation as mentioned in Section 2.2.1.

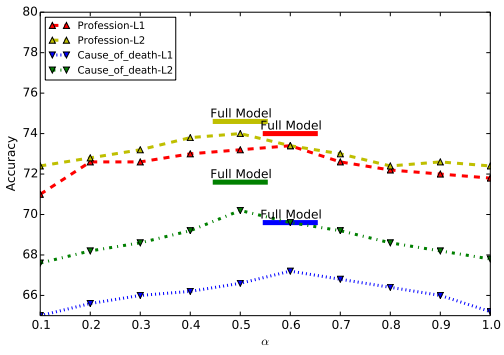

Figure 3: Experimental results with different $\alpha 1$ on the datasets.

We run experiments on two relation types with L1 and L2 norms, respectively. The results are illustrated in Figure 3. We can see that the performance of our full model is obviously better than the model with fixed trade-off weights. This is partly because that it is hard to measure the importances of entity representation and relational representation with a fixed weight for the complex phenomena in KB. The results also reveal the importance of an adaptive weighting strategy for semantic composition.

4 Related Work

We briefly describe existing studies on representation learning for natural language processing, learning continuous triple representation and gated recurrent neural network.

It is well accepted that feature representation is extremely important for natural language processing tasks. The main reason is that the effectiveness of a machine learner is highly dependent on the choice of data representation (Bengio et al., 2013). In past few decades, many studies leverage human ingenuity and prior knowledge to design hand-crafted features. Despite the effectiveness of feature engineering in some tasks, it is time consuming and typically fails to extract the discriminative information from the data. Recently, neural networks show their strengths in learning continuous representations of word/phrase (Mikolov et al., 2013), sentence (Socher et al., 2013c), document (Le and Mikolov, 2014), KB triple (Bordes et al., 2013) from data without any feature engineering. This study belongs to the family of neural network based representation learning for natural language processing tasks.

There are several neural network approaches proposed to model relational data, especially in the multi-relational case, where different kinds of relations are used to connect various data entities. Previous works focus on knowledge link prediction and triplet classification. Bordes et al. (2011) provide a structured embedding model where the regression loss was replaced by a ranking loss for learning embeddings of entities. Bordes et al. (2012) introduced a semantic matching energy function to map different instances in the same semantic vector space. Bordes et al. (2013) exploited a canonical model, which modeled relations by regarding the task as a translations operation on the low-dimensional embeddings of entities. Wang et al. (2014) made an extension on the translation model of TransE (Bordes et al., 2013) by projecting KB triple in relation-specific hyperplane. In this way, they can preserve the mapping properties of relation to some extent. Lin et al. (2015) considered that an entity may have multiple aspects, and different relations focused on different aspects of entities. They introduced TransR by representing entities and relations in distinct semantic vector space. Another related approach is introduced by Socher et al. (2013a), which used a neural tensor network to learn relational compositionality. Our relational representation method is similar to Socher et al. (2013a), which is on the basis of multiplicative vector-based semantic composition (Mitchell and Lapata, 2010).

The use of gated neural network in this paper shares some characteristics with the emerging gated recurrent neural network (Cho et al., 2014; Chung et al., 2015) and Long Short-Term Memory (Hochreiter and Schmidhuber, 1997; Tai et al., 2015). Standard recurrent neural network uses a set of shared parameters to represent a sequence of variable length to a vector representation. It suffers from the problem of vanishing gradient, which means that the influence of a given input on the hidden layer either decays or blows up exponentially. LSTM and gated recurrent neural network address this problem by adding several neural gates (e.g. input and forget gates) to adaptively memorize new content and forget history content. The gated neural network used in this work aims at integrating entity representation and relational representation in triple vector in an adaptive way.

5 Conclusion

We introduce a neural network approach for Knowledge Base (KB) translation from English (source) to Chinese (target) in this paper. We represent a triple in KB with an adaptive composition model, which produces triple representation by capturing entity- and relational- level information. The parameters of neural networks are effectively estimated with a ranking-type hinge loss function. We compare against several baseline methods on two KB translation datasets. Experimental results show that, our method performs better than baseline methods. In addition, we show that the newly introduced adaptive composition model improves standard composition method such as neural tensor network in terms of translation accuracy.

Keyphrase Annotation with Graph Co-Ranking

Adrien Bougouin and **Florian Boudin** and **Béatrice Daille**
Université de Nantes, LINA, France
{adrien.bougouin,florian.boudin,beatrice.daille}@univ-nantes.fr

Abstract

Keyphrase annotation is the task of identifying textual units that represent the main content of a document. Keyphrase annotation is either carried out by extracting the most important phrases from a document, keyphrase extraction, or by assigning entries from a controlled domain-specific vocabulary, keyphrase assignment. Assignment methods are generally more reliable. They provide better-formed keyphrases, as well as keyphrases that do not occur in the document. But they are often silent on the contrary of extraction methods that do not depend on manually built resources. This paper proposes a new method to perform both keyphrase extraction and keyphrase assignment in an integrated and mutual reinforcing manner. Experiments have been carried out on datasets covering different domains of humanities and social sciences. They show statistically significant improvements compared to both keyphrase extraction and keyphrase assignment state-of-the art methods.

1 Introduction

Keyphrases are words and phrases that give a synoptic picture of what is important within a document. They are useful in many tasks such as document indexing (Gutwin et al., 1999), text categorization (Hulth and Megyesi, 2006) or summarization (Litvak and Last, 2008). However, most documents do not provide keyphrases, and the daily flow of new documents makes the manual keyphrase annotation impractical. As a consequence, automatic keyphrase annotation has received special attention in the NLP community and many methods have been proposed (Hasan and Ng, 2014).

The task of automatic keyphrase annotation consists in identifying the main concepts, or topics, addressed in a document. Such task is crucial to access relevant scientific documents that could be useful for researchers. Keyphrase annotation methods fall into two broad categories: keyphrase extraction and keyphrase assignment methods. Keyphrase extraction methods extract the most important words or phrases occurring in a document, while assignment methods provide controlled keyphrases from a domain-specific terminology (controlled vocabulary).

The automatic keyphrase annotation task is often reduced to the sole keyphrase extraction task. Unlike assignment methods, extraction methods do not require domain specific controlled vocabularies that are costly to create and to maintain. Furthermore, they are able to identify new concepts that have not been yet recorded in the thesaurus or ontologies. However, extraction methods often output ill-formed or inappropriate keyphrases (Medelyan and Witten, 2008), and they produce only keyphrases that actually occur in the document.

Observations made on manually assigned keyphrases from scientific papers of specialized domains show that professional human indexers both extract keyphrases from the content of the document and assign keyphrases based on their knowledge of the domain (Liu et al., 2011). Here, we propose an approach that mimics this behaviour and jointly extracts and assigns keyphrases. We use two graph representations, one for the document and one for the specialized domain. Then, we apply a co-ranking algorithm to perform both keyphrase extraction and assignment in a mutually reinforcing manner. We perform

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2945–2955, Osaka, Japan, December 11-17 2016.

experiments on bibliographic records in three domains belonging to humanities and social sciences: linguistics, information science and archaeology. Along with this approach come two contributions. First, we present a simple yet efficient assignment extension of a state-of-the-art graph-based keyphrase extraction method, TopicRank (Bougouin et al., 2013). Second, we circumvent the need for a controlled vocabulary by leveraging reference keyphrases from training data and further take advantage of their relationship within the training data.

2 Related Work

2.1 Keyphrase extraction

Keyphrase extraction is the most common approach to tackle the automatic keyphrase annotation task. Previous work includes many approaches (Hasan and Ng, 2014), from statistical ranking (Salton et al., 1975) to binary classification (Witten et al., 1999), through graph-based ranking (Mihalcea and Tarau, 2004) of keyphrase candidates. As our approach uses graph-based ranking, we focus on the latter. For a detailed overview of keyphrase extraction methods, refer to (Hasan and Ng, 2010; Hasan and Ng, 2014).

Since the seminal work of Mihalcea and Tarau (2004), graph-based ranking approaches to keyphrase extraction are becoming increasingly popular. The original idea behind these approaches is to build a graph from the document and rank its nodes according to their importance using centrality measures.

In TextRank (Mihalcea and Tarau, 2004), the input document is represented as a co-occurrence graph in which nodes are words. Two words are connected by an edge if they co-occur in a fixed-sized window of words. A random walk algorithm is used to iteratively rank the words, then extract the keyphrases by concatenating the most important words.

The random walk algorithm simulates the "voting concept", or recommendation: a node is important if it is connected to many other nodes, and if many of those are important. Thus, let $G = (V, E)$ be an undirected graph with a set of vertices V and a set of edges E, and let $E(v_i)$ be the set of nodes connected to the node v_i. The score $S(v_i)$ of a vertex v_i is initialized to 1 and computed iteratively until convergence using the following equation:

$$S(v_i) = (1 - \lambda) + \lambda \sum_{v_j \in E(v_i)} \frac{S(v_j)}{|E(v_j)|} \quad (1)$$

where λ is a damping factor that has been set to 0.85 by Brin and Page (1998) for a trade-off between ranking accuracy and fast convergence.

Following up the work of Mihalcea and Tarau (2004), Wan and Xiao (2008) added edge weights (co-occurrence numbers) to the random walk and further improved the graph with co-occurrence information borrowed from similar documents. To extract keyphrases from a document, they first look for five similar documents, then use them to add new edges between words within the graph and reinforce the weight of existing edges. Liu et al. (2010) biased multiple graphs with topic probabilities drawn from LDA (Latent Dirichlet Allocation) (Blei et al., 2003), to rank the words regarding each graph and to merge the rankings together. This method performs as many rankings as the number of topics and gives higher importance scores to high-ranking words for as many topics as possible. By doing so, Liu et al. (2010) increase the topic coverage provided by the extracted keyphrases.

Most recently, Zhang et al. (2013) and Bougouin et al. (2013) explored further the value of topics for keyphrase extraction. Zhang et al. (2013) used graph co-ranking to improve the method of Liu et al. (2010) by introducing LDA topics right inside the graph. Bougouin et al. (2013) proposed to represent topics as clusters of similar keyphrase candidates within the document (i.e. words and phrases from the document), to rank these topics instead of the words and to extract the most representative candidate as keyphrase for each important topic. As our work extends that of Bougouin et al. (2013), we present a detailed description of their method in Section 3.1.

2.2 Keyphrase assignment

Keyphrase assignment provides keyphrases for every document of a specific domain using a controlled vocabulary. Dissimilar to keyphrase extraction, keyphrase assignment also aims to provide keyphrases that do not occur within the document. This task is more difficult than keyphrase extraction and has, therefore, seldom been employed for automatic keyphrase annotation. The state-of-the art method for keyphrase assignment is KEA++ (Medelyan and Witten, 2006).

KEA++ uses a domain-specific thesaurus to assign keyphrases to a document. First, keyphrase candidates are selected among the n-grams of the document. N-grams that do not match a thesaurus entry are either removed or substituted by a synonym that matches a thesaurus entry. This candidate selection approach induces a limitation of keyphrase assignment, refered to as keyphrase indexing by Medelyan and Witten (2006), because it only assigns keyphrases if they occur within the document. Second, KEA++ exploits the semantic relationships between keyphrase candidates within the thesaurus as the main feature of a Naive Bayes classifier. Compared to similar methods without domain specific resources, KEA++ achieves better performance. However, such resources are not readily available for most domains, and if so, they could be quickly out of date. The application scenario of KEA++ are thus restricted.

Our proposition is to model with graphs both keyphrase extraction and assignment and to take benefit of this unified modelling to perform accurate keyphrase annotation.

3 Co-ranking for Keyphrase Annotation

This section presents TopicCoRank[1], our keyphrase annotation method built on the existing method TopicRank (Bougouin et al., 2013) to which we add keyphrase assignment. We first detail TopicRank, then present our contributions.

3.1 TopicRank

TopicRank is a graph-based keyphrase extraction method that relies on the following five steps:

1. **Keyphrase candidate selection.** Following previous work (Hasan and Ng, 2010; Wan and Xiao, 2008), keyphrase candidates are selected from the sequences of adjacent nouns and adjectives that occur within the document (`/(N|A)+/`).

2. **Topical clustering.** Similar keyphrase candidates c are clustered into topics based on the words they share. Bougouin et al. (2013) use a Hierarchical Agglomerative Clustering (HAC) with a stem overlap similarity (see equation 2) and an average linkage. At the beginning, each keyphrase candidate is a single cluster, then candidates sharing an average of $1/4$ stemmed words with the candidates of another cluster are iteratively added to the latter.

$$\text{sim}(c_i, c_j) = \frac{|\text{stems}(c_i) \cap \text{stems}(c_j)|}{|\text{stems}(c_i) \cup \text{stems}(c_j)|} \tag{2}$$

   where $\text{stems}(c_i)$ is the set of stemmed words of the keyphrase candidate c_i.

3. **Graph construction.** A complete graph is built, in which nodes are topics and edges are weighted according to the strength of the semantic relation between the connected topics. The closer are the pairs of candidates $\langle c_i, c_j \rangle$ of two topics t_i and t_j within the document, the stronger is their semantic relation $w_{i,j}$:

$$w_{i,j} = \sum_{c_i \in t_i} \sum_{c_j \in t_j} \text{dist}(c_i, c_j) \tag{3}$$

$$\text{dist}(c_i, c_j) = \sum_{p_i \in \text{pos}(c_i)} \sum_{p_j \in \text{pos}(c_j)} \frac{1}{|p_i - p_j|} \tag{4}$$

   where $\text{pos}(c_i)$ represents all of the offset positions of the first word of the keyphrase candidate c_i.

[1]TopicCoRank is open source and publicly available at `https://github.com/adrien-bougouin/KeyBench/tree/coling_2016/`

4. **Topic ranking.** Topics t are ranked using the importance score $S(t_i)$ of the TextRank formula, as modified by Wan and Xiao (2008) to leverage edge weights:

$$S(t_i) = (1 - \lambda) + \lambda \sum_{t_j \in E(t_i)} \frac{w_{ij} S(t_j)}{\sum_{t_k \in E(t_j)} w_{jk}} \quad (5)$$

5. **Keyphrase selection.** One keyphrase candidate is selected from each of the N most important topics: the first occurring keyphrase candidate.

Our work extends TopicRank to assign domain-specific keyphrases that do not necessarily occur within the document. First, we add a second graph representing the domain and unify it to the topic graph. Second, we define a co-ranking scheme that leverages the new graph. Finally, we redefine the keyphrase selection step for both extracting and assigning keyphrases.

3.2 Unified graph construction

TopicCoRank operates over a unified graph that connects two graphs representing the document topics, the controlled keyphrases and the relations between them (see Fig. 1). The controlled keyphrases are the keyphrases that were manually assigned to training documents. Considering the manually assigned keyphrases as the controlled vocabulary circumvents the need for a manually produced controlled vocabulary and also allows us to further take advantage of the semantic relatonship between the domain-specific (controlled) keyphrases. Because controlled keyphrases are presumably non-redundant, we do not topically cluster them as we do for keyphrase candidates.

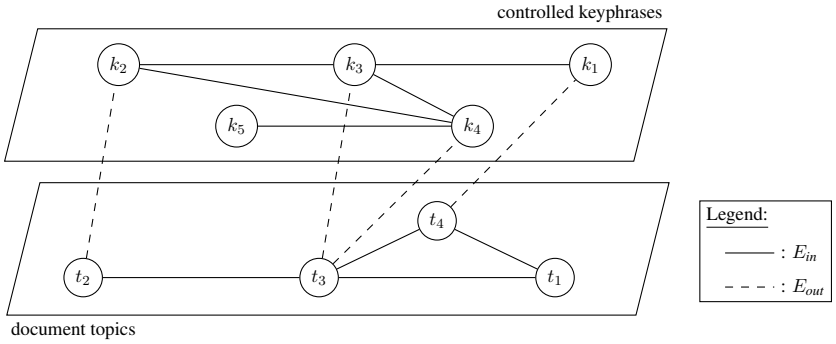

Figure 1: Example of a unified graph constructed by TopicCoRank and its two kinds of edges

Let $G = (V = T \cup K, E = E_{in} \cup E_{out})$ denote the unified graph. Topics $T = \{t_1, t_2, ..., t_n\}$ and controlled keyphrases $K = \{k_1, k_2, ..., k_m\}$ are vertices V connected to their fellows by edges $E_{in} \subseteq T \times T \cup K \times K$ and connected to the other vertices by edges $E_{out} \subseteq K \times T$ (see Fig. 1).

To unify the two graphs, we consider the controlled keyphrases as a category map and connect the document to its potential categories. We create an unweighted edge $\langle k_i, t_j \rangle \in E_{out}$ to connect a controlled keyphrase k_i and a topic t_j if the controlled keyphrase is a member of the topic, i.e. a keyphrase candidate of the topic[2]. We create an edge $\langle t_i, t_j \rangle \in E_{in}$ or $\langle k_i, k_j \rangle \in E_{in}$ between two topics t_i and t_j or two controlled keyphrases k_i and k_j when they co-occur within a sentence of the document or as keyphrases of a training document, respectively. Edges $\langle t_i, t_j \rangle \in E_{in}$ are weighted by the number of times ($w_{i,j}$) topics t_i and t_j occur in the same sentence within the document. Edges $\langle k_i, k_j \rangle \in E_{in}$ are weighted by the number of times ($w_{i,j}$) keyphrases k_i and k_j are associated to the same document among the training documents. Doing so, the weighting scheme of edges E_{in} is equivalent for both topics and controlled keyphrases. This equivalence is essential to ensure that not only controlled keyphrases occurring in the document can be assigned by properly co-ranking topics and controlled keyphrases.

[2]To accept inflexions, such as plural inflexions, we follow Bougouin et al. (2013) and perform the comparison with stems.

3.3 Graph-based co-ranking

TopicCoRank gives an importance score $S(t_i)$ or $S(k_i)$ to every topic or controlled keyphrase using graph co-ranking (see equations 6 and 7). Our graph co-ranking simulates the voting concept based on inner and outer recommendations.

The inner recommendation is similar to the recommendation computed in previous work (Bougouin et al., 2013; Mihalcea and Tarau, 2004; Wan and Xiao, 2008). The inner recommendation R_{in} comes from nodes of the same graph (see equation 8). A topic or a controlled keyphrase is important if it is strongly connected to other topics or controlled keyphrases, respectively.

The outer recommendation influences the ranking of topics by controlled keyphrases and of controlled keyphrases by topics. The outer recommendation R_{out} comes from nodes of the other graph (see equation 9). A topic or a controlled keyphrase gain more importance if it is connected to important controlled keyphrases or an important topic, respectively.

$$S(t_i) = (1 - \lambda_t)\ R_{out}(t_i) + \lambda_t\ R_{in}(t_i) \tag{6}$$

$$S(k_i) = (1 - \lambda_k)\ R_{out}(k_i) + \lambda_k\ R_{in}(k_i) \tag{7}$$

$$R_{in}(v_i) = \sum_{v_j \in E_{\text{in}}(v_i)} \frac{w_{ij} S(v_j)}{\sum_{v_k \in E_{\text{in}}(v_j)} w_{jk}} \tag{8}$$

$$R_{out}(v_i) = \sum_{v_j \in E_{\text{out}}(v_i)} \frac{S(v_j)}{|E_{out}(v_j)|} \tag{9}$$

where v_i is a node representing a keyphrase or a topic. λ_t and λ_k are parameters that control the influence of the inner recommendation over the outer recommendation ($0 \leqslant \lambda_t \leqslant 1$ and $0 \leqslant \lambda_k \leqslant 1$) for the topics and the controlled keyphrases, respectively.

3.4 Keyphrase annotation

Keyphrases are extracted and assigned from the N-best ranked topics and controlled keyphrases, regardless of their nature.

We extract topic keyphrases using the former TopicRank strategy. Only one keyphrase is extracted per topic: the keyphrase candidate that first occurs within the document.

We assign controlled keyphrases only if they are directly or transitively connected to a topic of the document. If the ranking of a controlled keyphrase has not been affected by a topic of the document nor by controlled keyphrases connected to topics, then its importance score is not related to the content of the document and it should not be assigned.

At this step, two variants of TopicCoRank performing either extraction or assignment can be proposed, namely TopicCoRank$_{extr}$ and TopicCoRank$_{assign}$. If keyphrases are only extracted from the topics, we obtain TopicCoRank$_{extr}$. If keyphrases are only assigned from the controlled keyphrases, we obtain TopicCoRank$_{assign}$.

4 Experimental Setup

4.1 Datasets

We conduct our experiments on data from the DEFT-2016 benchmark datasets (Daille et al., 2016)[3] in three domains: linguistics, information Science and archaeology. Table 1 shows the factual information

[3]Data has been provided by the TermITH project for both DEFT-2016 and this work. Parallely, the subset division has been modified for the purpose of DEFT-2016. Therefore, we use the same data as DEFT-2016, but the subset division is different. The subset division we used for our experiences can be found here: `https://github.com/adrien-bougouin/KeyBench/tree/coling_2016/datasets/`

about the datasets. Each dataset is a collection of 706 up to 718 French bibliographic records collected from the database of the French Institute for Scientific and Technical Information[4] (Inist). The bibliographic records contain a title of one scientific paper, its abstract and its keyphrases that were annotated by professional indexers (one per bibliographic record). Indexers were given the instruction to assign reference keyphrases from a controlled vocabulary and to extract new concepts or very specific keyphrases from the titles and the abstracts. Each dataset is divided into three sets: a test set, used for evaluation; a training set (denoted as train), used to represent the domain; and a development set (denoted as dev), used for parameter tuning.

Corpus	**Linguistics**			**Information Science**			**Archaeology**		
	train ⊃ dev		test	train ⊃ dev		test	train ⊃ dev		test
Documents	515	100	200	506	100	200	518	100	200
Tokens/Document	161	151	147	105	152	157	221	201	214
Keyphrases	8.6	8.8	8.9	7.8	10.0	10.2	16.9	16.4	15.6
Missing Keyphrases (%)	60.6	63.2	62.8	67.9	63.1	66.9	37.0	48.4	37.4

Table 1: Dataset statistics. "Missing" represents the percentage of keyphrases that cannot be retrieved within the documents.

The amount of missing keyphrases, i.e. keyphrases that cannot be extracted from the documents, shows the importance of keyphrase assignment in the context of scientific domains. More than half of the keyphrases of linguistics and information science domains can only be assigned, which confirms that these two datasets are difficult to process with keyword extraction approaches alone.

4.2 Document preprocessing

We apply the following preprocessing steps to each document: sentence segmentation, word tokenization and Part-of-Speech (POS) tagging. Sentence segmentation is performed with the PunktSentenceTokenizer provided by the Python Natural Language ToolKit (NLTK) (Bird et al., 2009), word tokenization using the Bonsai word tokenizer[5] and POS tagging with MElt (Denis and Sagot, 2009).

4.3 Baselines

To show the effectiveness of our approach, we compare TopicCoRank and its variants (TopicCoRank$_{extr}$ and TopicCoRank$_{assign}$) with TopicRank and KEA++. For KEA++, we use the thesauri maintained by Inist[6] to index the bibliographic records of Linguistics, Information Science and Archaeology.

4.4 TopicCoRank setting

The λ_t and λ_k parameters of TopicCoRank were tuned on the development sets, and set to 0.1 and 0.5 respectively. This empirical setup means that the importance of topics is much more influenced by controlled keyphrases than other topics, and that the importance of controlled keyphrases is equally influenced by controlled keyphrases and topics. In other words, the domain has a positive influence on the joint task of keyphrase extraction and assignment.

5 Experimental Results

This section presents and analyses the results of our experiments. For each document of each dataset, we compare the keyphrases outputed by each method to the reference keyphrases of the document. From the comparisons, we compute the macro-averaged precision (P), recall (R) and f1-score (F) per dataset and per method.

[4] http://www.inist.fr

[5] The Bonsai word tokenizer is a tool provided with the Bonsai PCFG-LA parser: http://alpage.inria.fr/statgram/frdep/fr_stat_dep_parsing.html

[6] Thesauri are available from: http://deft2016.univ-nantes.fr/download/traindev/

5.1 Macro-averages results

Table 2 presents the macro-averaged precision, recall and f1-score in percentage when 10 keyphrases are extracted/assigned for each dataset by TopicRank, KEA++, TopicCoRank$_{extr}$, TopicCoRank$_{assign}$ and TopicCoRank. First, we observe that the assignment baseline KEA++ mostly achieves the lowest performance, which is surprising compared to the performance reported by Medelyan and Witten (2006). The first reason for this observation is that KEA++ is restricted to thesauri entries while most keyphrases are missing within our documents. The second reason is that KEA++ relies on rich thesauri that contain an important amount of semantic relations between the entries, while our (real application) thesauri have a modest amount of semantic relations between the entries.

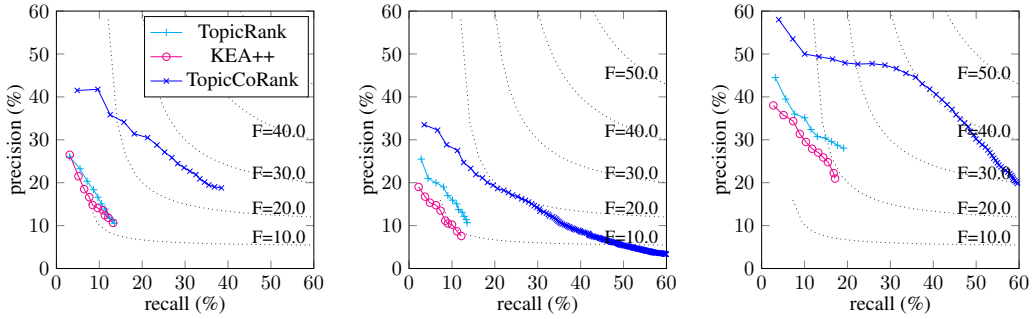
Overall, using graph co-ranking significantly outperforms TopicRank and KEA++. Comparing TopicRank to TopicCoRank$_{extr}$ shows the positive influence of the domain (controlled keyphrases) on the ranking of the topics. TopicCoRank$_{assign}$ outperforms every method, including TopicCoRank$_{extr}$ and TopicCoRank. Controlled keyphrases are efficiently ranked and the predominance of missing keyphrases in the dataset leads to a better performance of TopicCoRank$_{assign}$ over TopicCoRank.

Method	Linguistics			Information Science			Archaeology		
	P	R	F	P	R	F	P	R	F
TopicRank	11.82	13.1	11.9	12.1	12.8	12.1	27.5	19.7	21.8
KEA++	11.6	13.0	12.1	9.5	10.2	9.6	23.5	16.2	18.8
TopicCoRank$_{extr}$	15.9	18.2	16.7†	15.9	16.2	15.6†	39.6	26.4	31.0†
TopicCoRank$_{assign}$	**25.8**	**29.6**	**27.2**†	**19.9**	**20.0**	**19.5**†	**49.6**	**33.3**	**39.0**†
TopicCoRank	24.5	28.3	25.9†	19.4	19.6	19.0†	46.6	31.4	36.7†

Table 2: Results of TopicCoRank and the baselines at 10 keyphrases for each dataset. Precision (P), Recall (R) and F-score (F) are reported in percentages. † indicates a significant F-score improvement over TopicRank and KEA++ at 0.001 level using Student's t-test.

5.2 Precision/recall curves

Additionally, we follow Hasan and Ng (2010) and analyse the precision-recall curves of TopicRank, KEA++ and TopicCoRank. To generate the curves, we vary the number of evaluated keyphrases (cut-off) from 1 to the total number of extracted/assigned keyphrases and compute the precision and recall for each cut-off. Such representation gives a good appreciation of the advantage of a method compared to others, especially if the other methods achieve performances in the *Area Under the Curve* (AUC).



(a) Linguistics (b) Information Science (c) Archaeology

Figure 2: Precision-recall curves of TopicRank, KEA++ and TopicCoRank for each dataset

Figure 2 shows the precision/recall curves of TopicRank, KEA++ and TopicCoRank on each dataset. The final recall for the methods does not reach 100% because the candidate selection method does not provide keyphrases that do not occur within the document, as well as candidates that do not fit the POS tag pattern `/(N|A)+/`. Also, because TopicRank and TopicCoRank topically cluster keyphrase candidates

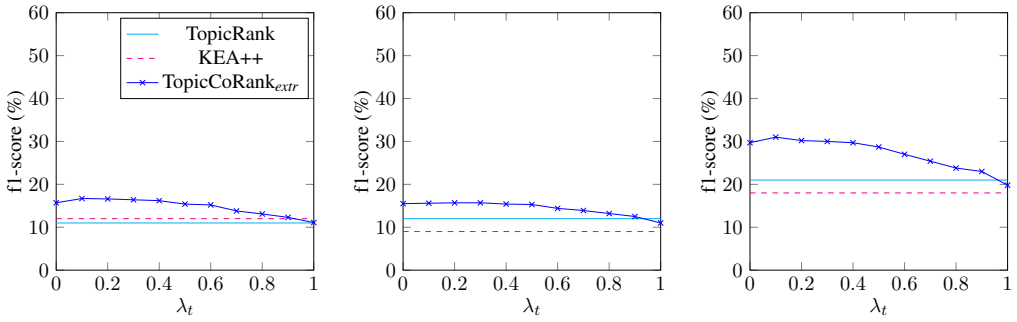
and output only one candidate per topic, their final recall is lowered every time a wrong keyphrase is chosen over a correct one from the topic.

We observe that the curve for TopicCoRank is systematically above the others, thus showing improvements in the area under the curve and not just in point estimate such as f1-score. Also, the final recall of TopicCoRank is much higher than the final recall of TopicRank and KEA++.

5.3 Extraction vs. assignment

As TopicCoRank is the first method for simultaneously extracting and assigning keyphrases, we perform an additional experiment that shows to which extent extraction and assignment contribute to the final results. To do so, we show the behavior of the extraction and the assignment depending on the influence of the inner recommendation on the ranking for each (test) document of each dataset.

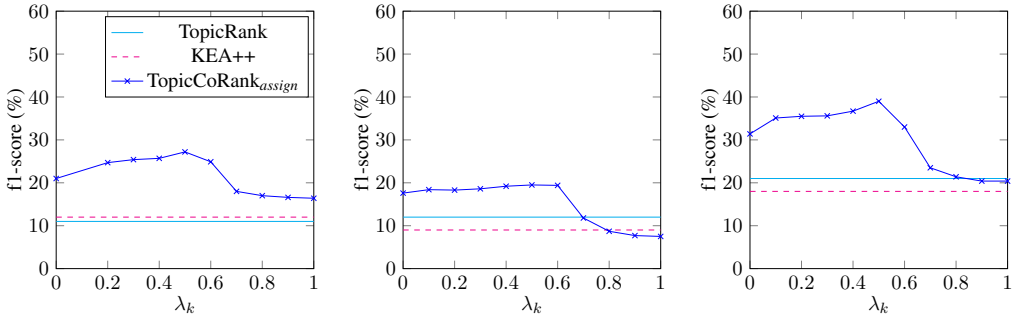
Fig. 3 shows the behavior of TopicCoRank$_{extr}$ when λ_t varies from 0 to 1. When $\lambda_t = 0$, only the domain influences the ranking of the topics. Slightly equivalent to KEA++, TopicCoRank$_{extr}$ with $\lambda_t = 0$ mainly extracts keyphrases from topics connected to controlled keyphrases. When $\lambda_t = 1$, the domain does not influence the ranking and the performance of TopicCoRank$_{extr}$ is in the range of TopicRank's performance. Overall, the performance curve of TopicCoRank$_{extr}$ decreases while λ_t increases. Thus, the experiment demonstrates that the domain has a positive influence on the keyphrase extraction.



(a) Linguistics (b) Information Science (c) Archaeology

Figure 3: Behavior of TopicCoRank$_{extr}$ depending on λ_t ($\lambda_k = 0.5$)

Fig. 4 shows the behavior of TopicCoRank$_{assign}$ when λ_k varies from 0 to 1. When $\lambda_k = 0$, only the document influences the ranking of the controlled keyphrases. As for TopicCoRank$_{extr}$ when $\lambda_t = 0$, TopicCoRank$_{assign}$ is slightly similar to KEA++ when $\lambda_k = 0$. When $\lambda_k = 1$, TopicCoRank$_{assign}$ always outputs the same keyphrases: the ones that are the most important in the domain. The first half of the curve increases, showing that the relations between the controlled keyphrases have a positive influence on the ranking of the controlled keyphrases. Conversely, the second half of the curve decreases. Thus, the sole domain is not sufficient for keyphrase annotation.



(a) Linguistics (b) Information Science (c) Archaeology

Figure 4: Behavior of TopicCoRank$_{assign}$ depending on λ_k ($\lambda_t = 0.1$)

Toucher : le tango des sens. Problèmes de sémantique lexicale **(The French verb 'toucher': the tango of senses. A problem of lexical)**

A partir d'une hypothèse sur la sémantique de l'unité lexicale 'toucher' formulée en termes de forme schématique, cette étude vise à rendre compte de la variation sémantique manifestée par les emplois de ce verbe dans la construction transitive directe 'C0 toucher C1'. Notre étude cherche donc à articuler variation sémantique et invariance fonctionnelle. Cet article concerne essentiellement le mode de variation co-textuelle : en conséquence, elle ne constitue qu'une première étape dans la compréhension de la construction des valeurs référentielles que permet 'toucher'. Une étude minutieuse de nombreux exemples nous a permis de dégager des constantes impératives sous la forme des 4 notions suivantes : sous-détermination sémantique, contact, anormalité, et contingence. Nous avons tenté de montrer comment ces notions interprétatives sont directement dérivables de la forme schématique proposée.

Keyphrases : *Français* (French); *modélisation* (modelling); *analyse distributionnelle* (distributional analysis); *interprétation sémantique* (semantic interpretation); *variation sémantique* (semantic variation); *transitif* (transitive); *verbe* (verb); *syntaxe* (syntax) and *sémantique lexicale* (lexical semantics).

Figure 5: Example of a bibliographic record in Linguistics (`http://cat.inist.fr/?aModele=afficheN&cpsidt=16471543`)

5.4 Qualitative example

To show the benefit of TopicCoRank, we compare it to TopicRank on one of our bibliographic records in Linguistics (see Figure 5). Over the nine reference keyphrases, TopicRank successfully identifies two of the reference keyphrases: "lexical semantics" and "semantic variation". TopicCoRank successfully identifies seven of them: "lexical semantics", "verb", "semantic variation", "French", "syntax", "semantic interpretation" and "distributional analysis".

TopicCoRank mostly outperforms TopicRank because it finds keyphrases that do not occur within the document: "French", "syntax", "semantic interpretation", and "distributional analysis". Some keyphrases, such as "French", are frequently assigned because they are part of most of the bibliographic records of our dataset[7] (48.9% of the Linguistics records contain "French" as a keyphrase); Other keyphrases, such as "semantic interpretation", are assigned thanks to their strong connection with controlled keyphrases occurring in the abstract (e.g. "lexical semantics").

Interestingly, the performance of TopicCoRank is not only better thanks to the assignment. For instance, we observe keyphrases, such as "verb", that emerge from topics connected to other topics that distribute importance from controlled keyphrases (e.g. "semantic variation").

6 Conclusion

In this paper, we have proposed a co-ranking approach to performing keyphrase extraction and keyphrase assignment jointly. Our method, TopicCoRank, builds two graphs: one with the document topics and one with controlled keyphrases (training keyphrases). We designed a strategy to unify the two graphs and rank by importance topics and controlled keyphrases using a co-ranking vote. We performed experiments on three datasets of different domains. Results showed that our approach benefits from both controlled keyphrases and document topics, improving both keyphrase extraction and keyphrase assignment baselines. TopicCoRank can be used to annotate keyphrases in scientific domains in a close way of professional indexers.

Abstract

QA systems have been making steady advances in the challenging elementary science exam domain. In this work, we develop an explanation-based analysis of knowledge and inference requirements, which supports a fine-grained characterization of the challenges. In particular, we model the requirements based on appropriate sources of evidence to be used for the QA task. We create requirements by first identifying suitable sentences in a knowledge base that support the correct answer, then use these to build explanations, filling in any necessary missing information. These explanations are used to create a fine-grained categorization of the requirements. Using these requirements, we compare a retrieval and an inference solver on 212 questions. The analysis validates the gains of the inference solver, demonstrating that it answers more questions requiring complex inference, while also providing insights into the relative strengths of the solvers and knowledge sources. We release the annotated questions and explanations as a resource with broad utility for science exam QA, including determining knowledge base construction targets, as well as supporting information aggregation in automated inference.

1 Introduction

Elementary science exams have recently become a common test of question answering (QA) models. Clark and Etzioni (2016) argue that these exams are an excellent benchmark for natural language processing (NLP) systems in many respects, both testing students for many different kinds of knowledge and inference abilities at varying levels of difficulty, while also allowing for a direct comparison of machine to human performance in the science domain on a standardized evaluation. Many different QA approaches have been developed and evaluated on these and similar exams, with methods using a range of representations from unstructured (BOW) lexical semantic models (Fried et al., 2015), structured relation-based representations (Clark et al., 2016; Khot et al., 2015), more complex first-order formalisms (Khot et al., 2015), and other inference methods (Khashabi et al., 2016). Together in concert, these methods can achieve substantial improvements in overall performance, with a 71% accuracy (i.e. passing performance) on one test set (Khashabi et al., 2016).

In this work, we focus on developing a deeper understanding of this problem domain by implementing a fine-grained characterization of the knowledge and inference requirements for science exam QA, driven by generating and annotating gold explanations that justify the correct answer. We believe that this can provide many tangible benefits. First, we can obtain a fine-grained assessment of the abilities of different QA systems to identify areas of competency, and those that need improvement. Second, the detailed knowledge requirements can serve as a specification for knowledge extraction. Third, it can support QA methods that can use problem solving strategies and knowledge tailored to the specific requirements of a given question. Finally, it can support design of QA systems that can provide explanations for why they choose an answer. In this last respect, multiple-choice elementary science questions currently lack a direct way to quantitatively assess systems on this aspect.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2956–2965, Osaka, Japan, December 11-17 2016.

Specifying broadly applicable knowledge requirements and explanations poses two main challenges. First, questions can be answered in many ways, and depending on the knowledge source used the type of knowledge ascribed to the question can differ. We follow a pragmatic approach, building on prior work in knowledge categorization, and use knowledge types that correspond to commonly used semantic structures relating to the automatic construction of knowledge bases (KB). Clark et al. (2013) compiled an initial analysis of the questions in these datasets, and identified 7 broad categories of knowledge and inference requirements. However, this analysis forced a single knowledge type for each question, for example *causality*, and from our detailed analysis we find that many types of knowledge are necessary to arrive at the correct answer, e.g., *causality, actions, and purposes*.

A second challenge relates to grounding the requirements and the explanations in appropriate resources such that they can facilitate automated analysis and provide compact, reusable, and linked knowledge for inference. To this end, we use grade appropriate texts, and first identify relevant sentences or nuggets of information that can serve as explanations or supports for the current answers. We then fill in sentences that provide missing links connecting knowledge and terminology in the sentences, while taking care to ensure as much reuse as possible.

We apply this methodology to obtain requirements on a set of 212 questions from an open standardized elementary science exam dataset, and present an analysis of these requirements. This work makes the following contributions:

- We construct a detailed characterization of the knowledge and inference requirements of elementary science exams, highlighting the prevalence of complex inference questions, which require inference methods that combine many facts across multiple types of knowledge.
- We provide an empirical analysis of the performance of different QA methods on questions with specific knowledge and inference requirements, demonstrating that while existing QA systems considerably outperform information retrieval (IR) methods on difficult questions, many of the more complex forms of inference remain to be addressed.
- We provide a knowledge resource in the form of gold explanations for hundreds of science exam questions, as well as annotation describing question-centered and explanation-centered knowledge and inference requirements. We believe this resource will be broadly useful for characterizing performance on current and future models, as well as developing automated methods supporting knowledge type identification, inference, and explanation construction.

2 Related Work

Analyzing knowledge and inference requirements is a first necessary step in designing QA systems. For factoid QA tasks, these requirements are often stated in terms of broad question categories (e.g., What, When, How) and finer-grained types for expected answers (e.g., cities, person, organization). Factoid QA systems use classifiers to identify the types of question and expected answers, which are subsequently used to select specific problem solving routines, and to filter answer candidates (Harabagiu et al., 2000; Li and Roth, 2006; Roberts and Hickl, 2008). For non-factoid QA tasks, requirements are often stated in terms of elements in knowledge representation ontologies. For instance, Chaudhri et al. (2014) study requirements for a QA task defined over AP Biology texts using relations and categories from the CLIB ontology (Barker et al., 2001). Some benchmarks, such as bAbI (Weston et al., 2016), are created to test specific reasoning abilities and come with a grouping of questions into the corresponding categories (e.g., negation reasoning, causal reasoning).

Our work aims to provide similar requirements for the elementary science QA benchmark (Clark and Etzioni, 2016). Prior analyses on this benchmark includes Clark et al. (2013), who identified seven broad kinds of knowledge and inference in three categories: *retrieval questions*, making use of taxonomic, definitional, or property knowledge; *inference questions*, testing a knowledge of causality, processes, or identifing examples of situations; and *domain-specific models*. Crouse and Forbus (2016) further identified questions that involve qualitative reasoning (13% of total), and provide a sub-categorization of these. Here we build upon these prior works and provide both a more fine-grained characterization of the knowledge types required to answer these questions, along with manually curated answer explanations.

This allows us to compare the relative strengths and weaknesses of different QA systems from knowledge and inference requirements identified using both bottom-up (from explanations) and top-down (from questions) approaches.

More broadly and with respect to explanations, there is a recent trend towards emphasizing interpretable models for machine learning (e.g. Ribeiro et al. (2016)) that are able to produce human-readable explanations for their reasoning, both to improve human trust in automated inference, as well as to verify that a given model is accurately capturing the aspects of complex reasoning required for a given task. We view this work as complementary, here characterizing the knowledge and inference requirements that an automated reasoning method for science exams must meet to assemble compelling human-readable explanations as part of the inference process.

3 Knowledge and Inference Analysis

Estimating knowledge and inference requirements is challenging for many reasons. Chief among these is that a question can be answered in many different ways, using different types of knowledge and reasoning depending on the sources of evidence used. At one extreme, with a large knowledge base (KB), many questions can be answered by simply retrieving a fact from the KB that readily provides the correct answer. At the other extreme, with a modest KB, multiple pieces of information have to be aggregated together using some inference method to arrive at the correct answer. A further difficulty in multiple choice exams is that a QA system may select the correct answer, but for the wrong reasons stemming from difficulties in retrieval, inference, or from simply using a backoff strategy (e.g. guessing)[1]. Question answering systems in the science and medical domains should also target providing human-readable explanations for why the selected answer is correct. We examine knowledge requirements for this explainable question answering task, which suggests that, at the very least, requirements must be grounded in explanations drawn from a reasonable collection of target sources of evidence.

Towards this goal, we develop an explanation-centered approach using appropriate grade-level resources, constructing gold natural language explanations that detail why a given answer is correct, and deriving a fine-grained distribution of common inference relations from these explanations. In this section, we first provide a question-centered analysis expanded to a larger set of questions compared to prior work, and demonstrate the challenges with this approach. We then present a fine-grained analysis using the explanation-centered approach on the same set of questions.

Questions: For the following analyses, we make use of the 432 training questions in the AI2 Elementary Science Questions set[2], collected from standardized 3^{rd} to 5^{th} grade science exams in 14 US states.

3.1 Question-centered Analysis

Figure 1 shows the distribution of knowledge and inference requirements when extending the question-centered analysis of Clark et al. (2013) to the larger AI2 elementary questions set. We find two differences when compared to their original analysis on 50 4^{th} grade questions from the New York Regents Science Exam: First, the distribution on this larger question set exhibits a much higher proportion of complex inference (77%) compared to retrieval methods. Second, even though we annotated one knowledge category per question according to the original procedure, we find that many of the complex inference questions naturally require integrating several different kinds of knowledge to arrive at the answer, with more than a third of the questions requiring at least two knowledge types.

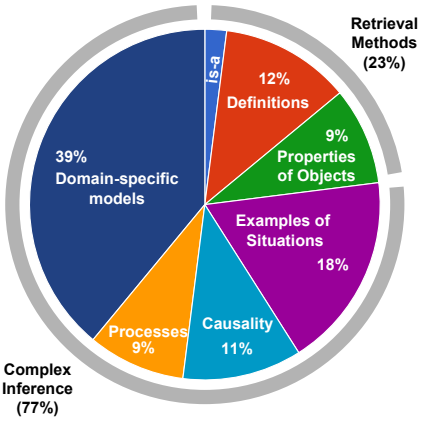

Figure 1: Knowledge types required to correctly answer a given question in the elementary science exam dataset.

[1]Jansen, Sharp, Surdeanu, and Clark (submitted) showed in their error analysis that, for elementary science questions, both retrieval and inference methods produce completely incorrect explanations approximately 20% of the time. A retrieval model produced complete explanations for 45% of questions, while an inference model incorporating intersentence aggregation produced complete explanations for 60% of questions.

[2]The original question set is available at: `http://allenai.org/data.html`

Question	Which of these organisms has cells with cell walls?
Answer Choices	(A) bluebird **(B) A pine tree** (C) A ladybug (D) A fox squirrel
Explanation	A pine tree is a kind of plant. A cell wall is a part of a plant cell.
Question	What form of energy causes an ice cube to melt?
Answer Choices	(A) mechanical (B) magnetic (C) sound **(D) heat**
Explanation	An ice cube is a solid. Changing from a solid to a liquid is called melting. Melting happens when solids are heated. Heated means added heat. Heat is a kind of energy.
Question	Which of the following events involves a consumer and producer in a food chain?
Answer Choices	(A) A cat eats a mouse. **(B) A deer eats a leaf.** (C) A hawk eats a mouse. (D) A snake eats a rat.
Explanation	A leaf is a kind of plant. A deer is a kind of animal. In a food chain, an animal is a consumer. In a food chain, green plants are producers.

Table 1: Explanations for three shorter example questions, including one simpler question about the property of an object (having cell walls), an explicitly causal question (melting), and one question about the role of two entities in a process or model (the food chain). Dashed underlines indicate bridge sentences.

3.2 Explanation-centered Analysis

3.2.1 Gold Explanations

For each question, we create gold explanations that describe the inference needed to arrive at the correct answer. Our goal is to derive an explanation corpus that is grounded in grade-appropriate resources. Accordingly, we use two elementary study guides, a science dictionary for elementary students, and the Simple English Wiktionary as relevant corpora. For each question, we retrieve relevant sentences from these corpora and use them directly, or use small variations when necessary. If relevant sentences were not located, then these were constructed using simple, straightforward, and grade-level appropriate language. Approximately 18% of questions required specialized domain knowledge (e.g. spatial, mathematical, or other abstract forms) that did not easily lend itself to simple verbal description, which we removed from consideration. This resulted in a total of 363 gold explanations.[3]

In addition to using grade-appropriate language, the following considerations were taken in developing the explanation corpus, with the aim to provide broad utility for a variety of tasks from automated knowledge type identification to information aggregation models of inference:

- *Single topic:* To help facilitate automated analysis and reuse, explanations were broken into multiple sentences, with each sentence focusing on a single aspect of the explanation.
- *Reuse:* To assist in identifying overlaps in knowledge between questions, the same explanation sentences were reused as much as possible, where applicable.
- *Sentence Linking:* To support automated inference, the terminology used in different explanation sentences is explicitly linked through "bridge sentences" that include both terms. For example, if one sentence mentions *melting*, and another mentions *heated*, here we include an explicit sentence that links the two, such as *"melting happens when solids are heated"*. Where appropriate, we also include other latent knowledge that may not be explicitly required to answer a question, but would likely be available to a human and link related questions. For example, for a process question about a specific stage of the *life cycle*, we also include a brief overview of where this stage fits in the process as a whole (e.g. *egg to baby to child to adult*). In this way many of the explanations appear overly verbose to a human, but contain enough information to make the inference explicit, link highly related topics, and evaluate the knowledge requirements for automated methods.

Example explanations are shown in Table 1. The 363 gold explanations contain a total of 1272 sentences, or an average of 4 sentences per explanation. With respect to reuse, 943 unique sentences appear across these explanations, with 180 appearing in more than one explanation, and the remaining 763 occurring in only a single explanation.[4]

[3]The gold explanations developed in this work are also available at: `http://allenai.org/data.html`

[4]Frequently-recurring sentences highlight common themes in questions: Sentences such as *"Evaporation is when a liquid changes to a gas", "Sunlight means solar energy", and "Metals conduct electricity"* are 5 of the 42 sentences found in the explanations of 4 or more questions.

Knowledge Type	Prop.	Structure and Examples
Retrieval Types		
Taxonomic	83%	*HYPONYM* is a kind of *HYPERNYM* a <*HYPO: plant*> is a kind of <*HYPER: living thing*>
Definition	64%	*ARG1* means *ARG2 (can be definitions or synonyms)* <*ARG1: cooling*> means <*ARG2: decreasing heat*> *(definition)*
Properties	41%	*PROPERTY* is a property of *ARG1* <*ARG1: iron*> is <*PROP: magnetic*>
PartOf	22%	*MERONYM* is a part of *HOLONYM*. a <*HOLO: bicycle*> has <*MERO: two pedals*>.
Contains	17%	*ARG1* contains *ARG2*. <*ARG1: soil*> contains <*ARG2: nutrients*> that plants absorb through their roots
ExampleOf	9%	*ARG1* is an example of *ARG2* an example of a <*ARG1: seasonal change*> is <*ARG2: growing thick fur*>
MadeOf	8%	*ARG1* is made of *ARG2*. a <*ARG1: rock*> is a hard substance composed of <*ARG2: minerals*>
Inference Supporting Types		
Actions	73%	*SUBJECT ACTION OBJECT* <*SUBJ: bees*> <*ACTION: eat*> <*OBJ: pollen*>
UsedFor	33%	*WHO* uses *WHAT*, and *WHY*. <*WHO: squirrels*> <*WHAT: store food in the autumn*> <*WHY: to eat over the winter*>
Source	23%	*WHO* generates/is a source of *WHAT*, and *HOW* . natural gas is can be burned in power stations to *make electricity* (note sourceof+generate)
IsWhen	22%	*ARG1* is when *ARG2* happens. *(often used for defining events/processes)* <*ARG1: mechanical weathering*> is when <*ARG2: rocks are broken down by mechanical ...*>
VehicleFor	17%	*WHAT* happens by/through some means or *VEHICLE*. ... when <*WHAT: pollen is carried from flower to flower*> <*VEHICLE: by pollinating animals*>
Requires	12%	*WHO* requires *WHAT*, and *WHY*. <*WHO: animals*> need to <*WHAT: eat food*> <*WHY: to get nutrients required for survival*>
Negation	12%	*ARG1* is not *ARG2*. aluminum is not <*NOT: magnetic*>
Duration	10%	*ARG1* has some *DURATION* many birds <*ARG1: migrate to warmer places*> <*DUR: for the winter*>
Complex Inference Types		
Changes	45%	*WHO/LABEL* changes *WHAT*, *FROM* something *INTO* something else. <*LABEL: boiling*> means changing from a <*FROM: solid*> to a <*INTO: liquid*>
Causes	21%	*ARG1* causes *ARG2*. <*ARG1: friction*> causes <*ARG2: the temperature of an object to increase*>
Transfer	21%	*WHAT* gets transfered from a *SOURCE* to *DESTINATION*, and *HOW* this happens. ... breaks down food into <*WHAT: nutrients*> that can be <*HOW: absorbed*> by <*DEST: the body*>
IfThen	14%	*IF* a condition occurs, *THEN* a result happens. if <*IF: something is on fire*>, <*THEN: it burns*>
Relationship	12%	As *EVENT1* happens, *EVENT2* will also happen. <*EVENT1: A decrease in the amount of water*> will cause <*EVENT2: a decrease in plant populations*>
Process	8%	A group of relations, e.g. A *PROCESS STAGE* takes some *ACTION* causing a *RESULT*. as an <*STAGE: adult bird*>, <*ACTION: it will reproduce*>, <*RESULT:starting the life cycle...*>

Table 2: Fine-grained knowledge types, and the proportion of explanations that include at least one instance of a given type. Types are *n-ary* relations, containing between two and five arguments each. Note that a given example sentence often includes more than one relation, as in the case of "cooling means decreasing heat", which includes both a *Definition* relation (i.e. means), and a *Change* relation (i.e. decreasing heat).

3.2.2 Fine-grained Knowledge Types

To characterize the knowledge present in these gold explanations, we annotated the explanation sentences with a fine-grained set of knowledge types which reuses many of the types from Clark et al. (2013) and includes additional types derived from frequently observed semantic structures in the explanation sentences. Each explanation sentence can contain more than one type (e.g. *"boiling means increasing temperature"* contains both a Definition type (*boiling means ...*) and a Change type (*increasing temperature*)). All types were manually annotated using a graphical annotation tool[5]. Due to the time involved in this process, we annotated 212 questions, or approximately 50% of the original set of questions.

Table 2 shows the new fine-grained set of knowledge types, their relative frequencies, and the associated semantic structures. About 21% of the annotated questions had between 1 and 5 instances of types

[5]This simple graphical annotation tool is included with the data distribution.

in their explanations, while 31% had between 6 and 10 instances. The remainder of questions with more than 10 relations across their explanations were largely complex questions that included latent or other background knowledge in their explanations.

The fine-grained types can also be grouped into three broad sets: *Retrieval Types* include binary relations commonly found in taxonomies, dictionaries, and property databases. *Inference Supporting Types* tend to ground the knowledge in the complex inference relations. This includes describing the vehicle that enables something to happen, it's purpose, it's needs, and specific actions that it can take. *Complex Inference Types* describe changes situated in particular contexts, such as causality (e.g. *X causes Y*), transfers (e.g. *X transfers from Y to Z*), and process knowledge (e.g. *Stage A follows Stage B*). Here, while our *Retrieval Types* are binary relations, both the *Complex Inference* and *Inference Supporting Types* can be viewed as *n-ary* relations or light semantic frames, often with two to five "slots" to fill.

4 QA Analysis

Here we conduct an empirical analysis of the performance of two types of QA solvers using the question-centered and explanation-centered views of knowledge and inference types.

4.1 Knowledge Bases

We evaluate performance on two knowledge bases, one free text, the other semi-structured:

Study Guides: A collection of free text from six resources: study guides for two elementary science exams, a teacher's manual, a set of flashcards, and two dictionary resources: a science dictionary for kids, and the open-domain Simple English Wiktionary[6]. A total of 3,832 science-domain sentences and 17,473 open-domain definition sentences were included.

Aristo TableStore: An open collection[7] of approximately 100 semi-formal tables (approximately 10k rows, 30k cells) containing knowledge tailored to elementary science exams, constructed using a mixture of manual and automatic methods (Dalvi et al., 2016). The table knowledge spans across knowledge types, from properties and taxonomic knowledge to causality, processes, and domain models. Each table encodes an aspect of the science domain (e.g., animal adaptations, measuring instruments, energy conversions, etc.), where variations are typically enumerated (e.g. "a <*grill*> converts <*chemical energy*> to <*heat energy*>", "a <*flashlight*> converts <*electrical energy*> into <*light energy*>", etc.).

4.2 Solvers

We characterize QA approaches from two families: a baseline that uses "learning to rank" (L2R) with information retrieval (IR) features, and more recent inference models.

Retrieval Model:

We use an L2R model which finds answers by scoring passage level evidence for each answer choice from the unstructured textual knowledge sources. Our implementation is based on the candidate ranking (CR) model described in Jansen et al. (2014). Short passages are scored based on how similar they are to the words in the question and the corresponding answer choice. The similarity scores are computed using cosine similarity of *tf.idf* representations of the question and passages, and used in a L2R framework to produce the final ranking of the answer choices. We created two versions of the solver: one that uses the study guide collection, and the other with a textual representation of the Aristo TableStore. Apache Lucene[8] is used to index and retrieve passages.

Inference Models:

For inference, we use two models that operate over a structured knowledge base of tables (TableStore). TableILP (Khashabi et al., 2016) is a model that finds answers by building a graph of chained facts, i.e., rows in the knowledge tables, to arrive at the answer. Starting from the question, the model selects rows from a table, and then iteratively uses the selected rows to find rows in other tables, as linkable facts,

AKBC'13 Knowledge Type	N	Proportion Correct L2R (StudyGuides)	L2R (TableStore)	ILP (TableStore)	STITCH (Tablestore)
Retrieval Methods					
Taxonomic	4	75% (0%)	75%	100% (+25%)	100% (+25%)
Definition	27	56% (-7%)	63%	59% (-4%)	63% (0%)
Properties	19	21% (-11%)	32%	53% (+21%)	53% (+21%)
Complex Inference					
Examples	40	35% (-13%)	48%	70% (+22%)	58% (+10%)
Causality	30	30% (-10%)	40%	60% (+20%)	53% (+13%)
Processes	26	52% (+4%)	48%	36% (-12%)	64% (+16%)
Domain-specific Models	66	38% (+6%)	32%	43% (+11%)	53% (+21%)
Overall	212	39% (-4%)	43%	54% (+11%)	56% (+13%)

Table 3: Proportion of questions answered correctly broken down by AKBC'13 knowledge types. Values in parentheses reflect absolute differences with the L2R solver that uses the TableStore knowledge base.

until it arrives at facts that contain or overlap with the answer choices. Rows are selected based on lexical overlap. This graph building problem is modeled using Integer Linear Program (ILP) to find paths that maximize QA performance. STITCH is an alternative algorithm for reasoning over the same tables. It achieves similar overall performance using different heuristics for matching a question to table rows. For both inference models, we made use of the stock models, and did not incorporate any further training. As described below, we make use of a different question corpus and an expanded knowledge base compared to Khashabi et al., evaluating on approximately twice as many questions as were originally reported, including many questions at a higher grade level, and including questions from 13 other state exams in addition to the original New York Regents questions. Similarly, we make use of an expanded knowledge base that is approximately twice the size of that used in Khashabi et al. (2016). As such, our overall inference model performance is slightly lower than they originally reported.

Questions: We compare performance on the 212 elementary science questions from Section 3.2.2 that included a gold explanation annotated with the knowledge and inference types.[9]

4.3 Question-centered Evaluation

We first characterize performance of the two solvers using the seven broad question-centered categories of Clark et al. (2013), with performance shown in Table 3. Overall, the L2R models have lower performance than the inference models. This is in line with our explanation-based analysis of the requirements, which showed that there are more complex inference questions than there are simple retrieval ones. The results also show that the gains in the inference solvers are not completely due to tailored knowledge. Using the highly tailored knowledge base as a retrieval corpus shows a small benefit (+4%), whereas using the knowledge via appropriate inference substantially increases performance (+13%).

In terms of performance on questions with particular knowledge and inference requirements, we find that bulk of the performance benefit for the inference solvers comes from addressing more complex inference questions, rather than simply answering more of the (subjectively easier) retrieval questions. Performance on *Example Identification* and *Causality* questions using the L2R model increases 10-13% when switching from the study guide knowledge base to the Tablestore, and further increases by 10-22% when the inference solvers are used in conjunction with the Tablestore, demonstrating that some complex questions separately benefit from highly tailored knowledge and the capacity to aggregate multiple pieces of that knowledge to form a solution. Conversely, the more challenging *Process* and *Domain Model* categories are not directly benefited by the tailored Tablestore knowledge resource, but show moderate benefits when this knowledge is combined with the inference solvers to form more complex solutions.

On the balance, this high-level analysis shows that inference methods designed to aggregate multiple pieces of information from a knowledge base specifically benefit questions requiring complex inference, more than the contribution of tailoring a similarly-sized retrieval-centered knowledge base alone.

[9]Note that because this set excludes the 18% of questions that did not easily lend themselves to textual explanation, and that 70% of these excluded questions were categorized as requiring model-based reasoning, this evaluation set can be viewed as somewhat easier and containing fewer extremely difficult questions than the broader corpus.

Knowledge Type	N	L2R (Corpus)	Knowledge Advantage	L2R (TableStore)	Inference Advantage	ILP (TableStore)	STITCH (TableStore)
Retrieval Types							
Taxonomic	176	39% (-7%)	→	46%	→	56% (+10%)	55% (+9%)

Table 4: Performance on questions whose gold explanations contain *at least one* instance of a given type.Values in parentheses reflect absolute differences with the score of the L2R solver that uses the TableStore knowledge base. Arrows represent where performance on a given relation shows a benefit from either knowledge base, or switching from a retrieval to an inference solver, where an "X" signifies no benefit.

4.4 Explanation-centered Evaluation

We conduct an explanation-centered evaluation to understand the comparative finer-grained competencies of the solvers. Table 4 compares performance relative to whether the *gold explanation* for a given question contains *at least one* instance of the specific type. If a question contains a specific type according to the annotation, then we assert that type of knowledge or inference is required to answer (and produce an explanation for) that science exam question. We note three main observations.

First, the inference solver outperforms L2R solvers across the board, with strong improvements when there are retrieval or inference-supporting types, and smaller improvements for explanations with complex inference types, except for the causal types (+18% gain in P@1). Conversely, despite gains with inference solvers, questions of some complex inference types, such as *If/Then* conditional sequences, or *Coupled Directional Relationships* (i.e. *as X increases, Y decreases*), have low overall absolute performance, pointing to areas for future improvement.

Second, there is a variance in performance across the broader groups when switching over to Tablestore for the L2R solver. For example, *Taxonomic, Containment, and MadeOf* see benefits, whereas *Definition, Properties, and ExampleOf* do not. *PartOf*, and *Requirement* types work better with study guides rather than Tablestore knowledge, suggesting the entirety of the study guide knowledge is not subsumed by the tablestore. Similar variance exist for the complex inference types, as well.

Third, the broad types of the question-based analysis can be inadequate in some cases. The broad *Process* category in Table 3 showed some general improvement with inference methods, but the fine-grained analysis shows the opposite. This is likely because the broad *Process* category is an umbrella for several different types of questions. Some query only a very specific stage of a process (like a *producer's role in the food chain*), and are amenable to being answered by single sentences found using retrieval methods. Others require integrating structural knowledge across many stages of a process (such as *from egg to adult in the life cycle*), and appear to require much more complex inference to explainably answer.

5 Conclusions

In this work we developed an explanation-centered fine-grained characterization of elementary science exams, helping improve our understanding of this problem domain. Rather than existing in easily decoupled categories, these exams show a rich distribution of knowledge and inference requirements, with a majority requiring complex inference. The analyses validate the gains with some inference-based solvers by showing that they specifically address questions requiring complex inference. While a modern inference solver shows steady improvements in complex inference broadly, performance for a number of specific types of complex inference is still quite low, and provides targets for future work.

We release the annotated questions and explanations as a knowledge resource that can be broadly useful for science exam QA. As question variety, difficulty, and domain-specificity increase, any *single* solver is unlikely to work well across the board. This motivates development of solver ensembles and question-specific solver selection, which need the capacity to automatically recognize a given question's knowledge and inference requirements. We believe this resource may have a range of other uses, from providing a specification of knowledge base construction targets, to informing methods of information aggregation in automated inference.

"All I know about politics is what I read in Twitter": Weakly Supervised Models for Extracting Politicians' Stances From Twitter

Kristen Johnson and **Dan Goldwasser**

{john1187, dgoldwas}@purdue.edu

Abstract

During the 2016 United States presidential election, politicians have increasingly used Twitter to express their beliefs, stances on current political issues, and reactions concerning national and international events. Given the limited length of tweets and the scrutiny politicians face for what they choose or neglect to say, they must craft and time their tweets carefully. The content and delivery of these tweets is therefore highly indicative of a politician's stances. We present a weakly supervised method for extracting how issues are framed and temporal activity patterns on Twitter for popular politicians and issues of the 2016 election. These behavioral components are combined into a global model which collectively infers the most likely stance and agreement patterns among politicians, with respective accuracies of 86.44% and 84.6% on average.

1 Introduction

The trending decline in popularity of traditional media outlets and continued rise of social media usage emerged in the 2008 U.S. presidential election campaign and has continued to the present 2016 campaign. Social media platforms, such as the microblogging outlet Twitter, allow politicians to directly access the public, express their beliefs, and react to current events. Unlike its traditional media predecessors, Twitter requires politicians to compress their ideas, political stances, and reactions to 140 character long tweets. Consequently, politicians must cleverly choose how to frame controversial issues, as well as how and when to react to each other (Mejova et al., 2013; Tumasjan et al., 2010). Due to this limit, we argue that the stance of a tweet is not independent of the social context in which it was generated. Thus, for accurate predictions these social behaviors must also be modeled.

Converse to previous works which predict stance per individual tweet (SemEval, 2016), we instead present a novel approach better suited to model the dynamic political arena of Twitter, which uses the *overall* Twitter behavior per politician to predict a *politician's* stance on an issue. We explore two aspects of the problem, *stance* prediction over a wide array of issues, as well as stance *agreement and disagreement* patterns between politicians over these issues. While the two aspects are related, we argue they capture different information, as identifying agreement patterns reveals alliances and rivalries between candidates, across and within their party. In an extreme case, even the lack of Twitter activity on certain issues can be indicative of a stance.

For example, consider the three tweets on the issue of gun control shown in Figure 1. To identify the stance taken by each politician, our model combines both content and behavioral features, accumulated from all of a politician's tweets on that issue. First, the tweet's relevance to an issue can be identified using *issue* indicators (highlighted in green). Second, the similarity between the stances taken by two of the politicians (agreement) can be identified by observing differences in how the issue is *framed* (shown in yellow), a tool often used by politicians to create bias toward a stance and contextualize the discussion (Tsur et al., 2015; Card et al., 2015). Tweets (1) and (3) frame the issue as a matter of safety, while tweet (2) frames it as related to personal freedom, thus revealing the agreement and disagreement patterns between the politicians. Third, we can consider the timing of these tweets, i.e. whether these tweets are posted continually or just around events concerning gun violence. Finally, we can also use sentiment indicators (e.g., the negative sentiment of tweet (1)). Notice that each feature individually might not contain sufficient information for correct classification, but combining all aspects,

(1) **Hillary Clinton (@HillaryClinton):** *We need to keep guns out of the hands of domestic abusers and convicted stalkers.*

(2) **Donald Trump (@realDonaldTrump):** *Politicians are trying to chip away at the 2nd Amendment. I won't let them take away our guns!*

(3) **Bernie Sanders (@SenSanders):** *We need sensible gun-control legislation which prevents guns from being used by people who should not have them.*

Figure 1: Tweets Discussing the Issue of Gun Control. Issue indicators (e.g. guns and gun-control) are highlighted in green and different frame indicators (e.g., domestic abusers or 2nd Amendment) are highlighted in yellow.

by propagating stance bias (e.g. from sentiment) to politicians who hold similar or opposing views (as determined from frame analysis), leads to a more reliable prediction.

Given the dynamic nature of political discourse on Twitter, we design our approach to use minimal supervision and naturally adapt to new issues. We build several weakly supervised local learners, whose only supervision is a small seed set of issue and frame indicators which characterize the stance of tweets (based on lexical heuristics (O'Connor et al., 2010) and framing dimensions (Card et al., 2015)), and Twitter activity statistics which capture temporally similar patterns between politicians. Our final model represents agreement and stance bias by combining these weak models into a weakly supervised joint model through Probabilistic Soft Logic (PSL), a recent probabilistic modeling framework (Bach et al., 2013). The information gained from the weakly supervised local learners is the only supervision used by PSL; the rest of the prediction is completely unsupervised. PSL combines these aspects declaratively by specifying high level rules over a relational representation of the politicians' activities (exemplified in Figure 2), which is further compiled into a graphical model called a hinge-loss Markov random field (Bach et al., 2013), and used to make predictions about stance and agreement between politicians.

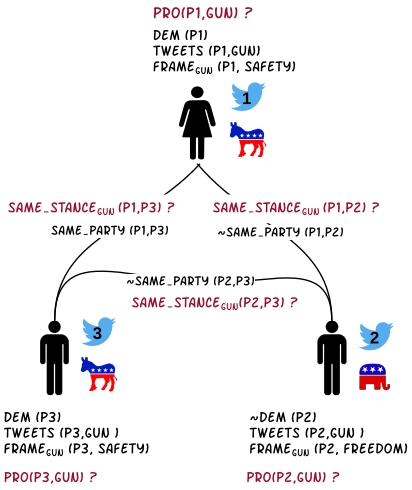

Figure 2: Relational Representation Example of Twitter Activity. P1, P2, and P3 represent 3 different politicians. Prediction target predicates (PRO and SAMESTANCE) are shown in red. Indicators of Twitter content and behavior include: DEM, TWEETS, FRAMEGUN, SAMEPARTY. GUN refers to the issue of gun control; SAFETY and FREEDOM refer to different frames for the issue.

We analyze the Twitter activity of 32 prominent U.S. politicians, including those who were U.S. 2016 presidential candidates, on 16 different issues. Our experiments demonstrate the effectiveness of our global modeling approach, which outperforms both the weak learners that provide the initial supervision and a supervised text based baseline. Our results show that understanding political discourse on Twitter requires modeling not only the word content of tweets but the social behavior associated with those tweets as well.

2 Related Work

To the best of our knowledge this is the first work predicting *politicians' stances using Twitter data, based on content, frames, and temporal activity*. Several works (Sridhar et al., 2015; Hasan and Ng, 2014; Abu-Jbara et al., 2013; Walker et al., 2012; Abbott et al., 2011; Somasundaran and Wiebe, 2010; Somasundaran and Wiebe, 2009) have studied mining opinions and predicting stances in online debate forum data by exploiting argument and threaded conversation structures, both of which are not always present in short Twitter data[1]. Social interaction and group structure has also been explored (Sridhar et al., 2015; Abu-Jbara et al., 2013; West et al., 2014). Works focusing on inferring signed social networks (West et al., 2014), stance classification (Sridhar et al., 2015), social group modeling (Huang et al., 2012), and PSL collective classification (Bach et al., 2015) are closest to our work, but these typically operate in supervised settings. Conversely, we use PSL *without direct supervision*, to assign *soft* values (0 to 1 inclusive) to output variables, rather than Markov Logic Networks, which assign *hard* (0 or 1) values to model variables and incur heavier inference time computational cost.

In recent years there has been a growing interest in analyzing political discourse in both traditional

[1]In our data set, there are few "@" mentions or retweet examples forming a conversation, thus we do not have access to argument or conversation structures for analysis.

and social media. Several previous works have explored topic framing (Tsur et al., 2015; Card et al., 2015; Baumer et al., 2015) of public statements, congressional speeches, and news articles. Other works focus on identifying and measuring political ideologies (Iyyer et al., 2014; Bamman and Smith, 2015; Sim et al., 2013; Lewenberg et al., 2016) and policies (Gerrish and Blei, 2012; Nguyen et al., 2015; Grimmer, 2010). To the best of our knowledge, this work is also the *first attempt to analyze issue framing in Twitter data*. To do so we use the frame guidelines developed by Boydstun et al. (2014). Issue framing is related to both analyzing biased language (Greene and Resnik, 2009; Recasens et al., 2013) and subjectivity (Wiebe et al., 2004).

Concerning Twitter specifically, analysis of users and political tweets has attracted considerable attention. Unsupervised and weakly supervised models of Twitter data for several various tasks have been suggested, such as user profile extraction (Li et al., 2014b), life event extraction (Li et al., 2014a), and conversation modeling (Ritter et al., 2010). Further, Eisenstein (2013) discusses methods for dealing with the unique language used in microblogging platforms.

Recently, SemEval Task 6 (SemEval, 2016) aimed to detect the stance of *individual tweets*. In contrast to this task, as well as most related work on stance prediction (e.g., those mentioned above), we *do not assume that each tweet expresses a stance*. Instead, we investigate how a politician's overall Twitter behavior, as represented by combined content and temporal indicators, is indicative of a stance (e.g., also capturing when politicians *fail to tweet about a topic*). Predicting political affiliation and other characteristics of Twitter users has been explored (Volkova et al., 2015; Volkova et al., 2014; Conover et al., 2011). Other works have focused on sentiment analysis (Pla and Hurtado, 2014; Bakliwal et al., 2013), predicting ideology (Djemili et al., 2014), analyzing types of tweets and Twitter network effects around political events (Maireder and Ausserhofer, 2013), automatic polls based on Twitter sentiment and political forecasting using Twitter (Bermingham and Smeaton, 2011; O'Connor et al., 2010; Tumasjan et al., 2010), as well as applications of distant supervision (Marchetti-Bowick and Chambers, 2012).

3 Data and Problem Setting

3.1 Data Collection

We collected tweets for 32 politicians, the 16 Republicans (all 2016 presidential candidates) and 16 Democrats (5 of which were candidates) listed in Table 1. Our initial goal was to compare politicians participating in the 2016 U.S. presidential election. To increase representation of Democrats, we collected tweets of Democrats who hold leadership roles within their party, because more well known politicians tend to focus their tweets on national rather than local (district/state) events. For all 32 politicians we have a total of 99,161 tweets: 39,353 Democrat and 59,808 Republican[2].

Based on tweet availability and politician coverage[3], we chose 16 issues (shown in Table 2) derived from the 58 questions used by `ISideWith.com` to match a user to politicians based on their responses as our stance prediction goals. These issues range over common policies including domestic and foreign policy, economy, education, environment, health care, immigration, and social issues.

Republicans	Jeb Bush, Ben Carson, Chris Christie, Ted Cruz, Carly Fiorina, Lindsey Graham, Mike Huckabee, Bobby Jindal, John Kasich, George Pataki, Rand Paul, Rick Perry, Marco Rubio, Rick Santorum, Donald Trump, Scott Walker
Democrats	Candidates: Lincoln Chafee, Hillary Clinton, Martin O'Malley, Bernie Sanders, Jim Webb
	Non-candidates: Joe Biden, Kirsten Gillibrand, John Kerry, Ben Lujan, Ed Markey, Nancy Pelosi, Harry Reid, Chuck Schumer, Jon Tester, Mark Warner, Elizabeth Warren

Table 1: Politicians Tracked in This Study. All Republicans were 2016 presidential candidates. Democrats are divided by whether or not they ran as a candidate.

[2]Our Twitter data set, keywords, and PSL scripts are available at: `purduenlp.cs.purdue.edu/projects/politicaltwitter`.

[3]For each of these 16 issues, at least 15 (with an average of 26) of the 32 politicians have tweeted on that issue; for the remaining issues, we found fewer than half (or none) of the politicians tweeted about that issue.

ISSUE	QUESTION
ABORTION	*Do you support abortion?*
ACA	*Do you support the Patient Protection and Affordable Care Act (Obamacare)?*
CONFEDERATE	*Should the federal government allow states to fly the confederate flag?*
DRUGS	*Do you support the legalization of Marijuana?*
ENVIRONMENT	*Should the federal government continue to give tax credits and subsidies to the wind power industry?*
GUNS	*Do you support increased gun control?*
IMMIGRATION	*Do you support stronger measures to increase our border security?*
IRAN	*Should the U.S. conduct targeted airstrikes on Irans nuclear weapons facilities?*
ISIS	*Should the U.S. formally declare war on ISIS?*
MARRIAGE	*Do you support the legalization of same sex marriage?*
NSA	*Do you support the Patriot Act?*
PAY	*Should employers be required to pay men and women, who perform the same work, the same salary?*
RELIGION	*Should a business, based on religious beliefs, be able to deny service to a customer?*
SOCIAL SECURITY	*Should the government raise the retirement age for Social Security?*
STUDENT	*Would you support increasing taxes on the rich in order to reduce interest rates for student loans?*
TPP	*Do you support the Trans-Pacific Partnership?*

Table 2: Sixteen Political Issues Used in This Study. Issues and their corresponding Yes/No questions were taken from `ISideWith.com`.

3.2 Data Pre-Processing

Using all tweets, we compiled a set of frequent keywords (an average of 7) for each issue. This set is small to avoid overselection, i.e., avoiding tweets about praying for a friend's *health* but keeping tweets discussing *health care*. Via Python scripts, these keywords are used to retain tweets related to the 16 issues shown in Table 2, while eliminating all irrelevant tweets (e.g., those about personal issues, campaigning, duplicates, and non-English tweets).

`ISideWith.com` uses a range of yes/no answers to their questions and provides proof (through quotes or voting records) of a politician's stance on that issue, *if available*. When unavailable, the site assigns an answer based on party lines or often provides no answer. Also, less popular politicians are not featured on the site. For these cases, we manually annotated the stance using online searches of newspapers or voting records. These stances are only used for evaluation of our predictions. Our weakly supervised approach requires *no* prior knowledge of the politician's stance, allowing it to generalize to situations such as these, where stance information is unavailable.

3.3 Prediction Goals

The collected stances represent the ground truth of whether a politician is for or against an issue. Based on these we define two target predicates using PSL notation (see Section 5.1) to capture the desired output as soft truth assignments to these predicates. The first predicate, PRO(P1, ISSUE), captures a positive stance by politician P1, on an ISSUE. A negative stance would be captured by its negation: ¬PRO(P1, ISSUE). The second target predicate, SAMESTANCE$_I$(P1, P2), classifies if two politicians share a stance for a given issue, i.e., if both are for or against an issue, where I represents 1 of the 16 issues of interest. Although the two predicates are clearly inter-dependent, we chose to model them as separate predicates since they can depend on different Twitter behavioral and content cues. Given the short and context-free style of Twitter we can often find indicators of politicians holding similar stances, *without* clear specification for which stance they actually hold.

4 Local Models of Twitter Activity

The only supervision required by our method consists of the keywords describing issues and frames, Twitter behavior patterns, and party affiliation, all of which is easily attainable and adaptable for new domains (e.g., different keywords to capture issues of another country). The weakly supervised local models described in this section capture similarities between tweet content and temporal activity patterns of users' timelines, as well as stance bias, and are used to provide the initial bias when learning the parameters of the otherwise unsupervised global PSL model.

4.1 Issue of Tweets

To capture which issues politicians are tweeting about, we used a keyword based heuristic, similar to the approach described in O'Connor et al. (2010), where each issue is associated with a small set of pre-selected keywords (as described previously). The keywords appearing in a given tweet may be mutually

exclusive (e.g., *fracking* for Environment will not appear in tweets discussing other issues); however, some may fall under multiple issues at once (e.g., *religion* may indicate the tweet refers to ISIS, Religion, or Marriage). Tweets are classified as relating to a certain issue based on the majority of matching keywords, with rare cases of ties manually resolved. The output of this classifier is all of the issue-related tweets of a politician, which are used as input for the PSL predicate TWEETS(P1, ISSUE), a binary predicate which indicates if that politician has tweeted about the issue or not.

4.2 Sentiment of Tweets

The sentiment of a tweet can indicate a politician's stance on a certain issue. OpinionFinder 2.0 (Wilson et al., 2005) is used to label each politician's issue-related tweets as positive, negative, or neutral. We observed, however, that for all politicians, a majority of tweets will be labeled as neutral. This may be caused by the difficulty of labeling sentiment for Twitter data. When this results with a politician having no positive or negative tweets, they are assigned their party's majority sentiment for that issue. The majority sentiment of a party is calculated by running all politicians' tweets through OpinionFinder and using whichever sentiment (positive or negative) is assigned the most per party. This output is used as input to the PSL predicates TWEETPOS(P1, ISSUE) and TWEETNEG(P1, ISSUE).

4.3 Content Agreement and Disagreement Patterns

We expect politicians that have a similar stance on an issue to use similar words in their tweets. To determine how well tweet content similarity captures agreement between politicians, we computed the pair-wise cosine similarity between all of the politicians' words used in tweets per issue. However, the use of similar words per issue resulted in most politicians being grouped together, even across different parties. To overcome this, we calculated the *frequency* of similar words within tweets (per issue). For each issue, all of a politician's words from tweets are aggregated and the frequency of each word is compared to all other politicians' word frequencies. Politicians, P1 and P2, are considered to have a similar LOCALSAMESTANCE$_I$(P1, P2) if their frequency counts per shared word of an issue are within the same range. For this study, we used a window of 10 (i.e., if the frequency count of a word is 30, then a count of 20 to 40 would be considered similar) to ensure that politicians who briefly mention an issue are not considered equivalent to those who discuss it more frequently.

4.4 Temporal Activity Patterns

We observed from reading Twitter feeds that most politicians tweet about an event the day it happens. However, for general issues, politicians will comment as frequently as desired to express their support or lack thereof for that particular issue. For example, Rand Paul tweeted daily in opposition of the NSA during his filibuster of the Patriot Act renewal. Conversely, Hillary Clinton has no tweets concerning the NSA or Patriot Act. To capture agreement patterns between politicians, we align their timelines based on days where they have tweeted about an issue. When two or more politicians tweet about the same issue on the same day, they are considered to have similar temporal activity, which may indicate stance agreement. This information is used as input to the predicate SAMETEMPORALACTIVITY$_I$(P1, P2).

4.5 Political Framing

Framing is a political strategy that describes the concept of how politicians word their statements in order to control the way the public views and discusses current issues. To investigate the intuition that the way politicians contextualize their tweets is strongly indicative of their stance on an issue, we compiled a list of unique keywords for each political framing dimension as described in Boydstun et al. (2014) and Card et al. (2015). We again use the keyword matching approach described in Section 4.1 to classify all tweets with a political frame. As noted in Card et al. (2015), some tweets may fall into multiple frames. After all tweets are classified, we sum over the total number of each frame type and use the frames with the maximum and second largest counts as that politician's frames for that issue. The top two frames are used because for most politicians a majority of their issue-related tweets will fall into two frames. In the event of a tie we assign the frame that appears most frequently within that politician's party. These frames are used as input to the PSL predicate FRAME(P1, ISSUE).

4.6 Temporal Framing Patterns

While we expect politicians within a party to use similar frames per issue (as captured by the PSL predicate FRAME), it is also possible that politicians will use certain frames around events. For example, when a mass shooting occurs, we observe that Democrats will tweet about enacting gun legislation and typically frame these tweets as a matter of a needed preemptive action for public safety (which falls under the *Health and Safety* frame). In reaction to this, Republicans will tweet about protecting American citizens' rights to gun ownership, which falls under the *Constitutionality* frame. Therefore, we expect similarities and differences in framing around events to indicate similarities and differences in stances and agreement patterns. To capture this idea, we combine the approaches of Sections 4.4 and 4.5: we align the politicians' timelines per issue and compare the frames used to discuss the issue-related events. When two or more politicians use the same frame for an issue on the same day, we consider them to have similar temporal framing patterns. This is used as input to the PSL predicate SAMETEMPORALFRAME$_I$(P1, P2).

5 Global Models of Twitter Activity

Information obtained from the local models alone is not strong enough to quantify stance or agreement for politicians, as shown by our baseline measurements in Section 6. Therefore, we use PSL to build global connections among the output of the local models (which acts as weak supervision), resulting in global PSL models which successively build upon the previous model in order to obtain the highest accuracy possible. In addition to the PSL predicates representing the target output (PRO and SAMESTANCE$_I$) [4] and local models (as defined in Section 4), we also use directly observed information: party affiliation, denoted DEM(P1) for Democrat and ¬DEM(P1) for Republican, and SAMEPARTY(P1, P2) to denote if two politicians belong to the same political party.

5.1 Global Modeling using PSL

PSL is a recent declarative language for specifying weighted first-order logic rules. A PSL model is specified using a set of weighted logical formulas, which are compiled into a special class of graphical model, called a hinge-loss MRF, defining a probability distribution over the possible continuous value assignments to the model's random variables and allowing the model to scale easily (Bach et al., 2015). The defined probability density function has the form:

$$P(\mathbf{Y} \mid \mathbf{X}) = \frac{1}{Z} \exp\left(-\sum_{r=1}^{M} \lambda_r \phi_r(\mathbf{Y}, \mathbf{X})\right)$$

where λ is the weight vector, Z is a normalization constant, and

$$\phi_r(\mathbf{Y}, \mathbf{X}) = (\max\{l_r(\mathbf{Y}, \mathbf{X}), 0\})^{\rho_r}$$

is the hinge-loss potential corresponding to the instantiation of a rule, specified by a linear function l_r, and an optional exponent $\rho_r \in 1, 2$. The weights of the rules are learned using maximum-likelihood estimation, which in our weakly supervised setting was estimated using the Expectation-Maximization algorithm. For more details we refer the reader to Bach et al. (2015).

Specified PSL rules have the form:

$$\lambda_1 : P_1(x) \wedge P_2(x, y) \rightarrow P_3(y), \qquad \lambda_2 : P_1(x) \wedge P_4(x, y) \rightarrow \neg P_3(y)$$

where P_1, P_2, P_3, P_4 are predicates, and $x,\ y$ are variables. Each rule is associated with a weight λ, which indicates its importance in the model. Given concrete constants *a, b* respectively instantiating the variables $x,\ y$, the mapping of the model's atoms to soft [0,1] assignments will be determined by the weights assigned to each one of the rules. For example, if $\lambda_1 > \lambda_2$, the model will prefer $P_3(b)$ to its negation. This contrasts with "classical" or other probabilistic logical models in which rules are strictly true or false. In our domain, the constant symbols correspond to politicians and predicates to: party affiliation, Twitter activity, and similarities between politicians based on temporal Twitter behaviors.

[4] In a supervised setting, jointly modeling the 2 target predicates can improve performance. Experiments using this approach yielded improvement in performance *and* a more complex model containing more parameters, resulting in slower inference.

5.2 Baseline: Using Local Classifiers Directly

To show that the local models do not provide enough information individually to make an accurate prediction, we implement a local baseline (LB) PSL model which does not take advantage of the global modeling framework. It instead learns weights over rules (shown in Table 3), which directly map the output of the local noisy classifiers described in Section 4 to PSL target predicates.

PSL Rules: LOCAL BASELINE MODEL (LB)
LOCALSAMESTANCE$_I$(P1, P2) →SAMESTANCE$_I$(P1, P2)
¬LOCALSAMESTANCE$_I$(P1, P2) →¬SAMESTANCE$_I$(P1, P2)
TWEETS(P1,ISSUE) ∧TWEETPOS(P1,ISSUE) →PRO(P1, ISSUE)
TWEETS(P1,ISSUE) ∧TWEETNEG(P1,ISSUE) →¬PRO(P1, ISSUE)

Table 3: Subset of PSL Rules Used in the Local Baseline Model.

5.3 Model 1: Agreement with Party Lines

The observation that politicians tend to vote with their political party on most issues is the basis of our initial assumptions in Model 1. The PSL rules listed in Table 4 are designed to capture this party based agreement. For some issues we initially assume Democrats (DEM) are for an issue, while Republicans (¬DEM) are against that issue, (e.g., ¬DEM(P1) →¬PRO(P1, ISSUE)), or vice versa. In the latter case, the rules of the model would change accordingly, e.g. the second rule would become ¬DEM(P1) →PRO(P1, ISSUE), and likewise for all other rules. Similarly, if two politicians are in the same party, we expect them to have the SAMESTANCE, or agree, on an issue. Though this is a strong initial assumption, the model can incorporate other indicators to overcome this bias when necessary. For all PSL rules, the reverse also holds, e.g., if two politicians are not in the same party, we expect them to have different stances.

PSL Rules: MODEL 1 (M1)
SAMEPARTY(P1, P2) →SAMESTANCE$_I$(P1, P2)
DEM(P1) →PRO(P1, ISSUE)
¬DEM(P1) →¬PRO(P1, ISSUE)
SAMEPARTY(P1, P2) ∧DEM(P1) →PRO(P2, ISSUE)
SAMEPARTY(P1, P2) ∧¬DEM(P1) →¬PRO(P2, ISSUE)
SAMEPARTY(P1,P2) ∧PRO(P1, ISSUE) ∧DEM(P1) →PRO(P2, ISSUE)
SAMEPARTY(P1, P2) ∧¬PRO(P1, ISSUE) ∧ ¬DEM(P1) →¬PRO(P2, ISSUE)

Table 4: Subset of PSL Rules Used in Model 1.

5.4 Model 2: Politicians' Twitter Activity

Model 2 builds upon the initial party line bias of Model 1. In addition to political party based information, we also include representations of the politician's Twitter activity, as shown in Table 5. This includes whether or not a politician tweets about an issue (TWEETS) as well as the sentiment of the tweets as determined in Section 4.2. The predicate TWEETPOS models if a politician tweets positively on the issue, whereas TWEETNEG models negative sentiment. Two sentiment predicates are used instead of the negation of TWEETPOS, which would cause all politicians for which there are no tweets, and hence no sentiment, on that issue to also be considered.

PSL Rules: MODEL 2 (M2)
TWEETS(P1, ISSUE) ∧DEM(P1) →PRO(P1, ISSUE)
TWEETS(P1, ISSUE) ∧¬DEM(P1) →¬PRO(P1, ISSUE)
TWEETS(P1, ISSUE) ∧TWEETS(P2, ISSUE) ∧SAMEPARTY(P1, P2) →SAMESTANCE$_I$(P1, P2)
TWEETS(P1, ISSUE) ∧TWEETS(P2, ISSUE) ∧DEM(P1) →PRO(P2, ISSUE)
TWEETS(P1, ISSUE) ∧TWEETS(P2, ISSUE) ∧¬DEM(P1) →¬PRO(P2,ISSUE)
TWEETPOS(P1, ISSUE) ∧TWEETPOS(P2, ISSUE) →SAMESTANCE$_I$(P1, P2)
TWEETPOS(P1, ISSUE) ∧TWEETNEG(P2, ISSUE) →¬SAMESTANCE$_I$(P1, P2)
TWEETPOS(P1, ISSUE) ∧TWEETPOS(P2, ISSUE) ∧DEM(P1) →PRO(P2, ISSUE)
TWEETNEG(P1,ISSUE) ∧TWEETNEG(P2,ISSUE) ∧¬DEM(P1) →¬PRO(P2,ISSUE)
TWEETPOS(P1, ISSUE) ∧TWEETPOS(P2, ISSUE) ∧SAMEPARTY(P1, P2) →SAMESTANCE$_I$(P1, P2)
TWEETPOS(P1,ISSUE) ∧TWEETNEG(P2,ISSUE) ∧¬SAMEPARTY(P1,P2) →¬SAMESTANCE$_I$(P1,P2)

Table 5: Subset of PSL Rules Used in Model 2.

5.5 Model 3: Politicians' Agreement Patterns

Table 6 presents a subset of the rules used in Model 3 to incorporate higher level Twitter information into the model. The incorporation of this information allows Model 3 to overcome Model 2 inconsistencies between stance and sentiment (e.g., when someone is attacking their opposition). Our intuition is that politicians who have similar tweets would also have similar stances on issues, which we represent with the predicate LOCALSAMESTANCE$_I$. SAMETEMPORALACTIVITY represents the idea that if politicians tweet on an issue around the same time range then they also share a stance for that issue. FRAME indicates the frame used by that politician for different issues. Finally, SAMETEMPORALFRAME$_I$ conveys that two politicians use the same frames for an issue at the same time. More details on these predicates are in Sections 4.3, 4.4, 4.5, and 4.6 respectively.

PSL Rules: MODEL 3 (M3)
LOCALSAMESTANCE$_I$(P1, P2) $\wedge$PRO(P1, ISSUE) $\rightarrow$PRO(P2, ISSUE)
SAMETEMPORALACTIVITY$_I$(P1, P2) $\wedge$SAMEPARTY(P1, P2) $\rightarrow$ SAMESTANCE$_I$(P1, P2)
SAMETEMPORALACTIVITY$_I$(P1, P2) $\wedge$FRAME(P1,ISSUE) $\wedge$FRAME(P2, ISSUE) $\rightarrow$SAMESTANCE$_I$(P1, P2)
FRAME(P1, ISSUE) $\wedge$FRAME(P2, ISSUE) $\rightarrow$SAMESTANCE$_I$(P1, P2)
FRAME(P1, ISSUE) $\wedge$FRAME(P2, ISSUE) $\wedge$SAMEPARTY(P1,P2) $\rightarrow$SAMESTANCE$_I$(P1, P2)
FRAME(P1, ISSUE) $\wedge$DEM(P1) $\rightarrow$PRO(P1, ISSUE)
FRAME(P1, ISSUE) $\wedge\neg$DEM(P1) $\rightarrow\neg$PRO(P1, ISSUE)

SAMETEMPORALFRAME$_I$(P1, P2) $\wedge$PRO(P1, ISSUE) $\rightarrow$PRO(P2, ISSUE)

Table 6: Subset of PSL Rules Used in Model 3.

6 Experiments

6.1 Experimental Settings

Supervised Baseline: Previous works exploring stance classification typically predict stance based on an *individual item of text* (e.g., forum post or single tweet) in a *supervised* setting, making it difficult to directly compare to our approach. To facilitate comparison, we implemented a tweet-based supervised baseline, per issue. We labeled each tweet with the politician's stance (either for or against) on that tweet's issue. We trained an SVM on 80% of the politicians' tweets and tested on the remaining 20%, using 5-fold cross-validation. Because we aim to predict each politician's stance and *not* the stance of each tweet, we aggregated the SVM predictions by politician, i.e., the SVM predicts a stance for each tweet and the majority prediction among a politician's tweets is used as his or her stance. For agreement prediction, we compared this stance prediction across politicians to determine if the predicted stances agreed and whether or not this agreement was correct.

PSL Models: As described in Section 4, the data generated from the local models is used as weak supervision to initialize the PSL models described in Section 5. The Local Baseline model (LB) is initialized with only the information from the weak local models. We initialize Model 1 (M1), as described in Section 5.3, using knowledge of the politician's party affiliation. Model 2 (M2) builds upon (M1) by incorporating the results of the issue and sentiment analysis local models, as described in Sections 4.1 and 4.2 respectively. Model 3 (M3) combines all previous models with higher level knowledge of Twitter activity: tweet agreement (Section 4.3), temporal activity (Section 4.4), frames (Section 4.5), and temporal framing patterns (Section 4.6). We implement our PSL models to have an initial bias that candidates do not share a stance and are against an issue. Stances collected in Section 3.2 are used as the ground truth for evaluation of the predictions of the PSL models only, not for any form of supervision.

6.2 Experimental Results

Results Per Issue: Table 7 presents the results of using the supervised baseline and our three proposed PSL models. While the supervised baseline results (SVM) are not directly comparable to our weakly supervised model, since the supervised model uses a different data split and approach, it does show that direct supervision does not lead to immediate prediction improvement and can result in weaker prediction scores. LB refers to using only the weak local models for prediction with no additional information about party affiliation. We observe that for prediction of stance (PRO) LB performs better than random chance in 11 of 16 issues; for prediction of agreement (SAMESTANCE$_I$), LB performs slightly lower overall, with only 9 of 16 issues predicted above chance. Using M1, we improve stance prediction accuracy for

Issue	Stance (Results of Pro Prediction)					Agreement (SameStance Prediction)				
	SVM	LB	M 1	M 2	M 3	SVM	LB	M 1	M 2	M 3
Abortion	61.25	81.25	96.88	96.88	96.88	44.34	49.31	93.75	93.75	95.36

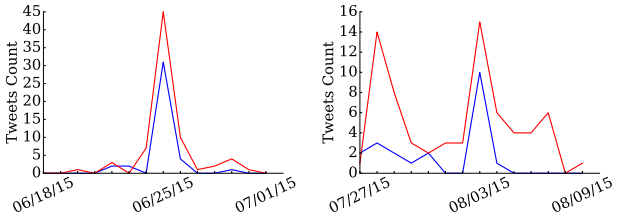
Table 7: Stance and Agreement Accuracy by Issue. The SVM columns show the results of the tweet-based, supervised baseline. LB columns show the results when using only the weak local models. M1 columns are the results based on party line agreement, M2 columns are the results when adding Twitter activity to M1, and M3 columns are the results when adding higher level Twitter behaviors to M1 and M2.

	Global		Rep		Dem	
	St	Ag	St	Ag	St	Ag
LB	68.36	52.49	66.80	49.10	69.92	44.86
M1	81.25	76.34	75.39	75.16	87.11	85.44
M2	85.16	87.30	81.25	84.26	89.06	91.37
M3	89.84	87.76	87.11	85.35	92.58	91.49

Table 8: Overall Accuracy for Stance (St) and Agreement (Ag) Prediction. Global represents the accuracy over all politicians, while Rep and Dem refer to Republicans or Democrats only.



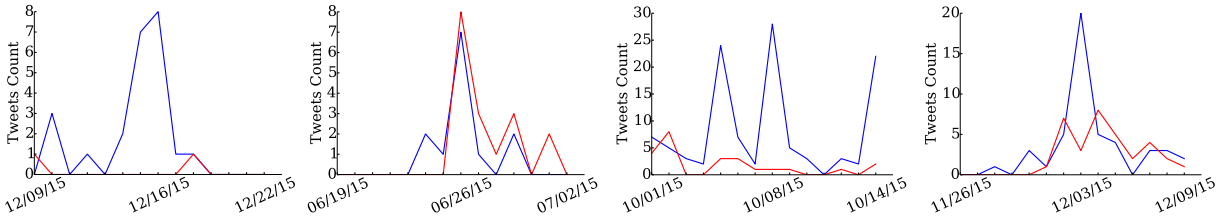
a ACA b Abortion

Figure 3: Temporal Twitter Activity by Party. The red and blue lines represent the temporal overlaps, or lack thereof, of Republicans and Democrats (respectively) in Twitter activity 1 week before and after a major event.

10 of the issues and agreement accuracy for all issues. M2 further improves the stance and agreement predictions for an additional 8 and 12 issues, respectively. M3, the combination of the previous models with Twitter behavioral features, increases the stance prediction accuracy of M2 for 9 issues and the agreement accuracy for 12 issues.

The final agreement predictions of M3 are notably improved over the initial LB for all issues, indicating that similarities and differences in Twitter behaviors help capture agreement and disagreement patterns among politicians. The final stance predictions of M3 are improved over all issues except Guns, Iran, and TPP. For Guns, the stance prediction remains the same throughout all models, meaning party information does not boost the initial predictions determined from Twitter based behaviors. For Iran, the addition of M1 and M2 lower the accuracy, but the temporal features from M3 are able to restore it to the original prediction. For TPP, this trend is likely due to the fact that all models incorporate party information and the issue of TPP is the most heavily divided within and across parties, with 8 Republicans and 4 Democrats in support of TPP and 8 Republicans and 12 Democrats opposed. Even in cases where M1 and/or M2 remained steady or lowered the initial baseline result (e.g. stance for Religion and Pay), the final prediction by M3 is still higher than that of the baseline.

Overall Results: Table 8 presents our overall results for stance and agreement prediction in terms of accuracy. The Global score is the overall average for all politicians, while Rep and Dem consider only Republicans or Democrats, respectively. Each model increases the accuracy of the previous model's prediction, showing that additional Twitter behavioral features can help overcome the strong party line biases captured by M1.



(a) Environment (b) Marriage (c) Guns (d) Guns

Figure 4: Temporal Twitter Activity by Party for Three Issues.

6.3 Effects of Framing and Temporal Activity Patterns

As shown in Table 7, performance for *some* issues does not improve in M3. Upon investigation, we found that for all issues, except Abortion which improves in agreement, one or both of the top frames for the party are shared across party lines. For example, for ACA both Republicans and Democrats have the *Economic* and *Health and Safety* frames as their top two frames. For TPP, both parties share the *Economic* frame. In addition to similar framing overlap, the Twitter timeline for ACA also exhibits overlap, as shown in Figure 3(a). This figure highlights one week before and after the Supreme Court ruling to uphold the ACA. The peak of Twitter activity is the day of the ruling, 6/25/2015.

Conversely, Abortion, which shares no frames between parties (Democrats frame Abortion with *Constitutionality* and *Health and Safety* frames; Republicans use *Economic* and *Capacity and Resources* frames), exhibits a timeline with greater fluctuation. The peak of Figure 3(b) is 8/3/2015, which is the day that the budget was passed to include funding for Planned Parenthood. Despite sharing a peak, both parties have different patterns over this time frame, allowing M3 to extract enough information to increase agreement prediction accuracy by 1.61%.

Figure 4(a) shows an example of one event for the Environment issue: when the mayor of Flint, Michigan declared a state of emergency over lead in the city's water supply. Due to different temporal patterns and frames for such events, the Environment accuracy improves across all models, as shown in Table 7. Similarly, Figure 4(b) shows the week before and after the Supreme Court ruled to uphold the legality of same-sex marriage. The two central peaks are shared by both parties, but each party also has one peak before (Democrats) or after (Republicans) the event. Additionally, both parties share the *Constitutionality* frame as their top frame, but the second most used frame is *Morality* for Republicans and *Fairness and Equality* for Democrats. These slight differences allow the M3 model to improve over the M2 prediction. Finally, Figure 4(c) shows the week before and after Democratic Senators pushed for gun control legislation after the Umpqua Community College shooting and Figure 4(d) shows tweets around the San Bernadino shooting. For these events, both parties exhibit different timeline patterns and frames. Consequently, these behavioral features dominate the stance prediction and allow agreement accuracy to reach 99.59%.

7 Conclusion

In this work we present a framework for modeling the dynamic nature of political discourse on Twitter. Though we focus on a small set of politicians and issues, our approach can be modified to handle additional politicians or issues, as well as those of other countries, by incorporating the proper domain knowledge (e.g., replacing party with voting history, using new keywords for different issues in other countries, or changing events such as Supreme Court rulings to Parliament votes), which we leave as future work. Contrary to previous works, which typically focus on a single aspect of this complex microblogging behavior, we build a holistic model connecting party line biases, temporal behaviors, and issue framing into a single predictive model which identifies fine-grained stances and agreement patterns. Despite having no direct supervision and using only intuitive local classifiers to bootstrap our global model, our approach results in a strong predictive model which helps shed light on political discourse within and across party lines.

Leveraging Multiple Domains for Sentiment Classification

Fan Yang **Arjun Mukherjee** **Yifan Zhang**
Department of Computer Science, University of Houston, TX, USA
fyang11@uh.edu arjun4787@gmail.com aeryen@gmail.com

Abstract

Sentiment classification becomes more and more important with the rapid growth of user-generated content. However, sentiment classification task usually comes with two challenges: first, sentiment classification is highly domain-dependent and training sentiment classifier for every domain is inefficient and often impractical; second, since the quantity of labeled data is important for assessing the quality of classifier, it is hard to evaluate classifiers when labeled data is limited for certain domains. To address the challenges mentioned above, we focus on learning high-level features that are able to generalize across domains, so a global classifier can benefit with a simple combination of documents from multiple domains. In this paper, the proposed model incorporates both labeled and unlabeled data from multiple domains and learns new feature representations. Our model doesn't require labels from every domain, which means the learned feature representation can be generalized for sentiment domain adaptation. In addition, the learned feature representation can be used as classifier since our model defines the meaning of feature value and arranges high-level features in a prefixed order, so it is not necessary to train another classifier on top of the new features. Empirical evaluations demonstrate our model outperforms baselines and yields competitive results to other state-of-the-art works on the benchmark dataset.

1 Introduction

With the rapid growth of user-generated content, such as product reviews and microblogs, sentiment analysis and opinion mining have become more and more important as they address the problem of analyzing user's opinions, emotions, sentiments and attitudes. The applications of sentiment analysis have been found in almost every business and social domain (Liu, 2012; Bollen et al., 2011; Ku et al., 2006). Document-level sentiment classification predicts sentiment polarities for a given document or review. The large number of reviews not only help customers make better decisions but also make it possible yet challenge for product manufacturers to keep track opinions of the products (Hu and Liu, 2004).

While machine learning techniques provide interesting methods for analyzing sentiments (Turney, 2002; Go et al., 2009; Pang et al., 2002), challenges also arise certain limitations for the development of sentiment classification. For example, sentiment expression is highly domain-dependent (Pang and Lee, 2008), but training sentiment classifier for every domain is inefficient and often impractical. Simply combining data from different domains may not contribute to a generalized classifier for every domain, as users express the same sentiment in different domains using different words, or even express different sentiment using same words. For example, a user would prefer computer or car to "run fast" but not wish to use battery "die fast" or to see watch "move fast". A book or a movie can attract people by "unpredictable" endings but "unpredictable" economic trends scare away investors. In addition, certain domains don't have enough labeled data for building the classifier, which makes it indispensable to transfer knowledge between different domains.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2978–2988, Osaka, Japan, December 11-17 2016.

A common observation is, even though sentiment expression is domain-dependent and various words are isolated by domain categories, there are always domain-independent words expressing general sentiment polarities. In traditional sentiment domain adaptation that focuses on one domain to another domain (Daumé III et al., 2010; Ben-David et al., 2007; Ben-David et al., 2010), such words are usually defined as pivot features (Blitzer et al., 2006; Blitzer et al., 2007; Pan et al., 2010). Existing works have focused on generating new feature representations for pivot features (Glorot et al., 2011; Chen et al., 2012; Yang and Eisenstein, 2015; Bollegala et al., 2015) so that classifiers trained on new features can generalize well across domains.

In this paper, we follow the motivation of using new feature representations (Bengio et al., 2012) to bridge domain divergence and transfer knowledge among domains. The idea of proposed work is to learn a high-level feature space where three constraints are enforced: the model can incorporate multiple domains with both labeled and unlabeled data; the high-level feature space maximizes the margin between sentiment polarities; the high-level feature can represent original features well so that two feature space can be transformed to each other through a shared parametric matrix. Some of the key characters of the proposed model are:

1. Given multiple domains, our model can leverage sentiment similarity between instances across different domains regardless of the dissimilarity between domains. This is achieved by maximizing the distance between sentiments and minimizing the distance between domains in the high-level feature space.

2. Compared with one domain(source) to another domain(target) schema, our model collaborates all possible domains with both labeled and unlabeled data, which is a more generic framework and caters for better transfer across domains.

3. Our model directly maximizes the margin of sentiment polarities in the learned feature space. This is achieved by exploiting non-linear transformation with sigmoid function and aligning instances to pseudo-sentiment centroids.

4. Unlike traditional representation learning method which involves two stages: learning representation and building classifier, the new feature space learned by our model can be taken as classifier by itself. This is achieved through setting the order of learned high-level features and defining the meaning of feature values. As a result, it is not necessary to train another classifier on top of the new features.

5. We extend autoencoder (Vincent et al., 2010) by incorporating sentiment polarities. Unlike existing semi-supervised autoencoder (Liu et al., 2015; Socher et al., 2011) that needs another layer for labels, our model introduces pseudo-sentiment centroids, which can be prefixed and selected without fine-tuning.

2 Related Work

In this section, we review related works on sentiment analysis and transfer learning.

2.1 In-Domain Sentiment Analysis

For sentiment analysis of user generated content, traditional works have focused on textual content and dictionaries based approaches (Taboada et al., 2011; Hu and Liu, 2004; Pang and Lee, 2008). Pang et al. (2002) built sentiment classifier to predict sentiment polarities of movie reviews. Hu et al. (2013) exploited contextual emotional signals for effective sentiment analysis in an unsupervised manner. Tumasjan et al. (2010) evaluated and analyzed Twitter messages with the political sentiment to predict the popularity of parties. Bollen et al. (2011) explored how Twitter mood patterns can identify economic events. Other trends of sentiment analysis are based on visual content (Siersdorfer et al., 2010; Borth et al., 2013) and multi-modalities (Socher et al., 2011). All these works consider training and testing data are within the same domain or following similar distributions.

Even though our work only focuses on textual content, we omit explicit word to word analysis but project word features into high-level feature space, where visual content or multi-modalities can also be transformed. In addition, we examine the limitation of domain-dependent sentiment expression and investigate efforts on building a generalized representation for all domains.

2.2 Knowledge Transfer and Leveraging Multiple Domains

Knowledge-based sentiment analysis have been explored in (Mukherjee and Liu, 2012; Liu, 2014; Chen et al., 2013a; Chen et al., 2013b; Chen et al., 2013c). However, they have focused on aspect term extraction as opposed to sentiment polarity extraction which is the focus of this work. Another thread is to transfer sentiment knowledge across domains. It is usually defined as domain adaptation (Daume III and Marcu, 2006; Ben-David et al., 2010; Ben-David et al., 2007). It utilizes the knowledge learned from one domain, referred as the source domain, to solve tasks in another domain, referred as the target domain. Studies have focused on re-weighting features that cross domains (Jiang and Zhai, 2007; Xia et al., 2013), using feature embeddings to convert word feature to vector feature (Yang and Eisenstein, 2015; Bollegala et al., 2015) or generating new feature representations that align domain-specified features onto a generalized feature space which can bridge domain divergence (Blitzer et al., 2006; Cheng and Pan, 2014). Blitzer et al. (2007) proposed Structural Correspondence Learning by selecting pivot feature and creating correlations between the pivot and non-pivot features. Pan et al. (2010) introduced a bipartite graph based approach to connect domain-independent features and domain-specific features. Xiao et al. (2013) proposed supervised word clustering, which assumed that a document was composed of latent (topical) clusters and used expectation-maximization algorithm to find those clusters to transform documents from bag-of-words representation to clusters representation.

Besides transferring knowledge from one domain to another domain, researchers have also explored the area of leveraging multiple domains (Mansour et al., 2009; Duan et al., 2009; Daumé III et al., 2010). In addition, Gong et al. (2012) introduced a kernel metric identifying the optimal adaptability among different domains. Li and Zong (2008) leveraged domains by combining sentiment classifiers of different domains to make the final prediction. Wu and Huang (2015) collaborated multiple domains by exploring textual content relations and sentiment word relations via labeled data. Glorot et al. (2011) utilized unlabeled data through unsupervised deep learning approach with rectifier. Chen et al. (2012) extended linear autoencoder by learning with marginalized corrupted features. Liu et al. (2015) incorporated domain and sentiment supervision for sentiment classification cross domains.

While the above works have made important progress, there are some major differences from this proposed work. First, instead of considering the transfer from "source" to "target", our model leverages multiple domains and at the time is capable of learning from both labeled and unlabeled data across multiple domains. This is closer to the reality because the amount of labels are various among domains and we want the model to leverage all possible knowledge. Second, our model exploits non-linear transformation with the sigmoid function. The sigmoid function shrinks feature value within $(0, 1)$, which enable us to directly maximize the margin of sentiment polarities by supervised instances alignment. Moreover, we fix the order of high-level features and define the meaning of feature values, so classification can be acquired by the learned representation. This is more efficient in terms of performance as it does not require retraining another classifier as other methods do.

3 The Proposed Model

The general idea of the proposed work is to learn a high-level feature space for multi-domain sentiment classification with three constraints. First, the collaboration constraint, which allows the model to collaborate multiple domains with both labeled and unlabeled data. Second, the max-min constraint, that employs high-level feature space to maximize the margin between sentiment polarities of instances across different domains and minimize the distance between domain clusters. Third, the transformation constraint where the high-level feature space and original feature space are transformed to each other through a shared weight matrix, which reduces overfitting.

3.1 Notations

Given a binary sentiment classification problem with positive and negative labels, we have access to P domains. There are total N documents, M of which are labeled. So for each domain j, documents and labels are denoted as $\{\mathbf{X}^j \in \mathbb{R}^{N_j \times D}, \mathbf{y}^j \in \mathbb{R}^{M_j \times 1}\}$, where D is the dimensions of the original feature space. We assume the original feature space is shared across different domains. $\mathbf{x}_i^j \in \mathbb{R}^{1 \times D}$ is the i^{th} document in domain j and represented as a Boolean vector of bag-of-words. If the i^{th} document is labeled, then $y_i^j \in \{+1, -1\}$. The shared weight matrix is denoted as $\mathbf{W}$. The bias vectors for transformation between original space and high-level feature space are denoted as $\mathbf{b}_1, \mathbf{b}_2$, separately.

3.2 The Model with Three Constraints

3.2.1 The Collaboration Constraint

The collaboration constraint enforces the model to collaborate multiple domains with all possible data. We adopt one layer denoising autoencoder (Vincent et al., 2010) to encourage this constraint and treat all data as unlabeled at this point. A denoising autoencoder learns high-level feature space $h(\mathbf{x})$. It corrupts input $\mathbf{x}$ and feeds the corrupted version $\bar{\mathbf{x}}$ into the encoding layer. The decoder undoes the corruption by generating results back to uncorrupted $\mathbf{x}$. The parameters of denoising autoencoder are learned by minimizing the reconstruction loss $\mathcal{L}_r\big(\mathbf{x}, g(\bar{\mathbf{x}})\big)$, where

$$g(\bar{\mathbf{x}}) = s_2(\mathbf{w}_2 h(\bar{\mathbf{x}}) + \mathbf{b}_2) \quad \text{and} \quad h(\bar{\mathbf{x}}) = s_1(\mathbf{w}_1 \bar{\mathbf{x}} + \mathbf{b}_1) \tag{1}$$

We utilize masking noise for the corruption and implement component wise logistic sigmoid as the non-linear function for both $s_1(\mathbf{x})$ and $s_2(\mathbf{x})$. It is important to have the value of each high-level feature of $h(\mathbf{x})$ between $\big(0, 1\big)$, as it paves the way for the following steps and makes the learned representation advisable for different classifiers. Note that the focus of this work is sentiment classification and we only utilize a single layer autoencoder, so the stack version of our implementation and the issue of handling the vanishing gradient are not discussed.

3.2.2 The Max-Min Constraint

The max-min constraint utilizes labeled data and supports the new representation $h(\mathbf{x})$ to maximize the margin of sentiment polarities. Sentiment classification is highly domain-dependent, which implies domain clusters are easier separated than sentiment clusters in the original feature space. While in $h(\mathbf{x})$, instances are aligned to prefixed sentiment pseudo-centroids if they have same sentiment polarities. Since the value of each high-level feature is between $\big(0, 1\big)$, we prefix $[1, \cdots, 1, 0, \cdots, 0]^T$ for positive pseudo-centroid $\mathbf{c}^+$ and $[0, \cdots, 0, 1, \cdots, 1]^T$ for negative pseudo-centroid $\mathbf{c}^-$, so the pseudo-centroids are maximized by cosine distance. This prefix also allows the learned representation to be used as classifier. The dimension of pseudo-centroid $|\mathbf{C}|$ is same as the dimension of learned feature space $|h(\mathbf{x})|$. After the alignment, the true sentiment centroids of labeled data would also be maximized. The alignment is achieved by minimizing the alignment loss $\mathcal{L}_a\big(\mathbf{C}, h(\mathbf{x})\big)$, where

$$\mathbf{C} = \begin{cases} \mathbf{c}^+, \text{if the label of } \mathbf{x} \text{ is positive} \\ \mathbf{c}^-, \text{if the label of } \mathbf{x} \text{ is negative} \end{cases} \tag{2}$$

When maximizing sentiment polarities between instances, the distance between domains is also minimized as positive instances across domains are moving towards $\mathbf{c}^+$ and negative instances are moving towards $\mathbf{c}^-$. This alignment can suppress domain-specific features because domains would be hardly partitioned.

3.2.3 The Transformation Constraint

We share the weight matrix between encoding layer and decoding layer in equation 1, so the equations are updated to:

$$g(\bar{\mathbf{x}}) = sigmoid(\mathbf{W}^T h(\bar{\mathbf{x}}) + \mathbf{b}_2) \quad \text{and} \quad h(\bar{\mathbf{x}}) = sigmoid(\mathbf{W}\bar{\mathbf{x}} + \mathbf{b}_1) \tag{3}$$

By sharing the weight matrix, the transformation would be more robust and provide a better feature representation as it reduces overfitting. The shared weights can also be interpreted as a trade-off between suppressing and preserving domain-specific features. We cannot fully eliminate those features, as domain-specific features give the ability to reconstruct to the original feature space.

3.3 Loss Function and Optimization

We use sum of Bernoulli Cross Entropy for reconstruction loss $\mathcal{L}_r\big(\mathbf{x}, g(\bar{\mathbf{x}})\big)$ and alignment loss $\mathcal{L}_a\big(\mathbf{C}, h(\mathbf{x})\big)$. Combined with equation 2 and 3, the final loss function $\mathcal{L}$ is

$$\begin{aligned}\mathcal{L} =& \mathcal{L}_r\big(\mathbf{x}, g(\bar{\mathbf{x}})\big) + \alpha\mathcal{L}_s\big(\mathbf{C}, h(\mathbf{x})\big) \\ =& -\frac{1}{N}\sum_{i}^{N}\sum_{k}^{|\mathbf{x}|}\mathbf{x}_{i,k}\log g(\bar{\mathbf{x}}_i)_k + \big(1-\mathbf{x}_{i,k}\big)\log\big(1-g(\bar{\mathbf{x}}_i)_k\big) \\ & -\alpha\frac{1}{M}\sum_{j}^{M}\sum_{l}^{|\mathbf{C}|}\mathbf{C}_l\log h(\mathbf{x}_j)_l + \big(1-\mathbf{C}_l\big)\log\big(1-h(\mathbf{x}_j)_l\big)\end{aligned} \tag{4}$$

We use $\alpha = 1$ in the model[1]. The equation 4 is non-convex but can be optimized with gradient descend. The partial derivatives of $\mathcal{L}$ with respect to $\mathbf{b}_1, \mathbf{b}_2$ and $\mathbf{W}$ is

$$\frac{\partial\mathcal{L}}{\partial\mathbf{W}} = \frac{1}{N}\sum_{i}^{N}(h(\bar{\mathbf{x}}_i) + h(\bar{\mathbf{x}}_i)(1-h(\bar{\mathbf{x}}_i))^T\mathbf{W}\bar{\mathbf{x}}_i\big) \times \big(g(\bar{\mathbf{x}}_i) - \mathbf{x}_i\big)^T + \frac{\alpha}{M}\sum_{j}^{M}(h(\mathbf{x}_j) - \mathbf{C})\mathbf{x}_j^T \tag{5}$$

$$\frac{\partial\mathcal{L}}{\partial\mathbf{b}_1} = \frac{1}{N}\sum_{i}^{N}h(\bar{\mathbf{x}}_i)(1-h(\bar{\mathbf{x}}_i))^T\mathbf{W}\big(g(\bar{\mathbf{x}}_i) - \mathbf{x}_i\big) + \frac{\alpha}{M}\sum_{j}^{M}(h(\mathbf{x}_j) - \mathbf{C}) \tag{6}$$

$$\frac{\partial\mathcal{L}}{\partial\mathbf{b}_2} = \frac{1}{N}\sum_{i}^{N}\big(g(\bar{\mathbf{x}}_i) - \mathbf{x}_i\big) \tag{7}$$

The output of our model is the learned feature representation $h(\mathbf{x})$. This representation can be used as features for another classifier or can be used as a classifier by itself.

3.4 Using the Representation as Classifier

To use $h(\mathbf{x})$ as a classifier, we calculate the distance from data points to the prefixed pseudo-centroids $\mathbf{C}$. Data points closer to $\mathbf{c}^+$ should have first half of $h(\mathbf{x})$ closer to 1 and the second half closer to 0, while data points closer to $\mathbf{c}^-$ should have first half of $h(\mathbf{x})$ closer to 0 and second half closer to 1. Therefore, the predicted label of a data point is:

$$sgn\big(\sum_{i=0}^{|\mathbf{C}|/2-1}h(\mathbf{x})_i - \sum_{j=0}^{|\mathbf{C}|/2-1}h(\mathbf{x})_{j+\frac{|\mathbf{C}|}{2}}\big) \tag{8}$$

The classifier can also be interpreted as using the decision of multiple logistic regression models. For the first half of $h(\mathbf{x})$, we define values greater than 0.5 represent positive and smaller than 0.5 represent negative, while for the second half, we define values greater than 0.5 represent negative and smaller than 0.5 represent positive.

4 Experimental Evaluations

We first report results of multi-domain sentiment classification, comparing different methods with in-domain classifier and multi-domain classifier. Then, we extend our model to domain adaptation problem with multiple source domains and one target domain. Finally, we evaluate the model with different metrics for a better understanding. All SVM classifiers are implemented through linear LibSVM (Chang and Lin, 2011) without tuning other parameters.

[1]We have tested the impact of different values of α from 0.2 to 10 and found the value of α does not significantly affect the performance of our model. A larger α generally gives a slightly better result.

4.1 Dataset

We use the Amazon product reviews (Blitzer et al., 2007) as our experimental dataset. The dataset has been widely used in multi-domain sentiment classification and domain adaptation for sentiment classification. There are 22 domains and more than 300,000 reviews in this dataset. We conduct experiments on reviews of 4 domains: **B**ooks, **D**vd, **E**lectronics and **K**itchen. Each of selected domain has 1000 positive and 1000 negative labeled reviews and roughly 5000 unlabeled reviews. The top 5000 of frequent 1-gram and 2-gram features are selected, as low frequent features are usually related to domains. The experiments are conducted based on 5-folder cross-validation by randomly splitting the labeled data into 5 partitions with equal size and we report the average result[2].

4.2 Performance Evaluation

We report results of multi-domain sentiment classification. The compared methods are listed below:

SVM-ID, SVM-MD: SVM classifier used for in-domain(ID) sentiment classification, and multi-domain(MD) sentiment classification with document-level combination.

ClassifierFusion (Li and Zong, 2008): Multi-domain sentiment classification with classifier-level combination. For each domain, a classifier is trained and used for all domains. The final prediction is the combination of the predictions of each individual classifier.

T-SVM (Sindhwani and Keerthi, 2006): Transductive SVM with document-level combination. All unlabeled data are used during learning. This method explicitly shows the performance of introducing unlabeled data to an SVM classifier, so it can be interpreted as SVM-MD with both labeled and unlabeled data.

SDA (Glorot et al., 2011): Unsupervised denoising autoencoder for representation learning. The feature space for the final SVM classifier is the concatenation of the original feature space and the learned representation feature space.

SDA-DSS (Liu et al., 2015): Representation learning with domain and sentiment supervision. The original implementation only incorporated sentiment labels of one domain, so we extend the model to incorporate labeled data of 4 domains. Same as SDA, the feature space for the SVM classifier is the concatenation of the original feature space and the learned representation feature space.

Proposed-R: Using representation learned from the proposed model. The feature space of the final SVM classifier is only the learned representation feature space. The hyper-parameter are explored as follow and selected by cross-validation: a masking noise probability in $\{0,0.5,0.6,0.7,0.8\}$ for corrupted $\bar{\mathbf{x}}$; dimension of learned feature space $h(\mathbf{x})$ in $\{100,250,500\}$; L_2 regularization penalty on shared weight matrix $\mathbf{W}$ in $\{0, 10^{-4}, 10^{-3}, 10^{-1}, 1\}$; learning rate for gradient descent in $\{0.01, 0.03, 0.1, 0.3\}$. The implementation is through Theano (Bastien et al., 2012).

Proposed-C: The learned representation is used as classifier with Equation 8. Because we only focus on the learned representation without tuning the parameter of SVM, the result of Proposed-C is only presented for a reference, not to demonstrate it is better than other classifiers.

All models, except SVM-ID, utilize the training set of 4 domains together and then make prediction on the test data of each domain. All models, except SVM-ID, SVM-MD, and ClassifierFusion, are implemented through transductive inference to better leverage the unlabeled data. However, it could be easily extended to inductive inference as all models return the feature transformation matrix.

Table 1: Performance on Accuracy and F1 for Multi-Domain Sentiment Classification Tasks

[2]Micro average F1 on positive class is reported in this paper

According to Table 1, we find that our method consistently outperforms all other competitors showing that leveraging multiple domains can provide better results for sentiment classification if dissimilarities between domains are taken care of. It also shows that arbitrarily combining data together with bag-of-word representation cannot guarantee better results compared to in-domain sentiment classification. Compared to ClassifierFusion, the results validate that unlabeled instances and transductive inference can improve sentiment classification. Compared to T-SVM, it can be concluded that learning a new representation would benefit a generalized sentiment classifier across domains. Compared to SDA and SDA-DSS, the improvements can be explained as credit of transforming with sigmoid function, maximizing margin of sentiment polarities in learned feature space and suppressing domain-specific features during representation learning.

4.3 Unsupervised Knowledge Transfer

When incorporating multi-domains with both labeled and unlabeled data, a possible scenario is certain domains have very limited or even zero labels. In the literature of domain adaptation, unsupervised knowledge transfer or unsupervised domain adaptation usually refers to the situation where certain domains have no labeled instance at all, so the unlabeled domain, usually denoted as target domain, has to borrow labels from other domains denoted as source domain (Daume III and Marcu, 2006). In this experiment, we check the ability of our model for unsupervised domain adaptation. We consider 3 source domains and 1 target domain, and remove labels of each target domain separately. Table 2 presents the results of training on 3 domains and testing on the other. More specifically, SVM-ID remains the same as in Table 1 and the result is interpreted as an upper-bound for unsupervised knowledge transfer, while all other models are adjusted to access the training set of 3 source domains and test on the test set of the target domain.

Ave.	80.68	80.89	78.36	78.65	79.50	79.34	79.79	79.71	80.54	80.26	80.49	80.53	**80.71**	**80.82**	84.17	84.16

Table 2: Performance on Accuracy and F1 for Unsupervised Domain Adaptation with Multiple Sources

Comparing with transfer from one source to one target (Glorot et al., 2011; Liu et al., 2015), we observer from Table 2 that arbitrarily combining data together decreases the best transfer performances of SDA and SDA-DSS, which suggests domain-specific features are hurting unsupervised transfer. Moreover, our model yields limited improvements this time. One reason could be SDA and SDA-DSS separate domain-dependent and domain-independent features and keep all features in the learned representation, while our model suppresses domain-dependent feature. However, in general, "domain-dependent" is a relative definition. A word "story" could be a domain-independent feature for Books and DVD but also could be a domain-dependent feature for Books and Kitchen. Therefore, suppressing domain-dependent features for multiple domains which works better in the previous task could be the reason that limits our model on this unsupervised domain adaptation task.

4.4 Performance on Additional Metrics

We assess our model with additional metrics for multi-domain sentiment classification: sensitivity of labeled instances, proxy-A-distance, performance on different classifiers and suppressed features.

Sensitivity of Labeled Instances In this experiment, we explore how the proportion of labels affects the model as the model collaborates both labeled and unlabeled data from multiple domains. We limit the accessible labels in $\{0, 100, 300, 500, 1000, 1500\}$ for each domain to learn the representation and repeat the experiment of multi-domain sentiment classification with Proposed-R. With 0 labels, the model would be similar to a fully unsupervised SDA (Glorot et al., 2011) implementation, except with sigmoid activation and a lower feature dimension. According to Figure 1, limiting labels decreases the

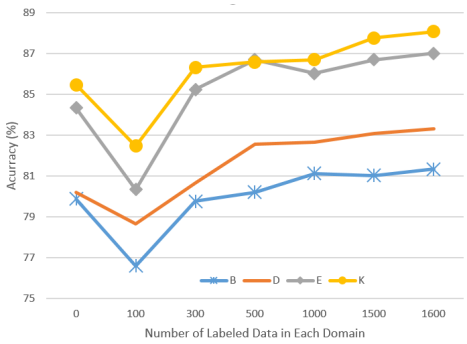

Figure 1: Sensitivity of Labeled Instances

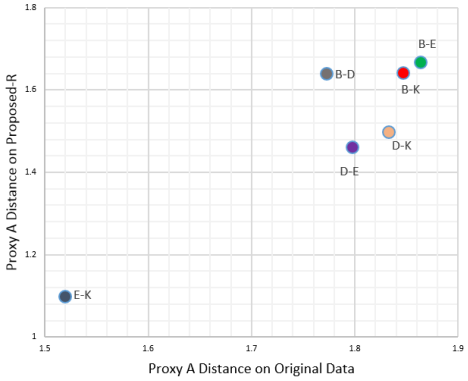

Figure 2: Proxy-A-Distance

performance, but this issue is generally solved as the proportion of labels is further increased and we see that at about 1000 labels performance starts to stabilize.

Proxy-A-Distance (PAD) We use PAD as an indirect metric to measure the ability to minimize dissimilarities between domains. The intuition is that removing domain-dependent features would weaken the discrimination among domains. The PAD metric (Ben-David et al., 2007) is defined as $2(1 - 2\epsilon)$, where ϵ is the generalization error and obtained by measuring how distinguishable are the two domains. In other words, we use the learned representation to accomplish domain recognition task. We randomly choose 1000 instances for training and 1000 for testing from each domain. Then we set up the recognition task as a binary classification problem with 6 combinations, for example, recognition between B and D. After applied our model, the PAD value of every recognition pair has decreased, which indicates the new feature representation learned from our model suppresses domain-dependent features.

According to Figure 2, recognizing Kitchen and Electronics are more difficult than Books and DVD. One reason is the reviews in Kitchen and Electronics are expressed using more domain-independent words. This observation also explains the sentiment classification results in Table 1 that classifying sentiment in Kitchen and Electronics generally have a better performance across different methods.

Performance of Different Classifiers We argue that a good representation should be able to benefit classification task without explicitly choosing or fine-tuning classifiers. Therefore, We repeat the experiment of multi-domain sentiment classification by comparing our Proposed-R(P-R) and SDA with another three state-of-art classifiers: K-Neighbors Classifier(KNC), Gaussian Naive Bayes(GNB) and RandomForest Classifier(RFC). According to Table 3, our model can still yield good results.

	KNC(%)		GNB(%)		RFC(%)	
	P-R	SDA	P-R	SDA	P-R	SDA
B	83.96	64.17	84.30	74.68	82.35	68.01
D	85.03	63.58	85.22	75.28	83.69	68.32
E	87.50	70.04	88.33	80.89	86.39	71.78
K	89.12	67.86	89.54	81.19	87.87	76.37

Table 3: Accuracy of Different Classifiers

Reconstructed	Original	Suppressed
not, poor, great, dont, was, after, bad, no, excellent, well, easy, best	was, my, so, num, you, all, one, if, very, great, good, just, not	since, way, all about, other, your time, them, when now, so, this_book

Table 4: Top Frequent Reconstruct Features, Original Features and Suppressed Features

Suppressed Features Our model has reconstructed 3785 features on average, compared to the original 5000, that means 1215 features are suppressed during the learning. We report some of the top frequent features in 3 ways: reconstructed by our model, in original space and suppressed by our model. From Table 4, the reconstructed feature are carrying more sentiment meaning than the original features, and the suppressed features involve domain-specific feature, such as "this_book", and non-sentiment features, such as "all", "so" and "your". This is what we expect by maximizing distance between sentiments in the learned representation feature space and sharing the transformation matrix between decoding and encoding layer.

5 Conclusion

This work proposed to leverage multiple domains with both labeled and unlabeled instances. The model learns high-level feature space with 3 constraints and achieves improved performance on multi-domain sentiment classification as attested by results on the benchmark dataset.

As our future work, we plan to explore multi-modality (e.g., mapping visual, video and sentiment content on the same space from multiple domains), and develop a recursive system where labeling work can be performed recursively with high confidence.

Abstract

This paper presents classification results for the analysis of sentiment in political news articles. The domain of political news is particularly challenging, as journalists are presumably objective, whilst at the same time opinions can be subtly expressed. To deal with this challenge, in this work we conduct a two-step classification model, distinguishing first subjective and second positive and negative sentiment texts. More specifically, we propose a shallow machine learning approach where only minimal features are needed to train the classifier, including sentiment-bearing Co-Occurring Terms (COTs) and negation words. This approach yields close to state-of-the-art results. Contrary to results in other domains, the use of negations as features does not have a positive impact in the evaluation results. This method is particularly suited for languages that suffer from a lack of resources, such as sentiment lexicons or parsers, and for those systems that need to function in real-time.

1 Introduction

In the rapidly changing World Wide Web, getting informed opinions about facts is becoming increasingly challenging for users. In online news, the same event can be presented from very different perspectives depending on the source. Journalism is supposed to be objective, yet opinions are also expressed in newswire text (Belyaeva and van Der Goot, 2008; Blaz et al., 2009). In this type of texts, opinions are generally expressed in a subtle way, by using language resources other than sentiment vocabulary, such as irony, sarcasm, metaphors, etc., as it is illustrated in the following example, where the use of an ironic comparison *som rundingsbøyer* 'as if they were human buoys' suggests a negative opinion:

> - Den nye forskriften betyr at i vannene der friluftsfolket fortsatt kunne få være i fred, i en liten bortgjemt vik, der er det nå åpent for skuterfolket å bruke turfolket som rundingsbøyer, sier Bjørn Hansen, på vegne av Naturvernforbundet i Finnmark. *(- Given by the new regulation, places near the waters where people still could have piece and quiet, such as small secluded coves, are now open for people on jet skis to make use of the former as if they were human buoys, says Bjrn Hansen, on behalf of the Nature Conservatory of Finnmark.)*[1]

In this context it is difficult for readers to have informed opinions about the events happening in the world. Thus there is a growing need for resources that can help readers filter out news information, so that they can have an informed opinion about the current events. These resources would be particularly useful in the domain of political news, where readers want to be informed about political parties, politicians, and policies. If successfully employing sentiment analysis in the political news domain, possible biases and opinions will be revealed, and readers will get a more complete and transparent news scenario to gain knowledge from, leading to more informed political opinions.

However, the unstructured nature of news articles together with the subtle ways of expressing opinions in these texts make this task particularly challenging for machines. To deal with these challenges, in this paper we propose an unsupervised machine learning approach that takes sentiment-bearing Co-Occurring

[1] https://www.nrk.no/finnmark/_-de-blir-a-bruke-turfolk-som-rundingsboyer-1.12519921

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2989–2996, Osaka, Japan, December 11-17 2016.

Terms (COTs) and negation words as features. We argue that this approach is suited for languages other than English where computational linguistics resources for sentiment analysis are scarce, and also for those systems that perform in real-time.

The contents of this paper are as follows. After introducing the state of the art in 2, in 3 we present the method used to deal with sentiment analysis in political news. Lastly, the results are evaluated in 4 and the paper closes with a discussion and conclusion in 5 and 6.

2 Related work

In sentiment analysis, classifiers have been trained to automatically detect the polarity and subjectivity of texts. The former takes into account that not all incoming text is opinionated, and that a system might have to distinguish between subjective and objective texts.

For example, (Yu and Hatzivassiloglou, 2003) focus on separating subjective texts from those that portray factual information. The latter assumes text to be opinionated, and thus classifies the text as falling in one out of two sentiment categories − in general, positive or negative (Pang and Lee, 2008). (Turney, 2002; Pang et al., 2002; Hu and Liu, 2004; Kim and Hovy, 2004, among others) focus on distinguishing an author's positive or negative opinion towards a certain topic or object. To perform these tasks, both supervised and unsupervised approaches have been used (Feldman, 2013).

A combination of these two classification tasks can be seen in (Wilson et al., 2005). Here, a two-step binary classification takes place, which firstly filters out neutral expressions, and secondly, classifies the polarity of the selected set of expressions. As (Mihalcea et al., 2007) suggest, improvements in the more challenging task of subjectivity detection might have a positive impact on polarity classification. By firstly increasing precision and recall in subjectivity detection, the performance of the second task in a live system will also be improved. In this paper we present work in this line, in that we perform a two-step classification task, where first subjective and second positive and negative texts are detected within those classified as subjective.

In both tasks, negation is often considered one of the most important training features. (Wilson et al., 2005) argue that a phrase's sentiment will be better understood if the contextual and prior polarity of the phrase is taken into account. In contrast, other research, such as (Kim and Hovy, 2004; Hu and Liu, 2004; Grefenstette et al., 2004), focuses on local negation - negation terms occurring within sentiment words. Negation is a very complex linguistic issue, with different semantic effects in the sentence depending on the scope of the negative term, see (Lasnik, 1972; Partee, 1992; Ladusaw, 1992, among many others). In order to determine the scope of the negative phrase, most computational approaches make use of a syntactic parser. However, for languages suffering from a lack of such resources, such as Norwegian, this strategy would be too expensive. Due to the lack of resources for the Norwegian languages, in the present paper we present a very simple method where only the presence of negative terms, such as English *not*, are considered.

Initial efforts for sentiment analysis in the newswire domain have been conducted by (Belyaeva and van Der Goot, 2008) and (Blaz et al., 2009). Similar work to that of ours has been completed for Turkish in the political news domain by (Kaya et al., 2012). In this work four supervised machine learning algorithms are evaluated, namely Naïve Bayes, Maximum Entropy, SVM and N-Gram character based Language Model, in which features are unigrams or single words pertaining to relevant morphosyntactic classes. Their approach yields a maximum accuracy of 76.78%. Our approach is different from the latter in that we focus on different machine learning algorithms, such as J48, known to be computationally faster. Besides, we employ a two-step binary classifier and analyze all paragraphs in a collection of newswire text, whereas they look at the overall sentiment of selected newspapers columns.

3 Method

Figure 1 shows a high-level overview of the two-step sentiment analysis approach presented in this paper. Firstly, the input dataset consists of paragraphs annotated with three different classes: positive, negative,

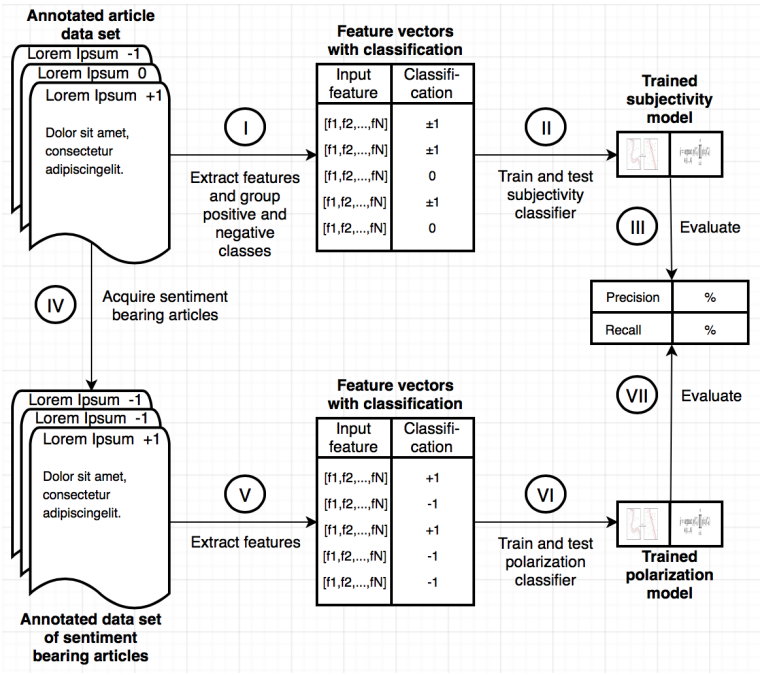

Figure 1: High-level system overview with two-step binary classification during testing and training.

or neutral. Features are then extracted from this dataset and used for training the subjectivity model. The precision of the resulting model is then evaluated using 10-fold crossvalidation. In the second phase, only the sentiment-bearing paragraphs from the dataset are used, and then the same procedure is followed for training and evaluation. We will now explain in further detail the different parts of our system.

3.1 Data and annotation

A total number of 3961 paragraphs within the political category was selected from the Norwegian online news sources *NRK*[2] and *VG*[3]. This dataset includes news articles over a span of four months during the summer of 2015, right before the municipal elections in October that year. Paragraphs were chosen instead of documents, sentences or phrases, because we noticed that in political news articles the presence of a sentiment target is more likely to be found at the paragraph level.

This dataset was annotated by the first two authors of this paper, obtaining an agreement of $\sim$76% (κ = 0.62), which is well within the range of other studies of sentiment analysis in similar domains (Njølstad et al., In press). The 3016 remaining paragraphs were used for training and testing using 10-fold crossvalidation. The paragraphs are labeled with one of the following three categories: positive, negative and neutral. The subjective class consists of both positive and negative paragraphs.

The criteria used for the authors to annotate the paragraphs were adapted from (Balahur and Steinberger, 2009), and are summarized in the following points: (i) world knowledge can be used if it is not clearly biased towards an entity; (ii) factual information should not be annotated as subjective; (iii) if polarity shifting occurs, the text should be annotated according to the one bearing the strongest sentiment and the most important entity; (iv) in case of uncertainty, the text should be annotated as objective.

3.2 Features

As summarized in Table 1, the features used to train the classifier are positive, negative and neutral Co-Occurring Terms (COTs), and negation words.

COTs are words with importance to each other that co-occur in a sentence (Pang and Lee, 2008; Matsuo and Ishizuka, 2004). In languages with a lack of computational resources to perform domain-

[2] https://www.nrk.no/
[3] http://www.vg.no/

Features	Description	Type
PositiveCots	Number positive COTs in a paragraph	Discrete
NeutralCots	Number of neutral COTs in a paragraph	Discrete
NegativeCots	Number of negative COTs in a paragraph	Discrete
Negations	Number of negation words in a paragraph	Discrete

Table 1: Input features for machine learning classifier.

specific sentiment analysis, the use of COTs as a sentiment lexicon has been shown to work effectively. Such domain-specific lexicon of sentiment-bearing COTs can be acquired with a reasonable amount of manual labour (Njølstad et al., In press).

The COTs used in the present work are two-word co-occurring terms, with a maximum of four words between, and belonging to one of the following morphosyntactic categories: adjectives, nouns, verbs and adverbs. The *term frequency - inverse document frequency* ranking function was used to limit the lexicon size to 4000 COTs. This ranking is important as we only want to include COTs that are relevant to our domain of investigation. The Oslo-Bergen-Tagger[4] for the Norwegian language was used to tokenize and part-of-speech tag paragraphs. Table 2 shows an excerpt from the lexicon obtained. Details on how this lexicon was acquired are outside the scope of this paper, but are described in detail in (Njølstad et al., In press).

Term 1	Term 2	Translation	Sentiment
ta	*ordet*	'take the word'	0
er	*allerede*	'is already'	0
stor	*glede*	'big happiness'	1
er	*misfornyd*	'is unsatisfied'	-1
skape	*arbeidsplasser*	'achieve job positions'	1
kan	*svekke*	'can weaken'	-1
skal	*i stedet*	'will instead'	0

Table 2: Excerpt from sentiment lexicon.

The second set of features used in this paper are negations. Negations are words that change the polarity of words, phrases or sentences and have been shown to work effectively to detect sentiment (Wilson et al., 2005). Table 3 shows the Norwegian negative words considered as features in this paper. As the dataset includes paragraphs written in both *bokmål* and *nynorsk* Norwegian, negation words from both varieties are included in this table.

Norwegian *bokmål*	Norwegian *nynorsk*	English
ikke	*ikkje*	'not'
ei	*ei*	'not'
nei	*nei*	'no'
aldri	*aldri*	'never'
neppe	*neppe*	'hardly'
ingen, inga, intet	*ingen, inga, inkje*	'none, any'

Table 3: Negation words in the Norwegian language.

We hypothesize that there will be more negations in negative sentiment-bearing paragraphs, which can positively contribute to classify a paragraph's sentiment. In order to observe this before obtaining the features, we analyzed the average number of negation words in each paragraph. As can be seen in

[4]http://www.tekstlab.uio.no/obt-ny/

Table 4, on average each paragraph annotated as negative has 0.53 negations, compared to only 0.23 per neutral paragraph. Besides, the subjective (positive+negative) class has 0.43 negations per paragraph, whereas the neutral class has only 0.23. These numbers suggest that negations can also be relevant to detect subjective paragraphs.

Annotated class	**Paragraphs**	**Negations per paragraph**
Positive	698	0.29
Neutral	1426	0.23
Negative	892	0.53
Positive+Negative	1590	0.43
All	3016	0.33

Table 4: Average number of negations per paragraphs.

4 Evaluation

The main goal of this paper was to experiment with simple feature combinations in a two-step binary classification process, in order to achieve state-of-the-art results within the domain of Norwegian political news. Tables 5 and 6 summarize the evaluation of this work. Three different classifiers were used: J48, Random Forest (RF), and Naïve Bayes (NB). These classifiers were selected because of their computational speed, as opposed to the more computational heavy algorithms such as SVM (Zhao and Zhang, 2008). In addition, current research has shown that J48 and RF yield higher precision results in the financial news domain (Njølstad et al., In press). All three classifiers in our system are set up using the WEKA framework.[5]

Table 5 presents the results of subjectivity classification. Highlighted in bold is the precision of the feature combination with the best result – 67.1%. This feature combination includes all three types of COTs. However, it does not include negations at all. We hypothesized that the difference in negations per paragraph between the neutral class and the subjective class could have a positive impact on the precision results for this step. Looking at these results, where there is a higher precision without the use of negations for both NB and J48, our hypothesis does not hold after all. RF is the only machine learning model which benefits from negations, though this model yielded unsatisfying results in general.

	PosCots	NeutCots	NegCots	Negations	Precision
NB	✓	✓	✓		**67.1**
	✓	✓	✓	✓	66.6
				✓	59.9
RF	✓	✓	✓		62.5
	✓	✓	✓	✓	63.8
				✓	59.8
J48	✓	✓	✓		67.2
	✓	✓	✓	✓	67.0
				✓	61.8

Table 5: Subjectivity classification precision results with various feature combinations.

As can be seen from Table 6, there are more feature combinations in the polarity classification step. The goal of this step is to differentiate between positive and negative paragraphs, and thus we could experiment with combinations that did not include neutral COTs. As can be seen from the highlighted precision score, this is in fact what yields the best result of 73.2%, which is in line with the current

[5] http://www.cs.waikato.ac.nz/~ml/index.html

state-of-the-art. Before objective paragraphs were removed, the system only yields 59.7% precision, which shows that a significant improvement is obtained by using a two-step classification system. It is interesting to observe that negations do not have a positive impact on these results either. Throwing out COTs yields very low precision scores in all cases.

	PosCots	NeutCots	NegCots	Negations	Precision
NB	✓	✓	✓		72.8
	✓	✓	✓	✓	69.5
	✓		✓		**73.2**
	✓		✓	✓	71.4
				✓	57.4
RF	✓	✓	✓		64.2
	✓	✓	✓	✓	63.5
	✓		✓		66.1
	✓		✓	✓	64.2
				✓	55.6
J48	✓	✓	✓		72.2
	✓	✓	✓	✓	71.1
	✓		✓		72.3
	✓		✓	✓	71.6
				✓	—

Table 6: Polarity classification precision results with various feature combinations.

For both steps, NB is the machine learning algorithm that performs best. However, J48 outperforms the other two when including negations. It is important to note that there is no score for J48 with only negations included. This is because this model was not able to build a decision tree based on this feature. Lastly, RF is the worst performer in all cases.

5 Discussion

The results in tables 5 and 6 only include the overall precision scores obtained during testing. However, in each classification step there are separate precision and recall scores for each class involved in the classification. These results can shed some light on which parts of the system perform better than others. Tables 7 and 8 summarize those results.

Class	**Precision**	**Recall**
Neutral	57.1%	**85%**
Subjective	**76%**	42.7%
Overall	67.1%	61.1%

Table 7: Precision and recall for subjectivity classification.

As can be seen in Table 7, the subjective class achieves a precision of 76%, which means that in a live system where the input of polarity classification are only subjective texts, 76% of these will be correctly classified. On the other hand, there will be many false negative cases, as can be seen from the low recall value. In contrast, the recall yields 85% in the objective class, while the precision is lower, 57.1%. This means that our engine does not have enough information to decide when a paragraph bears a sentiment. Instead, the features represented in this classification step are not suitable in order to detect sentiment, and thus it misclassifies too many subjective paragraphs as objective. As discussed in 3.2, the difference in the average of negations per paragraph seemed to indicate that this feature was suitable for subjectivity

classification. However, this is not the case. We believe that the complexity of the scope negation can be the reason for this. In order to include negations and observe a positive impact in the classifier, the syntactic structure of the sentence should probably be considered. This could, in turn, make the system considerably lower and make this solution unpractical from a real-system point of view.

Similar results are presented in Table 8. The positive class shows poor results in terms of recall, though in terms of precision ranks higher than the overall, achieving satisfactory results. For the negative class, precision is good enough, 70% whereas recall yields a much higher value of 88.2%.

Class	Precision	Recall
Positive	**77.4%**	51.6%
Negative	70%	**88.2%**
Overall	73.2%	72.1%

Table 8: Precision and recall for polarity classification.

6 Conclusion and future work

In this paper we have presented a two-step classification system to detect sentiment in the political news domain for an under-resourced language such as Norwegian. COTs and simple negation counts were included as features in this system. By performing a 10-fold crossvalidation, we obtain close to state-of-art results in this task, over 70%, which is an optimistic value given the inherent complexity of this domain. Interestingly, negation words do not contribute to either classification task. We believe that this is because of the semantics of the scope of negation, that goes beyond singular words. We intend to investigate further on how to deal with negation in real-time systems in future work. All experiments have been conducted in the Norwegian political newswire domain at the paragraph level. In future work, we want to continue the work in this domain. More specifically, we plan to experiment with sentiment targets, such as events or named entities, within text units to detect the sentiment around them.

Abstract

Probabilistic models are a useful means for analyzing large text corpora. Integrating such models with human interaction enables many new use cases. However, adding human interaction to probabilistic models requires inference algorithms which are both fast and accurate. We explore the use of Iterated Conditional Modes as a fast alternative to Gibbs sampling or variational EM. We demonstrate superior performance both in run time and model quality on three different models of text including a DP Mixture of Multinomials for web search result clustering, the Interactive Topic Model, and MOMRESP, a multinomial crowdsourcing model.

1 Introduction

One of the most popular and useful approaches for analysis of large bodies of text documents is probabilistic models. For example, topic models such as Latent Dirichlet Allocation (LDA) can automatically learn topics from a set of documents, giving users a glimpse into the common themes of the data (Blei et al., 2003). Other models such as the Mixture of Multinomials can be used to perform document clustering allowing users to automatically organize text data (Meila and Heckerman, 2001; Walker and Ringger, 2008).

We are interested in use cases for probabilistic models of text which include human interaction. For example, the Interactive Topic Model (ITM) is a topic model that extends LDA to allow the user to inject model constraints in the form of word groupings while the topics are being learned (Hu et al., 2011). By including the user in the training process rather than simply learning the topics offline, the user can fine-tune the resulting topic model to better suit individual user needs and to accommodate a user's domain knowledge. However, if the training algorithm is too slow, the delay between receiving user feedback and presenting the updated model will harm the interaction due to increased cognitive load. Consequently, we require an inference algorithm which is both fast enough to facilitate interaction, and maintains (or improves upon) the accuracy of existing inference techniques.

For models like LDA, we typically perform training by calculating *maximum a posteriori* estimates of the latent topic variables and parameters given observed document data, with the idea that the setting of topic variables and parameters which maximizes the posterior distribution will best explain the observed data. Although various exact methods exist, such as belief propagation (Pearl, 1988) and the junction tree algorithm (Koller and Friedman, 2009), the complexity of exact posterior inference on such models is NP-HARD in general, so we resort to various approximations in order to optimize the posterior distribution (Sontag and Roy, 2009; Cooper, 1990). Some popular algorithms for approximate posterior inference include Gibbs sampling and mean field variational inference.

Each of these approximate inference algorithms has some drawbacks. For example, while variational inference is often very fast, it makes simplifying assumptions about the posterior distribution which can seriously degrade the quality of solutions for certain models, such as Mixture of Multinomials (Walker, 2012). However, for other models such as LDA we can achieve good estimates very quickly (Asuncion et al., 2009). Gibbs sampling provably generates samples from the posterior distribution and unlike

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 2997–3006, Osaka, Japan, December 11-17 2016.

variational inference, it is theoretically able to explore the entire support of the posterior manifold. Unfortunately, any reasonable restriction on the run time of the sampler means that we will only be able to explore a localized area of the support. Consequently, for most uses of probabilistic models of text, practitioners run a sampler for a period of time in the hope of finding an area of high probability, and then use the final sample as an approximation for the mode. While for some models, such as Mixture of Multinomials, this technique gives very good results (Walker and Ringger, 2008; Rigouste et al., 2007; Zhong and Ghosh, 2005), the lack of a convergence criteria can make the technique too slow for applications which require user interaction. For example, (2004) found that LDA requires hundreds of iterations of sampling before the log-likelihood of the model stabilizes in distribution. In practice, many of the probabilistic models of text we are interested in require similar numbers of sampling iterations.

As an alternative to techniques which introduce strong assumptions for posterior inference (e.g., variational inference) or lack clear and timely convergence criteria (e.g., Gibbs sampling), we will examine the use of Iterated Conditional Modes or ICM (Besag, 1986; Wellner et al., 2004), This algorithm is able to quickly achieve locally optimal *maximum a posteriori* estimates.

In section 2, we will briefly describe the ICM algorithm and compare it with other existing techniques. Then in section 3 we will empirically examine the performance of ICM in the context of three very different probabilistic models of text which can be used interactively. We first show that ICM performs well in the context of a non-parametric model by experimenting with a Dirichlet Process Mixture of Multinomials applied to the problem of web search result clustering. We then turn our attention to the Interactive Topic Model (Hu et al., 2011) to show that ICM improves performance over the previously published Gibbs sampler. Finally, we use ICM in the context of MOMRESP, a probabilistic model designed to infer true document class labels from noisy crowdsourced judgments (Felt et al., 2014).

2 Iterated Conditional Modes

Suppose we are given a probabilistic model of text with observed data x and unobserved variables θ. For the purpose of this discussion, θ may represent any number of unobserved parameters and latent variables. These parameters and variables can be either continuous or discrete. Like Gibbs sampling, Iterated Conditional Modes (ICM) relies on the fact that while computing a posterior distribution of the form $p(\theta|x)$ may be intractable, computing the complete conditional for a single variable θ_i while holding fixed both x and the rest of the parameters $\theta_{\neg i}$ is feasible in models with local conjugacy. By using the tractable complete conditional distribution $p(\theta_i|\theta_{\neg i}, x)$ we are able to locally maximize the posterior without the need to approximate the posterior with samples.

The general procedure for ICM is very similar to Gibbs sampling. We cycle through each unobserved variable θ_i in the model and update current value of the variable to be the mode of its complete condition distribution. The ICM update is repeated until convergence when the value of each θ_i is already the mode of its complete conditional distribution.

To see that Iterated Conditional Modes will find a local maxima of the posterior distribution, we will demonstrate that the ICM updates monotonically increase the current estimate of the posterior probability $p(\theta|x)$. Since the data x is fixed, the posterior is proportional to the joint distribution over all of the variables and data:

$$p(\theta|x) = \frac{p(\theta, x)}{p(x)} \propto p(\theta, x) \tag{1}$$

Using the chain rule, for some i we can then factor the joint distribution as:

$$p(\theta, x) = p(\theta_i|\theta_{\neg i}, x) \cdot p(\theta_{\neg i}|x) \cdot p(x) \tag{2}$$

Since x is fixed, we can also write

$$p(\theta, x) \propto p(\theta_i|\theta_{\neg i}, x) \cdot p(\theta_{\neg i}|x) \tag{3}$$

While updating the parameter θ_i, $\theta_{\neg i}$ is held fixed, which means that the second term $p(\theta_{\neg i}|x)$ is constant and the factored joint distribution is proportional to the complete conditional, thus:

$$p(\theta|x) \propto p(\theta_i|\theta_{\neg i}, x) \tag{4}$$

Since these two expressions are proportional, setting θ_i to the mode of its complete conditional will only increase the value of the posterior probability. Thus our update rule for the variable θ_i is given as:

$$\hat{\theta}_i = \underset{k}{\operatorname{argmax}}\ p(\theta_i = k|\theta_{\neg i}, x) \tag{5}$$

Since this update equation monotonically increases the estimate of the posterior probability, and the value of the posterior probability is bounded above by 1, we can use the monotone convergence theorem to conclude that this algorithm will converge to a local maximum in the posterior distribution. Furthermore, the ICM algorithm is able to do so without approximating the whole posterior distribution.

Iterated Conditional Modes is related to Expectation Conditional Maximization (Meng and Rubin, 1993) in that it employs conditionals to find local maxima in a distribution. However, unlike Expectation Conditional Maximization which maximizes a likelihood, ICM is not a variant of EM, as it takes into account prior distributions when computing the complete conditionals. In fact, we could describe ICM as a particular limit of Gibbs sampling in the same way that K-means can be viewed as the deterministic limit of the EM algorithm (Bishop, 2006).

Note however that the efficiency of the ICM algorithm depends entirely on the ability to quickly compute the mode of the conditional distributions. If the complete conditional distribution is a density, this may involve continuous optimization. However, there is a wide class of models for computing the mode of the conditional distribution is easy. Typically this is done through the use of conjugate priors which make the conditional distributions tractable. For example, for many probabilistic models of text, computing the mode of the conditional distribution is often easy due to the frequent use of the Dirichlet-Multinomial conjugate pair.

To be clear, Iterated Conditional Modes is a coordinate ascent algorithm, and as such, it can only locally optimize the posterior — there is no guarantee of finding a global maximum. Thus if the posterior manifold contains many sub-par local maxima, then ICM will be sensitive to initialization and may perform poorly. Random restarts may mitigate the problem. Alternatively, an initialization strategy which consistently starts the inference procedure near a good solution will yield better *maximum a posteriori* estimates. The best initialization strategy depends on the model to be optimized. Thus each experiment described below includes its own initialization strategy.

3 Experiments

We now demonstrate that Iterated Conditional Modes converges quickly enough to allow for interactive use cases involving various probabilistic models of text, while yielding high quality estimates. In the hopes of demonstrating the general applicability of the technique, we do so on three different models and tasks. The first model is a DP Mixture of Multinomials applied to the task of web search result clustering. We choose this model to show that ICM can work in the context of non-parametric models. The second task is the Interactive Topic Model or ITM. We choose this model to suggest that ICM may be viable for a wide variety of interactive topic modeling applications. Finally, we will apply ICM to the MOMRESP model, which is a probabilistic model for producing annotated corpora for NLP and machine learning research.

3.1 Web Search Result Clustering

As many as 16% of queries issued to search engines contain ambiguous search terms (Song et al., 2007). After issuing a search query with this kind of ambiguity, users may become confused by seemingly unrelated search results, or they may be slowed by the need to narrow the scope of the query. For example, suppose a user issues the query "tiger." The user may be surprised to see results about the large feline, the golfer Tiger Woods and the German tanks used in the 1940s, when only one of those meanings of "tiger" was intended. Web search result clustering helps users deal with query ambiguity by automatically discovering clusters among the search results and presenting the results as clusters (Carpineto et al., 2009b). With a web search result clustering system, the user can select the cluster in which they are actually interested, and immediately filter out irrelevant results. An example of such a system is the Carrot[2]

search framework, which is available online both as a web service and as a downloadable application.*

Client-side web search result clustering systems do not maintain their own search index or data but instead rely on search results (specifically the snippets) returned from an external search engine chosen by the user. This allows users to utilize web search result clustering systems on a wide variety of search engines, both public and private. Since web search result clustering systems are meant to work with arbitrary search results, the computation typically takes place client-side. An important consequence is that web search result clustering systems should be able cluster extremely small amounts of data: rather than tens of thousands of full documents encountered in typical document clustering tasks, a web search result clustering systems uses around 100 documents, each of which consist of no more than a sentence or two. Furthermore, web search result clustering systems must be run quickly enough to facilitate web search. For simple interactions like issuing a web search query, the interaction take less than one second (Cook and Thomas, 2005). This stands in contrast to typical document clustering settings which can be run offline possibly using parallel computation resources rather than online using a single commodity machine. Due to these run time constraints, it has been argued that traditional document clustering techniques may not work out of the box (Carpineto et al., 2009b). Consequently, various specialized algorithms for the problem of web search result clustering have been published.

The best reported solution to the problem of web search result clustering employs maximal spanning trees to perform word sense induction (Di Marco and Navigli, 2011). The algorithm, referred to as MST, uses the Google Web1T n-gram data set (Brants and Franz, 2006) to create a co-occurrence graph on the words in the snippet results and then calculates maximal spanning trees to remove edges from the graph. This process repeats until the desired number of word clusters is formed. Unfortunately, the requirement of large amounts of n-gram data is not amenable to client-side computation. Even just maintaining an up-to-date n-gram data set (so that the system can handle queries related to fast-changing subjects such as recent popular culture) is also necessary but requires web-scale data-gathering resources. Consequently, MST is not a client-side solution.

There are, however, a number of approaches which are amenable to client-side web search result clustering. One such system is Lingo, which was developed for use in the Carrot^2 search framework (Osiński et al., 2004). Another is KEYSRC, which extracts key phrases from snippet data and then uses hierarchical agglomerative clustering on those phrases (Bernardini et al., 2009).

Despite the fact that model-based approaches tend to yield higher quality results in the general problem of document clustering (Zhong and Ghosh, 2005), no study has applied model-based clustering to the specialized problem of web search result clustering. We rectify the lacuna by applying Iterated Conditional Modes to a Dirichlet Process Mixture of Multinomials model (hereafter referred to as DP-MOM), and we compare our results to those of the previously studied web search result clustering solutions.

Our model-based approach employs a Dirichlet Process (DP) mixture model, a well studied Bayesian non-parametric model (Antoniak and others, 1974; Neal, 2000). This type of model has been used to perform document clustering, albeit with modifications to include feature selection in the model (Yu et al., 2010). Given the scarcity of data in this application, we cannot realistically perform feature selection (although the snippet generation itself might be viewed as feature selection).

DP mixture models have a known relationship with the Chinese Restaurant Process (CRP) in that if we integrate over the random mixing measure in the DP mixture, the resulting model will have a CRP prior over the mixture components (Blackwell and MacQueen, 1973). Taking advantage of this relationship, the DP-MOM model can be written with the following form:

$$\phi_k|\beta \sim Dirichlet(\beta), k = 1, ..., K$$

$$z_d|\alpha \sim CRP(\alpha), d = 1, ..., M$$

$$w_d|z_d, \phi \sim Multinomial(N_d, \phi_{z_d}), d = 1, ..., M$$

where ϕ_k is the word distribution for topic k with a symmetric Dirichlet prior of β, z_d is the cluster assignment of document d, α is CRP concentration, and w_d gives the observed token counts for document d. M is the number of documents, and N_d is the number of tokens in the dth document.

Algorithm	AMBIENT	MORESQUE	All
ICM DP-MOM	**.768**	**.570**	**.625**
Gibbs DP-MOM	.758	.544	.604
KEYSRC	.665	.558	.588
Lingo	.628	.527	.555
MST	.815	.867	.852

Table 1: Clustering quality results, as measured by the Rand index. We include the MST results for reference though they do not constitute client-side results. Bold indicates the best client-side result, and underline indicates the absolute best result.

Following the advice of (2000), we derive a collapsed Gibbs sampler by integrating over ϕ. The complete conditional probability for the cluster assignment z_d, given the other assignments $z_{\neg d}$ and data is

$$p(z_d = j | z_{\neg d}, w) \propto \begin{cases} c_j \prod_{v \in V} \frac{\Gamma(\beta + n_{jv} + w_{dv})}{\Gamma(|V|\beta + n_{j\cdot} + w_{d\cdot})} \frac{\Gamma(|V|\beta + n_{j\cdot})}{\Gamma(\beta + n_{jv})}, & \text{if } c_j > 0 \\ \alpha \prod_{v \in V} \frac{\Gamma(\beta + w_{dv})}{\Gamma(|V|\beta + w_{d\cdot})} \frac{\Gamma(|V|\beta)}{\Gamma(\beta)}, & \text{otherwise} \end{cases} \tag{6}$$

where V is the set of words in the data, c_j is the count of documents assigned to cluster j, n_{jv} is the number of times the word type v is present in a document assigned to cluster j, and w_{dv} is the number of times word v is found in document d. Dots in the subscripts of these counters indicate marginalization over the missing index. For the sake of space, we omit the derivation, but it is similar to the derivation for the finite Mixture of Multinomials given by (2008).

We can also derive a mean field variational inference algorithm for DP-MOM. Such an algorithm, while fast, yields extremely poor *maximum a posteriori* estimates for DP-MOM (Walker, 2012). At least for this model, the independences introduced by the mean field assumption are too strong. Consequently, we compare ICM to a baseline Gibbs sampler instead of variational inference.

The final detail needed for implementing DP-MOM is an initialization strategy. A key advantage of using a non-parametric model is that the model can learn the number of clusters from data, thereby allowing our model to perform well with varying amounts of query term ambiguity. We can either initialize with a large number of clusters and let the model shrink to fit the data or to start with a small number of clusters and grow to fit the data. Our experiments indicate that starting with a single cluster performed the best, so we utilized this initialization strategy for our results.

In order to validate that our model-based approach performs well, we follow the same methodology as Di Marco and Navigli (2011) when evaluating the MST algorithm. We experiment with two different datasets: AMBIENT (Carpineto et al., 2009a) and MORESQUE (Di Marco and Navigli, 2011). Each dataset is a set of search queries issued to the YAHOO! search engine, along with the top 100 search result snippets which have all been manually labeled with topics. The primary difference between the two datasets is that the earlier AMBIENT dataset consists of single word queries, while the MORESQUE dataset extends AMBIENT to queries of length 2–4[†]. Taking both datasets together, we have a total of 158 ambiguous queries, each with between 3 and 15 topics.

Still following Di Marco and Navigli (2011), we evaluate clustering performance on these ambiguous query datasets with two metrics. The first is the Rand Index (Rand, 1971), a measure of similarity between two clusterings over the same set of elements. The Rand Index can be viewed a kind of accuracy, since it gives the percentage of pairing decisions which were correctly made with respect to a base clustering.

Table 1 summarizes the results of the various web search clustering algorithms measured by Rand Index. We see that the MST algorithm performs the best, but we remind the reader that this algorithm far exceeds the computation resource requirements for client-side web search result clustering so it only serves as a baseline. Among previously studied algorithms which respect resource constraints, our model-based approach outperforms existing techniques by a wide margin. Interestingly, Iterated Conditional Modes outperforms Gibbs sampling, indicating that for this model and this task, the extra exploration within

[†]Note that the data we use to cluster is the resulting snippets, *not* the queries themselves.

Algorithm	K=3	K=5	K=10	K=15	K=20

Gibbs DP-MOM	.508	.635	.795	.873	.917
YAHOO!	.492	.600	.729	.785	.827
KEYSRC	.443	.558	.720	.791	.832
MST	.547	.656	.792	.867	.907

Table 2: Diversification results on all queries, as measured by S-recall@K. The ordering provided by the YAHOO! search engine is included as a baseline. Bold indicate the best client-side result, and underline indicates the best absolute result.

a region of high probability from sampling is not as important as the ability to jump to a mode in that region of high probability. Furthermore, our approach is extremely fast. Using a single core of an AMD Phenom II X6 1090T processor, the median time spent using ICM to perform clustering on results for a single query was 1.18 milliseconds. Our experiments using Gibbs sampling on the other hand took 6.78 milliseconds to complete.

Our second measure evaluates the diversification produced by a clustering algorithm. As outlined by Di Macro and Navigli (2011), we can use the clustering labels to re-rank the search results such that the top search results are more diverse. We measure the diversification with S-recall@K, which measures the percentage of ground-truth labeled topics present in the top K search results after re-ranking. We use the ordering returned by YAHOO! as a baseline for S-recall@K.

Table 2 shows the results of the various web search result clustering algorithms with respect to S-recall@K. In both cases, our model-based approach outperforms the baseline ranking. Both KEYSRC and Lingo actually did worse than the YAHOO! baseline. For $K \leq 5$, MST performs the best. However, for all other values of K, our model-based approach performs the best. This is likely due to the fact that our non-parametric model is able to increase the number of clusters in the presence of highly ambiguous queries, whereas the MST algorithm uses a pre-specified number of clusters.

3.2 Interactive Topic Model

We now turn our attention to the Interactive Topic Model or ITM (Hu et al., 2011). This model extends LDA by replacing the per-topic categorical distributions over words with a tree-structured Dirichlet-forest distribution. The user interactively injects constraints into the model by placing token types into Dirichlet trees. Depending on the prior for the Dirichlet trees, the constraint can either be a "must link" (positive correlation) or a "cannot link" (negative correlation) type of constraint (Andrzejewski et al., 2009). Due to issues with transitivity in "cannot link" constraints, we follow Hu et al. (2011) and focus on "must link" constraints by setting the Dirichlet trees parameter to be extremely high. A user is able to employ constraints to tell the model to give a particular set of word types similar probability within each individual topic. For the sake of brevity, we omit details about the ITM including the specific distributions for the model and the complete conditionals used to drive the collapsed Gibbs sampler for the model since they are thoroughly explained by Hu et al. (2011). We also note that variational inference is inappropriate for this model, as it only achieves good performance when used in conjunction with hyper-parameter optimization. However, such optimization tends to undo the constraints, rendering the model useless (Hu et al., 2011). Consequently, we use the published Gibbs sampler as our baseline inference algorithm.

The ITM model is trained as follows: first we train a base model with no constraints (equivalent to learning a vanilla LDA model). The user is then presented with the outcome of an analysis using the model, possibly by showing them the traditional topic lists wherein a topic is represented by the most probable words in the topic. The user then injects word constraints into the model according to the individual needs of the user or specific domain knowledge. Using the document-level ablation strategy recommended by Hu et al. (2011) the topic assignments of any document which contains a newly constrained word are revoked. In order to enforce model consistency, the rest of the topic assignments remain unchanged. Finally, inference is rerun with the new constraints and the updated model is presented to the user. This interactive process is repeated until the user is satisfied with the final state of the model.

We now investigate which inference algorithm performs the interactive model updates best. Cook and

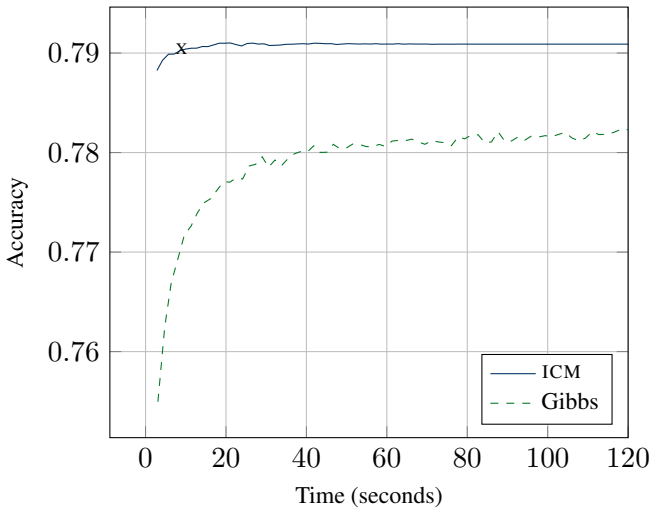

Figure 1: Accuracy versus time for both Iterated Conditional Modes and Gibbs sampling with the ITM. The X-mark indicates the median point of convergence for ICM.

Thomas (2005) show that for a complex user-initiated activity such as requesting a model update, we require a response time which is ten seconds or less or the human-computer interaction may suffer. Unfortunately, if we perform the recommended 30 iterations of sampling, even at one second per iteration, this can be taxing on the user. We turn to ICM as a faster alternative.

In order to validate the performance of Iterated Conditional Modes on the ITM, we employ an experimental setup similar to that of (2011) using the well-known 20 Newsgroups corpus, which consists of roughly 20,000 documents divided into 20 newsgroups. We simulate a user's constraints by selecting words using information gain with respect to the newsgroup labels. After training a base model with 100 iterations of Gibbs sampling for burn-in, we inject the simulated constraints into the model. Finally, we run inference using either ICM or Gibbs sampling from this point. We evaluate the model quality with a classification task in which we train a classifier to predict the source newsgroup of an unlabeled document using topic-word features. To do so, the corpus is split into a training and test set, and each word along with its assigned topic is used as a feature for the classifier. We report the classification accuracy from a support vector machine trained on the topic-word pairs from the documents in the training set. As with Hu et al. (2011), we do not hope to achieve state-of-the-art classification results for this dataset, but we do hope that the classification trends will demonstrate which inference algorithm better drives the model towards the original (withheld) human labels once the simulated constraints have been added.

As shown in Figure 1 Iterated Conditional Modes outperforms Gibbs sampling. This indicates that there is more value in reaching a local maximum than there is in the exploration that comes from sampling. More importantly, ICM has the potential to run much faster than Gibbs sampling: rather than running a Gibbs sampler for the recommended 30 iterations, the median number of iterations required for ICM to converge was 9, which allows us to present the updated model to the user within the ten second time frame recommended by Cook and Thomas (2005).

3.3 MOMRESP

Microtask markets such as Amazon's Mechanical Turk (mturk.com) allow corpora to be labeled at extremely low cost, a practice known as crowdsourcing. However, the recent emergence of crowdsourcing as the preferred method for labeling document corpora has introduced an important research problem: how to mitigate the inaccuracy of crowdsourced judgments. A common solution is to obtain multiple redundant judgments, or annotations, and aggregate them using a baseline strategy such as *majority vote*.

When annotations are both plentiful and highly accurate, majority vote works well. However, crowdsourced annotations are seldom highly accurate. State-of-the-art solutions are model-based and use standard inference algorithms. For example, the MOMRESP model presented by Felt et al. (2014) describes

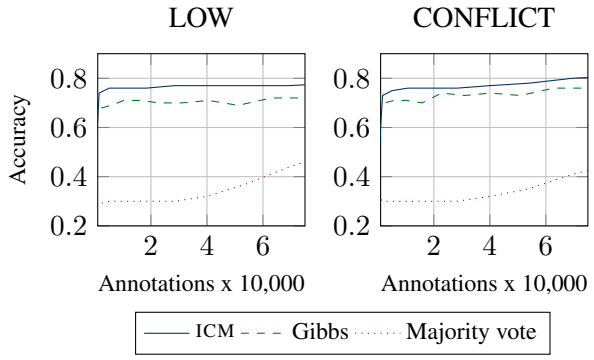

Figure 2: Accuracy of inferred labels versus the number of annotations given to the model. At the last plotted point each document has on average nearly 4 annotations. Gibbs and ICM use MOMRESP. A majority vote baseline is also shown for reference.

a joint model over document features and annotations. We include here a sketch of the model, deferring details to the referenced paper. Documents and annotations are both modeled as count vectors with multinomial distributions conditioned on the true but unobserved class label. Parameters include both per-class word distributions and class confusion matrices for each annotator. When annotations are scarce or of low-quality, the MOMRESP model trained with Gibbs sampling significantly outperforms majority vote in terms of inferred label accuracy. Labels inferred by Iterated Conditional Modes are even more accurate.

In order to validate this claim, we run MOMRESP with both Gibbs and ICM on synthetic annotations produced for the 20 newsgroups dataset. We draw synthetic annotators from the LOW and CONFLICT annotator pools described by (2014). Each pool consists of 5 annotators. In both pools, annotators give correct judgments with probabilities .5, .4, .3, .2, .1, respectively. In the LOW pool, annotator errors are distributed uniformly across incorrect classes. In the simulated CONFLICT pool, errors are systematic: a confusion matrix is created for each annotator whose diagonal is set to the annotator's accuracy and whose off-diagonal row entries are sampled from a symmetric Dirichlet distribution with parameter 0.1, to encourage sparsity, and then scaled so that each row sums to 1. CONFLICT errors are produced by corrupting true labels according to this confusion matrix. Documents are annotated in random order without replacement, and after all documents have one annotation, the process is repeated. Simulated annotation continues until we have reached the desired number of annotations. We then initialize MOMRESP using majority vote to set initial class label values and perform posterior inference using both Gibbs and ICM. We compare the model-inferred class labels with the gold standard class labels for each document in order to compute model accuracy.

Figure 2 plots the inferred label accuracy of Gibbs and ICM as well as majority vote for reference. Regardless of the number of annotations, ICM yields better accuracy than Gibbs sampling for both the LOW and the CONFLICT cases. While not shown, this trend hold even cases where majority vote outperforms MOMRESP.

In addition to inferring more accurate document labels than Gibbs, ICM has a run time which is orders of magnitude faster than that of Gibbs sampling. The median time of convergence was 6.72 seconds. This falls well within the run time recommended by Cook and Thomas (2005) for complex user-initiated tasks such as rerunning inference on MOMRESP given additional annotations. Consequently, if MOMRESP were to be adapted for an active learning task, then ICM would provide not only accurate posterior inference, but run times which are amenable to active learning.

4 Conclusion

Iterated Conditional Modes is a coordinate ascent algorithm that yields locally optimal *maximum a posteriori* estimates for models with tractable complete conditionals. We have shown that ICM identifies *maximum a posteriori* solutions that are superior to those found by Gibbs sampling for three applica-

tions: web search result clustering, topic modeling, and crowdsourcing problems. In addition, Iterated Conditional Modes has termination criterion which is easily identified, while it can be difficult to determine when a Gibbs sampler has reached the stationary distribution. Because of the convergence of ICM, we were able to significantly speed up the three applications compared to Gibbs sampling, enabling better human interactivity. These experiments motivate further exploration of this inference technique, particularly in interactive use cases of models in which both run time and model quality are crucial.

Abstract

In this paper we address a new problem of predicting affect and well-being scales in a real-world setting of heterogeneous, longitudinal and non-synchronous textual as well as non-linguistic data that can be harvested from on-line media and mobile phones. We describe the method for collecting the heterogeneous longitudinal data, how features are extracted to address missing information and differences in temporal alignment, and how the latter are combined to yield promising predictions of affect and well-being on the basis of widely used psychological scales. We achieve a coefficient of determination (R^2) of $0.71 - 0.76$ and a ρ of $0.68 - 0.87$ which is higher than the state-of-the art in equivalent multi-modal tasks for affect.

1 Introduction

The World Health Organisation describes mental health as "the foundation for well-being and effective functioning for an individual and for a community" and highlights the importance of selecting suitable indicators of mental health (Herrman et al., 2005). One can distinguish between macro-level indicators, which are meant to provide a picture of generic well-being across a large population, usually at national scale, and individual indicators of mental health. Most of the macro measures typically use statistics from census, administrative and economic sources to measure the social and economic macro-environment as important determinants of mental health (e.g. Human Development Index, Gender Development Index, Human Poverty Indices (OECD, 2013). With the advent of widely available social media data, there have also been efforts to automatically obtain macro indicators of well-being and happiness, primarily through the analysis of geolocated Twitter posts (Dodds et al., 2011; Lansdall-Welfare et al., 2012; Lampos et al., 2013). These pieces of work seek to identify occurrence patterns for words with pre-defined affect scores at different levels of temporal granularity. Such approaches, with more sophisticated components for emotion recognition in social media content, can be alternatives to public surveys for mood and happiness indicators.

At the other end of the spectrum we have individual indicators of mental health. These include measures of positive mental health, such as coherence & meaning in life, self-esteem etc. as well as indicators of mental distress, such as negativity, anxiety, depression (Herrman et al., 2005). These measures can be used by experts or individuals for diagnostic and management purposes, but also in aggregation, for large scale surveys. However, the reliance on self-reporting required to obtain these measures is time consuming and expensive and can only produce sparse data on small populations. Moreover, self-reporting is likely to introduce bias into results. Recent work (Rachuri et al., 2010; Lathia et al., 2012; Canzian and Musolesi, 2015; Pejovic et al., 2015) shows the potential of experience sampling using mobile devices

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3007–3018, Osaka, Japan, December 11-17 2016.

for behavioural studies and clinical care, especially relating to mental health. A variety of longitudinal sensor data from a smart phone as well as location information, obtained passively from the user's phone, can be calibrated against the user's responses to behaviour or emotion related questions. The latter are usually harvested through regular prompts for input provided by a smart phone application.

Here we combine heterogeneous and asynchronous textual as well as non-linguistic data to train predictors of well-being scores that will circumvent the need for user input. Our contributions include:

- **A novel and unique dataset of heterogeneous sources** consisting of textual data from social media posts (Twitter, Facebook), SMS messages ($> 100,000$), 2436 mood forms as well as asynchronous mobile phone use data including location, Wi-Fi connection, mobile phone use and sensor data (42 GB).
- **Methodology for handling heterogeneous, incomplete and asynchronous data for longitudinal predictions**. We consider a number of baselines and appropriate normalisations as well as an approach based on multi-kernel learning, which aims to maximise the joint predictive power of each data source, and show very promising results.
- **Calibration of well-being predictors based on well established affect and well-being scales**, namely the Warwick-Edinburgh Mental Well-Being Scale (WEMWBS) (Tennant et al., 2007) and the Positive and Negative Affect Scale (PANAS) (Watson and Clark, 1988; Crawford and Henry, 2004).

While studies on macro-indicators have exploited simple textual features, we are not aware of another study which has worked on such an heterogeneous dataset for the automatic prediction of individual well-being scores, basing predictions on well established psychometric scales. Indeed to the best of our knowledge this is the first study to tackle predictions from heterogeneous, asynchrounous, longitudinal user generated content.

2 Related Work

Mobile-based studies on well-being and mental health: Researchers have used mobile phones to assess student moods and stress by correlating data from phone sensors, daily probes on student states and termly behavioural surveys (Wang et al., 2015). They have identified a strong correlation between automatic sensing data and a broad set of well-being scales. Their work focuses on the calibration of sensor data against self-reported mood without any indication of how these can be combined for prediction purposes. In a related study (Wang and Harari, 2015) employ mobile phone use data and survey data from students to predict their GPA score at the end of term. The temporal granularity here is rather coarse, while no textual data is considered and the predictive model does not consider raw data, but rather pre-built classifiers which feed into a regression model. Work by Canzian and Musolesi (2015) shows how mobility patterns based on GPS strongly correlate with depression, but other data sources, such are text, are not exploited. Jacques et al. (2015) applied a multi-task, multi-kernel approach for predicting students' wellbeing using survey, mobility, smartphone and physiology data over a one-month period; despite the ability of the prediction model to provide interpretable results by using one kernel per modality, the textual modality was not used while one of the most predictive modalities (survey data) demanded manual effort from the subjects, which is in contrast to our objective. Other studies focusing on stress detection (Bogomolov et al., 2014) and happiness recognition (Bogomolov et al., 2013) have also ignored the textual modality or require user input (e.g. personality traits) to be used by their model.
Work on multi-modal affect aims to combine synchronous audio, visual and linguistic cues to predict affect dimensions and faces the challenge of source heterogeneity, which is tackled by two main approaches: in early fusion models, the features from the different modalities are combined into a single vector, which is fed to a learning algorithm. Such approaches have been employed in various tasks including sentiment (Wang et al., 2014) and emotion analysis (Poria et al., 2015; Wimmer et al., 2008) and benefit from the ability of the learning model to capture the semantic relations between different modalities; however, the resulting features are treated in the same way by the learning model (Akbari

et al., 2015). On the contrary, in late fusion approaches different models are trained per modality and their outputs are combined at a later stage, usually by employing weighted sum (Dobrišek et al., 2013; Poria et al., 2016). Gupta et al (2014) train separate classifiers on audio and video for a particular time frame and then fuse the results together to create new meta-features, while a product rule combination method is introduced for the emotion recognition task by (Dobrišek et al., 2013). Late fusion approaches suffer from inability to capture across-modality dependencies and thus are in contrast to our objective of combining heterogeneous data.

3 A Dataset of Heterogeneous Textual and Mobile phone data

Dataset Design: In designing our dataset we wanted to collect real-world user-generated content that could provide information about the spatio-temporal influence on users' mental well-being. For this purpose, our goal was to combine longitudinal textual sources, such as messages and social media posts, with behavioural data, as manifested by mobility patterns and mobile phone usage. To control for the effect of variable age and stage of life we recruited student participants from the same university in a large cosmopolitan city (New York); unlike (Wang et al., 2015) the study was not confined to a campus environment. A cohort of 29 students gave us access to their Twitter and Facebook posts, SMS and Facebook messages as well as their mobile phone use data, together with location information and mobile phone sensors, over a period of 4 months each. Data collection was passive, with the exception of on-line submission of psychological tests for well-being (WEMWBS)(Tennant et al., 2007) and affect (PANAS)(Watson and Clark, 1988; Crawford and Henry, 2004), which students were asked to complete once a day, in the evening. WEMWBS was chosen as a robust, widely used measure of well-being, suitable for the general population and employed by the NHS. Since WEMWBS focusses on positive attributes, we also used PANAS to capture negative emotions. Unlike other work, we did not require any other manual effort from students such as the completion of on-line questionnaires mapping them to personality traits or prompts for self-reported emotional status.

Data Collection: The data was primarily collected from the Twitter API and two applications (Apps) that were installed for the purpose of the study, on the participants' mobile phones. The first App is DeviceAnalyzer (Wagner et al., 2013), which collects a wide range of time-stamped data, including location and phone usage (e.g. number and duration of calls). SMS data was collected through the NUS SMS collection App[1], which was configured to retrieve a batch of SMS messages authorised by a participant, as a weekly email. Users were asked to complete psychological scales (mood forms) by logging into a secure webserver, set up for the study. We collected a total of 2436 mood forms, each corresponding to completed PANAS and WEMWBS scales. Facebook data was downloaded by our participants twice during their time on the study and was uploaded to the secure webserver, where the participants could choose the data they wished to share and make available to us. We thus collected 111,270 textual posts and 42GB of DA data spanning the period February 2015-December 2015. Note that participants' time on the study was staggered, with each participant contributing data for 4 months.

Dataset Description: The data is heterogeneous by nature and design and asynchronous, with variable temporal granularity, reflecting a real-world scenario and presenting numerous challenges. The most challenges are presented by the DeviceAnalyzer (DA) data, due to their sheer volume and natural redundancy. For example, aggregates are required to represent most DA features (e.g. number of calls, time spent in a location etc.) but choosing the best aggregate and its respective temporal granularity is not straightforward. Moreover, timestamps are presented in epochs, so they had to be converted to absolute values, to be in alignment with those of textual data. We experimented with different methods for aggregation; for the purpose of this study, the decision was made to aggregate DA features at the hour level, by taking mean or cumulative values for the feature within an hourly interval. We selected a subset (153) of the DA features that can be potentially indicative of user behaviour, as opposed to being related to purely technical aspects of the phone. The former, among others, include: volume of images and SMS messages, physical sensor readings (physical environment and movement), location in terms of longi-

[1] http://wing.comp.nus.edu.sg:8080/SMSCorpus/contribution.jsp

tude and latitude as well as wireless network and data transfer (digital environment), battery level, ringer and other phone settings (user choices). Data is collected anonymously and linked together through user identifiers.

Location and Wi-Fi connection data: A further challenge was presented by how to make use of location and Wi-Fi connection data to allow: (a) compatibility with numeric aggregates (b) direct comparisons between different users, who inevitably spend time at different locations with different Wi-Fi connections, with no direct semantic mappings. Our solution to the above was to rank locations and Wi-Fi connections, respectively, according to the time spent in each of them, by each user. Thus we collected the top 10 locations and Wi-Fi connections per user. See also section 4.2.

Sensor data: There are 15 different sensors of which only accelerometer and light sensor data are provided by 22 of the 29 participants. Each of the two sensors corresponds to 10 different values, including resolution and range of values at a particular time-point.

Textual data: The fields associated with each textual instance are the speaker, the raw text, the absolute time stamp, the data source (e.g. Facebook) and the type of text (e.g. message).

Mood forms: Obtaining scores for the mood forms is straightforward and based on the scoring instructions associated with each of the two psychological scales.

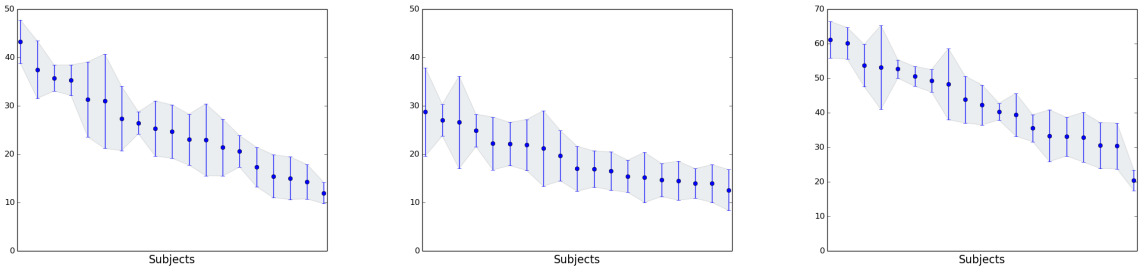
4 Methodology

4.1 Data matrix creation and Features

Our goal here is to combine features from both (i) the DeviceAnalyzer (DA) data and (ii) the textual sources (TEXT), in order to train a model that can automatically predict mood scores originating from the three daily mood forms. The latter correspond to the determination of positive affect ("positive") and negative affect ("negative"), calculated on the basis of the PANAS psychological scale and well-being ("wellbeing"), calculated on the basis of the WEMWBS psychological scale. Those three scores for positive, negative and well-being constitute our target values. Past research has shown a strong correlation between well-being and positive (r=.71) and a moderate (negative) correlation between well-being and negative affect (r=-.54) (Tennant et al., 2007). For the purpose of this work we keep the three targets distinct from each other, to aid the interpretability of results.

We had 29 participants on the study who agreed to give us access to both their DA and TEXT data and complete daily mood forms. During the study, two participants switched to iPhones, so they could no longer run DA on their mobile phones. For others, there was missing DA data, where missing data are defined as cases where one or more sources of DA data have no values for longer than a 6 hour period before the completion of a mood form, which was assumed as being most relevant for its completion. TEXT data on the other hand are never considered missing, as the lack of a post is considered to be a choice and a useful indicator of user behaviour. For the purposes of the current paper, we focused thus on the 19 users for whom we had both DA and TEXT data and no missing data in the 6 hour period prior to the completion of a mood form. This means that from an original set of 2436 mood forms, each corresponding to three mood score values, several textual posts (Twitter, Facebook, SMS) and several GB of DA data, we make use of 1438 mood forms and the corresponding features and target values.Thus, for this study, we used 40,786 textual posts written in English and the corresponding DA data ($\sim$10GB). Mood scores consist in scores for well-being, positive and negative affect. Figure 1 shows the mean values and the standard deviations for the three mood form scores based on the subjects that were used in our study. The average per-subject score is 25.2, 19.2 and 42.6 for the positive, negative and well-being target respectively. Interestingly, we observe that the average per-subject standard deviation is 5.0, 4.9 and 5.7 for the three targets, pointing to the subjects' affect and well-being fluctuations during the studied period, which makes our task more challenging and shows that simply identifying a subject based on his/her id is not sufficient for predicting his/her mood.

Our textual and DA data points have very different temporal granularity, with hundreds of DA data points in between textual posts. As mood forms are completed every 24 hours (some users being more diligent than others), we decided to extract features within the 24 hour window of a mood form. The



(a) Positive (b) Negative (c) Well-being

Figure 1: Average and standard deviations of the mood form scores obtained by the 19 subjects.

underlying assumption is that those features generated by a user during the past day are most likely to have influenced her mood, resulting in the observed mood scores. Thus, given a mood form completed by a certain user at time t, we focused on her past 24 hours before t, in order to extract our features from and aggregate these features in different time windows within the 24 hour period, and, more specifically, into 5 different windows (1, 6, 12, 18 and 24 hours before the completion of a mood form), to allow for an extra level of granularity to the effect of proximity to the mood form timestamp. This process was performed for the DA features that are described in the following section and not for the TEXT ones, which are only considered at the 24 hour window. This is due to the sparsity of some feature representations of the latter. In future work, we plan to make better use of the temporal granularity of the TEXT features and their interaction with the DA data. In the following, we describe a number of baselines, utilising subsets of the features (4.2) and different algorithms, tested under different settings (4.3) to establish the most effective approach to combining heterogeneous data for prediction.

4.2 Baseline definition

Baseline DA Features

Previous work in a controlled user study (Wang and Harari, 2015) looked at exploiting features from students' mobile phone usage within a semester, to predict student academic performance at the end of the semester. While we consider target objectives at much finer grained temporal intervals, we adopt a baseline from mobile phone data (DA) to approximate the ones considered in the StudentLife study (Wang et al., 2015). The latter relies on pre-built classifiers (i.e., accelerometer data (Lu et al., 2010)) to make use of sensor data, such as accelerometer, while we use aggregates of raw data. In our work, we have built classifiers that take into account all data variables, and as such offer more degrees of freedom, to better understand the underlying causes of emotions than studies that consist of disparate pre-built classifiers. Our DA baseline consists of:

- **Calls**: The total number and duration of the calls that a subject has made and received.
- **Locations**: The percentage of time that a subject has spent in her i^{th} preferred location.
- **Wi-Fi:**: The percentage of time that a subject has spent while connected to her i^{th} preferred Wi-Fi.
- **Other**: the percentage of time that a user's mobile: (i) headphones have been "on" ("off"); (ii) screen brightness has been set to "manual" ("auto"); (iii) airplane mode has been "active" ("inactive"); (iv) ringer mode has been set to "vibrate", "silent" and "normal"; (v) headset has been "on" ("off"); and (vi) has been disconnected, plugged in a USB port and plugged in AC.

For locations and Wi-Fi connections we generated features for $i = \{1, ..., 10\}$, the ten preferred locations and Wi-Fi connections respectively, and an eleventh feature, signaling respectively the total time spent in locations and Wi-Fi access points, other than the top ten. Figure 2 shows the projection of the locations visited by the subjects within the city of New York. All DA features were extracted from

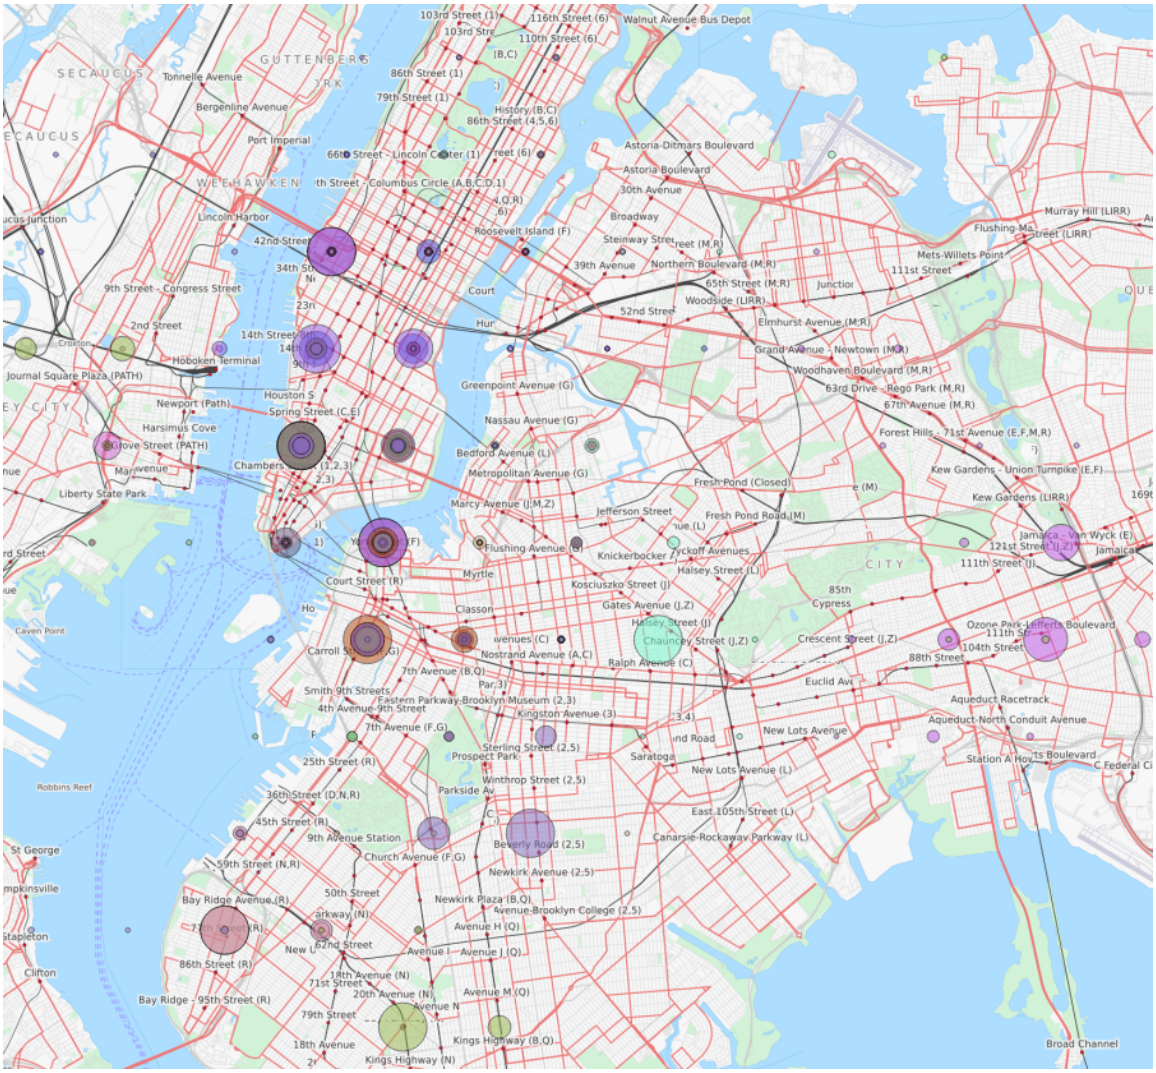


Figure 2: Geo-visual projection of the subjects' visited locations. Each colour indicates a unique user and the size of their spot indicates the number of unique GPS samples at that location.

five different time windows, before the completion of a mood form (1, 6, 12, 18 and 24 hours), leading to 200 DA features per instance. In the case of missing data for some feature (e.g. missing locations due to disconnections), we filled-in the gaps, by replacing the missing values of a feature with the past 6-hour mean of the same feature for that specific user. For example, if we have no indication of the time spent in particular locations 1 hour prior to the completion of a mood form, we use the 6-hour mean of each location feature from the 6-hour window leading up to the timestamp of the mood form for the user in question. If after this process an instance would still have some missing feature values, we would drop the instance out of our analysis. This resulted in reducing our dataset from 2436 instances (mood forms completed by 29 users) to 1, 438 complete ones, corresponding to 19 different users. Note that while we have sensor data from the phones (accelerometer and light sensor), and accelerometer data were quite predictive in the StudentLife study, we have not used them for the purposes of the current study, due to a large number of missing values exceeding a 6-hour window.

Baseline TEXT Features

All the texts (SMS and social media posts/messages) sent by a specific user over the past 24 hours before the completion of a mood form were concatenated in one 24-hour window. Focusing only on the English texts[2], the following commonly applied practices were performed: lowercasing, tokenisation (Gimpel et

[2]Language detection was performed using `https://pypi.python.org/pypi/langid`

al., 2011), replacement of usernames and URLs with placeholders, "usrmnt" and "urlink", respectively. We extracted the following textual features as potentially relevant to the mental state of users:

- **Ngrams**: We extracted *tfidf* representations of uni- and bi-grams, setting the max (min) document frequency to 99% (1%) and excluding all English stopwords, for noise reduction purposes.
- **Word embeddings**: We used the word embeddings created by (Tang et al., 2014), which have been used successfully before for the task of sentiment analysis, related to our problem. The unigrams of every text were matched against those vectors and seven functions were applied on every dimension of the resulting matrix (mean, median, min, max, stdev, first and third quartile).
- **Lexicons**: We employed several lexicons that have been effectively used in sentiment- or emotion-related works. Those were the Opinion Lexicon (Hu and Liu, 2004), NRC Hashtag, NRC Hashtag Emotion (Mohammad, 2012), Unigram and Bigram NRC Hashtag Sentiment and Sentiment 140 lexicons (Zhu et al., 2014), MaxDiff Twitter Sentiment Lexicon (Svetlana Kiritchenko and Mohammad, 2014), MSOL (Mohammad et al., 2009) and AFINN (Nielsen, 2011). For lexicons providing binary values (pos/neg), we counted the number of ngrams matching each of the positive and negative classes; for those lexicons with score values, we used the simple counts and the total summation of the corresponding scores from each ngram in the text matched against the lexicons.
- **Topics**: In order to better categorise the content that a subject has shared and to accommodate the sparse representations of the ngrams, we used the word clusters created by Preoţiuc-Pietro et al. (2015), which were based on word2vec representations of the most common keywords appearing on Twitter over a 2-month period. We measured the cosine similarity of the unigrams of every textual instance with each one of the 200 word clusters.
- **Other**: We extracted the following features related to the social activity level of a user: the number of SMS messages, Facebook posts, Facebook messages, Facebook images, twitter posts, twitter messages, and the total number of tokens and textual items (messages or posts) in the instance.

4.3 Experiments and Models

We applied five regression models, in order to predict each of the three target mood scores separately. All models were tested using 5-fold cross validation using the two sets of features (DA, TEXT) individually and in combination (ALL). Before feeding our features to the regression models, various transformations and normalisation techniques were tested. Those include:

- **The root transformation of the target labels**, often used in regression models to inflate the difference between lower values and stabilise the difference between higher scores[3].
- **Combinations of: (a) normalisation** (linear transformation of feature values to the $[-1, 1]$ range, based on the maximum/minimum value of the feature), **(b) standardisation** (zero mean, unit variance) or **(c) no transformation**.

Those transformations were performed on (i) a per-user basis (so that the feature values of different users become more comparable) and (ii) an overall basis (as a final transformation of all features from different users before applying our models). Notice that in the case of the per-user transformations, the model suffers from the cold-start problem, as it expects to have some past knowledge about the user, in order to predict her mood.

The algorithms that were tested under this setup were Linear Regression, LASSO, Random Forest for regression (RF), Support Vector Regression (SVR) and a multi-kernel SVR approach. The first four algorithms were chosen as widely accepted standards for regression problems, as well as for their diversity (two linear models, one with and one without feature selection, an ensemble of trees, a kernel-based method). Multi-kernel learning (MKL) was proposed in order to allow for a more advanced handling of the different data sources, by jointly learning different kernels, each optimised to a particular data source. For LASSO, different experiments with respect to the alpha parameter were tested (10^{-2}, ..., 10^{2}); for

[3]We also tried log-transformation but performance was lower.

RF we set the number of estimators to 200, after experimentation; for SVR we have used the Gaussian Kernel with varying kernel width and C values (all combinations of $\{10^{-2}, ..., 10^{2}\}$ for both)[4].

One drawback of SVR is the difficulty to interpret predictions and feature importance. Similarly performing algorithms, such as RF, can provide some indication of feature importance in the model learnt, but, when dealing with heterogeneous data sources, data source contribution is a lot less straightforward. For these reasons, we applied an MKL approach (Sonnenburg et al., 2006), which jointly learns an optimal combination of source-specific kernels. Formally, for a training set comprised of instances I and features S partitioned in subgroups $s \in S$, we apply a base kernel k per feature subgroup with some weight w, as follows: $f(\mathbf{x}) = \sum_{i \in I} \alpha_i \sum_{s \in S} w_s k_s(\mathbf{x}, \mathbf{x_i}) + b$ where the parameters α_i, the bias term b and the kernel weights are estimated by solving the optimisation problem:

$$\begin{aligned} \min \quad & \gamma - \sum_{i \in I} \alpha_i \\ \text{w.r.t.} \quad & \gamma \in R, \alpha \in R_+^{|I|} \\ \text{s.t.} \quad & 0 \leq \alpha_i \leq C \; \forall i, \;\; \sum_{i \in I} \alpha_i y_i = 0 \\ & \frac{1}{2} \sum_{i \in I} \sum_{j \in I} \alpha_i \alpha_j y_i y_j k_s(\mathbf{x}_i, \mathbf{x}_j) \leq \gamma \;\; \forall s \end{aligned}$$

We have opted for the L_2 norm to regularise the kernel weights. In order to compare our MKL approach with SVR, we selected one Gaussian kernel per feature set (9 kernels: 4 DA and 5 TEXT, for each of the feature sources defined in 4.2) and tuned the width of every kernel and the C parameter performing the same grid search as with SVR. This implies that we have used the same width for all nine kernels in every run. Further kernel selection and parameter optimisation techniques could be used, but those are out of the scope of the current work.

5 Evaluation and Results

We have used two standard measures for evaluating our models – the root mean squared error (RMSE, ϵ) and the coefficient of determination (R^2) . Those were selected in order to compare both the errors between the different approaches as well as the proportion of the variance that is predictable by them.

Table 1 presents the results obtained from our models. We provide separate results of the models for the two cases with respect to the per-user transformation of the features. Only the best transformation combinations are presented per model and the results obtained by Linear Regression are omitted, due to its poor performance. The feature transformation that was used is provided as an index.

In terms of comparing the three tasks (predicting each of the targets), our models can successfully capture much of the target variance in their predictions with respect to the well-being target. The lowest errors are observed with respect to the negative target (the comparison with the well-being case in terms of the error is not straight-forward, due to the larger scale that is used in WEMWBS). However, R^2 for this task is considerably lower, pointing to the low variance in each model's prediction.

The task of user normalisation does not appear to have any significant effect when applied on the DA features for any task, implying that our models trained on DA features are user-independent and can generalise well. However, this is not the case for the TEXT features: for all algorithms and all tasks, the performance drops significantly when no user normalisation is applied. This is an interesting finding, pointing to future work on text-based user modelling, as it provides some evidence that population-wide analyses on mood prediction tasks that do not take it into account can be ineffective.

The comparison between the different algorithms illustrates that RF is the best in most experiments with respect to all target scores, achieving an R^2 of .76 in the best case (predicting the well-being score based on ALL features with user normalisation). To allow comparison with multi-modal affect our ρ

[4]Python sklearn library (`http://scikit-learn.org/stable/`) was used for the first three models and the Python interface for the Shogun library (`http://www.shogun-toolbox.org`) was used for SVR and MKL.

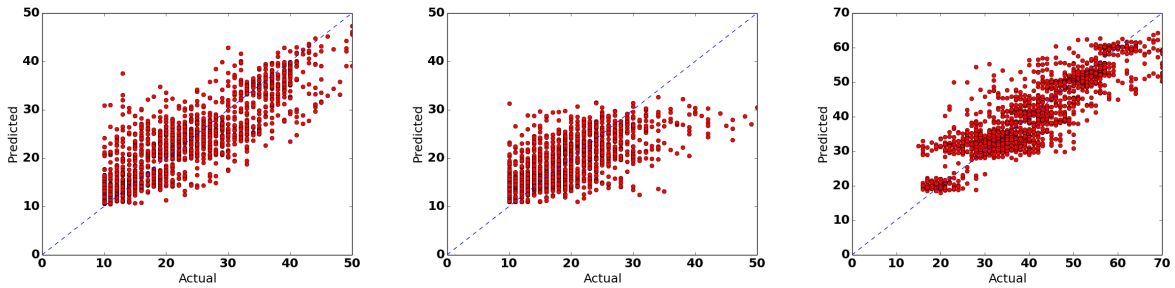
Table 1: R^2 root mean squared error (ϵ) of the different models based on the three feature sets (DA, TEXT, ALL) and with respect to the three different ground truth scores (positive, negative, well-being). Values for both setups with respect to the user normalisation (with and without) are presented. The index used in the R^2 column indicates the (i) final and (ii) per-user normalisation of the best-performing setup (n for normalisation, s for standardisation, $-$ for none). Only the final normalisation method (i) is indicated in experiments performed without per-user normalisation.



(a) Positive (b) Negative (c) Well-being

Figure 3: Actual VS Predicted charts for the best performing algorithm (RF) on the three targets.

scores for RF for {positive, negative, well-being} are {.84, .68, .87} respectively, which is higher than for equivalent multi-modal tasks (Gupta et al., 2014). The charts in Figure 3 illustrate the corresponding predictions graphically. While our MKL does not outperform the RF, it achieves higher accuracy compared to SVR, showing that heterogeneous sources or feature sets can be effectively modelled via multiple kernels with a different weight, depending on their relative impact on the task. Importantly, this improvement comes without any kernel selection or dense parameter optimisation, which can be explored in future work. Also, comparing the results between MKL and RF in the cases without user normalisations shows that MKL is more robust to the cold-start problem for all three targets. This is important, as expecting to have past knowledge from any user is more challenging and resource greedy. A major advantage of MKL compared to SVR is the interpretation of the feature weights. By comparing the different kernel weights, we can see the contribution of each feature set separately. The bar charts in Figure 4 show the weights of each kernel (feature set), as determined by MKL, normalised to sum up to 1. For comparison purposes, we also present the corresponding weights from RF that were extracted by measuring every feature's importance across the trees and manually mapping those to the MKL's feature sets. For both the positive and the well-being targets, there are three TEXT feature sets that are preferred by both models (ngrams, word embeddings and topics), albeit with different weights. On the one hand, this points to a possibly weak feature engineering with respect to the DA data. On the

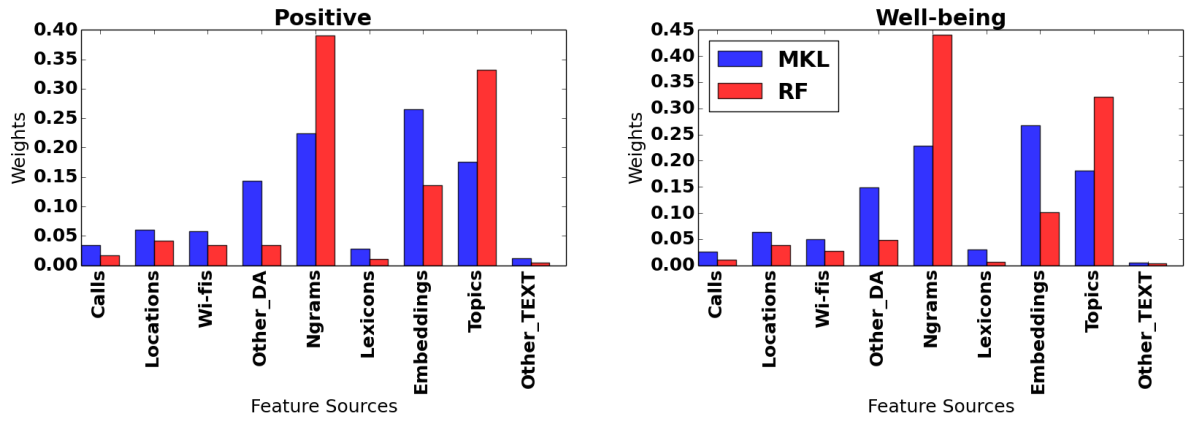


Figure 4: Feature set weights in RF (red) and MKL (blue) for the positive and the well-being targets, training on all features in the per-user normalisation approach.

other hand, it also explains the difference in accuracy between the two models, which can be highly reduced with further tuning of the MKL kernels and their parameters. Importantly though, the comparison between the feature weights of the two algorithms also explains the relatively small boost in accuracy that RF achieves when the DA features are incorporated in the TEXT-based RF (see Table 1), since the algorithm is relying much more on the TEXT features (12.7%, 18.0% and 12.7% of the feature weights come from DA sources with respect to positive, negative and well-being, compared to 29.5%, 28.9% and 28.7% for MKL). This means that MKL has much more potential in making use of heterogeneous sources compared to RF and further tuning of our MKL approach can provide an even more balanced kernel weighting for robustness purposes, while also increasing performance.

6 Conclusion and Future Work

We have presented a new real-world dataset consisting of heterogeneous, longitudinal and asynchronous textual and mobile phone use data. We have investigated different approaches for combining this heterogeneous data for daily predictions of mood scores and have proposed some strong baselines as well as a multi-kernel learning approach that learns a combination of source-specific representations, giving very promising results. We achieve a coefficient of determination (R^2) of $0.71 - 0.76$ and a ρ of $0.68 - 0.87$ which is higher than the state-of-the art in equivalent multi-modal tasks for affect.

In the future we aim to address the following: (a) optimise our MKL component and make better use of temporal granularity, by means of convolution and spectral mixture kernels (Lukasik and Cohn, 2016; Wilson et al., 2014) (b) look into the semantics of different locations and (c) address the challenge of missing data in one type of source, which is currently resulting in the loss of a large number of instances. Finally, we plan to apply our micro-level text-based model presented in this paper to the macro-level. Most approaches on predicting population-wide well-being indices based on online media have primarily relied on lists of pre-defined keywords, without using a per-user ground truth and ignoring the user modelling aspect. By applying our model on such a data stream, we will investigate whether we can build effective macro-level indicators for monitoring the well-being of a large population.

Abstract

Microblogging services allow users to create hashtags to categorize their posts. In recent years, the task of recommending hashtags for microblogs has been given increasing attention. However, most of existing methods depend on hand-crafted features. Motivated by the successful use of long short-term memory (LSTM) for many natural language processing tasks, in this paper, we adopt LSTM to learn the representation of a microblog post. Observing that hashtags indicate the primary topics of microblog posts, we propose a novel attention-based LSTM model which incorporates topic modeling into the LSTM architecture through an attention mechanism. We evaluate our model using a large real-world dataset. Experimental results show that our model significantly outperforms various competitive baseline methods. Furthermore, the incorporation of topical attention mechanism gives more than 7.4% improvement in F1 score compared with standard LSTM method.

1 Introduction

Over the past few years, microblogging has experienced tremendous success and become very important as both a social network and a news media. There is a significant amount of information generated every day. To facilitate the navigation in the deluge of information, microblogging services allow users to insert hashtags starting with the "#" symbol (e.g., #followfriday) into their posts to indicate the context or the core idea. In this way, hashtags help bring together relevant microblogs on a particular topic or event and enhance information diffusion in microblog services. It has been proven that hashtags are important for many applications in microblogs (Efron, 2010; Bandyopadhyay et al., 2012; Davidov et al., 2010; Wang et al., 2011; Li et al., 2015). However, not all microblog posts have hashtags created by their authors. Reported in a recent study, only about 11% of tweets were annotated with one or more hashtags (Hong et al., 2012). Hence, the task of recommending hashtags for microblogs has become an important research topic and attracted much attention in recent years.

Existing approaches to hashtag recommendation range from classification and collaborative filtering to probabilistic models such as naive Bayes and topic models. Most of these methods depend on sparse lexical features including bag-of-word (BoW) models and exquisitely designed patterns. However, feature engineering is labor-intensive and the *sparse* and *discrete* features cannot effectively encode semantic and syntactic information of words. On the other hand, neural models recently have shown great potential for learning effective representations and delivered state-of-the-art performance on various natural language processing tasks (Cho et al., 2014; Tang et al., 2015; Rush et al., 2015). Among these methods, the long short-term memory (LSTM), a variant of recurrent neural network (RNN), is widely adopted due to its capability of capturing long-term dependencies in learning sequential representations (Hochreiter and Schmidhuber, 1997; Gers et al., 2000; Palangi et al., 2016).

In this work, we model the hashtag recommendation task as a multi-class classification problem. A typical approach is to adopt LSTM to learn the representation of a microblog post and then perform text classification based on this representation. However, a potential issue with this approach is that all the

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3019–3029, Osaka, Japan, December 11-17 2016.

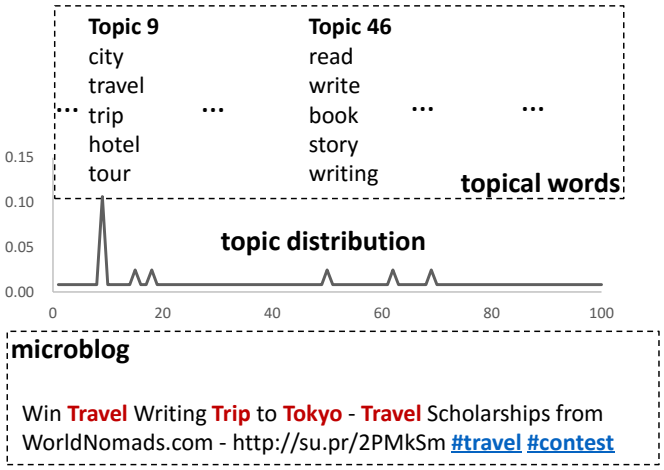

Figure 1: Illustration of hashtags of a microblog post and its topic distribution. The example post has a high probability in a travel topic (Topic 9). Words that are related to the topic (marked in red bold) can be selected through the topic distribution of the post. Using these words, we can predict its hashtag #travel.

necessary information of the input post has to be compressed into a fixed-length vector. This may make it difficult to cope with long sentences (Bahdanau et al., 2015). One possible solution is to perform an average pooling operation over the hidden vectors of LSTM (Boureau et al., 2011), but not all words in a microblog post contribute equally for hashtag recommendation. Inspired by the success of attention mechanism in computer vision and natural language processing (Mnih et al., 2014; Bahdanau et al., 2015; Luong et al., 2015), we investigate the use of attention mechanism to automatically capture the most relevant words in a microblog to the recommendation task. Furthermore, it has been observed that most hashtags indicate the topics of a microblog (Ding et al., 2012; Godin et al., 2013), as illustrated in Figure 1. To this end, we propose a novel attention-based LSTM model which incorporates LDA topics of microblogs into the LSTM architecture through an attention mechanism. By modeling the interactions between the words and the global topics, our model can learn effective representations of microblogs for hashtag recommendation. Experimental results on a large real microblogging dataset show that our model significantly outperforms various competitive baseline methods. Furthermore, the incorporation of topical attention mechanism gives more than 7.4% improvement in F1 score compared with standard LSTM method.

The main contributions of this paper can be summarized as follows:

- We thoroughly investigate several neural attention-based models for hashtag recommendation.
- We propose a novel attention-based LSTM model that incorporates topics of microblog posts into the LSTM architecture through an attention mechanism. Experiments on data from a real microblogging service show that our model achieves significantly better performance than various state-of-the-art methods.

2 Background

Before going to the details of our method, we provide some background on two topics relevant to our work: the attention mechanism and Latent Dirichlet Allocation (LDA).

2.1 Attention Mechanism

Attention-based models have demonstrated success in a wide range of NLP tasks including sentence summarization (Rush et al., 2015), reading comprehension (Hermann et al., 2015) and text entailment (Rocktäschel et al., 2016; Wang and Jiang, 2016). The basic idea of the attention mechanism is that it assigns a weight to each position in a lower-level of the neural network when computing an upper-level

representation (Bahdanau et al., 2015; Luong et al., 2015). Bahdanau et al. (2015) made the first attempt to use an attention-based neural machine translation (NMT) approach to jointly translate and align words. The model is based on the basic encoder-decoder model (Cho et al., 2014). Differently, it encodes the input sentence into a sequence of vectors and chooses a subset of these vectors adaptively through the attention mechanism while generating the translation.

In this work, we adopt the attention mechanism to scan input microblog posts and select key words to hashtag recommendtaion. Motivated by Bahdanau et al. (2015), we first investigate a vanilla attention-based LSTM model, which is referred to as VAB-LSTM in Section 4.2.1. In VAB-LSTM, we use the last hidden vector from the LSTM that processes a post as the global representation of that post and incorporate attentions to measure the interactions between each word and the global representation. Then we further compare it with our proposed topical attention-based LSTM model.

2.2 Latent Dirichlet Allocation (LDA)

Topic models have been a powerful technique for finding useful structures in a collection of documents. Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a well-developed and widely-used topic model for inferring the semantic meaning of documents through a set of representative words (topics). It models a document as a mixture of latent topics. In LDA, each document of the corpus is assumed to have a distribution over K topics, where the discrete topic distributions are drawn from a symmetric Dirichlet distribution. The high probability words in each distribution gives us a way of understanding the contents of the corpus at a very high level.

Given a collection of microblog posts, LDA is able to learn a sparse topic representation for each post. The topic representation is viewed as a kind of global semantic information of a post, which we can utilize to learn the interactions between each words and the whole microblog post.

3 The Approach

In this section, we will present our proposed model for hashtag recommendation. We formulate the hashtag recommendation task as a multi-class classification problem. It has been observed that hashtags indicate the primary topics of microblog posts (Ding et al., 2012; Godin et al., 2013). To incorporate the topics of microblogs, we take into account the attention mechanism and develop a novel Topical Attention-Based LSTM model, or TAB-LSTM for short. The basic idea of TAB-LSTM is to combine local hidden representations with global topic vectors through an attention mechanism. We believe that in this way our model can capture the importance of different local words according to the global topics of a microblog post.

Our overall model is illustrated in Figure 2. The model mainly consists of three parts, namely, LSTM based sequence encoder, topic modeling, and topical attention. In the rest of this section, we will present each of these three parts in detail. A basis of all three parts is that each word is represented as a low dimensional, continuous and real-valued vector, also known as word embedding (Bengio et al., 2003; Mikolov et al., 2013). All the word vectors are stacked in a word embedding matrix $L_w \in \mathbb{R}^{dim \times |V|}$, where dim is the dimension of word vector and $|V|$ is vocabulary size. We pre-train the values of word vectors from text corpus with embedding learning algorithms to make better use of semantic and grammatical associations of words (Mikolov et al., 2013). Given an input microblog s, we take the embeddings $\mathbf{x}_t \in \mathbb{R}^{dim}$ for each word in the microblog to obtain the first layer. Hence, a microblog post of length N is represented with $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N)$.

3.1 LSTM based Sequence Encoder

LSTM is special form of recurrent neural networks (RNNs), widely used to model sequence data. LSTM uses input gate, forget gate and output gate vectors at each position to control the passing of information along the sequence and thus improves the modeling of long-range dependencies (Hochreiter and Schmidhuber, 1997).

Given a microblog $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, ..., \mathbf{x}_N)$, LSTM processes it sequentially. For each position $\mathbf{x}_t$, given the previous output $\mathbf{h}_{t-1}$ and cell state $\mathbf{c}_{t-1}$, an LSTM cell use the input gate $\mathbf{i}_t$, the forget gate $\mathbf{f}_t$ and

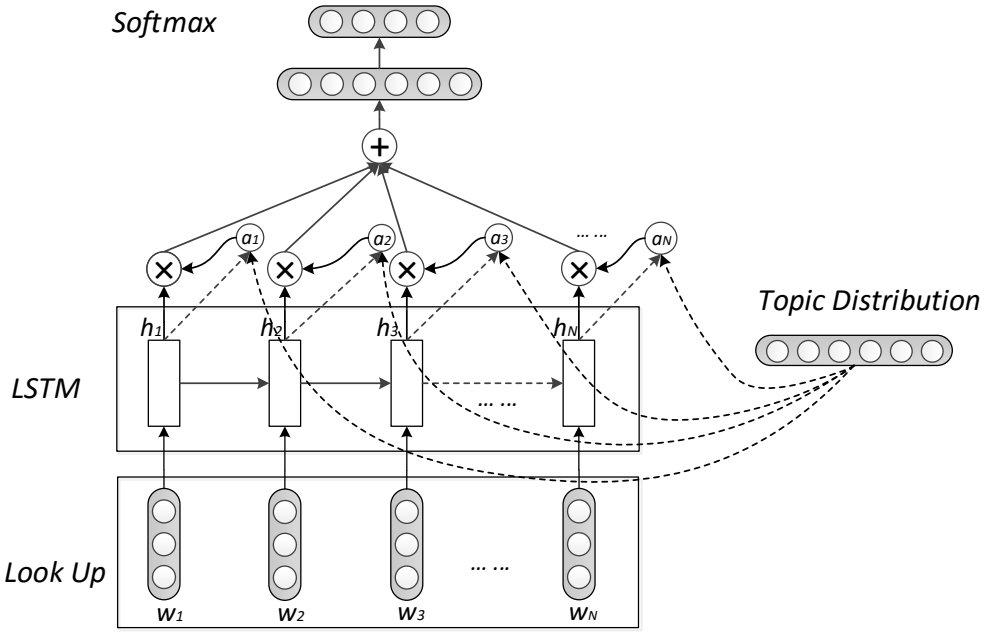

Figure 2: The graphical illustration of the proposed topical attention-based LSTM model (TAB-LSTM).

the output gate $\mathbf{o}_t$ together to generate the next output $\mathbf{h}_t$ and cell state $\mathbf{c}_t$. The transition equations of LSTM are defined as follows:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^i\mathbf{x}_t + \mathbf{U}^i\mathbf{h}_{t-1} + \mathbf{b}^i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}^f\mathbf{x}_t + \mathbf{U}^f\mathbf{h}_{t-1} + \mathbf{b}^f) \\
\mathbf{o}_t &= \sigma(\mathbf{W}^o\mathbf{x}_t + \mathbf{U}^o\mathbf{h}_{t-1} + \mathbf{b}^o) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tanh(\mathbf{W}^c\mathbf{x}_t + \mathbf{U}^c\mathbf{h}_{t-1} + \mathbf{b}^c) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned} \tag{1}$$

where $\odot$ stands for element-wise multiplication, σ is the sigmoid function, all $\mathbf{W} \in \mathbb{R}^{d\times l}$ and $\mathbf{U} \in \mathbb{R}^{d\times d}$ are weight matrices, all $\mathbf{b} \in \mathbb{R}^d$ are bias vectors.

The output of LSTM layer is a sequence of hidden vectors $[\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N]$. Each annotation $\mathbf{h}_t$ contains information about the whole input microblog with a strong focus on the parts surrounding the t-th word of the input microblog.

3.2 Topic Modeling

In TAB-LSTM, we propose an topical attention to introduce a series of attention-weighted combinations of these hidden vectors using the external topical distribution. We use LDA to learn the topic structures of microblogs and the model is trained offline. Specifically, given a set of microblog posts $\mathcal{S}$, where each post $s \in \mathcal{S}$ contains N_s words $\{w_{s,1}, w_{s,2}, ..., w_{s,N_s}\}$, LDA makes the following assumptions. There exist K topics, each associated with a multinomial word distribution φ_k. Each post has a topic distribution θ_s in the K-dimensional topic space. Each word in a microblog post has a hidden topic label drawn from the post's topic distribution. Formally, the generative process of LDA is described as follows:

- For each topic $k = 1, ..., K$, draw $\varphi_k \sim Dir(\beta)$
- For each microblog post $s \in \mathcal{S}$, draw $\theta_s \sim Dir(\alpha)$
  - For each word $w_{s,n}$, draw $z_{s,n} \sim Multi(\theta_s)$ and $w_{s,n} \sim Multi(\phi_{z_{s,n}})$

where α and β are parameters of the Dirichlet priors, θ_s is the topic distribution we will incorporate in our model.

3.3 Topical Attention

Taking all hidden states $[\mathbf{h}_1, \mathbf{h}_2, ..., \mathbf{h}_N]$ and the external topic vector $\theta_\mathbf{s} \in \mathbb{R}^{K\times 1}$, the topical attention layer outputs a continuous context vector $vec \in \mathbb{R}^{d\times 1}$ for each microblog post s. The output vector is computed as a weighted sum of each hidden state $\mathbf{h}_j$:

$$vec = \sum_{j=1}^{N} a_j \mathbf{h}_j \tag{2}$$

where d is the hidden dimension of LSTM, $a_j \in [0, 1]$ is the attention weight of $\mathbf{h}_j$ and $\sum_j a_j = 1$.

Next, we will introduce how we obtain $[a_1, a_2, ..., a_N]$ in detail. Specifically, for each $\mathbf{h}_j$, we use the following equation to compute scores on how well the inputs around position j and the topic distribution θ_s match:

$$g_j = v_a^\top \tanh(\mathbf{W^a}\theta_\mathbf{s} + \mathbf{U^a}\mathbf{h}_j) \tag{3}$$

where K is the number of topics, $\mathbf{W^a} \in \mathbb{R}^{d\times K}$, $\mathbf{U^a} \in \mathbb{R}^{d\times d}$ and $v_a \in \mathbb{R}^{d\times 1}$ are the weight matrices. After obtaining $[g_1, g_2, ..., g_N]$, we feed them to a $softmax$ function to calculate the final weight scores $[a_1, a_2, ..., a_N]$.

Finally, we use the output from the topical attention layer as the embedding of the microblog from our deep neural network. We feed the output vector vec to a linear layer whose output length is the number of hashtags. Then a softmax layer is added to output the probability distributions of all candidate hashtags. The softmax function is calculated as follows, where M is the number of hashtag categories:

$$softmax(m_i) = \frac{exp(m_i)}{\sum_{i'=1}^{M} exp(m_{i'})} \tag{4}$$

3.4 Model Training

We model hashtag recommendation as a multi-class classification task. We train our model in a supervised manner by minimizing the cross-entropy error of the hashtag classification. The loss function is given below:

$$\mathcal{J} = -\sum_{s\in S} \sum_{t\in tags(s)} \log p(t|s) \tag{5}$$

where S stands for all training instances, $tags(s)$ is the hashtag collection for microblog s.

4 Experiments

We apply the proposed method to the task of hashtag recommendation to evaluate the performance. In this section, we first describe our dataset and experimental settings, then the results and analysis.

4.1 Dataset

Our dataset is constructed from a large Twitter dataset which spans the second half of 2009 (Yang and Leskovec, 2011). We collect a dataset with 185,391,742 tweets from October to December 2009. Among them, there are 16,744,189 tweets including hashtags annotated by users. We randomly select 500,000 tweets as training set, 50,000 tweets as development and test set respectively. The statistics of our dataset is shown in Table 1.

# Tweets	# Hashtags	Vocabulary Size	Nt(avg)
600,000	27,720	337,245	1.308

Table 1: Statistics of the dataset, Nt(avg) is the average number of hashtags in the dataset.

4.2 Experimental Settings

4.2.1 Baseline Methods

For comparison, we consider the following baseline methods:

• **LDA**: We use the LDA based method proposed by Krestel et al. (2009) to recommend hashtags.

• **SVM**: We build a multi-class SVM classification model (Hearst et al., 1998) with LibSVM. The feature we use are word embedding features with 300 dimension. We believe that comparing to Bag-of-words, word embedding features can capture deep semantic information of the microblog posts. SVM parameters are chosen by grid search on the development set.

• **TTM**: The topical translation model is proposed by Ding et al. (2013) for hashtag extraction. We implement their method for evaluating it on the corpus constructed in this work.

• **LSTM**: We regard the last hidden vector from LSTM as the microblog representation. Then we feed it to a linear layer whose output length is the number of hashtags. Finally, a softmax layer is added to output the probability distributions of all candidate hashtags.

We also compare two degenerate versions of our model TAB-LSTM as follows.

• **AVG-LSTM**: We perform an average pooling operation on the hidden vectors at each position of LSTM that processes a post, and use the result as the representation of that post.

• **VAB-LSTM**: In this model, we use the last hidden vector from the LSTM that processes a post as the global representation of that post and incorporate attentions to measure the interactions between each word and the global representation. This method is similar to our model except that we replace the topic distribution θ_s with the last hidden vector h_N in Equation (3).

4.2.2 Experimental Setup

We perform hashtag recommendation as follows. Suppose given an unlabeled dataset, we first train our model on training data, and save the model which has the best performance on the validate dataset. For the microblog of the unlabeled data, we will encode the microblog post through our proposed model. We train four types of neural models including LSTM, AVG-LSTM, VAB-LSTM and our proposed model TAB-LSTM. For each of the above models, the sentences of length is up to 40 words. We set the dimension of all the hidden states of the LSTMs to be 500. We use a minibatch stochastic gradient descent (SGD) algorithm together with the Adam method to train each model (Kingma and Ba, 2014). The hyperparameters $\beta 1$ is set to 0.9 and $\beta 2$ set to 0.999 for optimization. The learning rate is set to be 0.001. The batch size is set to be 100. For TAB-LSTM, we tested with different numbers of LDA topic size K and found $K = 100$ is an optimal setting.

For both our models and the baseline methods, we use the validation data to tune the hyperparameters, we report the results of the test data in the same setting of hyperparameters. Furthermore, the word embeddings used in all methods are pre-trained from the original twitter data released by (Yang and Leskovec, 2011) with the word2vec toolkit (Mikolov et al., 2013).

We use hashtags annotated by users as the golden set. To evaluate the performance, we use precision (P), recall (R), and F1-score (F) as the evaluation metrics. The same settings are adopted by previous work (Ding et al., 2012; Ding et al., 2013; Gong et al., 2015).

4.3 Comparison to Other Methods

In Table 2, we compare the results of our method and the state-of-the-art discriminative and generative methods on the dataset. TAB-LSTM denotes our proposed model. We have the following observations. (1) First of all, SVM performs much better than LDA, showing that the embedding features capture more semantic information than bag-of-words (BoW). (2) Both TAB-LSTM and the degenerate models significantly outperform the baseline methods LDA, SVM and TTM. The results demonstrate that the neural network can achieve better performance on this task. (3) If we compare TAB-LSTM with LSTM and AVG-LSTM, we can see that TAB-LSTM improves the F1-score by nearly 7.4% in the same setting of parameters, showing that incorporating attention mechanism is useful. (4) Using topical attention, TAB-LSTM outperforms VAB-LSTM, which shows the effectiveness of topic information for this task.

Methods	Precision	Recall	F1-score
LDA	0.098	0.078	0.087
SVM	0.238	0.203	0.219
TTM	0.324	0.280	0.300
LSTM	0.470	0.404	0.434
AVG-LSTM	0.472	0.405	0.436
VAB-LSTM	0.489	0.419	0.452
TAB-LSTM	**0.503**	**0.435**	**0.467**

Table 2: Evaluation results of different methods for hashtag recommendation. The dimension of word embeddings is set to be 300 for all methods. All improvements obtained by TAB-LSTM over other methods are statistically significant within a 0.99 confidence interval using the t-test.

Considering that many microblog posts have more than one hashtags, we also evaluate the top k results of different methods. Figure 3 shows the precision, recall, and F1 curves of LDA, SVM, TTM, LSTM and TAB-LSTM on the test data. Each point of a curve represents the extraction of a different number of hashtags, ranging from 1 to 5. From Figure 3, we can see although the precision and F1-score of TAB-LSTM decreases when the number of hashtags is larger, the performance of TAB-LSTM still outperforms the other methods. In addition, the relative improvement on extracting only one hashtag is higher than that on more than one hashtags, showing that it is more difficult to recommend hashtags for a microblog post with more than one hashtags.

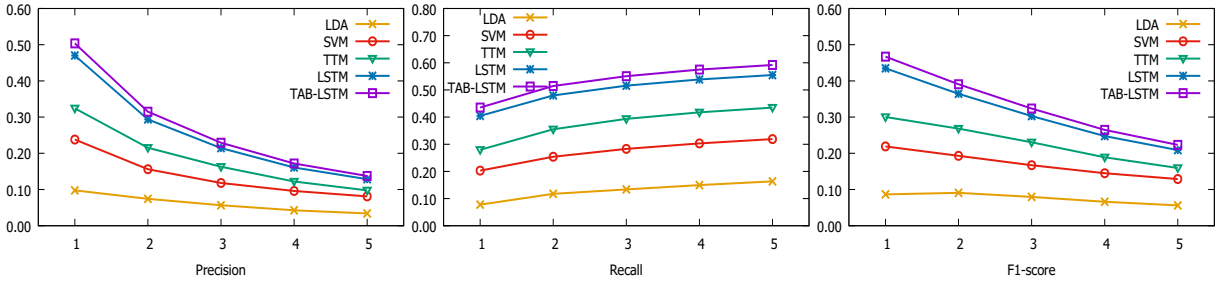

Figure 3: Precision, Recall and F1 with recommended hashtags range from 1 to 5.

4.4 Parameter Sensitive Analysis

We further investigate the effect of hyperparameters to the performance. First, we vary the values of topic size K while fixing the other parameters. We've tried various settings with $K = 50, 100, 150, 200$ when training the topic models with LDA. Results in Table 3 show that the best results are achieved when K is larger than 100.

Methods	Precision	Recall	F1-score
Attn50	0.492	0.422	0.454
Attn100	0.503	0.435	0.467
Attn150	0.501	0.432	0.464
Attn200	0.499	0.431	0.463

Table 3: Precision, Recall and F1 of TAB-LSTM with different number of topics when the dimension of word vectors is set to be 300.

It is well accepted that a good word embedding is crucial to composing a powerful text representation at a higher level. Next, we would like to study the effects of different word embeddings. Table 4 shows

the precision, recall and F1-score when we vary the dimension of word embeddings. We find a larger dimension of word embedding is more effective for this task.

Methods	Precision	Recall	F1-score
Emb50	0.470	0.403	0.434
Emb100	0.487	0.419	0.450
Emb200	0.495	0.425	0.457
Emb300	0.503	0.435	0.467

Table 4: Precision, Recall and F1 of TAB-LSTM with different dimension of word embeddings when the number of topics is 100.

4.5 Qualitative Analysis

We also perform qualitative analysis of our results. In Figure 4, we compare the attention heat maps learned by TAB-LSTM and VAB-LSTM of two example microblog posts. In the first example, hashtag #H1N1 is correctly recommended by TAB-LSTM because the word *H1N1* is selected by the topic of this post, while in the case of VAB-LSTM, H1N1 is not selected. In the second example, both hashtags are correctly predicted by TAB-LSTM, while VAB-LSTM missed the word "ff", which is short for #followfriday.

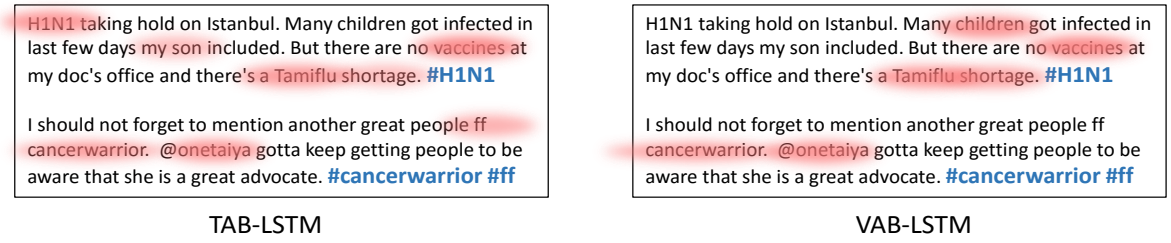

Figure 4: Attention heat maps for two example microblog posts.

5 Related Work

There has been a variety of work proposed for hashtag recommendation in the past few years. Zangerle et al. (2011) exploit the similarity between tweets. For a given tweet, they first retrieve its similar tweets and then rank the hashtags by their usage on the most similar tweets. Sedhai and Sun (2014) formulate hashtag recommendation task as a learning to rank problem. They represent each candidate hashtag as a feature vector and use pairwise learning to rank method to find the top ranked hashtags from the candidate set. Mazzia and Juett (2009) apply a Naive Bayes model to estimate the maximum a posteriori probability of each hashtag class given the words of the tweet. Furthermore, Godin et al. (2013) propose to incorporate topic models to learn the underlying topic assignment of language classified tweets, and suggest hashtags to a tweet based on the topic distribution. Under the assumption "hashtags and tweets are parallel description of a resource" that proposed by Liu et al. (2011), Ding et al. try to integrate latent topical information into translation model. The model uses topic-specific word trigger to bridge the vocabulary gap between the words in tweets and hashtags (Ding et al., 2012; Ding et al., 2013).

Most of the works mentioned above are based on textual information. There have also been some attempts that combine text with other types of data. Kywe et al. propose a collaborative filtering model to incorporate user preferences in hashtag recommendation (Kywe et al., 2012). Besides that, Zhang et al. (2014) and Ma et al. (2014) try to incorporate temporal information. Gong et al. (2015) propose to model type of hashtag as a hidden variable into their DPMM (Dirichlet Process Mixture Models) based method.

More recently, Gong and Zhang (2016) propose an attention-based convolutional neural network, which incorporates a local attention channel and global channel for hashtag recommendation. However, to the best of our knowledge, there is no work yet on employing both topic models and deep neural networks for this task.

6 Conclusion

In this paper, we investigated a novel topical attention-based LSTM model for the task of hashtag recommendation. We adopted the architecture of LSTM to avoid hand-crafted features. Our model incorporates topic modeling into the LSTM architecture through an attention mechanism and takes over the advantages of the both. Through evaluations run on a large dataset from Twitter, we have demonstrated that the proposed method outperforms competitive baseline methods effectively.

The present work does not consider the use of other types of data in microblogs for hashtag recommendation. In the future, other types of data such as user information and temporal information can be incorporated into the model. We will also consider using alternative topic models which are particularly designed for short microblog texts such as Twitter-LDA (Zhao et al., 2011).

Abstract

We present a novel way for designing complex joint inference and learning models using *Saul* (Kordjamshidi et al., 2015), a recently-introduced declarative learning-based programming language (DeLBP). We enrich *Saul* with components that are necessary for a broad range of learning based Natural Language Processing tasks at various levels of granularity. We illustrate these advances using three different, well-known NLP problems, and show how these generic learning and inference modules can directly exploit *Saul*'s graph-based data representation. These properties allow the programmer to easily switch between different model formulations and configurations, and consider various kinds of dependencies and correlations among variables of interest with minimal programming effort. We argue that *Saul* provides an extremely useful paradigm both for the design of advanced NLP systems and for supporting advanced research in NLP.

1 Introduction

Most of the problems in natural language processing domain can be viewed as a mapping from an input structure to an output structure that represents lexical, syntactical or semantic aspects of the text. For example, Part-of-Speech (POS) tagging provides a syntactic representation, Semantic Role Labeling (SRL) is a (shallow) semantic representation, and all variations of information extraction such as Entity-Relation (ER) extraction provide a lightweight semantic representation of unstructured textual data. Even though the text data looks initially unstructured, solving such problems requires one to consider various kinds of relationships between linguistic components at multiple levels of granularity.

However, designing machine learning models that deal with structured representations is a challenging problem. Using such representations is challenging in that designing a new learning model or tackling a new task requires a significant amount of task-specific and model-specific programming effort for learning and inference. Additionally, global background knowledge in these models is usually hard-coded, and changing or augmenting it is extremely time-consuming. There are several formal frameworks (Tsochantaridis et al., 2004; Chang et al., 2013) for training structured output models but these provide no generic solution for doing inference on arbitrary structures. Likewise, probabilistic programming languages (Pfeffer (2009), McCallum et al. (2009) *inter alia*) try to provide generic probabilistic solutions to arbitrary inference problems but using them in the context of training arbitrary structured output prediction models for real world problems is a challenge; in addition, encoding structured features and high-level background knowledge necessary for these problems is not a component of those frameworks.

In this paper we build on the abstractions made available in *Saul* programming language (Kordjamshidi et al., 2015), in order to create a unified and flexible machine learning programming framework using the generic Constrained-Conditional-Model (CCM) paradigm (Chang et al., 2012).

Specifically, we build upon *Saul*'s graph-based data representation and enrich it with primitive structures and *sensors* for the NLP domain that facilitate operating at arbitrary levels of 'globality' for learning and inference. For example, a programmer can easily decide if he or she needs to operate at document,

[*] Most of the work was performed at the University of Illinois.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3030–3040, Osaka, Japan, December 11-17 2016.

sentence, or phrase level. In other words, without any programming effort the user can specify at which level of granularity the context should be considered, and how 'global' should learning and inference be. This ability also better supports the declarative specification of the structured features and is useful in a wide range of tasks that involve mapping the language to its syntactic or semantic structure. Using this new framework, we show how one can design structured output prediction models in an easy and flexible way for several well-known and challenging NLP tasks and achieve comparable results to the existing state-of-the-art models.

The paper is structured as follows: Section 2, describes the general formulation used for structured output prediction and its possible configurations. Section 3 explains how the structured input and output spaces are represented as a graph, the form of the objective and the way arbitrary dependencies can be represented in *Saul*. In Section 4, various model configurations are presented for our case study tasks, alongside experimental results. Section 5 provides a brief overview of related work. Section 6 concludes.

2 Structured Output Prediction

Punyakanok et al. (2005) describe three fundamentally different and high level solutions towards designing structured output prediction models,

(a) **Learning Only (LO):** Local classifiers are trained to predict each output component independently;

(b) **Learning plus inference (L+I):** Training is performed locally as in the LO model, but global constraints/dependencies among components are imposed during prediction (Chang et al., 2012). In the context of training probabilistic graphical models this is referred to as *piecewise training* (Sutton and McCallum, 2009);

(c) **Inference based training (IBT):** Here, during the training phase, predictions are made globally so that constraints and dependencies among the output variables are incorporated into the training process (Collins, 2004; Taskar et al., 2002; Tsochantaridis et al., 2004).

When training structured output models there is a spectrum of *configurations* (model compositions) between the two extremes – only local training as in the LO and L+I schemes and the full global training as in the IBT scheme (Samdani and Roth, 2012). The key here is choosing the best decomposition of the variables/structures which is largely an empirical question; having an expressive and flexible machinery for modeling the data and for learning from it is thus useful and eases in designing, assessing, decomposing and improving the models (Kordjamshidi and Moens, 2013). With this as motivation, we aim here to enrich *Saul* with components that facilitate these analyses in the NLP domain (see Section 4).

We first introduce the notation and the formal framework for designing global (IBT) models in *Saul*. In supervised *structured* learning we are given a set of examples i.e. pairs of input and output, $E = \{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)}) \in \mathcal{X} \times \mathcal{Y} : i = 1 \dots N\}$, where both inputs ($\mathcal{X}$) and outputs ($\mathcal{Y}$) can be complex structures; the goal is learning the mapping, $g : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbb{R}$ (Bakir et al., 2007). Making predictions in this formulation requires an inference procedure over g, that finds the best $\hat{\boldsymbol{y}}$ for a given $\boldsymbol{x}$. Thus the prediction function h is, $h(\boldsymbol{x}; \boldsymbol{w}) = \arg\max_{\hat{\boldsymbol{y}} \in \mathcal{Y}} g(\boldsymbol{x}, \boldsymbol{y}; \boldsymbol{w})$. In the generalized linear models (Tsochantaridis et al., 2005), the function g is assumed to be a linear model of the input and output features $f(\boldsymbol{x}, \boldsymbol{y})$, i.e. $g(\boldsymbol{x}, \boldsymbol{y}; \boldsymbol{w}) = \langle \boldsymbol{w}, f(\boldsymbol{x}, \boldsymbol{y}) \rangle$, where $\boldsymbol{w}$ denotes the parameters of the model (weight vector). A commonly used discriminative training method is to minimize the following convex upper bound of the loss function over the training data (Tsochantaridis et al., 2004):

$$L = \sum_{i=1}^{N} \max_{\hat{\boldsymbol{y}} \in \mathcal{Y}} \Big[g(\boldsymbol{x}^i, \hat{\boldsymbol{y}}; \boldsymbol{w}) - g(\boldsymbol{x}^i, \boldsymbol{y}^i; \boldsymbol{w}) + \Delta(\boldsymbol{y}^i, \hat{\boldsymbol{y}}) \Big]$$

The inner maximization is called loss-augmented inference and quantifies the most violated output per training example. This is a crucial inference problem to be solved during training of such models. Here we assume that the distance function Δ is decomposed in the same way as the feature function. During training and at prediction time, there is a need to solve the same inference problem to find the best $\hat{\boldsymbol{y}}$

given the objective $g(\boldsymbol{x}, \boldsymbol{y}; \boldsymbol{w})$. This will be the focus of the paper: to show how we can write high level specifications of g and model it in a generic, efficient and flexible fashion.

3 Graph Representation

Saul is a powerful programming paradigm which uses graphs to explicitly declare the structure of the data that serves as the model of the domain. This graph is called *data-model*[1] and is comprised of nodes, edges and properties that describe nodes. The *data-model* is a global structure that facilitates designing a wide range of learning and inference *configurations*, based on arbitrary model decompositions.

Inputs $\boldsymbol{x}$ and outputs $\boldsymbol{y}$ are sub-graphs of the *data-model* and each learning model can pick specific correlations and substructures from it. In other words, $\boldsymbol{x}$ is a set of nodes $\{x_1, \ldots, x_K\}$ and each node has a *type* p. Each $x_k \in \boldsymbol{x}$ is described by a set of properties; this set of properties will be converted to a feature vector ϕ_p. For instance, an input type can be a word (*atomic node*) or a pair of words (*composed node*), and each type is described by its own properties (e.g. a single word by its part of speech, the pair by the distance of the two words). The output $\boldsymbol{y}$ is represented by a set of *labels* $\boldsymbol{l} = \{l_1, \ldots, l_P\}$ each of which is a *property* of a node. The labels can have semantic relationships. We conceptually (not technically) distinguish between two types of labels: the *single labels* and *linked labels* that refer to an independent concept and to a configuration of a number of related single labels respectively. *Linked label*s can represent different types of semantic relationships between single labels.

For convenience, to show which labels are connected by a *linked label*, we represent the *linked labels* by a concatenation of the labels' names that are linked together and construct a bigger semantic part of the whole output. For example an SRL predicate-argument relation (see Figure 1 in Section 4) can be denoted by *pred-arg* meaning that it is *composed-of* the two single labels, *pred* (predicate), and *arg* (argument). The labels are defined with a graph query that extracts a property from the *data-model*. The $l_p(x_k)$ or shorter l_{pk} denotes an indicator function indicating whether component x_k has the label l_p. Kordjamshidi et al. (2015) introduced the term *relational constrained factor graph* to represent each possible learning and inference configuration (Taskar et al., 2002; Taskar et al., 2004; Bunescu and Mooney, 2007; Martins et al., 2011).

The structure of the learning/inference i.e. the relational constraint factor graph is specified with a set of *templates* which can be constraint templates or feature templates, $\mathcal{C} = \{\mathcal{C}_1, .., \mathcal{C}_P\}$. Each template $\mathcal{C}_p \in \mathcal{C}$ is specified by three main components: 1) *A subset of joint features*, denoted by $f_p(\boldsymbol{x}_k, l_p)$, where $\boldsymbol{x}_k$ is an input component that is a node in the *data-model* graph, and l_p is a single/linked label (a property in the *data-model*). In the case of constraint templates, l_p is a Boolean label denoting the satisfiability of the constraint. 2) *A candidate generator*, that generates candidate components upon which the specified subset of joint features is applicable, the set of candidates for each template is denoted by C_{l_p}. For constraint templates the candidate generator is the propositionalization of the constraint's first-order logical expression. 3) *A block of weights* $\boldsymbol{w}_p$, which is a part of the main weight vector $\boldsymbol{w}$ of the model and is associated to the local joint feature function of $\mathcal{C}_p$. In general, $\boldsymbol{w}_p$ can also be defined for the constraint templates. The main objective g is written in terms of the instantiations of the (feature) templates and their related blocks of weights $\boldsymbol{w}_p$ in $\boldsymbol{w} = [\boldsymbol{w}_1, \boldsymbol{w}_2, \ldots, \boldsymbol{w}_P]$,

$$g(\boldsymbol{x}, \boldsymbol{y}; \boldsymbol{w}) = \sum_{l_p \in \boldsymbol{l}} \sum_{x_k \in C_{l_p}} \langle \boldsymbol{w}_p, f_p(x_k, l_p) \rangle = \sum_{l_p \in \boldsymbol{l}} \sum_{x_k \in C_{l_p}} \langle \boldsymbol{w}_p, \phi_p(x_k) \rangle \, l_{pk} = \sum_{l_p \in \boldsymbol{l}} \left\langle \boldsymbol{w}_p, \sum_{x_k \in C_{l_p}} (\phi_p(x_k) l_{pk}) \right\rangle, \quad (1)$$

where the local joint feature vector $f_p(\boldsymbol{x}_k, l_p)$, is an instantiation of the template $\mathcal{C}_{l_p}$ for candidate $\boldsymbol{x}_k$. This feature vector is computed by scalar multiplication of the input feature vector of $\boldsymbol{x}_k$ (i.e. $\phi_p(\boldsymbol{x}_k)$), and the output label l_{pk}.

Given this objective, we can view the inference task as a *combinatorial constrained optimization* given the polynomial g which is written in terms of labels, subject to the constraints that describe the relationships between the labels (either single or linked labels). For example, the *is-a* relationships can be defined as the following constraint, $(l(\boldsymbol{x}_c)\ is\ 1) \Rightarrow (l'(\boldsymbol{x}_c)\ is\ 1)$, where l and l' are two distinct

[1] Kordjamshidi et al. (2015) used the term *model-graph*.

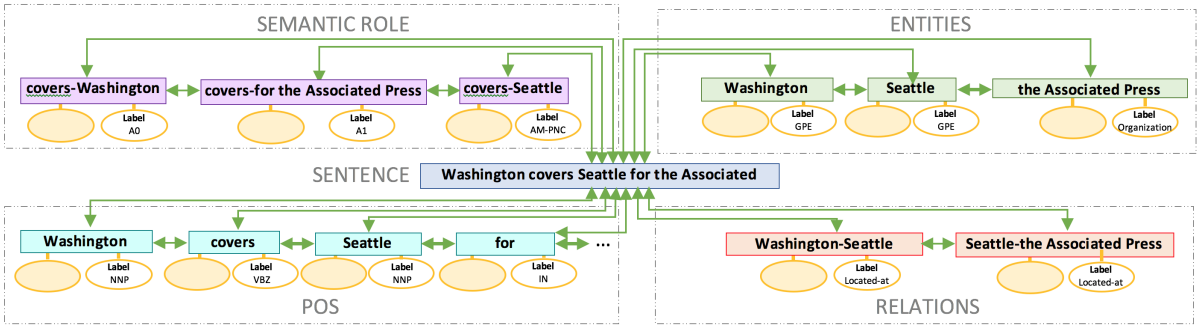

Figure 1: An instantiation of the *data-model* for the NLP domain. The colored ovals are some observed properties, while the white ones show the unknown labels. For the POS and Entity Recognition tasks, the boxes represent candidates for *single labels*; for the SRL and Relation Extraction tasks, they represent candidates for *linked labels*.

labels that are applicable on the node with the same type of $\boldsymbol{x}_c$. These constraints are added as a part of *Saul*'s objective, so we have the following objective form, which is in fact a constrained conditional model (Chang et al., 2012), $g = \langle \boldsymbol{w}, f(\boldsymbol{x}, \boldsymbol{y}) \rangle - \langle \rho, c(\boldsymbol{x}, \boldsymbol{y}) \rangle$, where c is the constraint function and ρ is the vector of penalties for violating each constraint. This representation corresponds to an integer linear program, and thus can be used to encode any MAP problem. Specifically, the g function is written as the sum of local joint feature functions which are the counterparts of the probabilistic factors:

$$g(\boldsymbol{x}, \boldsymbol{y}; \boldsymbol{w}) = \sum_{l_p \in \boldsymbol{l}} \sum_{\boldsymbol{x}_k \in \{\tau\}} \langle \boldsymbol{w}_p, f_p(\boldsymbol{x}_k, l_{pk}) \rangle + \sum_{m=1}^{|C|} \rho_m c_m(\boldsymbol{x}, \boldsymbol{y}), \tag{2}$$

where C is a set of global constraints that can hold among various types of nodes. g can represent a general scoring function rather than the one corresponding to the likelihood of an assignment. The constraints are used during training for loss-augmented inference as well as during prediction.

4 Calling *Saul*: Case Studies

For **programming global models** in *Saul* the programmer needs to declare a) the *data-model* which is a global structure of the data and b) the templates for learning an inference decompositions. The templates are declared intuitively in two forms of classifiers using `Learnable` construct and first order constraints using `ConstrainedClassifier` construct. With these components have been specified, the programmer can easily choose which templates to use for learning (training) and inference (prediction). In this way the global objective is generated automatically for different training and testing paradigms in the spectrum of local to global models.

One advantage of programming in *Saul* is that one can define a generic *data-model* for various tasks in each application domain. In this paper, we enrich *Saul* with an NLP *data-model* based on EDISON, a recently-introduced NLP library which contains raw data readers, data structures and feature extractors (Sammons et al., 2016) and use it as a collection of *Sensors* to easily generate the *data-model* from the raw data. In *Saul*, a *Sensor* is a 'black-box' function that can generate nodes, edges and properties in the graph. An example of a sensor for generating nodes and edges is a sentence tokenizer which receives a sentence and generates its tokens. Here, we will provide some examples of *data-model* declaration language but more details are available on-line[2].

In the rest of the paper, we walk through the tasks of Semantic Role Labeling (SRL), Part-of-Speech (POS) tagging and Entity-Relation (ER) extraction and show how we can design a variety of local to global models by presenting the related code[3].

[2]https://github.com/IllinoisCogComp/saul/blob/master/saul-core/doc/DATAMODELING.md
[3]https://github.com/IllinoisCogComp/saul/tree/master/saul-examples/src/main/scala/edu/illinois/cs/cogcomp/saulexamples/nlp

```
val sentences = node[TextAnnotation]
val predicates = node[Constituent]
val arguments = node[Constituent]
val pairs =  node[Relations]
val pos-tag = property(arguments)
val word-form = property(arguments)
val relationsToArguments = edge(relations, arguments)
relationsToArguments.addSensor(relToArgument _)
```

Figure 2: An Example of *data-model* declarations for nodes, edges, properties and using sensors. The `sentences` nodes are of type `TextAnnotation` class, which is a part of *Saul*'s underlying NLP library; many predefined sensors can be applied on it to generate various nodes of type `Constituent` and `Relations`, properties of those nodes and establish edges between them.

4.1 Semantic Role Labeling

SRL (Carreras and Màrquez, 2004) is a shallow semantic analysis framework, whereby a sentence is analysed into multiple propositions; each one consisting of a predicate and one or more core arguments, labeled with protosemantic roles (agents [Arg0], patient/theme [Arg1], beneficiary [Arg2], etc.), and zero or more optional arguments, labeled according to their semantic function (temporal, locative, manner, etc.). See Figure 1 for an example annotation.

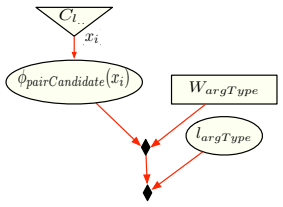
4.1.1 Input-Output Spaces

Each sentence is a node in the *data-model*, comprised of *constituents* (derived from a tokenizer *Sensor*). These constituents are atomic components of $\boldsymbol{x}$ (see Figure 1) and are identified as $\boldsymbol{x} = \{x_1, \ldots, x_4\}$, where x_i is the identifier of the ith constituent in the sentence. Each constituent is described by a number of properties (word-form, pos-tag, ...) and the corresponding feature vector representation of these properties is denoted by $\phi_{constituent}(x_i)$. There are also composed components – pairs of constituents; their descriptive vectors are referred to as $\phi_{pair}(x_i, x_j)$. The feature vector of a composed component such as a pair, $\phi_{pair}(x_1, x_2)$ is usually described by the local features of x_1, x_2 and the relational features between them, such as the order of their position, etc.

The main labels set for the SRL model is $\boldsymbol{l} = \{l_{isPred}, l_{isArg}, l_{argType}\}$ which indicate whether a constituent is a predicate, whether it is an argument and the argument role respectively. l_{isArg} and $l_{argType}$ are *linked labels*, meaning that they are defined with respect to another constituent (the predicate). Depending on the type of correlations we aim to capture, we can introduce new *linked labels* in the model. These labels are not necessarily the target of the predictions but they help to capture the dependencies among labels. For example, to capture the long distance dependencies between two different arguments of same predicate we can introduce a *linked label* linking the label of two pairs and impose consistency constraints between this new *linked label* and the label of each pair. Figure 2 shows some declarations of the *data-model*'s graph representing input and output components of the learning models. The graph can be queried using our invented graph traversal language and the queries are directly used as structured machine learning features later.

4.1.2 Classifiers and Constraints

As mentioned in Section 3, the structure of a learning model is specified by templates which are defined as classifiers (feature templates) and global constraints (constraint templates) in *Saul*. SRL has four main feature templates: 1) *Predicate* template: connects an input constituent to a single label l_{isPred}. The input features of this template are generated based on the properties of the constituents $\phi_{constituent}$. The candidate generator of this template is a filter that takes all constituents whose pos-tag is *VP*; 2) *Argument* template: connects a pair of constituents to a *linked label* l_{isArg}. The candidate generator of this template is a set of rules that are suggested by Xue and Palmer (2004); 3) *ArgumentType* template: connects a pair of constituents to the linked label $l_{argType}$. Same Xue-Palmer heuristics are used; 4) *ArgumentTypeCorrelations* template: connects two pairs of pairs of constituent (i.e. relations between relations) to their join linked label. The candidates are the pairs of Xue-Palmer candidates.



```
object ArgTypeLearner extends Learnable(pairs){
    def label = argumentLabelGold
    def feature = using(containsMOD, containsNEG,
    clauseFeatures, chunkPathPattern, chunkEmbedding,
    chunkLength, constituentLength, argPOSWindow,
    argWordWindow, headwordRelation, syntacticFrameRelation
    , pathRelation, phraseTypeRelation, predPosTag,
    predLemmaR, linearPosition)
}
```

Figure 3: Left: shows the components of the *ArgumentType* feature template. $l_{argType}$ is one *linked label* as a part of the objective in Equation 1, along with the corresponding block of weights and the `pair` candidates (diamonds show dot products). Right: shows the code for the template. `label` and `feature` are respectively one property and a list of properties of `pair` nodes declared in the *data-model*, these serve as the output and input parts of this template. This template can be used as a local classifier or as a part of the objective of a global model, depending on the indicated learning paradigm by the programmer.

```
val legalArgumentsConstraint = constraint(sentences) { x =>
    val constraints = for {
      predicate <- sentences(x) ~> sentenceToPredicates
      candidateRelations = (predicates(y) ~> -relationsToPredicates)
      argLegalList = legalArguments(y)
      relation <- candidateRelations
    } yield classiferLabelIsLegal(argumentTypeLearner, relation, argLegalList)
        or (argumentTypeLearner on relation is "none")
}

def classiferLabelIsLegal(classifier, relation, legalLabels) = {
    legalLabels._exists { l => (classifier on relation is l) }
}
```

Figure 4: Given a predicate, some argument types are illegal according to PropBank Frames (e.g. the verb 'cover' with sense 03 can take only Arg0 or Arg1), which means that they should be excluded from the inference. The `legalArguments(y)` returns the predefined list of legal arguments for a predicate y. In line 3, graph traversal queries (using the $\sim>$ operator) are applied to use an edge and go from a *sentence* node to all contained predicate nodes in the sentence and then apply the constraint to all of those predicates. Each constraint imposes the `argumentTypeLearner` to assign a legal argument type to each candidate argument or does not count it as an argument at all, i.e., to assign `none` value to the argument type.

The feature templates are instances of `Learnable` in *Saul* and in fact they are treated as local classifiers. The script of Figure 3 shows the *ArgumentType* template. The *Constraints* are specified by means of first-order logical expressions. We use the constraints specified in Punyakanok et al. (2008) in our models. The script in Figure 4, shows an example expressing the *legal argument* constraints for a sentence.

4.1.3 Model Configurations

Programming for learning and inference configurations in *Saul* is simply composing the basic building blocks of the language, that is, feature and constraint templates in different ways.

Local models. Training local models is as easy as calling the train function over each specified feature template separately (e.g. `ArgTypeLearner.train()`). The test on these models also is simply done by calling test for each template (e.g. `ArgTypeLearner.test()`). In addition, `TestClassifeirs(/*a list of classifiers*/)` and `TrainClassifiers(/*a list of classifiers*/)` can be used to train/test a number of classifiers independently by passing a list of classifier's names to these functions. The training algorithm can be specified when declaring the `Learnable`; here we have used averaged perceptrons in the experiments which is the default model.

Model	Precision	Recall	F1
ArgTypeLearner^{G}(GOLDPREDS)	85.35	85.35	85.35
ArgTypeLearner^{G}(GOLDPREDS) + C	85.35	85.36	85.35
ArgTypeLearner^{Xue}(GOLDPREDS)	82.32	80.97	81.64
ArgTypeLearner^{Xue}(GOLDPREDS) + C	82.90	80.70	81.79
ArgTypeLearner^{Xue}(PREDPREDS)	82.47	80.79	81.62
ArgTypeLearner^{Xue}(PREDPREDS) + C	83.62	80.54	82.05
ArgIdentifier^{Xue} | ArgTypeLearner^{Xue}(PREDPREDS)	82.55	81.59	82.07
ArgIdentifier^{G}(PREDPREDS)	95.51	94.19	94.85

Table 1: Evaluation of SRL various labels and configurations. The superscripts over the different Learners refer to the whether gold argument boundaries (G) or the Xue-Palmer heuristics (Xue) were used to generate argument candidates as input. GOLD/PREDPREDS refers to whether the Learner used gold or predicted predicates. 'C' refers to the use of constraints during prediction and |denotes the pipeline architecture.

Pipeline. Previous research on SRL (Punyakanok et al., 2008) shows that a good working model is the one that first decides on argument identification and then takes those arguments and decides about their roles. This configuration is made with a very minor change in the templates of the local models. Instead of using Xue-Palmer candidates, we can use the identified arguments by a isArgument classifier as input candidates for the ArgTypeLearner model. The rest of the model is the same.

L+I model. This is simply a locally trained classifier that uses a number of constraints on prediction time. We define a constrained argument predictor based on a previously trained local *Learnable* as follows:

```
object ArgTypeConstraintClassifier extends ConstrainedClassifier(ArgTypeLearner)
{
    def subjectTo = srlConstraints
}
```

where the srlConstraints is a constraint template. Having this definition we only need to call the ArgTypeConstraintClassifier constraint predictor during the test time as ArgTypeConstraintClassifier(x) which decides for the label of x in a global context.

IBT model. The linguistic background knowledge about SRL that is described in Section 4.1.2 provides the possibility of designing a variety of global models. The constraints that limit the argument arrangement around a specific predicate help to make sentence level decisions for each predicate during training phase and/or prediction phase. To train the global models we simply call the joint train function and provide the list of all declared constraint classifiers as parameters.

The results of some versions of these models are shown in Table 1. The experimental settings, the data and the train/test splits are according to (Punyakanok et al., 2008) and the results are comparable. As the results show the models that use constraints are the best performing ones. For SRL the global background knowledge on the arguments in IBT setting did not improve the results.

4.2 Part-Of-Speech Tagging

This is perhaps the most often used application in ML for NLP. We use the setting proposed by Roth and Zelenko (1998) as the basis for our experiments. The graph of an example sentence is shown in Figure 1. We model the problem as a single-node graph representing constituents in sentences. We make use of context window features and hence our graph has edges between each token and its context window. This enables us to define contextual features by traversing the relevant edges to access tokens in the context. The following code uses the gold POS-tag label (POSLabel) of the two tokens before the current token during training and POS-tag classifier's prediction (POSTaggerKnown) of the two tokens before the current token during the test.

```
val labelTwoBefore = property(tokens) { x: Constituent =>
  // Use edges to jump to the previous constituent
  val cons = (tokens(x) ~> constituentBefore ~> constituentBefore).head
  if (POSTaggerKnown.isTraining)
    POSLabel(cons)
  else POSTaggerKnown(cons)
}
```

4.2.1 Model configurations

Here, we point to a few interesting settings for this problem and report the results we obtained by *Saul* in Table 2.

Count-based baseline. The simplest scenario is to create a simple count-based baseline: for each constituent choose the most popular label. This is trivial to program in *Saul*.

Independent classifiers. We train independent classifiers for known and unknown words. Though both classifiers use similar sets of features, the unknown classifier is trained only on tokens that were seen fewer than 5 times in the training data. Here the 'Learnable' is defined as exampled in Section 4.1.2.

Classifier combination. Given the known and unknown classifiers, one easy extension is to combine them, depending whether the input instance is seen during the training phase or not. To code this, the defined Learnables for the two classifiers are simply reused in an 'if' construct.

Sequence tagging. One can extend the previous configurations by training higher-order classifiers, i.e. classifiers trained on pair/tuple of neighboring constituents (similar to HMM or chain-CRF). At the prediction time one needs to choose the best structure by doing constrained inference on the predictions of the local classifiers. The following snippet shows how one can simply write a consistency constraint, given a pairwise classifier `POSTaggerPairwise` which scores two consecutive constituents.

```
def sentenceLabelsMatch = constraint(sentences) {
    t: TextAnnotation =>
    val constituents = t.getView(ViewNames.TOKENS).getConstituents
    // Go through a sliding window of tokens
    constituents.sliding(3)._forall { cons: List[Constituent] =>
      POSTaggerPairwise on (cons(0), cons(1)).second === POSTaggerPairwise on (
    cons(1), cons(2)).first }
}
```

4.3 Entity-Relation extraction

This task is for labeling entities and recognizing semantic relations among them. It requires making several local decisions (identifying named entities in the sentence) to support the relation identification. The models we represent here are inspired some well-known previous work (Zhou et al., 2005; Chan and Roth, 2010). The nodes in our models consists of `Sentences`, `Mentions` and `Relations`.

4.3.1 Features and Constraints

For the entity extraction classifier, we define various lexical features for each mention – head word, POStags, words and POStags in a context window. Also, we incorporate some features based on gazetteers for organization, vehicle, weapons, geographic locations, proper names and collective nouns. The relation extraction classifier uses lexical, collocation and dependency-based features from the baseline implementation in Chan and Roth (2010). We also use features from the brown word clusters (Brown et al., 1992). The features for each word are based on a path from the root in its Brown clustering representation. These features are easily available in our NLP *data-model*. We also use a decayed down-sampling of negative examples between training iterations.

Setting	Accuracy
Count-based baseline	91.80%
Unknown Classifier	77.09%
Known Classifier	94.92 %
Combined Known-Unknown	96.69%

Table 2: The performance of the POStagger, tested on sections 22–24 of the WSJ portion of the Penn Treebank (Marcus et al., 1993).

	Scenario	Precision	Recall	F1
E	Mention Coarse-Label	77.14	70.62	73.73
	Mention Fine-Label	73.49	65.46	69.24
R	Basic	54.09	43.89	50.48
	+ Sampling	52.48	56.78	54.54
	+ Sampling + Brown	54.43	54.23	54.33
	+ Sampling + Brown + HCons	55.82	53.42	54.59

Table 3: 5-fold CV performance of the fine-grained entity (E) and relation (R) extraction on Newswire and Broadcast News section of ACE-2005.

Relation hierarchy constraint. Since the coarse and fine labels follow a strict hierarchy, we leverage this information to boost the prediction of the fine-grained classifier by constraining its prediction upon the (more reliable) coarse-grained relation classifier.

4.3.2 Model Configuration

Entity type classifier. For the entity type task, we train two independent classifiers - one for coarse-label and the second for the fine-grained entity type. We generate the candidates for entities by taking all nouns and possessive pronouns, base noun phrases, selective chunks from the shallow parse and named entities annotated by the NE tagger of Ratinov and Roth (2009).

Relation type classifier. For the relation types, we train two independent classifiers - coarse-grained relation type label and fine-grained relation type label. We use features from our unified *data-model* which are `properties` defined on the `relations` node in the data-model graph. We also incorporate the Relation Hierarchy constraint during inference so that the predictions of both classifiers are coherent. We report some of our results in Table 3.

5 Related Work

This work has been done in the context of *Saul*, a recently developed declarative learning based programming language. DeLBP is a new paradigm (Roth, 2005; Rizzolo, 2011; Kordjamshidi et al., 2015) which is related to probabilistic programming languages (PPL) (Pfeffer, 2009; McCallum et al., 2009) *(inter alia)*, sharing the goal of facilitating the design of learning and inference models. However, compared to PPL, it is aimed at non-expert users of machine learning, and it is a more generic framework that is not limited to probabilistic models. It focuses on learning over complex structures where there are global correlations between variables, and where first order background knowledge about the data and domain could be easily considered during learning and inference. The desideratum of this framework is the conceptual representation of the domain, data and knowledge, in a way that is suitable for non-experts in machine learning and, it considers the aspect of relational feature extraction; this is different also from the goals of Searn (Hal et al., 2009) and Wolf (Riedel et al., 2014). DeLBP focuses on data-driven learning and reasoning for problem solving and handling collections of data from heterogeneous resources, unlike Dyna (Eisner, 2008) which is a generic declarative problem solving paradigm based on dynamic programming. This paper exhibits the capabilities and flexibility of Saul for solving problems in the NLP domain. Specifically, it shows how a unified predefined NLP *data-model* can help performing various tasks at various granularity levels.

6 Conclusion

We presented three examples of NLP applications as defined in the declarative learning-based programming language *Saul*. The main advantage of our approach compared to traditional, task-specific, systems is that *Saul* allows one to define all the components of the models declaratively, from feature extraction to learning and inference with arbitrary structures. This allows designers and researchers a way to explore different way to decompose, learn and do inference and easily gain insights into the impact of these on the

task. We enriched *Saul* with an extensive NLP *data-model* that enables users to perform various tasks at different levels of granularity and eventually to perform multiple tasks jointly. This work will help pave the way for more learning-based programming applications which will allow both practitioners and researchers in the field to develop quick solutions to advanced NLP tasks and to focus on exploring the tasks while staying at a sufficient level of abstraction from the component's implementation.

Acknowledgments

The authors would like to thank all the students who have helped in the implementation of this project, as well as the anonymous reviewers for helpful comments. Abstract

This article presents the results we obtained on a complex annotation task (that of dependency syntax) using a specifically designed Game with a Purpose, ZombiLingo.[1] We show that with suitable mechanisms (decomposition of the task, training of the players and regular control of the annotation quality during the game), it is possible to obtain annotations whose quality is significantly higher than that obtainable with a parser, provided that enough players participate. The source code of the game and the resulting annotated corpora (for French) are freely available.

1 Introduction

For better or worse,[2] the overwhelming domination of machine-learning systems in natural language processing (NLP) over the past 25 years and the increasing use of evaluation campaigns and shared tasks have put human-annotated corpora at the heart of the field. Manual annotation is now the place where linguistics hides.

The availability of manually annotated corpora of high quality (or, at least, reliability) is therefore key to the development of the field in any given language. However, the creation of such resources is notoriously costly, especially when complex annotations, e.g. for dependency syntax, are at issue. For example, the cost of the Prague Dependency Treebank was estimated at $600,000 in (Böhmová et al., 2001).

Over the years, many solutions have been investigated in the attempt to lower manual annotation costs. One obvious avenue is to use an appropriate annotation tool, as shown for example in (Dandapat et al., 2009). As a complementary aid, NLP systems can be used to reduce the annotation burden – either beforehand, for example with tag dictionaries (Carmen et al., 2010) and more generally with pre-annotation (Skjærholt, 2013), or more iteratively during the annotation process, for instance through active learning (Baldridge and Osborne, 2004). These solutions have proved efficient and have indeed helped reduce the annotation cost, but the creation of a large annotated corpus in the traditional manner remains very expensive.

Another way to address the issue is simply to limit the amount paid to the human annotators. This is the case with microworking crowdsourcing, especially through the use of platforms like Amazon Mechanical Turk, via which the workers are (micro)paid to perform simplified tasks (Snow et al., 2008). Apart from the ethical issues raised by these platforms (detailed in (Fort et al., 2011)), microworking platforms do not support true training of the workers: tests can be set up to select them, but they have to perform hidden work to train themselves (as shown in (Gupta et al., 2014)). Consequently, tasks must be simplified to be manageable by workers: for example, a task related to recognition of textual entailment across several sentences (which might actually reflect entailment, neutrality, or contradiction)

[1] See: http://zombilingo.org/.

[2] See (Church, 2011) for an in-depth reflection on the subject.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3041–3052, Osaka, Japan, December 11-17 2016.

could be simplified by presenting only one pair of sentences and a binary response to a single question, such as "Would most people say that if the first sentence is true, then the second sentence must be true?" (Bowman et al., 2015). To paraphrase (Dandapat et al., 2009), it seems that there is no easy escape from the high cost of complex linguistic annotation.

We present here an on-line game that enables the production of quality annotations of complex phenomena (here, dependency syntax), tested on French. The produced corpus is constantly growing and is designed to be (i) completely free and available, and (ii) of sufficient quality. We first examine the existing treebanks for French and their limitations and detail some previous experiments with Games with a Purpose (GWAPs). Then we present the game we developed and the evaluation we performed on the produced annotations. We finally conclude by discussing the potentials and limits of GWAPs for the creation of complex language resources.

2 Previous Work

2.1 Treebanking for French

As surprising as it may seem, French has long been relatively low-resourced, primarily due to legal issues: lexicons and annotated corpora existed but could not be used or redistributed freely. This is in particular the case for the French Treebank (FTB or *corpus arboré de Paris 7*) (Abeillé et al., 2003), which is available for research purposes only and cannot be freely redistributed.[3] Several versions are reported in the literature, with the size varying from 12,351 sentences and 350,947 words (for the FTB-UC) to 18,535 sentences and 557,149 words[4] (for the FTB-SPRML).

To try and circumvent this restriction, Candito and Seddah created the Sequoia corpus (Candito and Seddah, 2012), which is freely available[5] under a LGPL-LR license, but is limited to 67,038 tokens. The same authors developed an additional question bank with 23,236 tokens (Seddah and Candito, 2016). Both corpora use the same annotation guide and set of relations as the FTB.

A Universal Dependency corpus (McDonald et al., 2013) was created for French and is freely available under a CC BY-NC-SA license. In version 1.3, released in May 2016, it contains 401,960 tokens, but it "has not been manually corrected systematically".[6] Moreover, the annotation format for Universal Dependencies suffers from certain drawbacks, for example, it does not distinguish between arguments and modifiers for nominal complements of verbs.

Other treebanks exist for French, but they either concern spoken language, as with Rhapsodie (Lacheret et al., 2014) or the oral Treebank (Abeillé and Crabbé, 2013), or specific language types, like the Social Media Treebank (Seddah et al., 2012).

This situation (in which references exist, but a large, fully available, manually annotated corpus is lacking) makes dependency syntax for French an appropriate candidate for testing a new paradigm for complex linguistic resource development: the use of on-line Games with a Purpose.

2.2 Playing to Create Language Resources

Games with a Purpose are games in which participants, knowingly or not, create data by playing. They are not serious games as such, as their main purpose is not to train people, but to produce data (such as annotations, lexicon entries, image labels, etc). GWAPs for NLP are broadly surveyed in (Lafourcade et al., 2015), and a detailed analysis of their performance in comparison with other means of language resource production is provided in (Chamberlain et al., 2013). Thus, we will focus here on the complexity of the resource to be produced, rather than on giving an exhaustive list of games.

Most GWAPs rely on the players' knowledge of the world and innate capabilities to enable creation of data, in our case language resources. This reliance was seen for example in the very well-known ESP Game (von Ahn and Dabbish, 2004), in which participants played by labeling images. Another early GWAP is JeuxDeMots[7] (Lafourcade, 2007), in which players created a lexical network of more than

47 million relations between more than 900,000 entries (terms and named entities), simply by entering terms and named entities associated in a more or less specified way with another entry. The video games presented in (Jurgens and Navigli, 2014) also seem[8] to target the users' intuition and knowledge of the world to perform word sense disambiguation and a mapping from WordNet senses to images. A more limited gamified interface is used in the Language Quiz[9], which asks the participants to perform sentence or tweet sentiment analysis, without any training.[10]

Other GWAPs benefit from the players' school knowledge. One such game is Phrase Detectives[11] (Poesio et al., 2013), in which participants are asked to identify the antecedent of a noun phrase in a text. The task is more complex than labeling images or associating ideas, so the game includes a mandatory short training phase, allowing the players to become familiar with it. Almost 8,000 players participated in the game, which enabled the annotation of anaphora relations in a 162,000 word corpus. The agreement between players and experts was evaluated overall at 84%.

The wordrobe website[12] presents a family of eight gamified tasks[13] whose results help to improve the Groningen Meaning Bank (Venhuizen et al., 2013). The proposed tasks all relate to semantic disambiguation (noun *vs* verb, co-reference identification, named entity annotation, etc) and while some are relatively easy – like Play Twins (noun *vs* verb) or Play Names (named entity annotation) – most require some more advanced (at least school-level) knowledge. However, the interface does not provide a training phase and the only help available is a short guide to the task.

In a very different domain (biochemistry), the creators of FoldIt[14] demonstrated that people with no specific knowledge of the subject could be trained to perform complex protein folding tasks with impressive results: players helped find the solution to a long-standing problem concerning protein crystal structure (Khatib et al., 2011). To achieve these results, players are trained within "introductory levels", solving puzzles of varying complexity "[...] introducing the player to new problem related concepts as though they are the rules of a game." (Cooper et al., 2010).

This approach seemed particularly suited to our task (dependency annotation with nearly twenty relations to annotate), so we decided to build upon it, asking the player to annotate one relation at a time, with a specific training process for each. We report here the results we obtained, which show that a GWAP can be used for a complex linguistic annotation task that is not directly linked to world knowledge or to human intuition. To our knowledge, no other such experiment has been carried out to date. The model of dependency syntax that we use is well-known in linguistics and NLP but not in the French educational system, so we can assume that people without a linguistic or NLP background have no knowledge of it.

It should be noted that an un-gamified crowdsourcing-based method has been proposed in (Hana and Hladká, 2012; Hladká et al., 2014) for the dependency syntax annotation of Czech. (In the Czech Republic, the presentation of syntax in school is very close to dependency syntax.) However, the authors report in (Hana and Hladká, 2012) that the accuracy of the annotations they obtained is significantly lower than that of their parser. Moreover, they evaluate the results on a small set of 100 sentences selected or created by the authors. In their more recent publication, they report only the tree editing distance between the produced annotation and the reference annotation; hence, we are unable to compare their results to those presented here.

3 Designing a Game for a Complex Task

We describe below the mechanisms used in the game to take into account the complexity of the task and the game's avoidance of direct reliance on intuition. We have chosen to rely on the Sequoia annotation guidelines (which largely follow the FTB guidelines). This is a natural choice if we want to use avail-

[8] The games do not seem to be running as of mid-July 2016, so we could not test them.

[9] See: `http://quiz.ucomp.eu`

[10] Two of the authors tested it in September 2016 and were at that time the only participants.

[11] See: `https://anawiki.essex.ac.uk/phrasedetectives/`.

[12] See: `http://wordrobe.housing.rug.nl`.

[13] The game features are reduced to a leader board and a betting option, we are therefore reluctant to call it a game, although there is obviously a continuum here.

[14] See: `http://fold.it`.

able resources for training players and for evaluation. Moreover, existing parsers for French have been developed with the same schema.

3.1 Decomposing the Complexity of the Task

Since the analysis of a whole sentence is complex,[15] we decided to decompose it: the full annotation of a sentence is split into atomic tasks, where each task is linked to one type of dependency relation. Thus, the player is trained on one type of relation at a time, instead of twenty, and must focus on only one type of dependency relation across several sentences. S/he therefore has fewer elements of information to remember at a time. Moreover, each relation was awarded a level which reflects its difficulty (from the point of view of the game developers) and corresponds to a level in the game. The player can therefore choose amongst more and more relations as s/he progresses in the game. We decided not to include certain relations in the current version of the game. This concerns **punct**, which is not consistently annotated in reference, reldep, which is an underspecified relation used in different types of contexts, and relations which are not processed by Talismane. Note that the results given in Section 4 is based on all the relations except **punct**.

For each relation, explanations and examples are provided with the different contexts where it may appear.[16]

In addition to explanations, it is also important to give players examples of real utterances taken from a corpus. Reference examples are taken from the Sequoia corpus and are used in the two game mechanisms, TRAINING and CONTROL, described below.

We used only a part of the corpus in order to keep sentences aside for the evaluation of the produced annotations (see Section 4). In Table 1, we show how the reference corpus is split for different uses.

$\text{REF}_{Train\&Control}$	REF_{Eval}	*Unused*
50%	25%	25%
1,549 sentences	776 sentences	774 sentences

Table 1: Uses of the 3,099 sentences of the Sequoia reference corpus.

3.2 Playing the Game

The organization of ZombiLingo is illustrated in Figure 1, which presents how the TRAINING and play phases are articulated with both the sub-corpora described in Table 1 and the raw corpora to be annotated (usually extracted from Wikipedia). The reference corpus is used in three different phases, TRAINING, CONTROL and EVAL, as explained below.

3.2.1 TRAINING phase

Following the decomposition of the task, for each dependency relation, a specific TRAINING phase is required before entering the game. During this phase, sentences from the $\text{REF}_{Train\&Control}$ corpus are presented to the player and feedback is given in case of error.

Figure 2 illustrates the feedback given to the players in the TRAINING phase: the player was asked to find the second conjunct of a coordination *et* (and) and s/he wrongly answered *Europe*. A skull and crossbones flashes and a message revealing the right answer *parvient* (reaches) are displayed.

An advantage of offering a separate TRAINING for each relation is that the player does not have to wait long before starting the game. Once s/he is connected to the game, only a few minutes are required before starting actual play and production of annotations.

3.2.2 Play phase

In the general mode, the player chooses a relation from those available and a sequence of ten questions is proposed. The questions vary as follows:

[15] Insight concerning the complexity of syntactic annotation for the Penn Treebank is provided in (Marcus et al., 1993), where the learning curve for syntax was estimated to be twice that for part-of-speech (two months *vs* one).

[16] This is much like in an annotation guide but with simpler vocabulary and fewer details.

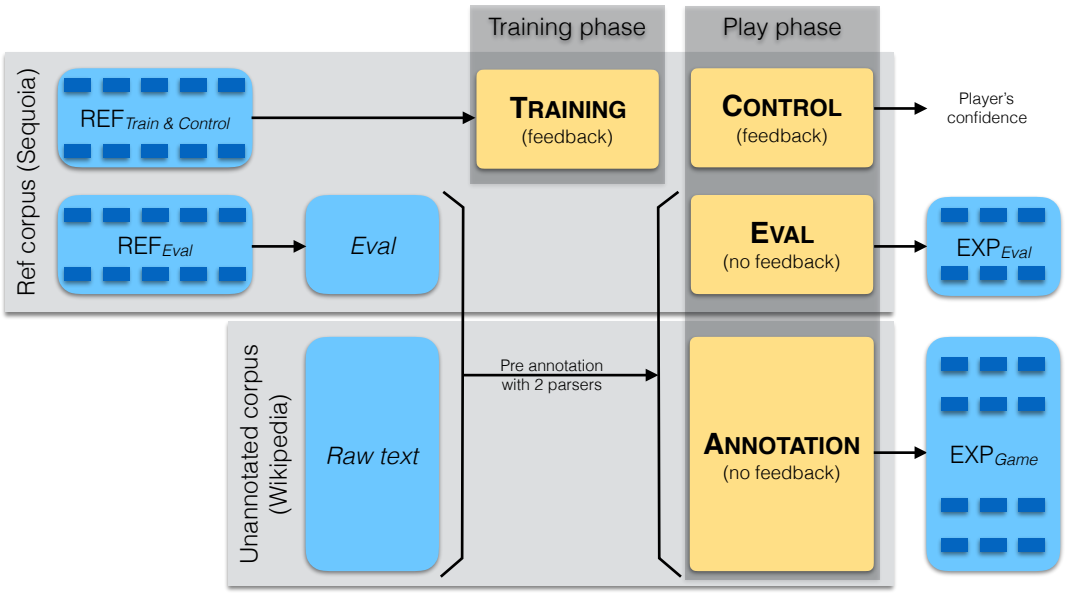

Figure 1: Organization of the different mechanisms and corpora

- For relations where the dependent element tends to be unique for a given governor (e.g. a verb has one subject, a noun has one determiner, and so on), the governor is given and the players must find the dependent;
- For relations involving several dependent elements (e.g. a verb has several prepositional phrases modifying it, a noun may be modified by several adjectives, and so on), the dependent element is given and the players must find the governor.

The player's answer is registered in the database and points are awarded if the same answer was previously given by a parser or by another player.[17] The number of points (in the game, they are represented as brains) that can be won on a certain relation depends on a global measure of the sentence complexity (measured as the maximum number of nested dependency relations) and on the level of the relation in the game.

3.2.3 CONTROL mechanism

TRAINING is not sufficient to ensure that players annotate data consistently: if they did the TRAINING on a certain relation a long time ago or if they play a lot, their ability to annotate this relation may decrease. To deal with this problem, we added a CONTROL mechanism during the game. The player is sometimes asked to annotate a relation in a sentence taken from the $\text{REF}_{Train\&Control}$ corpus. If the player fails to find the right answer, feedback including the solution is displayed (as in Figure 2). After a given number of failures on the same relation, the player has to redo the corresponding TRAINING. Using this CONTROL mechanism, we can also estimate our degree of confidence in a specific player on a specific relation (see Section 4) and take this into account to weigh his or her answer.

3.3 Behind the Curtain

3.3.1 Preprocessing Data

In the first version of the game, when new sentences were added, a parser was used to pre-annotate the sentences. Then, the players were asked to confirm or correct the parser's predictions. The main drawback of this arrangement is that the player would have a large number of very easy annotations to decide on and would usually agree with the parser.

[17] Unfortunately, if a player is the first to give a right answer, which is not given by the pre-annotation, s/he receives no points. A mechanism to give points off-line in this situation is planned but not yet implemented.

Figure 2: The main interface of the game during the TRAINING phase.

Modifying this arrangement, we now use two parsers to pre-annotate the corpora and ask the participants to play items for which the parsers give different annotations. The two parsers used are Talismane (Urieli, 2013) and FRDEP-PARSE (Guillaume and Perrier, 2015).

Talismane is a statistical parser trained on the training part of the FTB. It was evaluated on the dev and test part of the FTB with LAS scores ranging from 86.8% to 88.5%. As for FRDEP-PARSE, it is a parser which combines statistical methods for POS-tagging (using MElt (Denis and Sagot, 2012)) and symbolic methods for dependency parsing (with graph rewriting). FRDEP-PARSE was evaluated on Sequoia with a LAS score of 76.04% and a precision of 85.96%. (The system returns partial dependency syntax structures.)

It is important that the two parsers are based on different paradigms (statistical and symbolic): we can hope that the two tools are complementary and will produce different types of errors.

The next section will provide the two parsers' detailed results for the REF_{Eval} corpus.

3.3.2 Exporting Data

The players' annotations are stored in a database and each annotation receives a score. When a player is asked a question, we consider the set of possible answers in the database and adjust the score as follows:

- If the player's answer belongs to the set, the score of the answer is increased and the scores of its competing annotations (the rest of the set) are decreased.
- If the player gives an answer not in the set, a new annotation is created in the database with a default score and the scores of the answers in the set are decreased.

The positive or negative score adjustments are weighted by the level of the player, we thus award higher confidence to heavy players (who have usually reached higher levels) than to beginners. When a corpus is exported, for each token (lexical unit), we consider all the annotations in the database for which it is a dependent element and select the one with the highest score. Thus, each token receives exactly one governor with one relation and we can ensure that the exported corpus contains well-formed dependency trees.

4 Quantitative and Qualitative Evaluations

4.1 Participation and Production

If a crowdsourcing approach to annotation is to succeed, enough participants must be induced to participate and create data. As of 2016, July 10, there were 647 players registered for our game. They have

collectively produced 107,719 annotations.

As a reminder, Table 2 shows a quantitative comparison of the existing corpora for French. What this table does not show is that the corpus produced through the game is still growing, and will grow as long as we support and advertise the application.

	Sequoia 7.0	UD-French 1.3	FTB-UC	FTB-SPMRL	ZombiLingo
Sentences	3,099	16,448	12,351	18,535	5,221
Tokens	67,038	401,960	350,947	557,149	128,046
Tokens/sentence	21.6	24.4	28.4	30.1	24.5

Table 2: ZombiLingo corpus size, as compared to other existing French corpora annotated with dependency syntax.

On the ZombiLingo corpus the average number of players' annotations by tokens (called the *density*) is 0.84 (107,719 / 128,046). Figure 3 shows the density of annotations per relation. The coverage is clearly not homogeneous: the density on the relation **aff** (affix) is greater than 6, whereas for some relations it remains below 1.

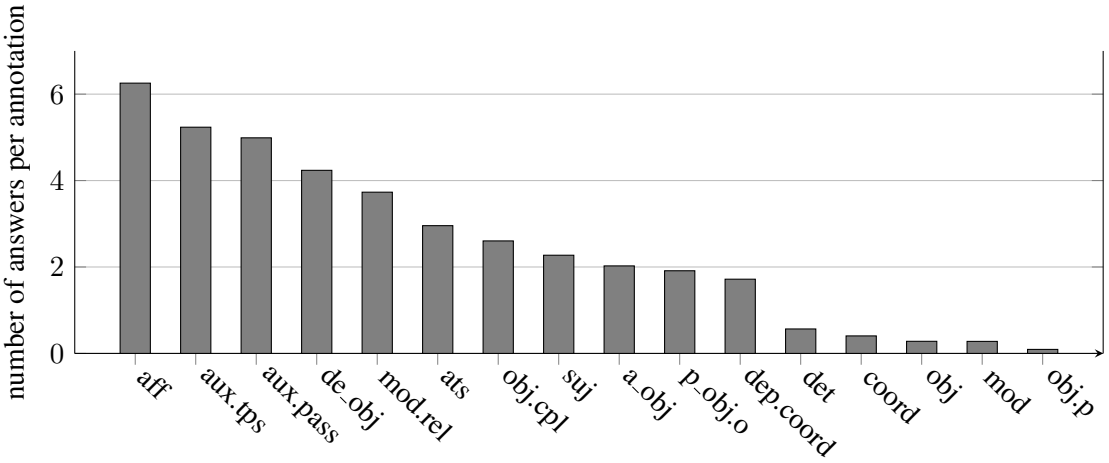

Figure 3: Density of answers for each relation.

This means that we need to attract at least some players to play a wider variety of relations types or to direct them towards some under-played relations, such as **mod** (modifier) or **coord** (coordination).

4.2 Qualitative Evaluation Methodology

In the first version of the game, we used the CONTROL mechanism to evaluate the quality of annotations produced by participants. We observed that 85.4% of CONTROL items were correctly annotated.

While this evaluation showed that it is possible to train players for a difficult task, it remains a partial evaluation, with severe drawbacks. It measures the performance of the participants on reference sentences but it gives no information about the annotations produced on pre-annotated sentences: if such a sentence contains a dependency relation not predicted by the parser, the player will never play this relation in this sentence. We call this omission *silence* in the produced data. On the other hand, if a relation is predicted by the parser but cannot be found in the sentence, the player will be asked to give an opinion on a question for which there is no sensible answer: we call such nonsensical situation *noise* in the data.

During the game, the user is supposed to click on a specific image (crossed bones) if a question has no answer but, although we train the participants on this alternative, we know that it is underused. For instance, when a player is tasked with finding the object of a verb, s/he tends to search for a word which looks like an object without realizing that this verb may actually have no object at all.

In order to obtain a precise evaluation of the produced annotations, we entered a part of our reference

corpus (named REF_{Eval}) into the game (see Figure 1), as if it were a raw corpus. We used it in the following way:

- the raw text corresponding to the REF_{Eval} corpus is put into the general pipeline (i.e., it is parsed with the two parsers, the differences in the annotation being proposed to the players; this is the EVAL mechanism in the Figure 1);
- we report the scores obtained by each parser (i.e., recall/precision/F-measure) and the score of the corpus EXP_{Eval}, as exported by the game.

4.3 Results

The REF_{Eval}corpus contains 12,660 relations which can be played. On this subset of relations, the two parsers give the same output in 10,134 of the cases. Their analysis is correct in 96.84% of the cases (i.e. in 9,814 cases out of 10,134) and it is wrong in only 320 cases, which represents 3.16% of the output (i.e. 320 cases out of 10,134). However, even in cases where the two parsers provide two different wrong answers, the players will be asked to give their opinion on these cases and, hopefully, will produce a correct final annotation. In the end, the number of wrong annotations that will never be proposed to the players represents only 2.53% (i.e. 320 cases out of 12,660) of the relations which can be played.

In Table 3, we report the scores in three settings: the Talismane parser, the FRDEP-PARSE parser, and data exported by the game (EXP_{Eval}). In all of these setting, we may have partial dependency structures, so we report recall, precision and F-measure. We consider all relations (except punctuation which is not consistently annotated in the Sequoia corpus).

	Talismane	FRDEP-PARSE	Game
LAS / Recall	0.745	0.743	0.674
Precision	0.759	0.852	0.932
F-measure	0.752	0.794	0.782

Table 3: Evaluation of the data produced by the game on the REF_{Eval} corpus (except punctuation).

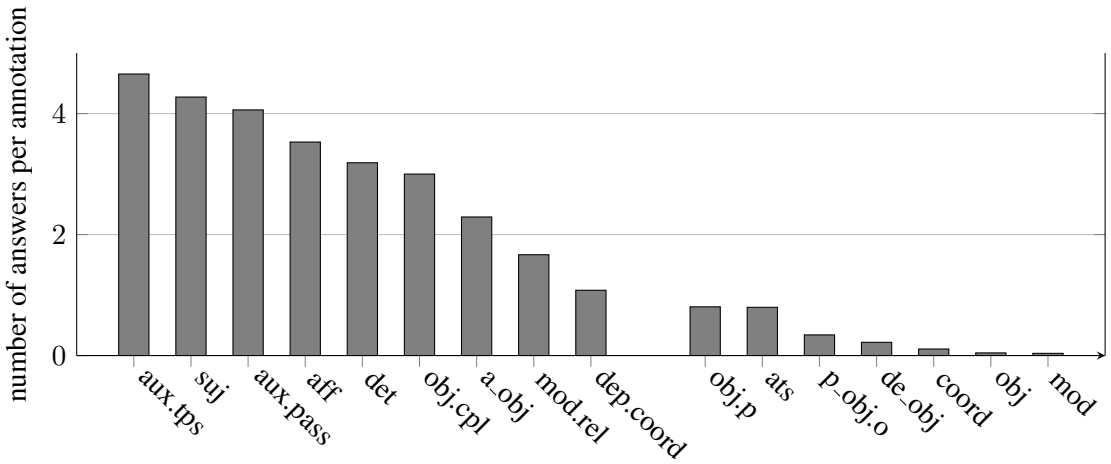

Figure 4: Density of answers for each relation on the REF_{Eval} corpus (a whitespace separates relations where density is greater than 1 from the others).

Note that the score of the annotations produced by the game is lower than that of the second parser. This difference comes about because some relations were not played by enough players, as already observed in Subsection 4.1. To explore in more detail how the players influence the corpus score, we must look at these values relation by relation.

First, 3,575 game items correspond to the REF_{Eval} corpus and only 2,644 game actions were performed by the player on these items (so the average density is 0.74). Moreover, as already observed in

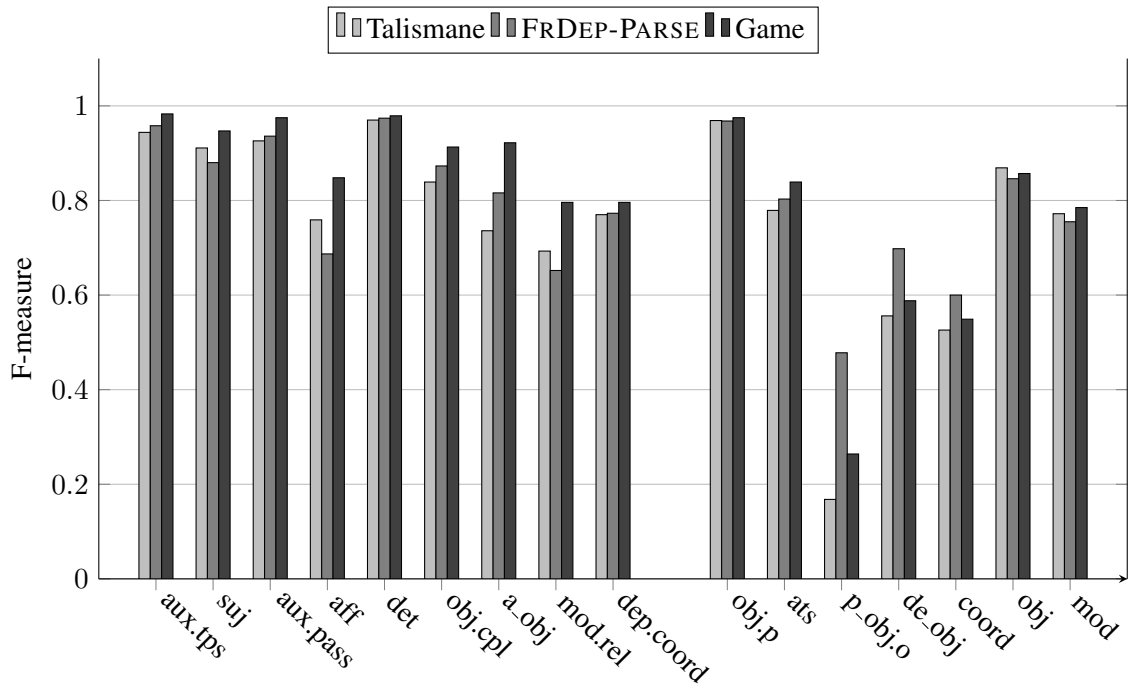

Figure 5: F-measures for the two parsers and the game, on each relation. (As in Figure 4, relations are split into two groups, with density greater than 1 on the left and density lower than 1 on the right.)

Figure 3, the distribution of the game actions is not at all homogeneous. If we discard relations for which the number of occurrences in the REF_{Eval} corpus is too low[18] to obtain significant results, the average density of game actions on game items ranges from 0.04 on **mod** (modifier) to 4.65 on **aux.tps** (tense auxiliary).

In Figure 4, we report the density of annotations on the corpus REF_{Eval} and Figure 5 gives, for the same relations in the same order, the values of the F-measure in the three settings (with Talismane in light gray, FRDEP-PARSE in a darker gray and finally the game export in dark gray).

For the relations where the density is higher than 1 (seen in the left hand part of the figures), we observe that the F-measure computed on the corpus from the game is always higher than that of the two parsers. From these experiments, we can conclude that we manage to obtain annotations with a quality significantly higher than that obtainable with a parser, provided that enough players participate. It is worth noting that amongst the relations which are densely played, some are considered as complex, such as **dep.coord** (the player has to find the head of the second conjunct of a coordination). Figure 2 shows an example of such a difficult case: the player has to read and to understand the whole sentence to give the right answer (it is a long distance dependency).

The next challenge is to induce players to annotate a wider variety of relations so as to increase the quality of the whole corpus. Relations with a very low density are either relations with a high number of occurrences (the REF_{Eval}corpus contains 1,874 **mod** relations) or relations which are less intuitive for the players. We will take this last factor into account and improve the documentation on these relations.

5 Conclusion

We have presented ZombiLingo, a game designed for a complex linguistic annotation task, namely dependency syntax. A first prototype of the game was released in July 2014 and an engineer started working on a production version in October 2015, completing the first version by the end of that year. As of July 2016, the game had enabled the production of more than 100,000 annotations for French, with a precision of 0.93. These results are very promising, especially for low-resourced languages. We still need to

[18]We have discarded relations with less than 25 occurrences in REF_{Eval}, namely **aux.caus** (causative auxiliary, 4 occurrences), **arg** (specific relation linking two parts of a range, 2 occurrences) and **dis** (dislocation, 1 occurrence).

fill some annotation gaps (e.g. for relations insufficiently played) and have developed for this purpose a new duel mode, which will allow senior players to compete with each other in the annotation of whole sentences.

The most difficult factor when using GWAPs is to find ways of attracting and keeping participants (Poesio et al., 2013), which requires a continuing communication effort. We have experienced "waves" of players following specific events we participated in or challenges we organized. We also attracted new players when advertising the game on social networks, but this effort must be regularly maintained and renewed.

The game source code is freely available on GitHub[19] under an CeCILL open-source license[20]. The code is designed to be easily adaptable to any human language: all messages are isolated from the code, which is Unicode compliant. We plan to adapt it to English and to a less-resourced language in the coming months.

The resource created for French is directly and freely available under a CC BY-NC-SA license from the game website[21] and is updated every night.

Acknowledgements

The development of ZombiLingo is funded by Inria, through an ADT grant. The French Ministry of culture has also helped us to communicate and publish results concerning ZombiLingo through two grants.

Above all, we want to thank all of the ZombiLingo players, without whom the resource would simply not exist! Special thanks to players JYA, Chouchou and Xohwohxo, who gave us valuable feedback on the game. We also wish to thank Djamé Seddah, for his help in building a solid state of the art and Guy Perrier, who, as Professor Frankenperrier, helped us to write the guidelines and to check errors in the reference. Finally, we want to thank the reviewers, who gave us interesting suggestions for improving this article.

Borrow a Little from your Rich Cousin: Using Embeddings and Polarities of English Words for Multilingual Sentiment Classification

Prerana Singhal and **Pushpak Bhattacharyya**

IIT Bombay, Maharashtra, India
{singhal.prerana,pushpakbh}@gmail.com

Abstract

In this paper, we provide a solution to multilingual sentiment classification using deep learning. Given input text in a language, we use word translation into English and then the embeddings of these English words to train a classifier. This projection into the English space plus word embeddings gives a simple and uniform framework for multilingual sentiment analysis. A novel idea is augmentation of the training data with polar words, appearing in these sentences, along with their polarities. This approach leads to a performance gain of 7-10% over traditional classifiers on many languages, irrespective of text genre, despite the scarcity of resources in most languages.

1 Introduction

Sentiment Analysis deals with extraction of opinion polarity from texts. Extensive work has been done in this field over the past years, mainly for English. Subsequently, rich English resources like SentiWordNet (Esuli and Sebastiani, 2006) and pre-trained word embeddings (Mikolov et al., 2013a) are available publicly. However, lack of rich resources and annotated corpora in other languages like Dutch, Russian or Hindi makes it difficult to analyze texts with as good accuracy as that in English.

Deep learning models have achieved astonishing results in several fields like Speech Recognition and Computer vision, and have shown promising results when used for several NLP tasks (like Convolutional Neural Networks for Sentence Classification (Kim, 2014), LSTMs for tweet classification (Wang et al., 2015) and Recursive Deep Models for Sentiment Analysis (Socher et al., 2013)). A key feature of deep learning models, which seems to attract NLP researchers, is their lack of demand for manual feature engineering, unlike other classical machine learning algorithms (SVM, *etc*.) (Pang et al., 2002).

Multilingual Sentiment Analysis has been a challenging, yet an important area of research since a long time, mainly involving other NLP tools like Sentence-level Machine translation (Joshi et al., 2010; Wan, 2009), Machine Translation with SentiWordNet scores (Denecke, 2008), semantic orientation calculator (Brooke et al., 2009), and Wordnets (Balamurali et al., 2012) to serve the purpose. Machine learning methods have been used and evaluated on different sets of languages (Boiy and Moens, 2009; Seki et al., 2010; Seki et al., 2008), which involve many constraints and manual functionalities. In addition, strategies to build a multilingual corpus (Schulz et al., 2010) have been devised which, quite frankly, are not possible for large number of languages, owing to the diversity involved.

In this paper, we present a simple approach to multilingual sentiment classification which: (a) poses minimal restrictions on the language or the text genre to be used, (b) has minimal demands for preprocessing tools, and (c) shows no aversion to the small size of datasets or inadequacy of resources in any language. **Our approach uses deep learning models for sentiment classification in a given language by *borrowing* word-embeddings and word polarities from the *rich cousin* English.**

The main idea is to combine existing lexical resources and neural network classification techniques and provide an effective solution to the problem of multilingual sentiment classification. Although the

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3053–3062, Osaka, Japan, December 11-17 2016.

individual components (polar words (Pang et al., 2002) and word embeddings (Wang et al., 2015)) have been used by others before, **the novelty of this paper lies in the method of integrating *known components* and *available resources*, for *languages with insufficient resources*.**

2 Motivation

Multilingual Sentiment Analysis faces several challenges including (a) linguistic variations and (b) lack of sufficient resources for supervised classification. We need a simple classification system which can perform efficiently on a dataset, independent of the language or the text genre. Quite often, the size of the annotated corpus available for a particular language and text genre is generally not sufficient enough, in fact, far too small, to be helpful on its own. Hence, we propose to **use deep learning models and leverage publicly available word embeddings and polar words of *English* for sentiment classification** to overcome the limitations in a multilingual framework.

2.1 Why Deep Learning?

Classical machine learning algorithms like SVM require (a) *pre-processing* and (b) *manual feature engineering*, (Pang et al., 2002) both of which vary across languages as well as text genres. Hence, building a classification system for a new language is cumbersome and may not be as effective for all languages. We need a model, which can train effectively on any dataset, irrespective of its language or text characteristics, with minimal or no manual adjustments across datasets. Hence, deep learning models like Convolutional neural networks (Collobert et al., 2011) assume importance, since they are well-known to have no such text dependent constraints.

2.2 Why English word-embeddings?

Deep learning NLP models require word representations (containing context information) as input. One way to do so is to randomly initialize the word vectors and trust the sentiment classification model itself to learn the word representations, besides the network parameters. However, this requires a large annotated corpus, which is difficult to obtain in most languages. The other way is to train a suitable deep learning model (Collobert et al., 2011; Mikolov et al., 2013a) on a raw corpus in that language and then use the obtained embeddings of these *in-language words* as input to the sentiment classification model. However, learning context-rich word embeddings in any language requires large datasets, generally of the order of billions of words, thereby eating up a lot of time as well as system resources.

Hence, the pre-trained word embeddings of *English* prove to be useful, which have already been obtained by training suitable models on billions of data. Their context-rich information can be utilized to compensate for the small size of the available corpora in a language. An interesting property of context-rich word embeddings is that they capture linguistic regularities (Mikolov et al., 2013b), including contextual similarities. Hence, similar words or synonyms will have closer word vectors (measured by cosine distance). Thus, for the purpose of sentiment polarity classification (with no intensity segregation), all synonyms will contribute to the same polarity in a similar manner. So, one can pick any one of the synonyms (say, one of *amazing, splendid, spectacular, etc*.) and it will not affect the underlying sentiment (say positive or negative or neutral) of the text.

We propose to *obtain a mapping between the in-language words and the English word-embeddings through word-to-word translation*. For this, any publicly available (decent) bilingual dictionary or translation tool (like Google translate) can be used. The in-language words are translated to English individually, *solely for the purpose of obtaining a mapping to the pre-trained English word vectors*; hence, the orientation of the input texts is not disturbed.

2.3 Why English polar words?

A small change in the choice of words, or the order in which the words occur in a piece of text, may change the whole opinion underlying the text. For instance, the sentence "*This is not good*" conveys negative sense, as opposed to the positive sense conveyed by "*This is good*", with a single word *not* reversing

the polarity. Also, the sentiment polarity of the sentence "*He does not seem bad, he is good*" is clearly opposite to that of "*He does not seem good, he is bad*", in spite of exactly the same words being used in both cases. So the classification system needs to *see all these patterns* for making correct predictions on *unseen* data.

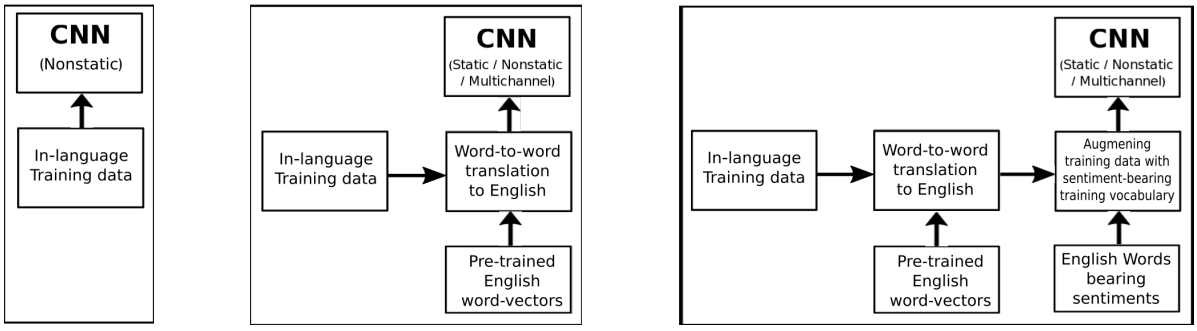
The point is, if enough instances are not provided to the classification system for training, it is likely to learn wrong patterns. For example, if the system has seen "*This may be nice but I do not like it.*" as the only training example with the word *nice*, it tends to associate the word *nice* with negative sentiment and is likely to wrongly predict an unseen sentence, say "*She seems nice to me.*", as negative. Generally, a large annotated corpus is able to overcome this anomaly, as the network gets enough data to learn the correct linguistic patterns. However, when the labeled dataset is small in size, as is often the case in most languages, this problem adversely affects the classification performance.

To overcome this hurdle, one way is to make use of some list of frequently used sentiment-polar words. The idea is to familiarize the network with the fact that the text "*This may be nice but I do not like it*" reflects negative opinion but "*nice*" portrays positive sentiment. This improves the chances of correct prediction, as now the network is able to learn that the word *nice* is generally used for positive opinion but when used in some particular context (say, with discourse particle *but* or negation element *not*), it displays negative sentiment.

Several rich English resources like SentiWordNet (Esuli and Sebastiani, 2006) or list of positive/negative English vocabulary (Hu and Liu, 2004) are publicly available. We propose to make use of this information for supervised sentiment classification in a multilingual scenario, *by augmenting sentiment bearing words with their polarities to the annotated training corpora*.

3 Proposed Method

We use a deep learning model like Convolutional neural network as our classification system. We use randomly initialized word-vectors and no other resources in our baseline model. For example, a simple CNN-Rand (Non-static) model (Kim, 2014) can be used to work as our baseline. The proposed method for sentiment classification, as depicted by the block diagram (Figure 1), can be divided into two stages (Figures 1b and 1c) to be applied on top of this base-line (Figure 1a).



(a) Baseline (b) 1st Stage (c) 2nd Stage

Figure 1: Block Diagrams of the Deep Learning Classification Methods

3.1 First Stage: *Mapping in-language texts to English Word Embeddings*

Given text in one language, we translate each word into English using bilingual dictionary or translation system like Google translate. Then, we initialize the word vectors using the corresponding English word embeddings, obtained from the existing list of pre-trained English word vectors. In case the in-language word fails to get translated, it is *transliterated* into English and its word-vector is randomly initialized during the training phase.

To illustrate our approach, let us consider dummy training data in Hindi:

1. Original Hindi text :: हम इस धारणा के प्रभाव को महसूस करते हैं, लेकिन उत्तेजित और प्रेरित नहीं होते।
   Transliteration :: *Hum is dharnaa ke prabhaav ko mehsoos karte hain, lekin uttejit aur prerit nahi hote.*
   Meaning in English :: ***We feel the effects of this notion, but do not get excited and motivated.***
   Label :: Negative
2. Original Hindi text :: फिल्म का संगीत कमजोर है।
   Transliteration :: *Film ka sangeet kamzor hai.*
   Meaning in English :: ***The film's music is weak.***
   Label :: Negative
3. Original Hindi text :: स्क्रिप्ट की बंदिशों के बावजूद अभिनेताओं ने लाजवाब काम किया है।
   Transliteration :: *Script ki bandishon ke baavajud abhinetaon ne laajawaab kaam kiya hai.*
   Meaning in English :: ***Despite the restrictions of the script, the actors did an amazing job.***
   Label :: Positive

Now, we translate (or transliterate) the training data on **word-level** to English and **map them to the corresponding English word-embeddings**. This results in the following as our training data:
*(**<w>** implies embedding of the English word **w** to which the in-language word has been translated)*

1. **Instance ::** ***<we> <this> <assumption> <of> <effect> <to> <are> <,> <but> <excited> <and> <inspired> <no> <there> <.>*** (Label :: Negative)
2. **Instance ::** ***<film> <of> <music> <weak> <is> <.>*** (Label :: Negative)
3. **Instance ::** ***<script> <of> <restrictions> <of> <despite> <actors> <has> <excellent> <work> <the> <is> <.>*** (Label :: Positive)

Once the word-vectors have been initialized, the network can be trained on the training data (Figure 1b), which now contains concatenated word vectors as training instances with their corresponding sentiment-labels. The word-to-word translation is done mainly *to obtain a mapping* between the in-language words and the English word embeddings. *The word order in original text sequence is not disturbed* and hence, there is neither any chaos nor any problems in handling phenomenon like negation. As compared to the baseline, this technique is expected to work better, because, unlike in the former case, it now has access to the extensive context information offered by the pre-trained English word embeddings, which can be exploited to improve the training procedure on *scarce* datasets.

3.2 Second Stage: *Augmenting training data with English Polar Words*

After obtaining the word vector mappings, we choose some authentic English resource like SentiWordNet or list of common positive-negative words (Hu and Liu, 2004), to form a list of frequently used polar sentiment-bearing lexicons. Then, once the in-language text is mapped to English on word level, the training data vocabulary is matched against this list and the intersection of the two is appended to the training data with their polarities as their labels. The idea is *to augment training data with polar words that have occurred in the training texts.*

In our example, the training data will now consist of following instances:
*(**<w>** implies embedding of the English word **w** to which the in-language word has been translated)*

1. **Instance ::** ***<we> <this> <assumption> <of> <effect> <to> <are> <,> <but> <excited> <and> <inspired> <no> <there> <.>*** (Negative)
2. **Instance ::** ***<film> <of> <music> <weak> <is> <.>*** (Negative)
3. **Instance ::** ***<script> <of> <restrictions> <of> <despite> <actors> <has> <excellent> <work> <the> <is> <.>*** (Positive)
4. **Instance ::** ***<excited>*** (Positive)
5. **Instance ::** ***<inspired>*** (Positive)

6. **Instance :: *<weak>*** (Negative)
7. **Instance :: *<restrictions>*** (Negative)
8. **Instance :: *<excellent>*** (Positive)

Now the word vectors are initialized as before and the network is trained as usual on *this extended training data* (Figure 1c). This technique is expected to further enhance the performance of the classification system, as it tries to fill gaps in the sentiment-related information of the small training datasets.

4 Datasets and Experimental Setup

We perform experiments on datasets in two Indian languages[1], and Russian and six European languages[2]. Neutral labels (if any) have been removed from these datasets for the purpose of *binary sentiment* (positive-negative) classification.

The datasets are essentially movie reviews in Hindi (Joshi et al., 2010), tourism reviews in Hindi and Marathi (Balamurali et al., 2012), and tweets from different contexts in Dutch, French, Spanish, Italian, German, Portuguese and Russian languages (Araujo et al., 2016). These datasets reflect the **diversity in terms of language family** (Indian languages are not as close to English as European languages), **text characteristics and length of the texts** (reviews are long and grammatically sane while tweets are short irregular piece of texts) as well as the **relatively small size of the labeled corpora**. Relevant information about the datasets have been summarized in Table 1.

Dataset Language	Average Text Length	Vocabulary Size	Dataset Size		
			#pos	#neg	Total
Reviews in Indian Languages					
Hindi (Movie)	27	1600	127	125	252
Hindi (Tourism)	128	3601	98	100	198
Marathi (Tourism)	89	3766	75	75	150
Tweets in Russian and European Languages					
Russian	15	8021	1145	1188	2333
Dutch	21	1258	88	63	151
French	17	1800	159	160	319
German	13	1254	143	95	238
Portuguese	16	2472	297	213	510
Spanish	21	5092	683	350	1033
Italian	19	8429	820	1422	2242

Table 1: Summary Statistics for the Binary Labeled Datasets in different languages

4.1 Neural Network Architecture

For the purpose of our experiments on all datasets, we use convolutional neural network (CNN), which consists of a convolutional layer with filter windows of sizes 3, 4 and 5, a feature map of size 50 for each of the filters and sigmoid as the activation function, followed by max-pooling and an output layer with softmax as activation function. For the network, we choose negative log likelihood as the error function, learning rate to be 0.95, dropout rate to be 0.4 and number of training epochs to be 30. We train the model through stochastic gradient descent with the Adadelta update rule (Zeiler, 2012).

The hyper-parameters of the CNN model have been chosen via a grid search on the *hindi-movie-review* dataset. Three different variants of this CNN model have been tried on the datasets, as shown by Yoon Kim (2014). which are:

- **CNN Static (C-S) ::** Here, pre-trained word-vectors are used and these undergo no change during training, *i.e.*, only the parameters of the network are learned through back-propagation and not the word embeddings.

[1]available at `http://www.cfilt.iitb.ac.in/Sentiment_Analysis_Resources.html`
[2]available at `http://homepages.dcc.ufmg.br/~fabricio/sentiment-languages-dataset/`

- **CNN Non-Static (C-N) ::** Here, either pre-trained word-vectors are used and/or word vectors are randomly initialized, and during training, apart from the parameters of the network, the word-vectors are also tuned through back-propagation in order to learn word-embeddings for the specific task of sentiment classification.
- **CNN Multi-Channel (C-M) ::** Here, two sets of pre-trained word-vectors are used with the convolutional filters applied separately on each, and during training, apart from the parameters of the network, one set of the word-vectors are tuned through back-propagation (non-static channel) while the other set undergoes no change (static channel).

4.2 Resources and Tools used

For our experiments, we use Google translate[3] for word-to-word translation from a given language to English. The English word embeddings we use are pre-trained vectors trained on a part of Google News dataset (about 100 billion words) [4]. These are 300-dimensional vectors for approximately 3 million words and phrases. We use the list of English words expressing sentiment polarities[5] compiled by Bing Liu and Minqing Hu (2004), which consists of approximately 6800 positive and negative words. We use these resources for our experiments solely because of their richness and easy availability; however, other alternatives can also be used.

4.3 Experimental Configurations

We perform two-fold validation of five repeats on the datasets, where the configurations of training and test documents are randomly chosen for each repeat. The data is not subjected to any tuning prior to training/testing, apart from changing all (English) words to lowercase and inserting space between letters and punctuations. This configuration is maintained across all datasets and model variants, in order to maintain uniformity while comparing results.

To compare the performance of the deep learning models, we also apply SVM (Pang et al., 2002) classifiers (with unigram as features) on the datasets. We perform experiments for the following models:

- Classical Machine Learning (Baseline) Classifier Models:
  1. **SVM (unigram)::** SVM (with unigram as features) on the original in-language training data.

  2. **C-N E-wv::** CNN model in non-static mode with the training data mapped to pre-trained English word embeddings through word-level translation.
  3. **C-M E-wv::** CNN model in multi-channel mode with the training data mapped to pre-trained English word embeddings through word-level translation.
- Proposed Deep Learning (CNN) Models (Stage-I and Stage-II Approach :: *mapping to English Word Vectors and augmenting training data with Polar Words (E-wv-pw)*):
  1. **C-S E-wv-pw::** CNN model in static mode with the training data mapped to pre-trained English word embeddings through word-level translation and augmented with English polar words.
  2. **C-N E-wv-pw::** CNN model in non-static mode with the training data mapped to pre-trained English word embeddings through word-level translation and augmented with English polar words.
  3. **C-M E-wv-pw::** CNN model in multi-channel mode with the training data mapped to pre-trained English word embeddings through word-level translation and augmented with English polar words.

5 Results

In Table 2, we report F-score values (mean of positive and negative class F-scores) of all our models on the different datasets.

Although an increase in the performance of the deep learning models, aided by the English word-embeddings and word-polarities, was expected, **the magnitude of the gains encountered is overwhelming, in spite of the incredibly small size of the annotated corpora in many cases.** In fact, the improvement in performance is almost consistent across all language datasets in spite of the varied nature of the texts (movie reviews, tourism reviews and tweets in different languages).

The best results, **more than 80%** in many cases, are reported in the last three columns of Table 2, which are the variants of the CNN models, utilizing the two stages of our proposed approach. These are not only better than the CNN baseline (C-N Lang) but also **show astonishing performance gains over the SVM model across all datasets, as high as 10% in some cases**.

6 Observations and Discussions

It is evident that across all languages and datasets, our proposed approach of using deep learning models (one of the variants of CNN in our case), leveraging the pre-trained word-embeddings and the polar words of English, consistently performs better than the classical model (SVM) as well as the CNN baseline.

The most significant property exhibited by our proposed system is effective handling of (a) unknown words and (b) scarcity of datasets; two challenges frequently faced by the task of sentiment classification in most languages.

6.1 Unknown Words

Unknown words pose a great challenge to almost all NLP tasks including Sentiment Analysis. They are infamous for bringing the performance of the NLP systems considerably down, as these can play no role to predict the label of unseen data. Table 3 shows the average number of unknown words encountered during

the testing phase with and without being mapped to English word embeddings. Clearly, *when relying solely on the in-language training data, the number of unknown words encountered is more than 50% of the test vocabulary size* in most cases. This is bound to decrease the performance of the classification system. However, *leveraging the context information of the pre-trained English word embedding space helps to 'know' a large fraction of the unknown words*. Consequently, the number of unknown words reduce considerably after applying our proposed method and Table 3 clearly backs up this argument. Furthermore, this 'knowledge' is useful for the task at hand, as clearly reflected by the performance gains by our system (Table 2).

Table 3: Statistics of Unknown words with and without being mapped to English word embeddings

6.2 Scarcity of data

One basic requirement of a supervised classification model is a substantial amount of data for training the network, which often becomes a major challenge for multilingual sentiment analysis. In-language classification results in far more amount of unseen instances and/or words than that which can be handled, because of which the baseline models do not perform very well on the scarce datasets. This shortcoming is somewhat overcome by our proposed method of *projecting the in-language text to the English word space and augmenting the training data with polar words*. Table 2 substantiates our claim: we see more than 80% accuracy for most of the datasets, in spite of their small size. These numbers are statistically significant too, despite the small size of the datasets, not only because the results show consistent improvements over several datasets which is *not a coincidence*, but also, large annotated corpora are *practically* not available for most languages.

7 Conclusion

In this work, we established that, even with a simple deep learning classification model, and easy usage of publicly available word embeddings and polar words of English, appreciable results can be obtained for *multilingual sentiment classification*. **The main idea of our proposed approach is to map the in-language words with English word embeddings and augment the training dataset with polar words**. Although the individual components like polar words and word embeddings have been utilized before, the proposed approach, as a whole, is substantially different from any of the previous works. The *novelty* of this paper lies in the method of *borrowing known components from the 'rich' language English, and integrating them using deep learning models, for the task of multilingual sentiment classification.*

The experimental results show more than 80% performance F-score values *with as high as 10% performance gain* over the classical models in many cases. These observations substantiate the viability of our proposed approach in handling the key issues of multilingual sentiment classification, namely, diversity of texts and scarcity of datasets across languages.

We currently targeted binary sentiment classification for different languages in this paper. We show that **exploiting the embeddings and sentiment polarities of English words (without relying on any complex tools), and effectively applying deep learning models, is a viable approach to sentiment classification in a multilingual setup**. This work can further be extended to multi-class sentiment classification and possibly aspect classification in different languages. Also, further experimentations can be conducted with other publicly available resources, datasets and tools as well as other deep learning neural network configurations for multilingual sentiment analysis.

A Character-Aware Encoder for Neural Machine Translation

Zhen Yang, Wei Chen*, Feng Wang, Bo Xu

{yangzhen2014, wei.chen.media, feng.wang, xubo}@ia.ac.cn

Abstract

This article proposes a novel character-aware neural machine translation (NMT) model that views the input sequences as sequences of characters rather than words. On the use of row convolution (Amodei et al., 2015), the encoder of the proposed model composes word-level information from the input sequences of characters automatically. Since our model doesn't rely on the boundaries between each word (as the whitespace boundaries in English), it is also applied to languages without explicit word segmentations (like Chinese). Experimental results on Chinese-English translation tasks show that the proposed character-aware NMT model can achieve comparable translation performance with the traditional word based NMT models. Despite the target side is still word based, the proposed model is able to generate much less unknown words.

1 Introduction

Neural machine translation conducts end-to-end translation with a source encoder and a target decoder, producing promising results (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014). With the emerging of the attention-based encoder-decoder model, NMT has achieved comparable even better translation performance with the traditional statistical machine translation (SMT) (Bahdanau et al., 2014; Ranzato et al., 2015; Shen et al., 2015; Tu et al., 2016). The success of NMT lies in its strong ability of composing the global context information. However, as a newly approach, the NMT model has some flaws and limitations that may jeopardize its translation performance (Luong et al., 2014; Sennrich et al., 2015; He et al., 2016). One of the most glaring limitations is that the NMT model is weak in handling the rare and out-of-vocabulary (OOV) words, since the NMT system usually uses the top-N (30000-50000) frequent words in the training corpus and regards other words as unseen words (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2014; Cohn et al., 2016). Two different kinds of approaches have been proposed to handle the OOV problem in NMT: ***vocabulary-specific*** approaches and ***unit-specific*** approaches.

The ***vocabulary-specific*** approaches seek to cover more words by using a larger vocabulary (Mnih and Kavukcuoglu, 2013; Cho et al., 2015) or using an identity translation dictionary in a post-processing step (Luong et al., 2014). Intuitively, these approaches can alleviate the OOV problems to a certain extent only if the vocabulary can be expanded large enough. However, these approaches are incapable of solving the OOV problems completely since the vocabulary is always limited.

As opposed to ***vocabulary-specific*** approaches, the ***unit-specific*** approaches try to use more fine-grained processing units than words, like sub-word units (Sennrich et al., 2015) or even character-level units (Ling et al., 2015b; Chung et al., 2016). Regarding the character as the basic processing unit is a new trend in the field of NLP and the character-level models have been widely used in NLP tasks (Ling et al., 2015a; Zhang et al., 2015; Golub and He, 2016). Developing character-level NMT models is attractive for multiple reasons. Firstly, it opens the possibility for models to generate unseen source words, since each word can be composed from different characters. Secondly, the vocabulary size of the

*Wei Chen is the corresponding author of this paper

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3063–3070, Osaka, Japan, December 11-17 2016.

model can be reduced dramatically as only the characters need to be modeled explicitly. This enables the character-level NMT model to solve many scalability issues, both in terms of computational speed and memory requirements. Finally, as each character occurs frequently in the training corpus, all of the character embeddings are able to get full trained. Hence they represent their corresponding characters very well. However, in the word-based NMT, the word embeddings for rare words, which hardly occur in the training corpus, are absent of enough training. Based on the state-of-the-art attention based encoder-decoder framework, some character-level NMT models have been proposed recently. (Chung et al., 2016) focus on representing the target side as a character sequence with a bi-scale recurrent neural network. In (Ling et al., 2015b), a character-based word representation model is proposed in the source side. (Luong and Manning, 2016) proposes a hybrid architecture for NMT that translates mostly at the word level and consults the character components for rare words when necessary. Most of the works mentioned above apply the bidirectional RNN to compose the word representation from its characters. Hence, its necessary to know the boundary between two words beforehand. These models are applicable for languages in which the words are segmented with explicit boundaries, such as English, French and etc.

In this work, we propose a novel character-aware NMT model that learns to encode at the character level. On the use of row convolution, the proposed model can be applied to the language which has no explicit word segmentations, like Chinese. We still represent the target side as a sequence of words. This paper has two main contributions:

- We propose a simple and novel NMT model which views the input as sequences of characters. We firstly rule out the word segmentation processing step for languages without explicit word segmentations.
- We introduce several different row convolution methods and investigate their effectiveness in NMT. Row convolution is a newly-emerged technique and has shown its great effectiveness in speech recognition (Amodei et al., 2015).

Experimental results show that contrarily to previous belief, the proposed character-aware NMT model can generate results on par with the word-based NMT models. The rest of this paper is organized as follows. Section 2 describes related works. In Section 3, we propose our character-aware NMT model. Experiments and results are described in Section 4. We conclude in Section 5.

2 Related works

In this section, we describe the basis of this work: the attention-based encoder-decoder NMT model and the row convolution method.

2.1 Attention-based encoder-decoder

This subsection briefly describes the attention-based NMT (RNNsearch) (Bahdanau et al., 2014), on which the character-aware NMT model is built. The RNN search model simultaneously conducts dynamic alignment and generation of the target sentence and it produces the translation sentence by generating one target word at every time step. Given an input sequence $\boldsymbol{x} = (x_1, \ldots, x_{T_x})$ and previous translated words $(y_1, \ldots, y_{i-1})$, the probability of next word y_i is:

$$p(y_i|y_1, \ldots, y_{i-1}, \boldsymbol{x}) = g(y_{i-1}, s_i, c_i) \tag{1}$$

where s_i is an decoder hidden state for time step i, which is computed as:

$$s_i = f(s_{i-1}, y_{i-1}, c_i) \tag{2}$$

Here f and g are nonlinear transform functions, which can be implemented as long short term memory network(LSTM) or gated recurrent unit (GRU), and c_i is a distinct context vector at time step i, which is

calculated as a weighted sum of the input annotations h_j:

$$c_i = \sum_{j=1}^{T_x} a_{i,j} h_j \tag{3}$$

where h_j is the annotation of x_j from a bidirectional RNN. The weight a_{ij} for h_j is calculated as:

$$a_{i,j} = \frac{exp(e_{ij})}{\sum_{t=1}^{T_x} exp(e_{i,t})} \tag{4}$$

where

$$e_{i,j} = v_a tanh(W s_{i-1} + U h_j) \tag{5}$$

The mechanism of attention in RNN search makes the decoder focus on relevant words in the source sentence when generating the target word. The graphical illustration of the RNN search model is depicted in Fig.1(a).

2.2 Row convolution

(Amodei et al., 2015) firstly proposes the row convolution, which is used to look forward for a small portion of future information at the current time-step. Suppose at time-step t, the input h_t is a d-dimensional continuous vector and a future context of τ steps is considered. The model gets a feature matrix $h_{t:t+\tau}$ of size $d \times (\tau + 1)$. A parameter matrix of the same size as $h_{t:t+\tau}$ is defined as W. The activation r_t at the time-step t is computed as:

$$r_{t,i} = \sum_{j=1}^{\tau+1} W_{i,j} h_{t+j-1,i}, for 1 \leq i \leq d \tag{6}$$

Since the convolution-like operation in Eq.6 is row oriented for both W and $h_{t:t+\tau}$, it is called row convolution.

3 The character-aware NMT model

In this section, we describe the proposed character-aware NMT model in detail. Fig.1(b) is the graphical illustration of the proposed model. The basic architecture is a character-level encoder, which composes the input character embedding and its context embedding into the corresponding word-level representation.

3.1 Model overview

In a slightly generalized sense, the proposed character-aware NMT model is still an encoder-decoder. The encoder transformed the source sequence into the vector representation, which is then read by decoder to generate the output sequence.

Encoder The encoder in the proposed model is utilized in the character level. Specifically, the model is designed to compose the word-level information from the input sequence of characters. Compared to the RNN-encoder in (Bahdanau et al., 2014), there are two important differences

- **Context Computing** The proposed model builds a row convolution layer to compute the context vector for the current input character. The context vector preserves the context information which guides how to compose the word-level information.
- **Character composing** A character composing layer is used to compose the word-level information from the current input character and its corresponding context vector. The word-level information is then fed as input to the bidirectional RNN.

Decoder An RNN that reads the hidden variables of the encoder and predicts the target sequence. It is almost the same with the canonical RNN-decoder in (Bahdanau et al., 2014).

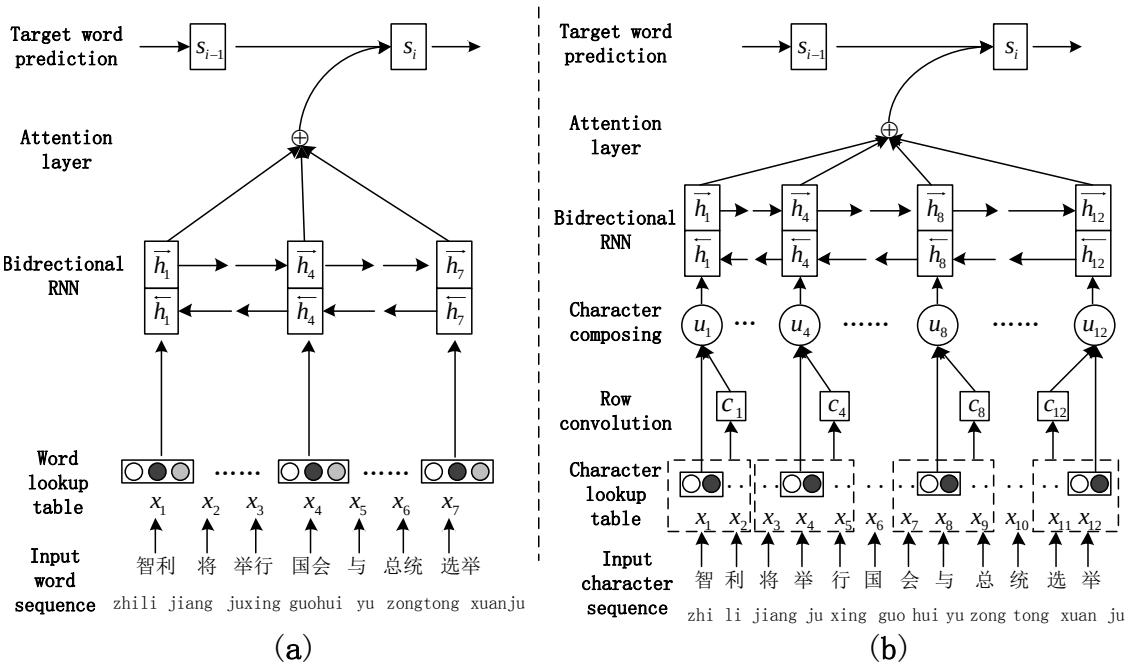

Figure 1: The graphical illustration of the proposed model. (a) is the traditional attention-based encoder-decoder model proposed by (Bahdanau et al., 2014). (b) is the proposed character-aware NMT model in this paper. Both of the two models try to translate the Chinese sentence "zhi li jiang ju xing guo hui yu zong tong xuan ju". The traditional attention-based model needs to segment the input sentence into Chinese words first. However, our character-aware model encodes the characters of the input sentence directly.

3.2 Bidirectional and concatenated row convolution for context

Given an input sequence of characters, the model projects each character into a continuous d-dimensional character vectors x_i using a character lookup table, which is similar to the word lookup table in the word-based NMT. Then, it builds a bidirectional and concatenated row convolution layer to compute the context vector c_i for x_i. Different from the traditional row convolution proposed in (Amodei et al., 2015) which only looks forward for the future context, the proposed bidirectional row convolution also looks behind to the history context. The intuition behind this layer is that, in additional to the future context, a small portion of history context is also needed to compose a full word-level representation for the character in current context. Suppose the input character x_i at time-step i, and the window size of the bidirectional row convolution is set as τ, we get a context matrix $x_{i-\tau,i+\tau}$ of size $d \times (2\tau + 1)$. We define a convolution matrix W of the same size as $x_{i-\tau,i+\tau}$. The activation c_i for the layer at time-step i is computed as:

$$c_i = [v_{i-\tau}; v_{i-\tau+1}; \ldots; v_{i+\tau}] \tag{7}$$

where $v_{i-\tau+t}$ is computed as:

$$v_{i-\tau+t} = w_t \times x_{i-\tau+t} (1 \leq t \leq (2\tau + 1)) \tag{8}$$

Since c_i is concatenated from $v^{i-\tau:i+\tau}$, the row convolution proposed in this paper is referred to as concatenated row convolution. For comparison and clarity, we call the row convolution in (Amodei et al., 2015) as summed row convolution.

3.3 Character composing

To fully utilize the character embedding x_i and its context vector c_i, we propose two different structures to compose the word-level representation u_i.

Forward character composing The forward character composing simply uses a linear transformation to combine the character embedding and its context embedding. For each character x_i, the corresponding word-level representation u_i is computed as:

$$u_i = M_1 x_i + M_2 c_i + b \tag{9}$$

where the weight matrix $M_1 \in R^{d \times d}$, the transformation matrix $M_2 \in R^{2\tau+1}$ convert the context c_i into the same dimension with x_i, the bias vector $b \in R^d$. Hence, the word-level representation u_i is kept the same dimension. In this model, the forward character composing layer is expected to learn the word-formation from the character and its neighboring characters automatically.

Recurrent character composing The recurrent character composing considers the interference from the former word-level representation u_{i-1} when computes u_i. Since the character x_{i-1} shares part of the neighboring characters with x_i, the context c_{i-1} and c_i hold some information in common. To reflect this interaction, or articulation, the u_i is calculated as:

$$u_i = M_1 x_i + M_2 c_i + M_3 u_{i-1} + b \tag{10}$$

Where the matrix $M_3 \in R^{d \times d}$ reflects the interference from u_{i-1}. The intuition behind this recurrent connection is that if the shared neighboring characters have provided much information for u_{i-1}, they should show less effects on u_i.

4 Experiments and results

We evaluate the proposed character-aware NMT model on the Chinese to English translation task. The open-source NMT system, GroundHog [*] (Bahdanau et al., 2014) is used as the baseline system.

4.1 Dataset

For the Chinese to English translation task, the training data consists of 2.3M pairs of sentences. As the traditional RNN search model relies on vector representations for words, we build a fixed vocabulary for each language respectively by choosing 45k of the most frequent words for the source language and 41k of the most frequent words for the target language. Words not included in the vocabulary are replaced with "UNK". For the proposed character-aware NMT model, we build a fixed character vocabulary with the size of 7009 for Chinese, which covers all of the Chinese characters in the training data. The vocabulary for English is the same with the traditional RNN search model. We use the BLEU metric to evaluate the translation quality and test the translation performance on IWSLT04, IWSLT05, IWSLT07, IWSLT08, MT08 and MT12.

4.2 Training detail

In the character-aware NMT model, the character embedding of the source side and the word embedding in the target side are all regarded as part of the model's parameters, and initialized by Gaussian distribution or uniform distribution, same as other parameters of the model. The window size of the row convolution τ is a hyper-parameter which can be set by the user ahead of time. In our implementation, we test the influence of τ by setting it as two, three and four respectively. We use parallel corpus to train RNN search model on a cluster with 8 Tesla K40 GPUs and it takes about 3 days to train the model for a total of 6 epochs. We use the same corpus to train the character-aware NMT model on the same cluster and the training time is longer than RNN search model: 4 days are needed to train the character-aware model for 6 epochs.

4.3 Impacts of the window size

The window size τ is a hyper-parameter which can be set by the user beforehand and it shows great impacts on the translation performance of our proposed model. Table 1 shows the translation performance of the character-aware NMT model when the window size is set as two, three and four respectively.

[*] https://github.com/lisa-groundhog/GroundHog

From table 1, it's easily to be found that the character-aware NMT model achieves the best performance when the window size is set as two. When the window size comes to four, the model can't be trained to converge. We explain this as that when the window size set as four, the neighboring word-level representations share too much information so that there is no distinction between the inputs to the bidirectional RNN. Hence the model may get confused and uneasily to be trained to converge.

Window size	IWSLT04	IWSLT05	IWSLT07	IWSLT08
2	50.01	52.13	33.10	43.15
3	48.62	51.30	31.15	41.26
4	—	—	—	—

Table 1: The impacts of the window size on the character-aware NMT model which has the recurrent connections.

4.4 Results on Chinese-English translation

Table 2 shows the BLEU score on Chinese-English test sets. The word embedding in traditional RNN search model and the character embedding in the proposed character-aware NMT model are all initialized to 512 dimensions by Gaussian distribution. The window size τ is set as two. In table 2, the RNNsearch-Word is the traditional RNN search model which serves as a baseline. To show the ability of our proposed character-aware NMT model, we also test the performance of the model RNNsearch-Char. The only difference between the RNNsearch-Char and the RNNsearch-Word is that the former regards the input sentence as a sequence of characters and the latter regards it as a sequence of words. The Character-aware-forward is the proposed character-aware NMT model which composes the word-level representation with the forward character composing layer and the Character-aware-recurrent utilize the recurrent character composing. By comparing the RNNsearch-word and RNNsearch-Char, we can find that the traditional RNN search model is incapable of handling the case where the input is a sequence of characters. Compared to the RNNsearch-Char, the proposed Character-aware-forward model leads to improvement up to 1.4 BLEU points although its performance is still worse than the baseline of RNNsearch-Word. The Character-aware-recurrent model leads to more significant improvement than the RNNsearch-Char and achieves comparable results with RNNsearch-Word.

Model	IWSLT04	IWSLT05	IWSLT07	IWSLT08	MT08	MT12
RNNsearch-Word	50.14	51.99	33.12	43.02	20.66	20.20
RNNsearch-Char	45.18	49.33	31.29	40.72	17.64	18.39
Character-aware-forward	47.56	50.74	32.48	42.17	19.25	19.65
Character-aware-recurrent	50.01	52.13	33.10	43.15	20.58	20.31

Table 2: The results on the Chinese to English translation tasks.

4.5 Comparison between the summed and concatenated row convolution

To show the effectiveness of our proposed concatenated row convolution, we compare the translation performance between the bidirectional summed row convolution and the bidirectional concatenated row convolution. Both of the two models have recurrent connections in the row convolution layer and the window size are both set as two. From table 3, we can find that the concatenated row convolution outperforms the summed row convolution at every test set. We conjecture that the summed row convolution have lost the information of the context vectors' relative position, which may be vital for composing word-level representation from characters.

Model	IWSLT04	IWSLT05	IWSLT07	IWSLT08
Concatenated row convolution	50.01	52.13	33.10	43.15
Summed row convolution	49.14	50.56	32.48	41.83

Table 3: The comparison between the summed and concatenated row convolution.

Table 4: The translation performance on name entity.

4.6 Performance on name entity and unknown words

To our surprise, the character-aware NMT model is able to translate the name entity very well, as shown in table 4. According to table 4, we can see that the proposed model achieves better translation performance on name entity than the traditional word-based RNN search model. This is partly because that the name entity usually occurs rarely in the training corpus and is often mapped to an unknown word by the RNN search model. However, in character-aware NMT model, the name entity is split into a sequence of characters and each character can be found in the vocabulary. Despite that we still use a word-based decoder in the proposed character-aware NMT model, the number of unknown words in output sentences has decreased dramatically.

5 Conclusions and future work

In this work, we present a novel and simple character-aware NMT model which encodes the input sentence at the character-level. In addition to be applied to the language that has a clear boundary between words, the proposed model is also applied to the language without explicit word segmentation. Hence, no relying on the word boundaries is the most obvious advantage of our model. We firstly introduce the row convolution into NMT and test the effectiveness of several different row convolution methods. Experimental results show that the proposed character-aware NMT model can achieve comparable results with the traditional word-based RNNsearch model. Despite the target side of the proposed model is still word based, the number of unknown words in the output sentences get decreased dramatically. Moreover, the character-aware NMT model shows its superiority on the translation of name entities.

One limitation of our model is that the decoder is still word based. However, this has allowed us a more fine-grained analysis. But in the future, a setting where the target side is also represented as a character sequence must be investigated.

Abstract

Estimating similarities at different levels of linguistic units, such as words, sub-phrases and phrases, is helpful for measuring semantic similarity of an entire bilingual phrase. In this paper, we propose a convolution-enhanced bilingual recursive neural network (ConvBRNN), which not only exploits word alignments to guide the generation of phrase structures but also integrates multiple-level information of the generated phrase structures into bilingual semantic modeling. In order to accurately learn the semantic hierarchy of a bilingual phrase, we develop a recursive neural network to constrain the learned bilingual phrase structures to be consistent with word alignments. Upon the generated source and target phrase structures, we stack a convolutional neural network to integrate vector representations of linguistic units on the structures into bilingual phrase embeddings. After that, we fully incorporate information of different linguistic units into a bilinear semantic similarity model. We introduce two max-margin losses to train the ConvBRNN model: one for the phrase structure inference and the other for the semantic similarity model. Experiments on NIST Chinese-English translation tasks demonstrate the high quality of the generated bilingual phrase structures with respect to word alignments and the effectiveness of learned semantic similarities on machine translation.

1 Introduction

Recently, adapting deep neural networks to statistical machine translation (SMT) is of growing interest due to their superior capacity against conventional lexical models in feature learning and representation (Yang et al., 2013; Liu et al., 2013; Li et al., 2013; Devlin et al., 2014; Liu et al., 2014; Setiawan et al., 2015). As phrases are the basic translation units in many SMT systems, one line of research among these studies is to learn the semantic similarity of bilingual phrases for translation selection in SMT (Zhang et al., 2014a; Gao et al., 2014; Cho et al., 2014; Su et al., 2015; Hu et al., 2015).

Typically, these bilingual semantic similarity models learn source and target phrase representations with some bilingual constraints (Gao et al., 2014; Hu et al., 2015; Zhang et al., 2014a). In spite of their success, they often suffer from two problems. Firstly, it is difficult for them to recover the semantic hierarchy (binary tree structure) of a bilingual phrase. In this respect, Su et al. (2015) improve tree construction by incorporating word alignments into their objective function. Unfortunately, they still employ the recursive autoencoder (RAE) as the underlying model to build tree structures of phrases according to the minimum reconstruction error. As a result, word alignments are not fully exploited for phrase structure generation. Secondly, the previous bilingual semantic similarity models are incapable of leveraging representations at different levels of linguistic units, such as words, sub-phrases and phrases. They usually represent a phrase (a sequence of words) with a single, fixed vector. However, as demonstrated in attention-based neural machine translation (Bahdanau et al., 2014), one vector is not semantically sufficient to encode a sequence of words preserving representations at different levels of linguistic units may be beneficial.

*Corresponding author.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3071–3081, Osaka, Japan, December 11-17 2016.

To solve these problems, we propose a convolution enhanced bilingual recursive neural network (ConvBRNN), which exploits word alignments to guide the generation of phrase structures and then integrates embeddings of different linguistic units on the phrase structures into bilingual semantic modeling. Specifically, we develop a new recursive neural network, in which the composition criterion for tree construction is the degree of consistency to word alignments rather than the reconstruction error. Furthermore, we propose a variant of the tree-based convolutional neural network (Mou et al., 2015) to fully access all embeddings on the phrase structures, which can be used to produce better phrase representations (see Section 3.2). All these make ConvBRNN more suitable for the subsequent bilingual semantic modeling, where a bilinear model is introduced to interact and compare the source and target phrase representations in terms of the degree of semantic equivalence. To train our model, we introduce two max-margin losses: one for the bilingual semantic structure inference and the other for the semantic similarity model, both of which are derivable.

We conduct experiments on large-scale corpus to examine the effectiveness of ConvBRNN on bilingual phrase structure learning and semantic similarity estimation. Experiment results on NIST MT06 and MT08 datasets show that our system achieves significant improvements over baseline methods. We further analyze the generated bilingual phrase structures and semantic scores, both of which indicate that ConvBRNN indeed learns information from word alignments that is beneficial for bilingual semantic representations.

Our major contributions lie in the following three aspects:

- We develop a new recursive neural network with an alignment-based semantic composition metric to generate word-alignment-consistent bilingual phrase structures.
- we develop a variant of tree-based convolutional neural model, which utilizes all embeddings on a phrase structure rather than the embedding of the entire phrase to model bilingual semantics.
- We carry out a series of experiments and demonstrate that our model is superior to baselines in terms of both the learned phrase structures and semantic similarities.

2 Related Work

A straightforward approach to learning bilingual phrase representations is to adapt monolingual phrase models with bilingual supervisions. For example, Li et al. (2013) encode reordering orientations into RAE-generated embeddings. To utilize the semantic equivalence constraint between source and target phrases, Gao et al. (2014) use a feedforward neural network to model phrase embeddings and try to maximize their semantic similarity, while Zhang et al. (2014a) introduce a bilingually-constrained RAE. Furthermore, Hu et al. (2015) incorporate context information to disambiguate translation selection. Very recently, neural machine translation trains a unified encoder-decoder (Sutskever et al., 2014; Bahdanau et al., 2014) neural network for translation, where an encoder maps the input sentence into a fixed-length vector, and a decoder generates a translation from the encoded vector.

Unlike the work mentioned above, our model mainly explore word alignments to guide the generation of bilingual phrase structures. The most relevant work to ours is the model proposed by Su et al. (2015), where they treat word alignments as a constraint to the RAE model. However, as discussed in Section 1, the composition criterion in RAE (i.e. reconstruction errors) does not allow us to fully benefit from word alignments. Therefore, we introduce a new composition criterion based on word alignment consistency. The proposed recursive neural network works in a way similar to that in (Socher et al., 2011b) except for our specific bilingual supervision. Zhang et al. (2014b) also propose a recursive neural network. However, their model mainly focuses on the composition in machine translation process (namely, *swap* or *monotone*), which is different from ours.

Additionally, our model also adapts convolutional neural network (Kalchbrenner et al., 2014; Kim, 2014) to extract semantic information encoded in phrase structures. Our model is related to the tree-based convolution (Mou et al., 2015). The differences are 1) that we treat the whole tree structure as the window for convolution; and 2) that the underlying phrase structure for a sentence is generated automatically in our model, instead of taking from a given constituency or dependency tree. Besides, the exploration of the semantic embeddings at different levels of granularity is firstly investigated in

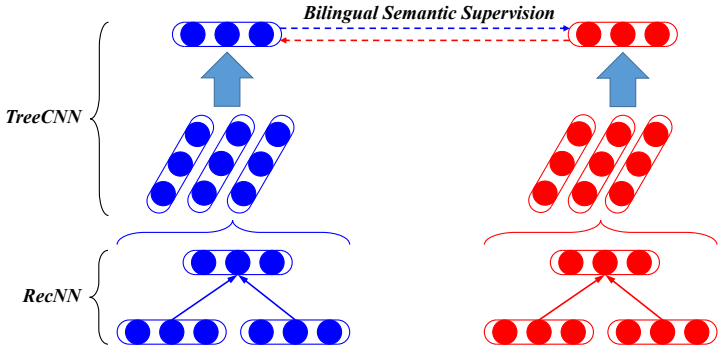

Figure 1: An illustration of the convolution-enhanced bilingual recursive neural network.

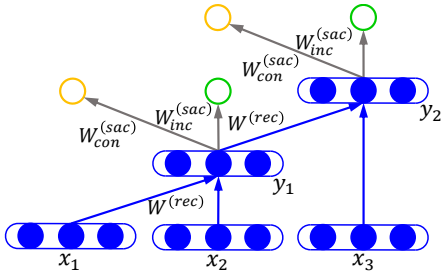

Figure 2: An illustration of the proposed RecNN. We use a yellow/green circle to represent the preference score of a node to be an SAC/non-SAC node.

(Socher et al., 2011a), where they compute an interaction matrix from which discriminative features are dynamically extracted for paraphrase identification. He et al. (2015) and Yin et al. (2015b) further extend this idea to convolutional neural network. Although our method is partially inspired by them, we implement it in a completely different manner.

3 Convolution-Enhanced Bilingual Recursive Neural Network

This section elaborates the proposed ConvBRNN model, of which network structure is shown in Figure 1. We begin with the generation of phrase structures via a recursive neural network. We then elaborate how to perform convolution upon the generated phrase structures. After that, we describe our bilingual semantic similarity model. Finally, we provide a detailed illustration on the training of ConvBRNN.

3.1 Recursive Neural Network for Generating Phrase Structures

To generate phrase structures, the conventional RAE usually composes neighboring nodes based on their reconstruction errors, which we argue are insufficient to model bilingual semantics. In SMT, one important auxiliary for a bilingual phrase is its word alignments, which contain some useful guidance signals for the bilingual structure construction, as discussed in Section 1. To make better use of these signals, we introduce the following recursive neural network (*RecNN*).

As shown in Figure 2, the input to our RecNN is a list of ordered d-dimensional vectors x=(x_1, x_2, x_3), each of which can be retrieved from a word embedding matrix $\mathbb{L} \in \mathbb{R}^{d \times |V|}$ via its corresponding word index. Here $|V|$ is the size of the vocabulary. Given two neighboring children c_1 and c_2, we compose them into a parent node n (For example, in Figure 2, if we set c_1=x_1 and c_2=x_2, then n=y_1) and produce its semantic vector p_n through a non-linear transformation:

$$p_n = f(W^{(rec)}[c_1; c_2] + b^{(rec)}) \tag{1}$$

where $[c_1; c_2] \in \mathbb{R}^{2d}$ is the concatenation of c_1 and c_2, $W^{(rec)} \in \mathbb{R}^{d \times 2d}$ and $b^{(rec)} \in \mathbb{R}^d$ is the parameter matrix and bias term respectively, and $f(\cdot)$ is an element-wise activation function such as $\tanh(\cdot)$, which is used throughout our experiments. As discussed in Section 1, the previous RAE-style models (Zhang

et al., 2014a; Su et al., 2015) adopt reconstruction error to measure how well p_n represents its children c_1 and c_2, which, however, is not a good solution to directly fully exploit word alignments for bilingual semantic modeling. To fully exploit different levels of bilingual semantic constraints within phrase pairs, we design a new semantic composition metric based on word alignments. As word alignments are shared across the source and target language, they are suitable to act as a desirable bridge for modeling bilingual semantics.

To achieve this goal, we first use the *structural alignment consistency* (SAC) (Su et al., 2015) that is the basis of our model to classify resultant nodes of semantic compositions into two categories. Specifically, if the node n covers a sub-phrase, and there exists a sub-phrase in the other language such that these two sub-phrases are consistent with word alignments (Och and Ney, 2003), we say n satisfies the structural alignment consistency, and it is referred to as an SAC node, otherwise, it is a non-SAC node.

Then, we introduce two functions $Score_{con}(n)$ and $Score_{inc}(n)$ to measure the preference strength of node n to be an SAC or a non-SAC node, respectively

$$Score_{con}(n) = W_{con}^{(sac)}\, p_n, \quad Score_{inc}(n) = W_{inc}^{(sac)}\, p_n \tag{2}$$

where $W_{con}^{(sac)} \in \mathbb{R}^{1\times d}$ and $W_{inc}^{(sac)} \in \mathbb{R}^{1\times d}$ are parameter matrices. Furthermore, we calculate the final semantic composition score of node n as follows

$$Score_{sc}(n) = \frac{exp(Score_{con}(n))}{exp(Score_{inc}(n))} \tag{3}$$

Obviously, the larger $Score_{con}(n)$ is than $Score_{inc}(n)$, the larger $Score_{sc}(n)$ should be.

We traverse each possible semantic composition of neighboring children and calculate its semantic composition score, and finally select the composition with the largest score. This combination process on neighboring children repeats at each node until the structure and embedding of the entire bilingual phrase are generated. To obtain the optimal binary tree and phrase representation for x, we minimize the following objective function formulated as follows:

$$\begin{aligned} E_{align}(x) = & \sum_{n\in T_{con}(x)} max\{0, 1 - Score_{con}(n) + Score_{inc}(n)\} \\ & + \sum_{n\in T_{inc}(x)} max\{0, 1 - Score_{inc}(n) + Score_{con}(n)\} \end{aligned} \tag{4}$$

where $T_{con}(x)$ and $T_{inc}(x)$ denote the SAC and non-SAC node sets in the binary tree of x, respectively. It should be noted especially that we use different max-margin loss functions for different types of nodes. On the one hand, we simultaneously maximize the $Score_{con}(*)$ and minimize the $Score_{inc}(*)$ of SAC nodes. On the other hand, we take an opposite approach to deal with non-SAC nodes. In this way, the node type (SAC/non-SAC) with word alignment information performs as a guidance signal to encourage the generation of word-alignment-consistent phrase structures.

3.2 Convolutional Neural Network for Learning Phrase Representations

Given a generated phrase structure, a straightforward way to obtain phrase representation is to extract the embedding of the root node of the phrase structure, as implemented in the conventional RAE. However, a major limitation of this method is the neglect of lower-level linguistic units, e.g. words and sub-phrases. To alleviate this problem, we stack a variant of tree-based convolutional neural network (*TreeCNN*) to incorporate all the embeddings inside the phrase structure.

Upon the generated structure $T(x)$ of an input phrase x, we first perform postorder traversal to extract embeddings of all nodes, and then concatenate them column-wisely into a matrix $M \in \mathbb{R}^{d\times|n|}$, where $|n|$ is the number of nodes in $T(x)$. Note that the node number varies with different phrases. In this way, the representations at different levels are interlaced along the rows of M, which facilitates the upcoming window-based convolution. To construct our TreeCNN, we take the matrix M as the input layer. Figure

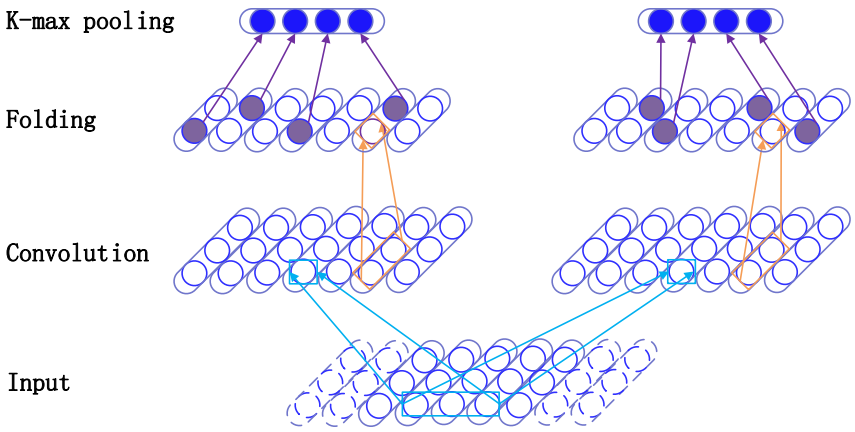

Figure 3: Illustration of the proposed TreeCNN with window size 3, pooling size 2 and filter number 2. We use a light blue, orange and purple color to indicate the convolution, folding and pooling operation, respectively. The nodes with dashed circles represent zero-padded embeddings for wide convolution.

3 shows the architecture of our TreeCNN, which consists of three different layers: *convolution*, *folding* and *k-max pooling*.

Convolution Layer This layer iteratively convolves an h-sized sliding window on M, and uses a filter F to summarize the information inside the window. Since the length of phrases in the translation model is usually not long, we pad the matrix M with h-1 zero embeddings on both sides and adopt the wide convolution (Kalchbrenner et al., 2014) (see the dashed circles in Figure 3). To discover semantic information at a finer granularity, we further construct *per-dimension filters* $F^{[r]}$ ($1 \leq r \leq d$) (He et al., 2015) to convolve the embeddings in the r-th row of M.

Formally, applying the per-dimension filter $F^{[r]}$ on M produces an output vector $C^{[r]} \in \mathbb{R}^{|n|+h-1}$ where the i-th entry ($1 \leq i \leq |n| + h - 1$) is computed as follows:

$$C_i^{[r]} = (W_{F^{[r]}})^T M_{i:i+h-1}^{[r]} \tag{5}$$

where $W_{F^{[r]}} \in \mathbb{R}^h$ is the parameter vector of $F^{[r]}$. This procedure is illustrated in Figure 3 with a light blue color. By applying all per-dimension filters to traverse all windows of matrix M, we can obtain a feature map $C \in \mathbb{R}^{d \times (|n|+h-1)}$. It encodes complex dependencies across different levels of linguistic units and contains linguistic properties implied in each dimension, which, nevertheless, makes different dimensions independent of each other. Next we will introduce a folding layer to exploit these dimensions simultaneously.

Folding Layer This layer bridges the gap across different dimensions through averaging each nonoverlapping neighboring rows in the convoluted feature map C. Specifically, for each row index r ($1 \leq r \leq \lfloor \frac{d}{2} \rfloor$), the output can be computed as follows (shown in the orange color in Figure 3):

$$A^{[r]} = (C^{[2r-1]} + C^{[2r]})/2 \tag{6}$$

where $A^{[r]} \in \mathbb{R}^{|n|+h-1}$ is the r-th row of $A \in \mathbb{R}^{\lceil \frac{d}{2} \rceil \times (|n|+h-1)}$. Different from previous work, we allow dimension size d to be odd. In this case, we simply append the last row of C onto A.

After the above operation, each element of A captures complex dependencies across both rows and columns of M. To mingle these dependencies, we further perform a non-linear transformation following Yin et al. (2015a):

$$U = f(A + b_{[:]}) \tag{7}$$

where $b \in \mathbb{R}^{\lceil \frac{d}{2} \rceil}$ is the bias term that is shared across different columns, and the subscript $[:]$ indicates a column-wise *broadcasting* operation. It should be noted that the column dimension of U (i.e. $|n|+h-1$) differs for different phrases. This raises a key problem: how can we transform the variable-length matrix

U into a fixed-length vector. In order to deal with this problem, we further stack a K-max Pooling layer (Kalchbrenner et al., 2014).

K-max Pooling Layer This layer extracts the top-k values over each row of U so as to: 1) preserve rich semantic information of a sentence; and 2) eliminate the variance in the column dimension of U (shown in the purple color in Figure 3). In doing so, we obtain a phrase vector representation with the dimension size $\lceil \frac{d}{2} \rceil \cdot k$. Notice that k in this layer is predefined. Although we can use the dynamic version of k-max pooling to stack more convolution, folding and pooling layers (Kalchbrenner et al., 2014), we do not take this strategy due to the trade-off between performance and cost. Theoretically, more layers should capture much deeper semantic information. We leave this for our future research.

So far we have described how we apply the wide convolution, folding layer and k-max pooling layer onto an input phrase matrix to obtain a fixed-length phrase representation. Inspired by studies on convolutional networks for object recognition, we introduce L filters to produce multiple feature maps, which are used to capture semantics of input phrases. Finally, we concatenate the vector representations derived from L filters to obtain the final phrase representation $p \in \mathbb{R}^{\lceil \frac{d}{2} \rceil \cdot k \cdot L}$.

3.3 Bilingual Semantic Supervision

Through the above procedures, we obtain the semantic representations of bilingual phrase (f, e), denoted by p_f and p_e. To measure the semantic similarity of f and e, we introduce two transformation matrixes $W_f^{(sem)} \in \mathbb{R}^{d_{sem} \times (\lceil \frac{d_s}{2} \rceil \cdot k \cdot L)}$ and $W_e^{(sem)} \in \mathbb{R}^{d_{sem} \times (\lceil \frac{d_t}{2} \rceil \cdot k \cdot L)}$ to project their semantic representations p_f and p_e into a common semantic space:

$$p'_f = f(W_f^{(sem)} p_f + b^{(sem)}), \;\; p'_e = f(W_e^{(sem)} p_e + b^{(sem)}) \tag{8}$$

where p'_f and p'_e are transformed representations of f and e, d_s/d_t is the dimension size of phrase representation in the source/target semantic space, d_{sem} is the that of the common semantic space. Although we distinguish the transformation matrices for the source and target language, we share the same bias term $b^{(sem)}$ for both languages. The advantage of this is that our model will learn to encode bilingual semantics into these transformation matrices, rather than biases.

Then, we further stack a bilinear model over the transformed representations to compute the semantic similarity score $Sim(f, e)$:

$$Sim(f, e) = {p'_f}^T W_{bi}^{(sem)} p'_e \tag{9}$$

where $W_{bi}^{(sem)} \in \mathbb{R}^{d_{sem} \times d_{sem}}$ is a squared matrix of parameters to be learned. Intuitively, each element in $W_{bi}^{(sem)}$ represents an interaction between p'_f and p'_e, which is used to capture the semantic correspondence within f and e.

To make the semantic scores of translation equivalents as large as possible while scores of non-translation pairs as small as possible, we introduce the following max-margin loss for (f, e):

$$\begin{aligned} E_{sem}(f, e) = & \; max\{0, 1 - Sim(f, e) + Sim(f, e^-)\} \\ & + max\{0, 1 - Sim(f, e) + Sim(f^-, e)\} \end{aligned} \tag{10}$$

where f^-/e^- is a bad translation that replaces the words in f/e with randomly chosen source/target language words.

3.4 Model Training

As described above, there are two types of errors involved for the phrase pair (f, e): (1) structural alignment error $E_{align}(f, e)$ that estimates how well the generated structures of f and e comply with word alignments, and (2) semantic error $E_{sem}(f, e)$ that measures how well the learned phrase embeddings of f and e are semantically equivalent.

Given a training corpus $D = \{(f, e)\}$, the final objective of ConvBRNN is formulated as follows:

$$J_{ConvBRNN}(\theta) = \frac{1}{|D|} \sum_{(f,e) \in D} \{\alpha E_{align}(f, e) + (1 - \alpha) E_{sem}(f, e)\} + R(\theta) \tag{11}$$

where $E_{align}(f,e)$ is the sum of $E_{align}(f)$ and $E_{align}(e)$, the hyper-parameter α is used to balance the effects of $E_{align}(f,e)$ and $E_{sem}(f,e)$, and $R(\theta)$ is a regularization term.

Parameters θ are divided into four sets[1]: (1) θ_L: the word embedding matrix (Section 3.1); (2) θ_{RT}: the structure parameters of RecNN (Section 3.1) and TreeCNN (Section 3.2); (3) θ_{wa}: the parameters for structural alignment consistency (Section 3.1); (4) θ_{sem}: the parameters for semantic similarity (Section 3.3). Following previous work (Zhang et al., 2014a; Su et al., 2015), we assign each parameter set a unique weight for regularization:

$$R(\theta) = \frac{\lambda_L}{2}\|\theta_L\|^2 + \frac{\lambda_{RT}}{2}\|\theta_{RT}\|^2 + \frac{\lambda_{wa}}{2}\|\theta_{wa}\|^2 + \frac{\lambda_{sem}}{2}\|\theta_{sem}\|^2 \quad (12)$$

We apply L-BFGS to tune parameters based on gradients over the joint error, as implemented in (Socher et al., 2011c). Word vector embeddings θ_L are initialized with the toolkit Word2Vec[2] on a large scale unlabeled data. Other parameters are randomly initialized according to a normal distribution (μ = 0,σ = 0.01). With the trained model parameters, we can easily obtain the dense semantic vectors for bilingual phrases. During translation, we incorporate the derived phrasal similarity feature into the standard log-linear framework (Och and Ney, 2002) of SMT for translation selection.

4 Experiment

We conducted experiments on NIST Chinese-English translation task to validate the effectiveness of ConvBRNN.

System Overview Our baseline decoder is a state-of-the-art phrase-based translation system equipped with a maximum entropy based reordering model, which adopts three bracketing transduction grammar rules (Wu, 1997; Xiong et al., 2006). We compared the proposed model with two models: (1) the bilingual correspondence model (*BCorrRAE*) proposed by Su et al. (2015); (2) the proposed model without the convolutional neural network (*ConvBRNN-CNN*), which simply treats the embedding of root node of the phrase structure as the semantic representation of the whole phrase, instead of the convoluted one. Other components of ConvBRNN-CNN are the same as those in the ConvBRNN model.

All translation systems used the log-linear framework. The adopted sub-models include: (1) rule translation probabilities in two directions, (2) lexical weights in two directions, (3) targets-side word number, (4) phrase number, (5) language model score, (6) the score of maximal entropy based reordering model, (7) the semantic similarities of phrase pairs. We performed minimum error rate training to tune the optimal feature weights on the development set (Och and Ney, 2003).

Experiment Setup Our training corpus contains 1.0M sentence pairs (25.2M Chinese words and 29M English words) that are from the FBIS corpus and Handsards part of LDC2004T07 corpus. We ran GIZA++[3] on the training data in two directions and applied the "*grow-diag-final-and*" heuristic rule to obtain word alignments. We trained a 5-gram language model on the Xinhua portion of the GIGAWORD corpus using *SRILM* Toolkit[4] with modified Kneser-Ney Smoothing. We chose the 2005 NIST MT evaluation test data as the development set, and the 2006, 2008 NIST MT evaluation test data as the test sets. We used case-insensitive BLEU-4 metric (Papineni et al., 2002) to evaluate translation quality, and conducted paired bootstrap sampling (Koehn, 2004) for significance test.

Network Training To train ConvBRNN, we applied forced decoding (Wuebker et al., 2010) on the training corpus to extract high-quality bilingual phrases for model training. We tuned the optimal hyper-parameters via *random search* method (Bergstra and Bengio, 2012) to minimize the joint error on a small portion of our training data. Finally, we set $d_s = d_t = d_{sem} = 50$, $h = 5$, $L = 10$, $k = 3$, $\alpha = 0.116$, $\lambda_L = 2.14e^{-7}$, $\lambda_{RT} = 2.43e^{-5}$, $\lambda_{wa} = 7.33e^{-5}$ and $\lambda_{sem} = 4.03e^{-6}$, the L-BFGS iteration number N_{iter}=100. To train BCorrRAE, we used the same training data and method for hyper-parameter optimization.

[1]Note that the source and target languages have different four sets of parameters.

Table 1: Experiment results on the MT 06/08 test sets, where we highlight the best result in bold. **AVG** = average BLEU scores on test sets; "+": significantly better than *Baseline* ($p < 0.01$); "$*$": significantly better than *BCorrRAE* ($p < 0.05$);

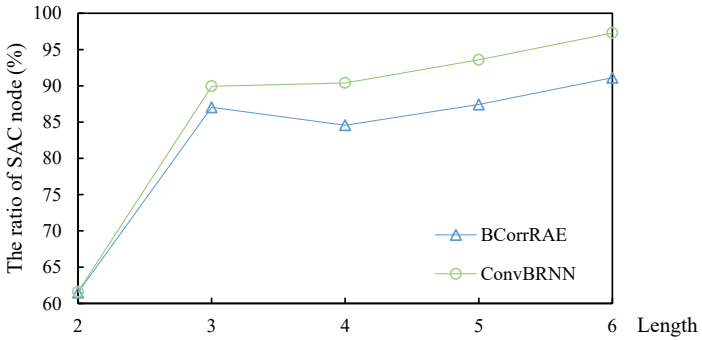

Figure 4: The ratio of *SAC* node specific to the length of covered source phrase. We limit the maximal length of source and target phrase to be 7, and the results when length is 1 and 7 are not shown because they are the same for both models.

4.1 Translation Results

The first experiment checks whether the learned bilingual semantic similarity is able to improve the translation quality. Table 1 summarizes the detailed results. We can observe that our ConvBRNN model significantly improves translation quality in terms of BLEU score on all test sets. Overall, ConvBRNN obtains a gain of up to *2.1* BLEU points on average over the Baseline. Particularly, on the MT08 data set, the improvements over the Baseline can be up to *2.37* BLEU points.

The integration of bilingual correspondence helps BCorrRAE gain *1.55* BLEU points on average over the Baseline. With the recursive neural network for phrase structure generation, ConvBRNN-CNN performs slightly better than BCorrRAE. By integrating the tree-based convolution network for phrase representation learning, our ConvBRNN achieves further improvements over BCorrRAE, which is significant at $p<0.05$. For this result, the reasons may be the following two points: 1) bilingual phrase structures generated by ConvBRNN are more close to the actual semantic structures of phrases; 2) the ConvBRNN model encodes different levels of linguistic units inside phrase structures into final phrase representations. These two points are not adequately considered in BCorrRAE.

4.2 Result Analyses

In order to know how the ConvBRNN model improves the performance of the SMT system, we study the bilingual phrases of our model from the following two respects:

First, we investigate the ability of our model in generating word-alignment-consistent bilingual phrase structures. For this, we extracted phrase pairs from our translation model filtered by NIST test sets and computed the percentage of SAC nodes (Section 3.1) specific to the length of covered source phrase. Following the previous work (Su et al., 2015), we define this percentage as the ratio of the number of SAC nodes to that of all nodes.

Figure 4 reports the ratio values. The ConvBRNN model consistently outperforms the BCorrRAE model. Additionally, as the length grows, the ratio gap between two models becomes larger, with a gain of up to absolute 6%. This indicates that word alignments are more efficiently exploited by our

Source Phrase	BCorrRAE	ConvBRNN
wǒ rènwéi zhè zhǒng	((((*i think*) *this*) *is*) *a*) (((*i think*) *that*) *was*) ((*i regard*) *this*)	((*i think*) ((*this type*) *of*)) ((*i think*) ((*this kind*) *of*)) ((*i find*) ((*that kind*) *of*))
biǎoshì qiángliè bùmǎn	(*strong* ((*opposition against*) *the*)) ((((*expressed strong*) *opposition*) *to*) *the*) (*voice* (*my* (*strong* (*opposition against*))))	((*strongly* (*dissatisfied with*)) *the*) (((*voice* (*my* (*strong opposition*))) *against*) *the*) ((*express* (*strong dissatisfaction*)) *at*)
jiānjué zh̄ichí zhèngfǔ	((*resolutely* (*support the*)) *government*) ((*firm* (*supporter* (*of our*))) *government*) ((*staunchly* (*support* (*the Chinese*))) *government*)	((*staunchly support*) ((*the Chinese*) *government*)) ((*resolutely support*) (*the government*)) ((*firm supporter*) (*of* (*our government*)))

Table 2: Semantically similar target phrases in the training set for example source phrases. The brackets indicate the learned binary tree structure.

ConvBRNN model to generate word-alignment-consistent bilingual phrase structures.

Second, we study whether ConvBRNN can extract meaningful information for semantic similarity from the learned phrase structures. We show some source phrases in Table 2 with their most semantically similar translations learned by BCorrRAE and ConvBRNN in the training corpus. We find that both models are able to distinguish semantic equivalents from non-translation pairs. However, in contrast to BCorrRAE, ConvBRNN prefers diverse expressions. For example, "zhǒng" can be translated into "*type*" or "*kind*", and "bùmǎn" also has two candidate translations "*opposition*" and "*dissatisfaction*". Therefore, during translation, the decoder has many candidate translations for the same source phrase, which we argue is one of the reasons for our success.

We also provide phrase structures in Table 2. We observe that the semantic compositions in BCorrRAE are relatively meaningless because they often do not respect the linguistic phenomena. For example, BCorrRAE prefers branching structures in the same composition direction, such as "(*voice* (*my* (*strong* (*opposition against*))))". Besides, BCorrRAE is more likely to produce undesirable nodes covering high-frequency sub-phrases. For instance, the target phrase "*firm supporter of our government*" has different structures learned by BCorrRAE and ConvBRNN: "((*firm* (*supporter* (*of our*))) *governmen-t*))" (BCorrRAE) and "((*firm supporter*) (*of* (*our government*)))" (ConvBRNN). Obviously, the phrase structure learned by ConvBRNN is more syntactically meaningful. This again demonstrates the advantage of ConvBRAE over BCorrRAE in exploiting word alignments for learning better bilingual phrase structures.

5 Conclusion and Future Work

In this paper, we have presented a convolution-enhanced bilingual recursive neural network to learn bilingual semantic similarity. We first introduce a recursive neural network which directly exploits word alignments to generate word-alignment-consistent bilingual phrase structures. Based on these structures, we further employ a variant of tree-based convolutional neural network to produce bilingual phrase embeddings by summarizing embeddings at different levels of lingual units. Experiment results and analyses on machine translation demonstrate the effectiveness of our model.

In the future, we would like to explore more different selection functions in Eq. (3) for our model due to its importance for the generation of bilingual phrase structures. Besides, as discussed in Section 3.2, we will further enhance the proposed model by trying more effective components, such as dynamic version of k-max pooling, multi-layer convolutions.

Abstract

In neural machine translation, the attention mechanism facilitates the translation process by producing a soft alignment between the source sentence and the target sentence. However, without dedicated distortion and fertility models seen in traditional SMT systems, the learned alignment may not be accurate, which can lead to low translation quality. In this paper, we propose two novel models to improve attention-based neural machine translation. We propose a recurrent attention mechanism as an implicit distortion model, and a fertility conditioned decoder as an implicit fertility model. We conduct experiments on large-scale Chinese–English translation tasks. The results show that our models significantly improve both the alignment and translation quality compared to the original attention mechanism and several other variations.

1 Introduction

Sequence-to-sequence neural machine translation (NMT) has shown promising results lately (Sutskever et al., 2014; Cho et al., 2014b). An NMT model typically consists of an encoding neural network which transforms the source sentence into some vector representation, and a decoding neural network which generates the target sentence from the vector representation. This is called the encoder-decoder model. In order to handle variable length inputs, recurrent neural networks (RNN) are usually used as the encoder and the decoder. The encoder RNN will read the words in the source sentence one by one and generate a sequence of corresponding hidden states; the decoder will then by conditioned on the encoder states to output each word in the target sentence. In (Cho et al., 2014b), only the last encoder state is used for target sentence generation, so the single hidden state vector must preserve all the necessary information in the source sentence for the decoding process , which is very difficult when the source sentence is long.

To leverage the whole sequence of encoder states and retrieve information from the source sentence in a more flexible way, the attention mechanism (Bahdanau et al., 2014) was introduced into the encoder-decoder model. In an attention-based encoder-decoder model, matching scores between the source and target words are calculated based on their corresponding encoder and decoder states. These scores are then normalized and used as weights for the source words given each target word. This can be seen as a soft alignment and the attention mechanism here plays similar role to that of a traditional alignment model.

In alignment models used in traditional machine translation models such as IBM Models (Brown et al., 1993), distortion and fertility are modeled explicitly. By comparison, in the attention mechanism, alignment is computed by matching the previous decoder hidden state with all the encoder hidden states, without modeling distortion and fertility. Since the translation of target words is guided by the attention

† Work done while author was an undergraduate student of Shanghai Jiao Tong University and intern at Microsoft Research.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3082–3092, Osaka, Japan, December 11-17 2016.

mechanism, the translation accuracy of an attention-based NMT model is largely dependent on the accuracy of the alignment, and a large portion of errors seen in the translation result can be associated with the lack of distortion and fertility models. Without a distortion model, the generated alignment sometimes contains incorrect word reordering and as a result the meaning of the sentence could be twisted. Due to the lack of a fertility model, the number of times that each word in the source sentence be aligned to is not restricted, and as a result we sometimes observe that part of the sentence is translated repeatedly, or part of the sentence is missing in the translation.

In the following sections, we first review the attention-based encoder-decoder model, and then give a detailed analysis of these problems using example alignment matrices generated by the standard model. In Section 4 we introduce the two proposed extensions to the attention-based encoder decoder. We first introduce a recurrent attention mechanism with extra recurrent paths as an implicit distortion model to solve the reordering problem. To address the lack of fertility model, we use a fertility vector which memorizes the words that have been translated and design a decoder that is conditioned on this vector. In Section 6 we will show the results of our experiments on large-scale Chinese–English translation tasks and demonstrate that our proposed methods can significantly improve the translation performance.

2 Attention-based Encoder-Decoder

Long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) and gated recurrent unit (GRU) (Cho et al., 2014b) are often used as RNNs in attention-based encoder-decoder models. In this section, we will briefly introduce GRU, followed by a short review of how attention is modeled between encoder and decoder states as described in (Bahdanau et al., 2014).

2.1 Gated Recurrent Unit

At time i, a recurrent function RNN computes its hidden state $\boldsymbol{h}_i$ based on the input $\boldsymbol{x}_i$ and previous hidden state $\boldsymbol{h}_{i-1}$:

$$\boldsymbol{h}_i = \text{RNN}(\boldsymbol{h}_{i-1}, \boldsymbol{x}_i)$$

A GRU uses reset gate and update gate to help model long-term dependencies:

$$\begin{aligned}
\boldsymbol{r}_i &= \sigma(\boldsymbol{W}^r \boldsymbol{x}_i + \boldsymbol{U}^r \boldsymbol{h}_{i-1}) \\
\boldsymbol{z}_i &= \sigma(\boldsymbol{W}^z \boldsymbol{x}_i + \boldsymbol{U}^z \boldsymbol{h}_{i-1}) \\
\boldsymbol{h}'_i &= \tanh(\boldsymbol{U}(\boldsymbol{r}_i \odot \boldsymbol{h}_{i-1}) + \boldsymbol{W}\boldsymbol{x}_i) \\
\boldsymbol{h}_i &= (1 - \boldsymbol{z}_i) \odot \boldsymbol{h}'_i + \boldsymbol{z}_i \odot \boldsymbol{h}_{i-1}
\end{aligned}$$

where $\boldsymbol{x}_i$ is the input, and $\boldsymbol{h}_{i-1}$ is the previous hidden state. $\boldsymbol{r}_i$ and $\boldsymbol{z}_i$ are reset and update gates respectively. $\odot$ denotes element-wise product.

2.2 RNNSearch

RNNSEARCH referes to the attention-based encoder-decoder model proposed by (Bahdanau et al., 2014). It consists of two RNNs: an encoder RNN that maps the source sentence to a sequence of hidden states, and a decoder RNN that generates the target sentence based on the encoder states with attention mechanism.

Encoder The encoder used in RNNSEARCH is a bi-directional GRU. It consists of two independent RNNs, one reading the source sentence from left to right, another from right to left, generating two hidden states at each position. The two hidden states produced by forward and backward RNNs are concatenated to generate the sequence of encoder states $\boldsymbol{s}_1^J$, where J is the length of source sentence.

Decoder Unlike the decoder of (Cho et al., 2014b; Sutskever et al., 2014), which takes only the last encoder state as the context vector, the decoder with attention mechanism uses encoder states from all time-stamps as context. Decoder with attention mechanism is illustrated in Figure 5.

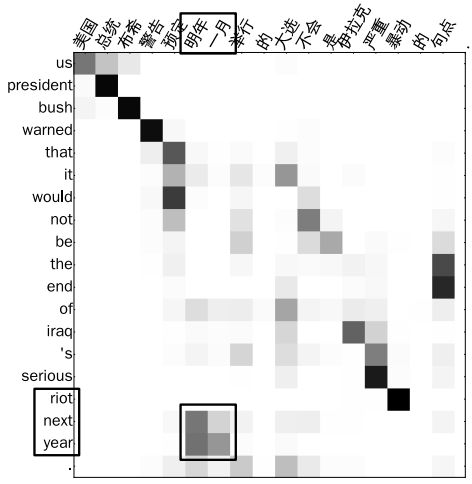

Figure 1. Incorrect reordering by the attention mechanism. The correct translation is "US president Bush warned that the election to be held on January 30th next year would not be an end to serious violence in Iraq."

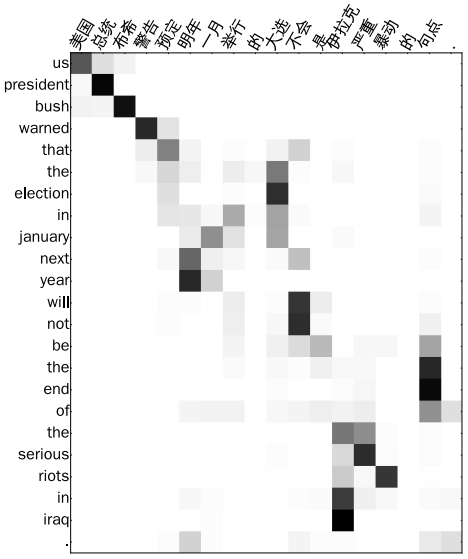

Figure 2. Our proposed model RECATT produced the correct reordering of the source words, and based on that generated a better translation.

At position i in the target sentence, the attention model computes a matching score e_{ij} with match function α, for the previous decoder state $\boldsymbol{h}_{i-1}$ and each encoder state $\boldsymbol{s}_j$.

$$e_{ij} = \boldsymbol{v}^\top \tanh\left(\alpha(\boldsymbol{h}_{i-1}, \boldsymbol{s}_j)\right)$$
$$w_{ij} = \frac{\exp(e_{ij})}{\sum_k \exp(e_{ik})}$$

We wrap this computation of weights as ALIGN:

$$\boldsymbol{w}_i = \text{ALIGN}(\boldsymbol{h}_{i-1}, \boldsymbol{s}_1^J)$$

There are various match functions, as analyzed in (Luong et al., 2015). In our paper we use the sum match function $\alpha(\boldsymbol{h}_{i-1}, \boldsymbol{s}_j) = \boldsymbol{W}^\alpha \boldsymbol{h}_{i-1} + \boldsymbol{U}^\alpha \boldsymbol{s}_j$. The weighted average of the encoder states $\boldsymbol{s}_1^J$ is calculated as the context $\boldsymbol{c}_i = \sum_j w_{ij} \boldsymbol{s}_j$. It is added to the input of each gate in the decoder, together with previous state $\boldsymbol{h}_{i-1}$ and previous target word embedding $\boldsymbol{y}_{i-1}$:

$$\boldsymbol{h}_i = \text{RNN}(\boldsymbol{h}_{i-1}, \boldsymbol{y}_{i-1}, \boldsymbol{c}_i)$$

3 Problems of the Attention Mechanism

Although attention modeling works well in finding translation correspondence between source and target words, there are still some issues that can be systematically identified, which fall into three categories: incorrect reordering, missing translation and repeated translation.

Incorrect Reordering Reordering is often required for the translation between two languages with different grammars. When the source words are translated in the wrong order, the meaning of the sentence can be twisted.In the example shown in Figure 1, the phrase "明年 一月" (meaning "January next year") in the source is attended to after the translation of "暴动" (meaning "riot"), resulting in a translation that twisted the meaning of the source sentence.

Missing Translation In Figure 3, we can see that only the first half of the source sentence is translated, because the last half sentence is never chosen for attention.

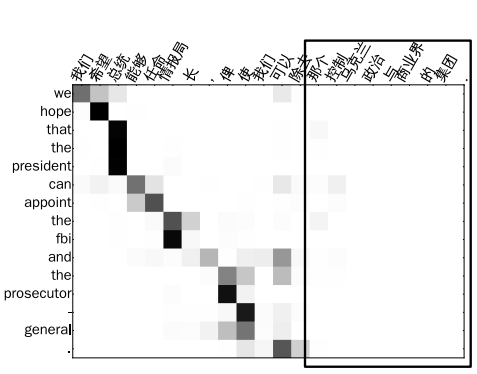

Figure 3. Missing translation example. The correct translation is "We hope that the president could appoint the chief of the intelligence bureau so we can eliminate groups that control Ukrainian's politics and business."

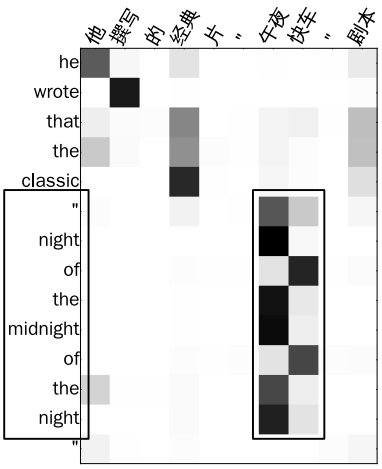

Figure 4. Repeated translation example. The correct translation is "Powell will attend the annual meeting of the organization of europe."

Repeated Translation In the example shown in Figure 4, part of the source sentence, "欧安 组织" ("the organization of europe"), is repeatedly translated into "the organization of europe the organization of europe". This is because the attention mechanism focused on this phrase twice.

4 Our Methods

In traditional SMT methods, the distortion model controls the order of target word generation. It can thus prevent the meaning of source sentences to be twisted due to wrong reordering. We propose to address the incorrect reordering problem using a implicit distortion model which leverages information about previous alignments.

In traditional SMT methods, the fertility model controls how many target words should be generated from a source word. It can thus prevent a source word to be repeatedly translated, which corresponds to the repeated translation problem, or not translated, which corresponds to the missing translation problem. We propose to address the missing and repeated translation problems in NMT by by using a fertility model which memorizes which words have been translated and which have not.

In the following sections, we introduce our extended attention-based encoder-decoder models. For implicit distortion model, we propose a recurrent attention mechanism, RECATT; for implicit fertility model, we propose a fertility-conditioned decoder FERTDEC.

4.1 RECATT

The structure of RECATT is illustrated in Figure 6. At position i in the target sentence, the attention model outputs a weight vector for the encoder states and a weighted-average context. To inform the attention model about the previous alignments, we pass the previous context vector $\boldsymbol{c}_{i-1}$ to it. The decoder with RECATT follows:

$$\boldsymbol{w}_i = \text{ALIGN}(\boldsymbol{h}_{i-1}, \boldsymbol{c}_{i-1}, \boldsymbol{s}_1^J)$$

$$\boldsymbol{c}_i = \sum_{j=1}^{J} w_{ij} \boldsymbol{s}_j$$

$$\boldsymbol{h}_i = \text{RNN}(\boldsymbol{h}_{i-1}, \boldsymbol{y}_{i-1}, \boldsymbol{c}_i)$$

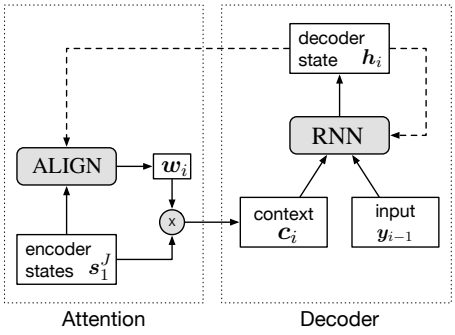

Figure 5. Decoder with attention mechanism. The dashed lines denote passing the previous state to the current attention model and current state.

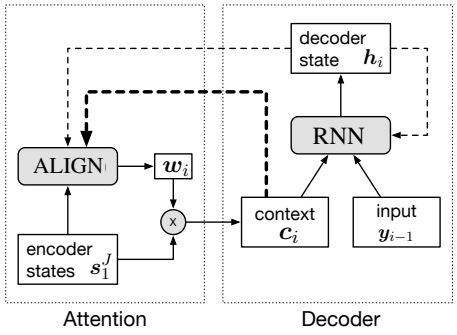

Figure 6. RECATT, decoder with recurrent attention mechanism. The thick dashed line denotes passing the previous attention-generated context to the attention model.

The new ALIGN function with modified match function α is computed as:

$$\alpha(\boldsymbol{h}_{i-1}, \boldsymbol{c}_{i-1}, \boldsymbol{s}_j) = \boldsymbol{W}^\alpha \boldsymbol{h}_{i-1} + \boldsymbol{U}^\alpha \boldsymbol{c}_{i-1} + \boldsymbol{V}^\alpha \boldsymbol{s}_j$$
$$e_{ij} = \boldsymbol{v}^\top \tanh \alpha(\boldsymbol{h}_{i-1}, \boldsymbol{c}_{i-1}, \boldsymbol{s}_j)$$
$$w_{ij} = \frac{\exp(e_{ij})}{\sum_k \exp(e_{ik})}$$

By using the previous context vector, the new attention model can avoid focusing on the same position repeatedly, or jumping from the previous attended position incorrectly. We note that RNNSEARCH is a special case of RECATT where the previous context $\boldsymbol{c}_{i-1}$ is ignored in the match function.

One important design choice of RECATT is to use the previous context vector instead of the previous weight vector. Using the context vector makes the attention model aware of the content of source words, instead of the weight vector, which contains only the position information. Furthermore, the length of the source sentence is variable, so is the length of the weight vector. To use it in the match function, transformation to a fixed-length vector is needed. Possible methods including taking a fixed-size window or passing it through a convolution, both result in a local and partial recurrent information. When we need a long-distance jump from the previous attended position, especially out of the window, partial information might not suffice. Using the context vector, as in RECATT, is not restricted in this scenario. The attention model can always have full information about the previous alignments even when a long-distance jump happens, which makes the implicit distortion model much more flexible.

4.2 FERTDEC

To address the missing and repeated translation problems, we introduce fertility-conditioned decoder FERTDEC. FERTDEC uses a coverage vector [1] to represent the information of the source sentence that has not been translated. Initialized by the sum of source word embeddings $\sum_{j=1}^{J} \boldsymbol{x}_j$ and updated along the translation dynamically, our trainable coverage vector is different from the predefined condition vector used in (Wen et al., 2015). In order to leverage the coverage vector in decoding, we change the

[1]The coverage vector in our work plays a similar role with the one used in beam search decoder (Koehn, 2004).There are two major two differences between them: 1. our coverage vector is used as a soft constraint instead of a hard constraint. 2. we tract untranslated words instead of translated words.

decoding recurrent unit as follows:

$$
\begin{aligned}
\boldsymbol{d}_i &= \boldsymbol{e}_{i-1} \odot \boldsymbol{d}_{i-1} \\
\boldsymbol{r}_i &= \sigma(\boldsymbol{W}^r \boldsymbol{y}_{i-1} + \boldsymbol{U}^r \boldsymbol{h}_{i-1} + \boldsymbol{V}^r \boldsymbol{d}_i) \\
\boldsymbol{z}_i &= \sigma(\boldsymbol{W}^z \boldsymbol{y}_{i-1} + \boldsymbol{U}^z \boldsymbol{h}_{i-1} + \boldsymbol{V}^z \boldsymbol{d}_i) \\
\boldsymbol{e}_i &= \sigma(\boldsymbol{W}^e \boldsymbol{y}_{i-1} + \boldsymbol{U}^e \boldsymbol{h}_{i-1} + \boldsymbol{V}^e \boldsymbol{d}_i) \\
\boldsymbol{h}'_i &= \tanh(\boldsymbol{U}(\boldsymbol{r}_i \odot \boldsymbol{h}_{i-1}) + \boldsymbol{W}\boldsymbol{y}_{i-1} + \boldsymbol{V}\boldsymbol{d}_i) \\
\boldsymbol{h}_i &= (1 - \boldsymbol{z}_i) \odot \boldsymbol{h}'_i + \boldsymbol{z}_i \odot \boldsymbol{h}_{i-1} + \tanh(\boldsymbol{V}^h \boldsymbol{d}_i)
\end{aligned}
$$

where $\boldsymbol{d}_i$ is the coverage vector, $\boldsymbol{e}_i$ is the new added *extract gate*, which is used to update $\boldsymbol{d}_i$ based on the words that has been translated.

$\boldsymbol{d}_i$ is designed to track the untranslated words during decoding, so it is not expected to change drastically between consecutive time-stamps. Also, it should converge to zero at the end of the sentence. Therefore in the training stage, we update the loss function as follows:

$$
\sum_{i=1}^{T} -\log p(y_i) + \frac{1}{T} \sum_{i=1}^{T} ||\boldsymbol{d}_i - \boldsymbol{d}_{i-1}||_2 + ||\boldsymbol{d}_i||_2
$$

where the first term is the negative log-likelihood used in the encoder–decoder model. The new introduced second and third terms are **step-decay** and **left-over** costs. **Step-decay** cost prevents the extract gate from extracting too much information at each time-step. It is different than that of (Wen et al., 2015) [2]. While **left-over** cost ensures all the source words are translated after generating the whole target sentence.

5 Related Work

There are variations of the attention mechanism with recurrent paths similar to those in our recurrent attention mechanism. In this section, we put them in a general framework and compare them with ours.

INPUTFEED Input-feeding method (Luong et al., 2015) also has a recurrent path - the previous attention-generated context is passed to the decoder together with current one:

$$
\begin{aligned}
\boldsymbol{w}_i &= \text{ALIGN}(\boldsymbol{h}_{i-1}, \boldsymbol{s}_1^J) \\
\boldsymbol{c}_i &= \sum_{j=1}^{J} w_{ij} \boldsymbol{s}_j \\
\boldsymbol{h}_i &= \text{RNN}(\boldsymbol{h}_{i-1}, \boldsymbol{y}_{i-1}, \boldsymbol{c}_i, \boldsymbol{c}_{i-1})
\end{aligned}
$$

Using the previous context helps the decoder generate better target words, but it doesn't help the attention model select source words more accurately or generate better alignment. This makes INPUTFEED very different from our RECATT.

MARKOV In Markov condition model (Cohn et al., 2016), ξ takes a fixed-width window of the previous weight vector $\boldsymbol{w}_{i-1}$ and passes it to the attention model:

$$
\begin{aligned}
\xi(\boldsymbol{w}_{i-1}, j) &= [w_{i-1,j-k}, .., w_{i-1,j}, .., w_{i-1,j+k}]^\top \\
\boldsymbol{w}_i &= \text{ALIGN}(\boldsymbol{h}_{i-1}, \boldsymbol{s}_1^J, \xi(\boldsymbol{w}_{i-1})) \\
\boldsymbol{c}_i &= \sum_{j=1}^{J} w_{ij} \boldsymbol{s}_j
\end{aligned}
$$

This can be seen as a location-based counterpart of RECATT. As discussed in Section 4.1, this method is less flexible - it can only use partial recurrent information and is not content-aware.

[2] These two cost functions achieve similar result on our task, but our has no hyperparameter.

LOCFER In local fertility model (Cohn et al., 2016), ξ uses all previous weight vectors $\boldsymbol{w}_{<i}$ and computes the sum of previous attention weights.

$$\xi(\boldsymbol{w}_{<i}, j) = \left[\sum_{i'<i} w_{i',j-k}, .., \sum_{i'<i} w_{i',j+k}\right]^\top$$
$$\boldsymbol{w}_i = \text{ALIGN}(\boldsymbol{h}_{i-1}, \boldsymbol{s}_1^J, \xi(\boldsymbol{w}_{<i}))$$
$$\boldsymbol{c}_i = \sum_{j=1}^{J} w_{ij} \boldsymbol{s}_j$$

The intuition is to consider the fertility up to the current position, and use it to guide new alignment. This is done by a location-based recurrent path similar to that of MARKOV. LOCFER can prevent focusing nearby words already translated, and it is a blend of distortion and fertility model.

6 Experiments

6.1 Settings

Datasets We use NIST Chinese–English training set excluding Hong Kong Law and Hong Kong Hansard as the training set (500,000 sentence pairs after exclusion). The test set is Nist2005 (1082 sentence pairs). The validation set is Nist2003 (913 sentence pairs).

Following (Bahdanau et al., 2014), we use a vocabulary size of 30,000 for both source and target language, covering 97.4% and 98.9% of the words. Out-of-vocabulary words are replaced with a special token $\langle$UNK$\rangle$.

UNK Replacement With word alignment result on the training set generated by GIZA++ (Och and Ney, 2003), we build a translation table. We choose the most frequently aligned target word as the translation for each source word. UNK replacement is performed after the translation is completed, based on the alignment matrix generated by the attention model. If a target word is UNK, we replace it with the translation (from the translation table) of its aligned source word, the one with the highest attention weight.

Model & Baseline Two baseline systems are used in our experiment. The first one is HPSMT, our in-house implementation of hierarchical phrase-based SMT (Chiang, 2007) with standard features. For a fair comparison, the 4-gram language model is trained only with the target sentences of the training set. The second one is RNNSEARCH [3] (Cho et al., 2014b), the original attention-based encoder-decoder. Other compared models are our implementations of: INPUTFEED (Luong et al., 2015), MARKOV and LOCFER (Cohn et al., 2016) as discussed in Section 5.

Training Details For all the NMT models, the hidden GRU states are 1000-dimensional, source and target word embeddings are 620-dimensional. Dropout rate is 0.5. The settings of other hyperparameters follow (Bahdanau et al., 2014). Each model is trained with AdaGrad (Duchi et al., 2011) on a K40m GPU for approximately 4 days, finishing about $400,000$ updates, equivalent to 64 epochs.

6.2 Experiment Results

6.2.1 End-to-end Translation Quality

BLEU scores on the test set are shown in Table 1. The two proposed methods RECATT and FERTDEC both out-performed the original model RNNSEARCH. Note that RECATT gained the most improvement from UNK replacement, 5.04 BLEU points. The effectiveness of our UNK replacement depends largely on the quality of the alignment, so the gain can be seen as a measurement of alignment quality. This is an evidence that RECATT improved attention-generated alignment and as a result improved translation quality. The last line shows the results obtained by the combination of RECATT and FERTDEC, which further out-performed both models.

[3]The implementation of RNNSEARCH is from `https://github.com/mila-udem/blocks-examples`

	Before	After	Diff
HPSMT	/	32.25	/
RNNSEARCH	26.65	31.02	4.37
INPUTFEED	25.44	29.02	3.58
LOCFER	27.05	31.68	4.63
MARKOV	27.54	32.21	4.67
RECATT	28.10	33.14	5.04
FERTDEC	27.51	32.44	4.93
RECATT + FERTDEC	28.87	33.76	4.89

Table 1. BLEU scores w/o UNK replacement and the improvement from UNK replacement.

	SAER	AER
RNNSEARCH	54.75	44.13
RECATT	52.88	42.51
FERTDEC	52.70	42.37
RECATT + FERTDEC	52.40	42.11

Table 2. AER & SAER scores, lower is better.

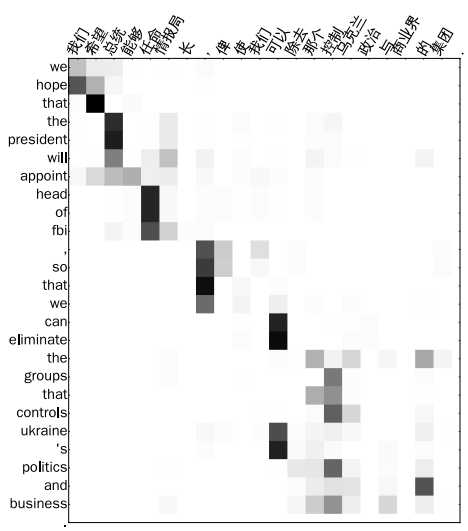

Figure 7. FERTDEC resolved the problem of missing translation problem that is shown in Figure 3.

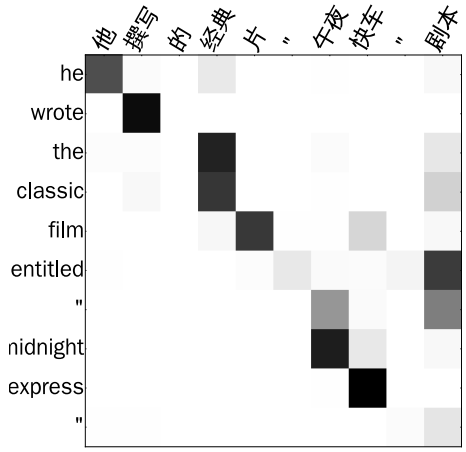

Figure 8. FERTDEC resolved the problem of repeated translation shown in Figure 4.

6.2.2 Alignment Quality

To analyze the effect of our extentions to the attention mechanism in detail, we evaluate the quality of attention-generated alignment by computing the AER (Och and Ney, 2003) and smoothed-AER (Tu et al., 2016) scores on a manually aligned Chinese–English alignment dataset (Haghighi et al., 2009), which contains 491 sentence pairs. We force the model to generate the correct target sentence and evaluate the attention-generated alignment matrix. From the results shown in Table 2, we can see that all three proposed methods achieved better alignment quality, compared with the original attention method.

6.3 Qualitative Analysis

In this section we qualitatively evaluate how our models addressed the problems analyzed in Section 3. All examples shown are from the test set.

Incorrect Reordering In Figure 2 we can see, RECATT generated the correct alignment on the example sentence shown in Figure 1: "will not" is correctly aligned to "不会" (means "will not") and "next year" is correctly translated after "the election to be held" instead of "riot in iraq". The meaning of the source sentence is correctly preserved in the translation.

Missing Translation As shown in Figure 7, FERTDEC resolved the missing translation problem of RNNSEARCH on the same sentence shown in Figure 3. All the information from the source sentence is captured by the translation.

Repeated Translation In Figure 8 we can see that, FERTDEC resolved the the repetition problem of RNNSEARCH shown in Figure 4. "东方 快车" (means "midnight express") is repeatedly focused on and translated into "night of the midnight of the night". As shown on the right, FERTDEC produces both the correct alignment and the correct translation "midnight express".

7 Conclusions and Future Work

In this paper we demonstrated how distortion and fertility models can improve the quality of alignment learned by attention mechanism in encoder-decoder models. We proposed recurrent attention mechanism RECATT as implicit distortion models, and FERTDEC as an implicit fertility model. We conducted various experiments and verified that our proposed methods can improve translation quality by generating better alignment. Compare to the original attention-based encoder-decoder, our best result achieved an improvement of over 2 BLEU points on large-scale Chinese–English translation task.

Our RECATT model is a simple yet effective extension to the attention mechanism, and potentially we can design more complicated mechanisms to model the distortion even better. The key observation is, in RECATT, only the previous context vector is used to provide information about previous alignments, and in effect only the alignment of the previous target word is considered. To extend this short-term information to a long-term one so that the model is aware of all previous alignments, we designed a attention unit that contains a recurrent neural network to encode all previous context vectors. The hidden state vector of this RNN should contain all the information about previous alignments. However in our experiment, this model and several variants did not perform as well as RECATT. But we still think that trying to provide more information about previous alignments, as a natural extension to this work, has the potential of improving both the alignment and translation accuracy.

Abstract

The attention mechanism is appealing for neural machine translation, since it is able to dynamically encode a source sentence by generating a alignment between a target word and source words. Unfortunately, it has been proved to be worse than conventional alignment models in alignment accuracy. In this paper, we analyze and explain this issue from the point view of reordering, and propose a supervised attention which is learned with guidance from conventional alignment models. Experiments on two Chinese-to-English translation tasks show that the supervised attention mechanism yields better alignments leading to substantial gains over the standard attention based NMT.

1 Introduction

Neural Machine Translation (NMT) has achieved great successes on machine translation tasks recently (Bahdanau et al., 2015; Sutskever et al., 2015). Generally, it relies on a recurrent neural network under the Encode-Decode framework: it firstly encodes a source sentence into context vectors and then generates its translation token-by-token, selecting from the target vocabulary. Among different variants of NMT, attention based NMT, which is the focus of this paper,[1] is attracting increasing interests in the community (Bahdanau et al., 2015; Luong et al., 2015). One of its advantages is that it is able to dynamically make use of the encoded context through an attention mechanism thereby allowing the use of fewer hidden layers while still maintaining high levels of translation performance.

An attention mechanism is designed to predict the alignment of a target word with respect to source words (Bahdanau et al., 2015). In order to facilitate incremental decoding, it tries to make this alignment prediction without the information about the target word itself, and thus this attention can be considered to be a form of a reordering model (see §2 for more details). In contrast, conventional alignment models are able to use the target word to infer its alignments (Och and Ney, 2000; Dyer et al., 2013; Liu and Sun, 2015), and as a result there is a substantial gap in quality between the alignments derived by this attention based NMT and conventional alignment models (54 VS 30 in terms of AER for Chinese-to-English as reported in (Cheng et al., 2016)). This discrepancy might be an indication that the potential of attention-based NMT is limited. In addition, the attention in NMT is learned in an unsupervised manner without explicit prior knowledge about alignment.[2] However, in conventional statistical machine translation (SMT), it is standard practice to learn reordering models in a supervised manner with the guidance from conventional alignment models (Xiong et al., 2006; Koehn et al., 2007; Bisazza and Federico, 2016).

Inspired by the supervised reordering in conventional SMT, in this paper, we propose a *Supervised Attention* based NMT (SA-NMT) model. Specifically, similar to conventional SMT, we first run off-the-shelf aligners (GIZA++ (Och and Ney, 2000) or fast_align (Dyer et al., 2013) etc.) to obtain the alignment of the bilingual training corpus in advance. Then, treating this alignment result as the supervision of attention, we jointly learn attention and translation, both in supervised manners. Since the

[1] Throughout this paper, without the special statement, NMT means attention-based NMT.

[2] We do agree that NMT is a supervised model with respect to translation rather than reordering.

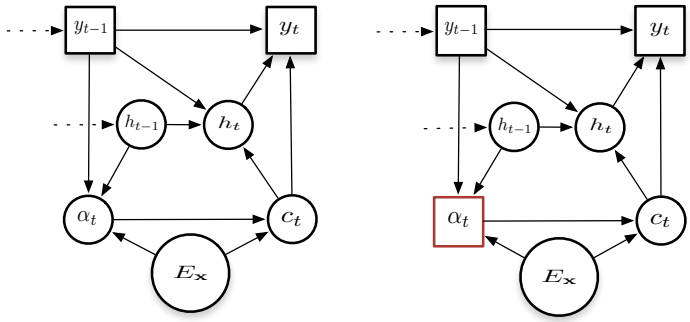
Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3093–3102, Osaka, Japan, December 11-17 2016.

conventional aligners delivers higher quality alignment, it is expected that the alignment in the supervised attention NMT will be improved leading to better end-to-end translation performance. One advantage of the proposed SA-NMT is that it implements the supervision of attention as a regularization in the joint training objective (§3.2). Furthermore, since the attention variables lies in the middle of the entire network architecture rather than the top (as the translation variables (see Figure 1(b)), it serves to mitigate the vanishing gradient problem during the back-propagation, by adding supervision into the intermediate layers in the network (Szegedy et al., 2015).

This paper makes the following contributions:

- It revisits the attention model from the point view of reordering (§2), and propose a supervised attention for NMT that is supervised by statistical alignment models (§3). The proposed approach is simple and easy to be implemented, and it is generally applicable to any attention-based NMT models, although in this case it is implemented on top of the model in (Bahdanau et al., 2015).
- On two Chinese-to-English translation tasks, it empirically shows that the proposed approach gives rise to improved performance (§4): on a large scale task, it outperforms three baselines including a state-of-the-art Moses, and leads to improvements of up to 2.5 BLEU points over the strongest one in this paper; on a low resource task, it even obtains about 5 BLEU points over the attention based NMT system on which is it based.

2 Revisiting Neural Machine Translation



(a) NMT (b) SA-NMT

Figure 1: One slice of the computational graphs for both (a) NMT and (b) SA-NMT. Circles denote the hidden variables; while squares denote the observable variables, which receive supervision during training. The difference (marked in red) in (b) regarding to (a) is treating α_t as an observable variable instead of a hidden variable.

Suppose $\mathbf{x} = \langle x_1, x_2, \cdots, x_m \rangle$ denotes a source sentence, $\mathbf{y} = \langle y_1, y_2, \cdots, y_n \rangle$ a target sentence. In addition, let $x_{<t} = \langle x_1, x_2, \cdots, x_{t-1} \rangle$ denote a prefix of $\mathbf{x}$. Neural Machine Translation (NMT) directly maps a source sentence into a target under an encode-decode framework. In the encoding stage, it uses two bidirectional recurrent neural networks to encode $\mathbf{x}$ into a sequence of vectors $E_{\mathbf{x}} = \langle E_{x_1}, E_{x_2}, \cdots, E_{x_m} \rangle$, with E_{x_i} representing the concatenation of two vectors for i_{th} source word from two directional RNNs. In the decoding stage, it generates the target translation from the conditional probability over the pair of sequences $\mathbf{x}$ and $\mathbf{y}$ via a recurrent neural network parametrized by θ as follows:

$$p(\mathbf{y} \mid \mathbf{x}; \theta) = \prod_{t=1}^{n} p(y_t \mid y_{<t}, E_{\mathbf{x}}) = \prod_{t=1}^{n} \text{softmax}\big(g(y_{t-1}, h_t, c_t)\big)[y_t] \quad (1)$$

where h_t and c_t respectively denote an RNN hidden state (i.e. a vector) and a context vector at timestep t; g is a transformation function mapping into a vector with dimension of the target vocabulary size; and $[i]$ denotes the i_{th} component of a vector.[3] Furthermore, $h_t = f(h_{t-1}, y_{t-1}, c_t)$ is defined by an activation

[3]In that sense, y_t in Eq.(1) also denotes the index of this word in its vocabulary.

function, i.e. a Gated Recurrent Unit (Chung et al., 2014); and the context vector c_t is a dynamical source representation at timestep t, and calculated as the weighted sum of source encodings $E_{\mathbf{x}}$, i.e. $c_t = \alpha_t^\top E_{\mathbf{x}}$. Here the weight α_t implements an attention mechanism, and $\alpha_{t,i}$ is the alignment probability of y_t being aligned to x_i. α_t is derived through a feedforward neural network a as follows:

$$\alpha_t = a(y_{t-1}, h_{t-1}, E_{\mathbf{x}}) \tag{2}$$

where a consists of two layers, the top one being a softmax layer. We skip the detailed definitions of a together with $E_{\mathbf{x}}$, f and g, and refer the readers to (Bahdanau et al., 2015) instead.[4] Figure 1(a) shows one slice of computational graph for NMT definition at time step t.

To train NMT, the following negative log-likelyhood is minimized:

$$-\sum_i \log p(\mathbf{y}^i \mid \mathbf{x}^i; \theta) \tag{3}$$

where $\langle \mathbf{x}^i, \mathbf{y}^i \rangle$ is a bilingual sentence pair from a given training corpus, $p(\mathbf{y}^i \mid \mathbf{x}^i; \theta)$ is as defined in Eq.(1). Note that even though the training is conducted in a supervised manner with respect to translation, i.e., $\mathbf{y}$ are observable in Figure 1(a), the attention is learned in a unsupervised manner, since α is hidden.

In Eq.(2), α_t is defined only on y_{t-1}, h_{t-1} and $E_{\mathbf{x}}$ but not on the target word y_t, as y_t is unknown at the current timestep $t-1$ during the testing. Therefore, at timestep $t-1$, NMT firstly tries to calculate α_t, through which NMT figures out those source words will be translated next, even though the next target word y_t is unavailable. From this point of view, the attention mechanism plays a role in reordering and thus can be considered as a reordering model. Unlike this attention model, conventional alignment models define the alignment α directly over $\mathbf{x}$ and $\mathbf{y}$ as follows:

$$p(\alpha \mid \mathbf{x}, \mathbf{y}) = \frac{\exp(F(\mathbf{x}, \mathbf{y}, \alpha))}{\sum_{\alpha'} \exp(F(\mathbf{x}, \mathbf{y}, \alpha'))}$$

where F denotes a feature function over a pair of sentences $\mathbf{x}$ and $\mathbf{y}$ together with their word alignment α, and it is either a log-probability $\log p(\mathbf{y}, \alpha \mid \mathbf{x})$ for a generative model like IBM models (Brown et al., 1993) or a well-designed feature function for discriminative models (Liu and Sun, 2015). In order to infer α_t, alignment models can readily use the entire $\mathbf{y}$, of course including y_t as well, thereby they can model the alignment between $\mathbf{x}$ and $\mathbf{y}$ more sufficiently. As a result, the attention based NMT might not deliver satisfying alignments, as reported in (Cheng et al., 2016), compared to conventional alignment models. This may be a sign that the potential of attention-based NMT is limited in end-to-end translation.

3 Supervised Attention

In this section, we introduce supervised attention to improve the alignment, which may lead to better translation performance for NMT. [5] Our basic idea is simple: similar to conventional SMT, it firstly uses a conventional aligner to obtain the alignment on the training corpus; then it employs these alignment results as supervision to train the NMT. During testing, decoding proceeds in exactly the same manner as standard NMT, since there is no alignment supervision available for unseen test sentences.

3.1 Preprocessing Alignment Supervision

As described in §2, the attention model outputs a soft alignment α, such that α_t is a normalized probability distribution. In contrast, most aligners are typically oriented to grammar induction for conventional SMT, and they usually output 'hard' alignments, such as (Och and Ney, 2000). They only indicate whether a target word is aligned to a source word or not, and this might not correspond to a distribution for each target word. For example, one target word may align to multiple source words, or no source words at all.

[4] In the original paper, α_t is not explicitly dependent on the y_{t-1} in Eq.(2), but this dependency was explicitly retained in our direct baseline NMT2.

[5] Although the alignment is loosely related to the downstream translation (Liu and Sun, 2015), substantial improvements in alignment usually leads to the improvements in translation as observed in our experiments.

Therefore, we apply the following heuristics to preprocess the hard alignment: if a target word does not align to any source words, we inherit its affiliation from the closest aligned word with preference given to the right, following (Devlin et al., 2014); if a target word is aligned to multiple source words, we assume it aligns to each one evenly. In addition, in the implementation of NMT, there are two special tokens 'eol' added to both source and target sentences. We assume they are aligned to each other. In this way, we can obtain the final supervision of attention, denoted as $\hat{\alpha}$.

3.2 Jointly Supervising Translation and Attention

We propose a soft constraint method to jointly supervise the translation and attention as follows:

$$-\sum_i \log p(\mathbf{y}^i \mid \mathbf{x}^i; \theta) + \lambda \times \Delta(\alpha^i, \hat{\alpha}^i; \theta) \tag{4}$$

where α^i is as defined in Eq. (1), Δ is a loss function that penalizes the disagreement between α^i and $\hat{\alpha}^i$, and $\lambda > 0$ is a hyper-parameter that balances the preference between likelihood and disagreement. In this way, we treat the attention variable α as an observable variable as shown in Figure 1(b), and this is different from the standard NMT as shown in Figure 1(a) in essence. Note that this training objective resembles to that in multi-task learning (Evgeniou and Pontil, 2004). Our supervised attention method has two further advantages: firstly, it is able to alleviate overfitting by means of the λ; and secondly it is easier to address the vanishing gradient problem by adding supervision into the intermediate layers of the entire network (Szegedy et al., 2015), because the supervision of α is more close to $E_{\mathbf{x}}$ than $\mathbf{y}$ as in Figure 1(b).

In order to quantify the disagreement between α^i and $\hat{\alpha}^i$, three different methods are investigated in our experiments:

- *Mean Squared Error* (MSE)

$$\Delta(\alpha^i, \hat{\alpha}^i; \theta) = \sum_m \sum_n \frac{1}{2}\big(\alpha(\theta)^i_{m,n} - \hat{\alpha}^i_{m,n}\big)^2$$

  MSE is widely used as a loss for regression tasks (Lehmann and Casella, 1998), and it directly encourages $\alpha(\theta)^i_{m,n}$ to be equal to $\hat{\alpha}^i_{m,n}$.

- *Multiplication* (MUL)

$$\Delta(\alpha^i, \hat{\alpha}^i; \theta) = -\log\big(\sum_m \sum_n \alpha(\theta)^i_{m,n} \times \hat{\alpha}^i_{m,n}\big)$$

  MUL is particularly designed for agreement in word alignment and it has been shown to be effective (Liang et al., 2006; Cheng et al., 2016). Note that different from those in (Cheng et al., 2016), $\hat{\alpha}$ is not a parametrized variable but a constant in this paper.

- *Cross Entropy* (CE)

$$\Delta(\alpha^i, \hat{\alpha}^i; \theta) = -\sum_m \sum_n \hat{\alpha}^i_{m,n} \times \log \alpha(\theta)^i_{m,n}$$

  Since for each t, $\alpha(\theta)_t$ is a distribution, it is natural to use CE as the metric to evaluate the disagreement (Rubinstein and Kroese, 2004).

4 Experiments

We conducted experiments on two Chinese-to-English translation tasks: one is the NIST task oriented to NEWS domain, which is a large scale task and suitable to NMT; and the other is the speech translation oriented to travel domain, which is a low resource task and thus is very challenging for NMT. We used the case-insensitive BLEU4 to evaluate translation quality and adopted the multi-bleu.perl as its implementation.

Alignment Losses	BLEU
Mean Squared Error (MSE)	39.4
Multiplication (MUL)	39.6
Cross Entropy (CE)	40.0

Table 1: Performance of SA-NMT on development set for different loss functions to supervise the attention in terms of BLEU.

Alignment Methods	BLEU
fast_align	39.6
GIZA++	40.0

Table 2: Comparision of aligners between fast_align and GIZA++ for SA-NMT in terms of BLEU on the development set.

4.1 The Large Scale Translation Task

4.1.1 Preparation

We used the data from the NIST2008 Open Machine Translation Campaign. The training data consisted of 1.8M sentence pairs, the development set was nist02 (878 sentences), and the test sets are were nist05 (1082 sentences), nist06 (1664 sentences) and nist08 (1357 sentences).

We compared the proposed approach with three strong baselines:

- Moses: a phrase-based machine translation system (Koehn et al., 2007);
- NMT1: an attention based NMT (Bahdanau et al., 2015) system at https://github.com/lisa-groundhog/GroundHog;
- NMT2: another implementation of (Bahdanau et al., 2015) at https://github.com/nyu-dl/dl4mt-tutorial.

We developed the proposed approach based on NMT2, and denoted it as **SA-NMT**.

We followed the standard pipeline to run Moses. GIZA++ with grow-diag-final-and was used to build the translation model. We trained a 5-gram target language model on the Gigaword corpus, and used a lexicalized distortion model. All experiments were run with the default settings.

To train NMT1, NMT2 and SA-NMT, we employed the same settings for fair comparison. Specifically, except the stopping iteration which was selected using development data, we used the default settings set out in (Bahdanau et al., 2015) for all NMT-based systems: the dimension of word embedding was 620, the dimension of hidden units was 1000, the batch size was 80, the source and target side vocabulary sizes were 30000, the maximum sequence length was 50, [6] the beam size for decoding was 12, and the optimization was done by Adadelta with all hyper-parameters suggested by (Zeiler, 2012). Particularly for SA-NMT, we employed a conventional word aligner to obtain the word alignment on the training data before training SA-NMT. In this paper, we used two different aligners, which are fast_align and GIZA++. We tuned the hyper-parameter λ to be 0.3 on the development set, to balance the preference between the translation and alignment. Training was conducted on a single Tesla K40 GPU machine. Each update took about 3.0 seconds for both NMT2 and SA-NMT, and 2.4 seconds for NMT1. Roughly, it took about 10 days to NMT2 to finish 300000 updates.

4.1.2 Settings on External Alignments

We implemented three different losses to supervise the attention as described in §3.2. To explore their behaviors on the development set, we employed the GIZA++ to generate the alignment on the training set prior to the training SA-NMT. In Table 1, we can see that MUL is better than MSE. Furthermore, CE performs best among all losses, and thus we adopt it for the following experiments.

[6] This excludes all the sentences longer than 50 words in either source or target side only for NMT systems, but for Moses we use the entire training data.

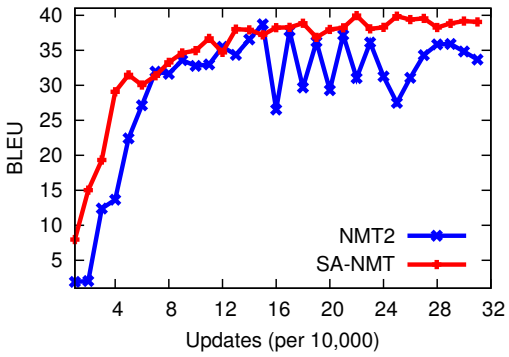


Figure 2: Learning curves of NMT2 and SA-NMT on the development set.

Systems	nist02	nist05	nist06	nist08
Moses	37.1	35.1	33.4	25.9
NMT1	37.8	34.1	34.7	27.4
NMT2	38.7	35.3	36.0	27.8
SA-NMT	40.0*	37.8*	37.6*	29.9*

Table 3: BLEU comparison for large scale translation task. The development set is nist02, and the test sets are nist05,nist06 and nist08. '*' denotes that SA-NMT is significantly better than Moses, NMT1 and NMT2 with $p < 0.01$. Note that Moses is trained with more bilingual sentences and an additional monolingual corpus.

In addition, we also run fast_align to generate alignments as the supervision for SA-NMT and the results were reported in Table 2. We can see that GIZA++ performs slightly better than fast_align and thus we fix the external aligner as GIZA++ in the following experiments.

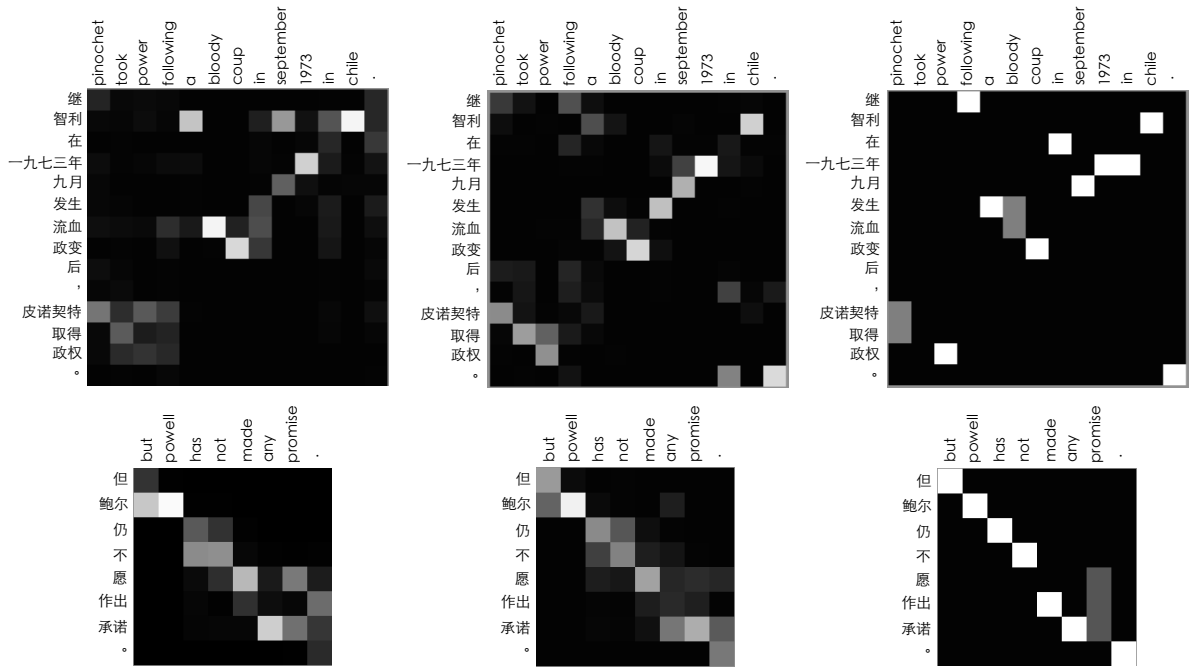
4.1.3 Results on Large Scale Translation Task

Figure 2 shows the learning curves of NMT2 and SA-NMT on the development set. We can see that NMT2 generally obtains higher BLEU as the increasing of updates before peaking at update of 150000, while it is unstable from then on. On the other hand, SA-NMT delivers much better BLEU for the beginning updates and performs more steadily along with the updates, although it takes more updates to reach the peaking point.

Table 3 reports the main end-to-end translation results for the large scale task. We find that both standard NMT generally outperforms Moses except NMT1 on nist05. The proposed SA-NMT achieves significant and consistent improvements over all three baseline systems, and it obtains the averaged gains of 2.2 BLEU points on test sets over its direct baseline NMT2. It is clear from these results that our supervised attention mechanism is highly effective in practice.

4.1.4 Results and Analysis on Alignment

As explained in §2, standard NMT can not use the target word information to predict its aligned source words, and thus might fail to predict the correct source words for some target words. For example, for the sentence in the training set in Figure 3 (a), NMT2 aligned 'following' to '皮诺契特 (gloss: pinochet)' rather than '继 (gloss: follow)', and worse still it aligned the word '.' to '在 (gloss: in)' rather than '。' even though this word is relatively easy to align correctly. In contrast, with the help of information from the target word itself, GIZA++ successfully aligned both 'following' and '.' to the expected source words (see Figure3(c)). With the alignment results from GIZA++ as supervision, we can see that our SA-NMT can imitate GIZA++ and thus align both words correctly. More importantly, for sentences in the unseen test set, like GIZA++, SA-NMT confidently aligned 'but' and '.' to their correct source words respectively as in Figure3(b), where NMT2 failed. It seems that SA-NMT can learn its alignment behavior from GIZA++, and subsequently apply the alignment abilities it has learned to unseen test sentences.



(a) NMT2 (b) SA-NMT (c) GIZA++

Figure 3: Example (soft) alignments of (a) NMT2 (i.e., standard NMT with unsupervised attention), (b) SA-NMT (i.e. NMT with supervised attention), and (c) GIZA++ on two Chinese-English sentence pairs. The soft alignments of (c) is converted from hard alignment as in §3.1. The first row shows the alignments of the sentence pair from the training set while the second row shows the alignments from test sets.

Methods	AER
GIZA++	30.6*
NMT2	50.6
SA-NMT	43.3*

Table 4: Results on word alignment task for the large scale data. The evaluation metric is Alignment Error Rate (AER). '*' denotes that the corresponding result is significanly better than NMT2 with $p < 0.01$.

Table 4 shows the overall alignment results on word alignment task in terms of the metric, alignment error rate. We used the manually-aligned dataset as in (Liu and Sun, 2015) as the test set. Following (Luong and Manning, 2015), we force-decode both the bilingual sentences including source and reference sentences to obtain the alignment matrices, and then for each target word we extract one-to-one alignments by picking up the source word with the highest alignment confidence as the hard alignment. From Table 4, we can see clearly that standard NMT (NMT2) is far behind GIZA++ in alignment quality. This shows that it is possible and promising to supervise the attention with GIZA++. With the help from GIZA++, our supervised attention based NMT (SA-NMT) significantly reduces the AER, compared with the unsupervised counterpart (NMT2). This shows that the proposed approach is able to realize our intuition: the alignment is improved, leading to better translation performance.

Note that there is still a gap between SA-NMT and GIZA++ as indicated in Table 4. Since SA-NMT was trained for machine translation instead of word alignment, it is possible to reduce its AER if we aim to the word alignment task only. For example, we can enlarge λ in Eq.(4) to bias the training objective towards word alignment task, or we can change the architecture slightly to add the target information crucial for alignment as in (Yang et al., 2013; Tamura et al., 2014).

Systems	CSTAR03	IWSLT04
Moses	44.1	45.1
NMT1	33.4	33.0
NMT2	36.5	35.9
SA-NMT	39.8*	40.7*

Table 5: BLEU comparison for low-resource translation task. CSTAR03 is the development set while IWSLT04 is the test set. '*' denotes that SA-NMT is significantly better than both NMT1 and NMT2 with $p < 0.01$.

4.2 Results on the Low Resource Translation Task

For the low resource translation task, we used the BTEC corpus as the training data, which consists of 30k sentence pairs with 0.27M Chinese words and 0.33M English words. As development and test sets, we used the CSTAR03 and IWSLT04 held out sets, respectively. We trained a 4-gram language model on the target side of training corpus for running Moses. For training all NMT systems, we employed the same settings as those in the large scale task, except that vocabulary size is 6000, batch size is 16, and the hyper-parameter $\lambda = 1$ for SA-NMT.

Table 5 reports the final results. Firstly, we can see that both standard neural machine translation systems NMT1 and NMT2 are much worse than Moses with a substantial gap. This result is not difficult to understand: neural network systems typically require sufficient data to boost their performance, and thus low resource translation tasks are very challenging for them. Secondly, the proposed SA-NMT gains much over NMT2 similar to the case in the large scale task, and the gap towards Moses is narrowed substantially.

While our SA-NMT does not advance the state-of-the-art Moses as in large scale translation, this is a strong result if we consider that previous works on low resource translation tasks: Arthur et al. (2016) gained over Moses on the Japanese-to-English BTEC corpus, but they resorted to a corpus consisting of 464k sentence pairs; Luong and Manning (2015) revealed the comparable performance to Moses on English-to-Vietnamese with 133k sentences pairs, which is more than 4 times of our corprus size. Our method is possible to advance Moses by using reranking as in (Neubig et al., 2015; Cohn et al., 2016), but it is beyond the scope of this paper and instead we remain it as future work.

5 Related Work

Many recent works have led to notable improvements in the attention mechanism for neural machine translation. Tu et al. (2016) introduced an explicit coverage vector into the attention mechanism to address the over-translation and under-translation inherent in NMT. Feng et al. (2016) proposed an additional recurrent structure for attention to capture long-term dependencies. Cheng et al. (2016) proposed an agreement-based bidirectional NMT model for symmetrizing alignment. Cohn et al. (2016) incorporated multiple structural alignment biases into attention learning for better alignment. All of them improved the attention models that were learned in an unsupervised manner. While we do not modify the attention model itself, we learn it in a supervised manner, therefore our approach is orthogonal to theirs.

It has always been standard practice to learn reordering models from alignments for conventional SMT either at the phrase level or word level. At the phrase level, Koehn et al. (2007) proposed a lexicalized MSD model for phrasal reordering; Xiong et al. (2006) proposed a feature-rich model to learn phrase reordering for BTG; and Li et al. (2014) proposed a neural network method to learn a BTG reordering model. At the word level, Bisazza and Federico (2016) surveyed many word reordering models learned from alignment models for SMT, and there are some neural network based reordering models, such as (Zhang et al., 2016). Our work is inspired by these works in spirit, and it can be considered to be a recurrent neural network based word-level reordering model. The main difference is that in our approach the reordering model and translation model are trained jointly rather than separately as theirs.

Supervising the attention variables for attention-based neural networks is pioneered by Liu et al.

(2016). On image caption task, Liu et al. (2016) supervise the attention with external guidances in either a strong or a weak supervision manner. Their method requires the training data to be associated with direct annotation or indirect annotation. In parallel to our work, particularly on machine translation, Mi et al. (2016) and Chen et al. (2016) guide the attention for NMT from conventional word alignment models as teachers without any annotation on machine translation task. The differences of our work lie in that: we consider the attention as a form of a reordering model, which is thereby straightforward to be learned from conventional word alignment models; and we also provide a theoretical explanation why the attention leads to the worse alignment accuracy than the conventional word alignment models, standing upon the point view of reordering.

6 Conclusion

It has been shown that attention mechanism in NMT is worse than conventional word alignment models in its alignment accuracy. This paper firstly provides an explanation for this by viewing the attention mechanism from the point view of reordering. Then it proposes a supervised attention for NMT with guidance from external conventional alignment models, inspired by the supervised reordering models in conventional SMT. Experiments on two Chinese-to-English translation tasks show that the proposed approach achieves better alignment results leading to significant gains relative to standard attention based NMT.

Abstract

Evaluating the quality of output from language processing systems such as machine translation or speech recognition is an essential step in ensuring that they are sufficient for practical use. However, depending on the practical requirements, evaluation approaches can differ strongly. Often, reference-based evaluation measures (such as BLEU or WER) are appealing because they are cheap and allow rapid quantitative comparison. On the other hand, practitioners often focus on manual evaluation because they must deal with frequently changing domains and quality standards requested by customers, for which reference-based evaluation is insufficient or not possible due to missing in-domain reference data (Harris et al., 2016). In this paper, we attempt to bridge this gap by proposing a framework for lightly supervised quality estimation. We collect manually annotated scores for a small number of segments in a test corpus or document, and combine them with automatically predicted quality scores for the remaining segments to predict an overall quality estimate. An evaluation shows that our framework estimates quality more reliably than using fully automatic quality estimation approaches, while keeping annotation effort low by not requiring full references to be available for the particular domain.

1 Introduction

Quality evaluation is a key requirement for developing and employing language technology, enabling users and engineers to judge overall quality of the output, detect key problems, improve systems, and choose among competing systems. Although most users and engineers share these goals, the chosen evaluation approaches can differ strongly, with some people resorting to automatic, reference-based evaluation, while others rely on manual evaluation for their purposes. This is especially pronounced in the case of machine translation (MT), as pointed out by Harris et al. (2016). On one hand, much research effort has been devoted to devising reference-based methods such as BLEU (Papineni et al., 2002) that are well-correlated with human judgment. On the other hand, practitioners need to react to changing domains from customer to customer, and reflect multi-faceted quality requirements that are difficult to measure in a single, generic score, often leaving manual evaluation as the only choice.

In recent years, automatic quality estimation (QE) has emerged as a method that could potentially address the lack of flexibility of reference-based evaluation to deal with changing requirements, and the high effort of manual evaluation. Automatic QE uses machine learning techniques that are trained on a dataset of output-quality pairs in order to predict the quality of some new system output. It can be used to predict arbitrary quality metrics, provided that suitably labeled training data is available. However, in practice automatic QE has been found difficult and not reliable enough when applied to new domains or unknown systems, e.g. in MT (de Souza et al., 2015a) and automatic speech recognition (ASR) (Negri et al., 2014).

In this work, we explore a middle ground between automatic QE and manual evaluation, aiming to allow the QE system to adapt to the particular test data under consideration while keeping manual effort at an affordable level. We refer to this approach as *lightly supervised*[1] QE. Our general approach is

[1]In this paper, the terms supervised and unsupervised refer to whether or not manual annotation is necessary at *test* time.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3103–3113, Osaka, Japan, December 11-17 2016.

to divide the test data into smaller segments such as sentences or utterances, obtain automatic quality estimates for all these segments, and manually annotate only a small number of segments. We then compute aggregated quality estimates by averaging over segment-level scores, and explore two ways to aggregate manual and automatic scores.

The first aggregation approach computes the overall quality by averaging over *only the automatic* segment scores, using the manual annotations to adapt the automatic QE regressor. The method has the potential to improve predictions by reflecting not only the topical domain, but also the particular ASR or MT system, and even use-case specific quality standards.

The second aggregation approach computes quality by averaging over only the collected *manual segment scores*, using the automatic scores to choose what segments should be manually evaluated. In particular, we expect segments that are predicted to be close to the average across segments to be most indicative of overall quality. Instead of QE predictions, this aggregation approach can also directly exploit confidence scores from the decoder, eliminating the need for training a QE regressor.

We evaluate our approach for a variety of situations, focusing on the output of MT and ASR systems. We find that for MT, we can achieve a desired accuracy of quality estimation with much less effort compared to fully manual annotation. For instance, when annotating 100 words, in an in-domain setting we reduce the error by 22% and 19% relative over a fully automatic and a fully manual baseline. In an out-of-domain setting, relative improvements are 10% and 71%. For ASR, we obtain no improvements using the regression approach, but obtain promising results when using confidence scores instead: At 100 annotated words, the relative improvements are 59% and 54%.

2 Lightly Supervised Estimation Framework

This section outlines our lightly supervised estimation framework. The input to the framework is the hypothesized translation (transcription) of some MT (ASR) system given some particular input document (audio). We will refer to these as *hypothesis*, *system*, and *document* throughout the paper. Here, the document can be any form of test corpus that is representative of our targeted application, such as a document written in a particular style, data from one or several speakers, or a topical domain. Our goal is to estimate the average quality of the generated target sentences for a particular document with respect to some evaluation measure. The evaluation measure can be chosen arbitrarily, the only requirement being that it can be assigned on a per-sentence level. Possible examples are translation edit rate (TER) or sentence-level BLEU for MT, word error rate (WER) for ASR, or human ratings. We assume that the hypothesis is segmented in some way. The choice of segmentation is arbitrary, but sentence or utterance boundaries are a natural choice.

For purposes of this paper, we define document-level quality as the weighted average of the segment-level scores. Let ALL denote the index set of all segments in our document, y_i and w_i the true quality and weight of the i-th segment. The overall quality $Q^{(\text{true})}$ to be estimated is defined as:

$$Q^{(\text{true})} := \sum_{i \in \text{ALL}} w_i y_i \tag{1}$$

Note that this definition does not aim to handle document-level discourse phenomena such as coherence, cohesion, and and consistency, but estimates the average sentence-level quality for the document in order to evaluate the overall quality of the whole output hypothesis. In this paper, we weigh segments proportionally to their length, although future work may investigate more sophisticated notions of segment importance. Our definition of document quality is simplistic, but widely used in both MT and ASR communities, e.g. document- or corpus-level WER, TER, METEOR (Banerjee and Lavie, 2005), and human rankings are usually computed this way. BLEU is computed on the corpus level and thus not directly usable with our approach, but we can instead resort to computing average sentence-level BLEU variants such as BLEU+1 (Lin and Och, 2004) that essentially differ only in the smoothing details.

Our lightly supervised estimation framework determines document quality in several steps. The first step is to automatically estimate the quality for each segment in the hypothesis (§4). This can be achieved by training a regressor with the desired target measure, as discussed in numerous previous works. The

second step is then to manually annotate the quality score for a certain number of segments. In our evaluation (§5), we experiment with typical amounts of tens to hundreds of annotated words. The final step is to aggregate manual and automatic scores into a document-level estimate (§3).

3 Aggregation of Manual and Automatic Scores

We assume for a moment that we know how to collect automatic and manual segment-level scores, and discuss how they may be aggregated into a document-level estimate. Let $p_i, \forall i \in \text{ALL}$ denote the automatically predicted scores for all segments in the document, corresponding to the index set ALL. Let $y_i, \forall i \in \text{SEL}$ denote the manually annotated segment scores for a subset of all segments in a document, with indices $\text{SEL} \subseteq \text{ALL}$. w_i is the number of tokens in the system output for the i-th segment, and $Z^{(\mathcal{S})}$ is the total length of all segments indexed by $\mathcal{S}$. $Q^{(\text{true})}$ is the true document quality to be estimated.

3.1 Baselines

First, consider a *fully manual* baseline: Here, we randomly select segments from ALL to create SEL, and use the weighted average of manually annotated quality scores over these segments. Note that even though the segment-level scores y_i are reliable, the aggregate $Q^{(\text{man})}$ will be inaccurate if we keep the size of the annotated sample SEL small, as desired:

$$Q^{(\text{man})} = \frac{1}{Z^{(\text{SEL})}} \sum_{i \in \text{SEL}} w_i y_i \tag{2}$$

In contrast, the *fully automatic* baseline uses only the automatically predicted scores. Because automatic scores are available for all segments, the sample size is much bigger. On the other hand, the regressor used for prediction is often biased to predicting values p_i close to those indicated by the training data, which may differ considerably from the true values for y_i, especially for documents that are less similar to the training data. The formula is as follows:

$$Q^{(\text{auto})} = \frac{1}{Z^{(\text{ALL})}} \sum_{i \in \text{ALL}} w_i p_i \tag{3}$$

3.2 Bias vs. Variance: Why Aggregation is Challenging

Our goal is to improve over these baselines, and to motivate our methods we first frame these baselines in the context of the bias-variance tradeoff widely discussed in machine learning (Hastie et al., 2009). Here, the $\text{bias} = \mathbf{E}\big[Q^{(\text{est})} - Q^{(\text{true})}\big]^2$ describes the (squared) average error of the document-level estimate, with the expectation averaging over the randomness in the selection of annotated segments SEL, and other factors that one would consider random, such as particular training data for automatic QE, or randomness in the document that one might want to abstract from. The $\text{variance} = \mathbf{E}\big[\big(Q^{(\text{est})} - \mathbf{E}[Q^{(\text{est})}]\big)^2\big]$ describes by how much the estimates vary from one another, by again taking into account the randomness in the selection of segments, data, etc.

Based on these definitions, we observe that $Q^{(\text{man})}$ is subject to high variance, because the small sample size makes it sensitive to the randomness of the data. On the other hand, its bias is zero, since averaging over all randomness would cancel out estimation errors exactly. $Q^{(\text{auto})}$, on the other hand, has low variance because it always considers the whole document, but high bias for documents that are less similar to the data used to train the regressor. Figure 1 illustrates this interplay.

A straight-forward way to combine automatic and manual scores would be some form of interpolation:

$$Q^{(\text{interp})} = \alpha Q^{(\text{man})} + (1 - \alpha) Q^{(\text{auto})} \tag{4}$$

We experimented with several interpolation approaches in this spirit, but found that they do not work, because the high bias of the automatic estimate hurts accuracy more than could be compensated for by reduced variance of the interpolated estimate. The following subsections describe our refined aggregation strategies, which are more suited to solving this problem.

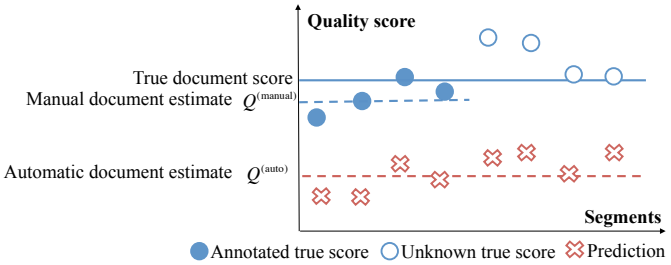

Figure 1: Schematic interplay between annotated and predicted estimates. The automatic aggregate has low variance because it includes all segments, but regressor-training data mismatch can lead to severely biased estimates. On the other hand, the manual annotations are unbiased per definition, but the potentially small number of samples causes high variance in the aggregate.

3.3 Proposed Strategy 1: Regressor Adaptation

In our first strategy, we use the annotated segments to adapt the regressor. This is done by casting the aggregation as a domain adaptation problem, in which we treat the original training data as background data, and the annotated segments of our document as in-domain data. Details for how the domain adaptation is performed are given in §4.1. As in the fully manual baseline, segments for annotation are selected at random. The document estimate is as in the fully automatic baseline, except that we now use the adapted regressor to produce the automatic scores $p_i^{(\text{adapt})}$. The hope is that the adaptation will reduce the regressor bias by shifting predictions closer to the document mean. The formula is as below:

$$Q^{(\text{adapt})} = \frac{1}{Z^{(\text{ALL})}} \sum_{i \in \text{ALL}} w_i p_i^{(\text{adapt})} \tag{5}$$

3.4 Proposed Strategy 2: Active Selection of Segments for Annotation

This approach attempts to select segments for manual annotation that are representative of the whole document. As a proxy for representativeness, we compute how close a segment's predicted quality is to the median prediction across the document. This choice is motivated by our definition of overall quality as the averaged segment-level quality. Specifically, we sort the segments by their automatic scores, and add the median[2] segment to SEL, the set of segments to annotate. Then, we add an equal number of segments to the left and to right according to this ordering, until the desired number of segments is reached. The document estimate is then calculated in the same manner as Equation 2.

The hope is that the active selection of annotated segments will reduce the sample variance. Note that unlike the first strategy, this one does not restrict the metric of the automatic scores to correspond to the target evaluation metric, because p_i does not appear directly in the sum. For instance, it would be possible to use segment-level BLEU scores or even confidence scores to compute SEL, despite our evaluation target being TER or human rating. The only requirement is that the predicted scores correlate with the target metric to some extent.

4 Automatic Segment Scores

4.1 Regression-based Approach

The first class of segment-level automatic scores we consider are QE scores obtained by a black box regressor that uses only surface features derived from the system input and output. It has the advantage of being agnostic to the interiors of the system that was used, and being able to predict any desired metric.

Features: We follow previous works for feature extraction. For MT, we use the 17 baseline features from the WMT QE shared task (Bojar et al., 2015), extracted using the QUEST toolkit (Specia et al., 2013). For ASR, we extracted signal-, hybrid-, and textual features as described in (Negri et al., 2014).

[2]We found the median criterion to outperform a mean criterion and other alternatives.

Regression Algorithm: We use extremely randomized trees (XTs) (Geurts et al., 2006), following Negri et al. (2014). XTs are a tree ensemble with a high amount of randomization, which has been reported to effectively reduce prediction variance, and can be trained quickly. Negri et al. (2014) report slight improvements for XTs over support vector regression (suggested by Bojar et al. (2015) as a baseline). In addition, our preliminary experiments indicate that XTs have more stable adaptation behavior.

Domain Adaptation: Our regressor adaptation aggregation strategy requires adapting the regressor using the collected manual labels. Our adaptation approach is to add binary indicator features for every document and system, including the document and system currently evaluated. Formally, we perform a projection $\Phi^{i,j} : \mathbb{R}^F \rightarrow \mathbb{R}^{F+D+S}$ from the original F-dimensional feature space into an $(F + D + S)$-dimensional augmented feature space. Here, F is the number of original features, D is the number of training documents plus one for the document under test, and S is the number of training systems plus one for the system under test. Further, i is the index of the particular training- or test-document, j is the index of the particular training- or test-system. The projection is defined as

$$\Phi^{ij}(\mathbf{x}) = \langle \mathbf{x}, \mathbf{e}_i, \mathbf{e}_j \rangle \tag{6}$$

with $\mathbf{e}_i$ being the D-dimensional zero-vector with only the i-th position set to one, and $\mathbf{e}_j$ an analogously defined S-dimensional vector.

We hope that this approach enables decoupled learning of the overall quality of a document or system (via the indicator features), and learning to distinguish quality between segments (via the original features). In general, the indicator features permit the regressor more flexibility to deal with the in-domain training samples, whose number is much smaller than that of the background data. We found the indicators to be helpful also when no adaptation is performed, possibly because it allows a form of multitask learning over the different documents and systems. Therefore, we use indicator features for both aggregation strategies. Our indicator features can be seen as a simplification of Daumé III (2007)'s method: here, in a typical adaptation scenario with in-domain and out-of-domain data, all features are *replicated* for both domains. In our case we deal with a potentially large number of domains (for each document and system), and feature replication would greatly enlarge the feature space and risk overfitting. Hence, we deem the proposed indicator features more appropriate for our purposes.

Predicting Deviation from the Document-Mean: Our active selection strategy only makes use of relative differences between segment scores. Therefore, at training time, we replace the label y_{ji} for the i-th segment of the j-th document (system output) by $y_{ji} - Q_j^{(true)}$, where $Q_j^{(true)}$ is the true overall quality of the j-th document. In this way, the regressor only needs to predict by how far (and in what direction) the segment deviates from the document mean, and the training objective becomes more directly meaningful. The indicator features are particular helpful here as they allow the model to learn and factor out the overall document quality. Note that predicting deviations is not useful for the regressor adaptation strategy, because the automatic scores are no longer meaningful in absolute terms.

4.2 Confidence-based Approach

The second class of automatic segment-level scores are confidence scores obtained directly from the system. Confidence scores are better-informed and potentially better correlated with true segment quality. However, unlike the regressor outputs, confidence scores do not share the same unit as the target evaluation metric. It would be possible to add these as a feature to a regressor as above, but at least for the QE training data used in our experiments, confidence scores were not available for all systems.

Instead, we propose using confidence scores as-is, which frees us from having to train a regressor and collecting training data for it. This approach can only be used with the active selection aggregation strategy. In this paper, we use confidence scores only in the ASR setting, and compute segment confidences as average word-level posterior probabilities derived from lattice- or consensus decoding.

5 Experiments

We conduct experiments to answer the following research questions:

Name	Description	# systems	# documents	# segments
MT.in-domain	WMT 2015 submissions, English to German news task	20	81	43380
MT.out-of-domain	WMT 2014 submissions, English to German medical task (khreshmoi testset)	6	1	6000
ASR.in-domain	IWSLT 2013 submissions, English TED task	13	28	28496
ASR.out-of-domain	English KIT lectures, decoded with a standard in-house ASR system	1	6	1849
ASR.conf-task	Mixed ASR data for which confidence scores were available	4	21	2431

Table 1: Data used in our experiments.

- How much effort is needed to produce quality estimates of a certain accuracy?
- Can we reduce effort, compared to the baselines, using our two proposed strategies?
- How effective are the proposed features, such as indicator features, predicting deviations, and using black box regression or confidences?
- Are there difference between in-domain and out-of-domain settings, or between MT and ASR?

We restrict ourselves to reference-based metrics for simplicity, namely TER for MT, and WER for ASR. Our experiments are simulated in the sense that we have reference translations/transcriptions available, and simulate a human annotator who replicates these exactly. Our main evaluation measure is mean absolute error (MAE)[3] between the predicted and true document-level TER/WER.

We use 5 datasets as indicated in Table 1, with testing data varying over all datasets, but only the ones labeled "in-domain" used for regressor training. Moreover, for each evaluated document the QE regressor was retrained with training data excluding that which corresponded to the same system *or* document currently tested (for in-domain tests). This makes even our in-domain scenario more challenging than some of the previous works on automatic QE (Specia et al., 2015).

We use scikit-learn (Pedregosa et al., 2011) for regressor training. We assign weights to training samples proportional to their segment length, because longer segments are weighted more strongly in our aggregation strategies (§3) and are thus more important to be accurately predicted. We perform random search with 20 iterations to optimize hyper-parameters (namely, the max-depth and min-samples-split parameters of XTs) in terms of mean squared error.[4] Tuning is conducted separately for every test document, using 10-fold cross validation on the respective training data. For regressor adaptation, we experimented with different weights for the adaptation samples, but observed only minor gains and decided to weight all data equally for simplicity.

5.1 Evaluation of Automatic Scores

We first analyze the performance of the fully automatic scores in terms of MAE and Pearson linear correlation coefficients. We investigate both segment-level and document-level performance, the latter being identical to the fully automatic baseline (§3.1). For comparison, we evaluate a mean-predictor baseline that always predicts the training mean, regardless of the input features. This baseline has been found surprisingly strong previously (Negri et al., 2014; Specia et al., 2015), which we confirm in Table 2. On segment-level, gains over the mean-predictor baseline are clearly visible only for the ASR setting. As expected, the out-of-domain tasks appear much more difficult than the in-domain setting. Note that even though the mean baseline sometimes achieves lower MAE, the XT regressor maintains the advantages

[3]Graham (2015) argues that correlation is better for evaluating *sentence-level* QE, because MAE can be improved by transformation to match estimated global mean and variance. However, we find MAE more indicative for our purpose as it measures not only how well systems are compared against one another, but also how well overall quality is judged in absolute terms. Moreover, collecting global statistics for transformation seems problematic when flexibility for domain changes is required.

[4]Tuning directly for MAE yielded similar results.

	Segment level			Document level		
	↓MAE mean	↓MAE XT	↑Pearson XT	↓MAE mean	↓MAE XT	↑Pearson XT
MT.in-domain	**21.0**	21.2	0.13	7.3	**5.8**	0.16
MT.out-of-domain	**14.9**	15.8	0.04	3.4	3.6	0.12
ASR.in-domain	15.4	**14.0**	0.35	9.6	**9.0**	0.29
ASR.out-of-domain	58.2	**52.9**	0.10	42.8	**37.7**	0.23

Table 2: Black box regression accuracy. Lowest MAE is in bold font if statistically significant (p=0.05) according to the bootstrap resampling significance test (Koehn, 2004).

Pearson correlation	Segment-level (all)	Segment-level (within document)	Document-level
Black box regressor	0.23	0.09	0.44
Negative confidence	0.34	0.61	0.12

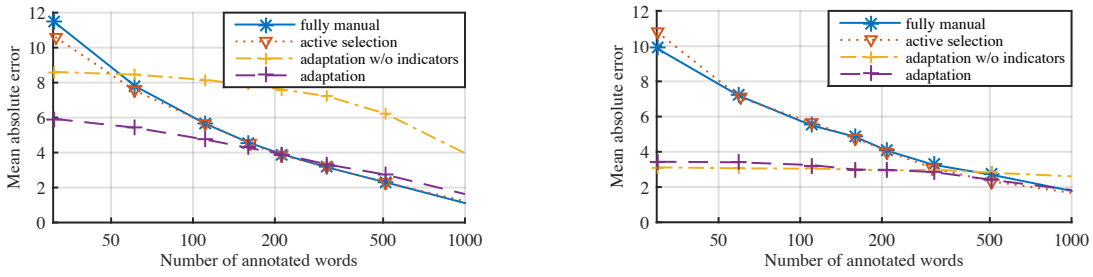
Table 3: Correlation for black box regressor vs. confidence scores with true WER labels on the ASR.conf-task dataset. Confidence scores are strong especially when evaluating the correlation on a per-document basis (averaging over documents), indicating that they may be more suitable for the active selection strategy than the black box approach.

of achieving positive segment correlation and supporting adaptation (§4.1). On document-level, the XT regressor outperforms the baseline in all but the MT.out-of-domain setting in terms of MAE, and correlation is stronger as well.

In Table 3 we also evaluate the performance of ASR confidence scores on the ASR.conf-task dataset. Since regressor outputs and confidences have different units, we compare them in terms of Pearson correlation. Compared to the black box regressor, it can be seen that confidence scores excel especially for the average within-document correlation. We would thus expect confidence scores to outperform black box regression for the active selection strategy.

5.2 MT Setting

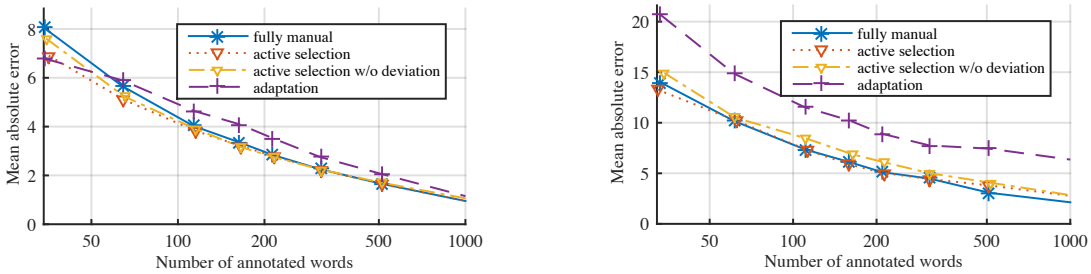
Figure 2 shows the results for the lightly supervised scenario for the MT datasets. Note that the fully automatic baseline corresponds to the leftmost point of the regressor adaptation curve. While the active selection strategy did not clearly outperform the fully manual baseline, regressor adaptation with enabled indicator features performed well. It can be seen that even a moderate amount of annotation improved the estimates, and the advantage over the fully manual baseline was especially strong for the out-of-domain setting. When removing the indicator features, regressor adaptation performs poorly in the in-domain setting. For the out-of-domain setting, performance changes only slightly. In both settings, it seems that the indicator features help to reach similar performance as the fully manual baseline for larger amounts of annotated data, suggesting that they help improve adaptation behavior.



(a) MT.in-domain

(b) MT.out-of-domain

Figure 2: Lightly supervised setting for MT.



(a) ASR.in-domain (b) ASR.out-of-domain

Figure 3: Lightly supervised setting for ASR.

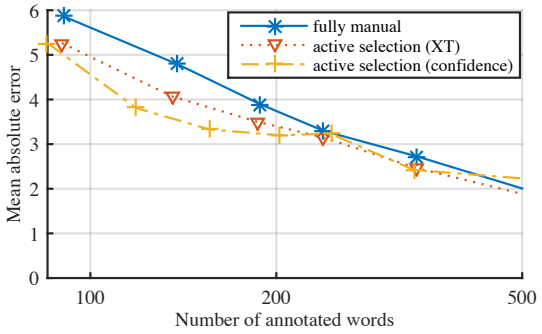


Figure 4: Active selection on the ASR.conf-task dataset, comparing the baseline and selection via XT regression scores and confidence scores.

5.3 ASR Setting

Figure 3 shows the results for the ASR datasets. The regressor adaptation strategy performs rather poorly. For active selection, we evaluate predicting deviations (§4.1), and observe small but consistent gains compared to the unaltered objective function. In result, we slightly outperform the fully manual baseline for the in-domain setting, and perform on par with the baseline for the out-of-domain setting.

However, the observed gains are probably too small to be considered worthwhile. We therefore also investigate replacing the XT regression scores by confidence scores provided directly by the ASR (§4.2). Here, XT regression was trained on data similar as in the test (in-domain setting), but again excluding all data from the particular document and system being tested. For the confidence scores, there is no distinction between in-domain and out-of-domain. Figure 4 reveals the more solid gains over both the fully manual baseline and active selection based on XT regression scores. We conclude that confidence scores are a promising way of reducing labeling effort in our slightly supervised quality estimation framework.

5.4 Discussion

As was seen in the above experiments, the proposed regressor adaptation strategy performed well for MT but not for ASR, whereas for the proposed active selection strategy it was the other way around. We also observe that for the MT datasets, there was relatively high between-segment variance compared to a relatively low between-document variance. This puts the fully manual baseline at a disadvantage, and may be the reason for the good regression-based results (fully automatic and regressor adaptation). In contrast, for the ASR datasets we observed relatively low between-segment variance and high between-document variance, which would put the annotation-based strategies at an advantage (fully manual and active selection). Scarton et al. (2015) made similar observations for MT, and we expect these findings to hold for other datasets. We also confirmed that results are similar when using BLEU+1 (Lin and Och, 2004) as the metric, instead of TER. Whether or not the situation changes when switching to very different metrics, such as non reference-based metrics, is left as a question for future work.

6 Relation to Prior Work

A good overview over the state-of-the-art in automatic QE for MT is given by Bojar et al. (2015) and Bojar et al. (2016), and for ASR by Ogawa et al. (2012) and Negri et al. (2014). Document-level QE was first explored by Soricut and Echihabi (2010) by exploiting document-level features, and was later improved by using sentence-level information (Soricut and Narsale, 2012; Specia et al., 2015; Bojar et al., 2015). Scarton and Specia (2014) and Scarton et al. (2015) argue that document-level quality metrics should consider discourse information that cannot be captured when processing segments individually, and explore features for QE that capture discourse information. Quantitative assessment of discourse information remains challenging (Bojar et al., 2016). Our aggregation approach supports only sentence-level information.

The out-of-domain case investigated in this work, i.e. predicting quality for a previously unknown system or task, has been found challenging in both ASR (Negri et al., 2014) and MT (de Souza et al., 2015a). The WMT 2015 shared task on QE considered only the scenario of training and testing on output produced by the same system (Bojar et al., 2015). The usual way to address domain mismatch when training data for all domains is available is via adaptation/multitask learning (Beck et al., 2014; de Souza et al., 2015b). Our indicator features can be seen as a form of multitask learning. A strategy for the case where no in-domain training data is available is to obtain such training data cheaply via active learning (Beck et al., 2013). This work is probably most similar in spirit to ours in that it attempts reliable quality estimation at low labeling costs.

A different line of research, crowd-sourced annotation, critically depends on quality control, as well. Approaches are usually based on comparing results between several workers (Passonneau and Carpenter, 2014), querying gold standard "testing" labels occasionally (Joglekar and Garcia-Molina, 2013), and/or automatically predicting quality (Roy et al., 2010; Gao et al., 2015). Our work can be seen as a generalization of the latter two, with the gold labels corresponding to our fully manual baseline, the automatic estimation corresponding to our fully automatic baseline, and the *workers* being our *systems*.

7 Conclusion

We proposed lightly supervised quality estimation at the document level, a framework that allows flexible quality estimation across changing domains and quality requirements, while requiring only moderate human annotation effort. We suggested two strategies for combining manual and automatic segment-level scores into a document-level estimate. The first strategy, regressor adaptation, was able to reduce annotation effort considerably for TER-based quality estimation in MT. The second strategy, active selection of segments for annotation, showed promising results for ASR quality estimation in terms of WER, when confidence scores are available.

As future work, we suggest exploring further evaluation metrics, in particular non reference-based metrics. Depending on the metrics, user interfaces that allow manual annotation at low effort should be designed. Also, the confidence-based active selection strategy may be worth investigating for MT.

Abstract

Selecting appropriate translations for source words with multiple meanings still remains a challenge for statistical machine translation (SMT). One reason for this is that most SMT systems are not good at detecting the proper sense for a polysemic word when it appears in different contexts. In this paper, we adopt a supersense tagging method to annotate source words with coarse-grained ontological concepts. In order to enable the system to choose an appropriate translation for a word or phrase according to the annotated supersense of the word or phrase, we propose two translation models with supersense knowledge: a maximum entropy based model and a supersense embedding model. The effectiveness of our proposed models is validated on a large-scale English-to-Spanish translation task. Results indicate that our method can significantly improve translation quality via correctly conveying the meaning of the source language to the target language.

1 Introduction

Phrase-based SMT has achieved better performance than word-based SMT. One of the reasons is that continuous phrases, rather than single words, are used as translation units so that useful context information can be captured for selecting appropriate translations. Even so, when translating sentences containing ambiguous words, which have multiple meanings, the state-of-the-art phrase-based SMT is still suffering from inaccurate lexical choice which makes translations unable to correctly convey the meaning of source sentences. Recent studies show that in order to improve translation quality, one must correctly identify the most likely senses of source-side ambiguous words when selecting target translation (Gao et al., 2013; Zou et al., 2013; Zhang et al., 2014).

One common approach to deal with ambiguity is to incorporate a word sense disambiguation (WSD) system into SMT system. At first, Carpuat and Wu (2005) attempt to use the senses of source ambiguous words predicted by a standard formulation of WSD directly in a word-based SMT but results are disappointing. They are skeptical of the assumption that WSD systems are useful for SMT. Instead of the standard WSD task, Vickrey et al. (2005) propose a novel formulation of WSD for SMT: directly predicting possible target translation candidates as senses for ambiguous source words. This reformulated WSD has been shown to help SMT by several subsequent studies, including later work by Carpuat and Wu (2007). Following this WSD reformulation for SMT, they integrate the WSD training, where sense definitions are drawn automatically from all phrasal translation candidates rather than from a predefined sense inventory into a phrase-based SMT.

In addition to WSD, topic model (Blei et al., 2003) is yet another technique used to detect most likely senses of source words. Various topic-specific lexicon translation models are proposed to improve translation quality. These models can be classified into two categories: word-level translation models (Zhao and Xing, 2006; Tam et al., 2007) and phrase-level models (Xiao et al., 2012). Especially, Xiong and Zhang (2014) propose a sense-based translation model that integrates hidden word senses into machine

translation to investigate whether hidden senses are useful for SMT. They resort to word sense induction (WSI) and build a broad-coverage sense tagger that relies on the nonparametric Bayesian model to obtain hidden senses for each source word in large-scale corpora. Different from what the previous reformulated WSD does, they first predict word senses which are automatically learned from data for ambiguous words and then make use of predicted word senses along with other context features to predict possible target translations for these words. They conclude that word senses automatically induced by WSI are very useful for SMT in dealing with inaccurate lexical choice.

However, all the models mentioned above are focusing on investigating how to exploit fine-grained word senses (e.g., predefined senses, target translation candidates, hidden senses) in SMT to improve translation quality. Then how about coarse-grained word senses such as supersenses that are WordNet (Fellbaum, 1998) semantic labels grouping semantically close synsets into a coarse-grained ontology? Are they useful for SMT? Since supersense tagging is the task of assigning high-level ontological classes to open-class words such as nouns, verbs, it is thus a coarse-grained word sense disambiguation task. To the best of our knowledge, we are the first to be dedicated to systematically investigating whether supersenses can be used in SMT to alleviate source word sense translation errors. Specifically, we try to model supersenses for SMT in the following two ways:

- A maximum entropy (MaxEnt) based model: Building multiple MaxEnt classifiers with one classifier per source word type, which incorporate supersenses as features.

- And a supersense embedding model: Projecting word supersenses to a multidimensional vector space with word2vec[1], and inducing source phrase supersense embeddings for phrasal translation.

These two supersenses-based translation models are integrated into a state-of-the-art SMT system and a series of experiments are conducted on English-to-Spanish translation based on large-scale training data. Results show that supersenses, high-level ontological concepts, are capable of improving translation quality and the supersense embedding model outperforms the MaxEnt classifiers-based model.

Our work is different from previous standard WSD, reformulated WSD and WSI with hidden senses for SMT. The first uses fine-grained senses predefined by WordNet. The second explores surrounding words to disambiguate word senses. And the third integrates topics inferred from pseudo documents as hidden senses. We employ coarse-grained predefined categories from WordNet to disambiguate ambiguous words for SMT.

The remainder of this paper is organized as follows. Section 2 introduces related studies exploiting word sense knowledge to improve lexical selection in SMT and various applications of supersenses and word embeddings. Section 3 elaborates how we obtain supersense tags for words in large-scale data. Section 4 describes our supersense-based translation models. Section 5 presents the way that we integrate supersense-based translation models into SMT. Section 6 discusses our experiments and results. In section 7 we summarize our findings and directions for future work.

2 Related Work

The problem of accurate lexical choice is an unsolved challenge for phrase-based SMT. Much work has been done to identify proper senses of source ambiguous words to aid system in choosing appropriate translations. Integrating WSD into an SMT system is typical of this work as described in Section 1 (Carpuat and Wu, 2005; Vickrey et al., 2005; Carpuat and Wu, 2007; Chan et al., 2007). Exploring topic model for SMT is another attempt. Gong et al. (2010) introduce document-level topics to help SMT generate target translations. They use a monolingual LDA model to assign a specific topic to the document to be translated. Similarly, each phrase pair is also assigned with one specific topic. A phrase pair will be filtered from phrase table if its topic mismatches the document topic. Xiao et al. (2012) propose a topic similarity model which incorporates the rule-topic distributions on both the source and target side into a hierarchical phrase-based system for rule selection.

	consumption	contact	creation	emotion	motion
	perception	possession	social	stative	weather

Table 1: Supersense labels for nouns and verbs in WordNet.

Supersenses are useful and have been used as high-level features in various tasks. Ciaramita and Altun (2006) define a tagset based on WordNet supersenses to perform broad-coverage word sense disambiguation and information extraction which they approach as a unified tagging problem. They achieve considerable improvements over the first sense baseline. Koo and Collins (2005) utilize supersense reranking that provides a partial disambiguation step in syntactic parse to build useful latent semantic features. Other tasks like preposition sense disambiguation (Ye and Baldwin, 2007), noun compound interpretation (Tratz and Hovy, 2010) can also employ supersenses to improve performance.

Word embeddings, also called distributed word representations, are used in many natural language processing areas such as information retrieval (Manning et al., 2008), search query expansions (Jones et al., 2006), or representing semantics of words (Reisinger and Mooney, 2010). As to SMT, Zou et al. (2013) propose a method to learn bilingual word embeddings for recognizing and quantifying semantic similarities across languages.

Our work is to integrate supersenses into a phrase-based SMT. We adopt two ways to train our supersense-based models: one is a MaxEnt classifier-based model which is closely related to Xiong and Zhang's (2014) work, the other is a model built on supersense embeddings that are different from word embeddings in that supersense embeddings can provide more high-level semantic information than word embeddings.

3 Supersense Tagging

Supersenses, first defined by Ciaramita and Johnson (2003), are coarse-grained semantic labels used by lexicographers to facilitate the development of WordNet. There are 45 supersense labels, 26 for nouns, 15 for verbs, 3 for adjectives and 1 for adverbs, used in WordNet to classify synsets into several domains based on syntactic category and semantic coherence. Normally, an ambiguous word belongs to several synsets. Since supersense labels are assigned to synsets, word sense ambiguity can be preserved to a certain degree at this level. In this paper, we focus on noun and verb supersenses. Table 1 shows the corresponding supersense labels in WordNet.

We use supersenses as our semantic classes to tag our training data for obtaining contextual information for the following advantages. First, this set of semantic labels is fairly general and therefore small. The reasonable size of the label set makes it possible to have only one model. In contrast, we have one model per word for fine-grained WSD. Second, the sensible semantic categories are easily recognizable and not too abstract. Since similar words tent to be merged together, these semantic categories seem promising to be used in MT. Third, while individual glossary can not embody too much about the narrow concept it is attached to, at the supersense level this information accumulates. In order to be more intuitive, we take the verb ***"help"*** as an example to show how fine-grained senses are grouped in supersenses, which is presented in Table 2.

In this paper, supersense tagging is carried out with a model based on Ciaramita and Altun's (2006) work. We deploy the implementation provided by Michael Heilman[2]. The model takes a sequence labeling approach to learn a model for supersense tagging. Specifically, we employ a sequential labeller

Supersense	WN Senses	Gloss
social	1	give help or assistance; be of service
social	6	contribute to the furtherance of
body	2	improve the condition of
stative	3	be of use
stative	4	abstain from doing; always used with a negative
change	8	improve; change for the better
consumption	5	help to some food; help with food or drink
consumption	7	take or use

Table 2: An example of grouping different fine-grained senses of a word into supersenses. WN senses: senses from WordNet.

that is based on a Hidden Markov Model (HMM) trained in a discriminative way. That is, the model can be seen as a perceptron-trained HMM (Collins, 2002) that jointly models observation/label sequences. The model is trained on Semcor Corpus (Miller et al., 1993) following the experimental setting described in Ciaramita and Altun (2006). WordNet fine-grained senses are mapped to their corresponding supersense. In our case, only nouns and verbs are mapped, labeling as "NULL" the rest of the tokens (including adjectives and adverbs). In some cases "noun.Tops" refers to more specific supersenses, such as "food", "person", or "animal". In those cases we substitute the "noun.Tops" with more specific label (e.g "animal" as "noun.animal"). Although the tagger learns 41 semantic categories, we included (B) beginning and (I) continuation as supersense prefixes to learn more categories. Thus, actual label space to be learned increases to 83 (including "NULL").

Semcor is divided in three parts: "brown1" and "brown2", in which nouns, verbs, adjectives and adverbs are annotated. But the section "brownv", contains annotations only for verbs. To avoid many nouns being labeled with "NULL" we take the same procedure as Ciaramita and Altun (2006) to extract the text segment including a verb but not a noun.

Regarding features, our implementation replicates the features used in the original work, which include words and part-of-speech tags occurring in a context-window, word-shapes of the surrounding words, the first-sense of the word and the surrounding words, and the previous label. Please refer to the original work for a more detailed description of the model.

4 Supersense-based Translation Model

In this section, we present two methods to build the proposed supersense-based translation models.

4.1 A MaxEnt Classifier-based Model

Given a source word c with its contextual information including supersenses, we resort to a MaxEnt classifier to estimate the probability $p(e|C(c))$ of a target phrase e. The MaxEnt classifier is formulated as follows.

$$P(e|C(c)) = \frac{exp(\sum_i \theta_i h_i(e, C(c)))}{\sum_{e'} exp(\sum_i \theta_i h_i(e', C(c)))} \quad (1)$$

where h_i are binary features, θ_i are weights of these features.

We use two groups of features: lexicon features and supersense features, which are used to define $C(c)$ as follows:

$$C(c) = \{c_{-k}, s_{c_{-k}}, ..., c_{-1}, s_{c_{-1}}, c, s_c, c_1, s_{c_1}, ..., c_k, s_{c_k}\} \quad (2)$$

where c represents words and s for supersenses. In this way, not only centered word c and its supersenses s_c are included, but the preceding and succeeding k words with their corresponding supersenses are also involved. Particularly c_{-k} is the kth preceding word of c and $s_{c_{-k}}$ is the supersense of word c_{-k}. We extract all training events defined by $C(c)$ for each source word c and train multiple MaxEnt classifiers with one classifier per source word.

4.2 A Supersense Embedding Model

A traditional way to generate a phrase table is to use the training component of Moses[3] that allows you to automatically train translation models for any language pairs. Normally, each entry in the phrase table contains a source phrase, a target phrase, their word alignments, and five types of translation scores. From the training corpora where the source side is annotated with supersenses, we want to learn the distribution of the supersenses tagged for a source-side phrase. In order to achieve this goal, we have made some changes on the phrase extraction and scoring module of Moses training system to make them output source word supersenses. The number of extracted phrase pairs are expanded greatly since the same source phrase may correspond to several sequences of tagged supersenses.

With word2vec, we can train word sense embeddings on the supersense-tagged corpus. Assuming that a source phrase src containing n words $(w_1, w_2, ..., w_n)$ has k supersense sequences: $ps_1, ps_2, ..., ps_k$. Since each word supersense in the phrase constitutes the phrase supersense sequence, we can use Eq. (3) to represent ps_i, and Eq. (4) to represent the supersense sequence embedding.

$$ps_i = (w_1|ws_1\ w_2|ws_2\ ...\ w_n|ws_n) \tag{3}$$

$$\overrightarrow{ps_i} = \overrightarrow{w_1|ws_1} + \overrightarrow{w_2|ws_2} + ... + \overrightarrow{w_n|ws_n} \tag{4}$$

where ws represents supersense labels and | is a separator between the word and its supersense label.

Each supersense sequence has a unique sense embedding according to the calculating method above. Then how can we represent the supersense embeding of a source phrase in the phrase table? We adopt a dividing and merging method.

The dividing method A translation rule in the original phrase table is divided into several rules for the reason that the source phrase of the rule has several supersense sequences. Direct and indirect phrase translation probability calculated in Eq. (5) and (6) are reformulated and recalculated according to Eq. (7) and (8) respectively.

$$P(e|f) = \frac{Count(e, f)}{Count(f)} \tag{5}$$

$$P(f|e) = \frac{Count(f, e)}{Count(e)} \tag{6}$$

$$P(e|f, ps) = \frac{Count(e, f, ps)}{Count(f, ps)} \tag{7}$$

$$P(f, ps|e) = \frac{Count(f, ps, e)}{Count(e)} \tag{8}$$

where f, e, ps stands for source phrase, target phrase, source phrase supersense sequence respectively. In this way, a source phrase may have multiple supersense embeddings.

The merging method Supposing a source phrase src has k supersense sequences: $ps_1, ps_2, ..., ps_k$, we study the probability distribution of each supersense sequence according to the following formula.

$$P(ps_i|src) = \frac{Count(ps_i, src)}{Count(src)} \tag{9}$$

We assign each source phrase a unique sense embedding $\overrightarrow{s_{src}}$ using the following formula (10).

$$\overrightarrow{s_{src}} = \lambda_1\overrightarrow{ps_1} + \lambda_2\overrightarrow{ps_2} + ... + \lambda_k\overrightarrow{ps_k} \tag{10}$$

where λ_i represents the probability of the ith supersense sequence calculated according to Eq. (9).

[3] http://www.statmt.org/moses/

5 Decoding

We integrate the proposed supersense-based translation models described above into a log-linear translation framework of SMT as a new knowledge source to disambiguate source words. Both supersense-based translation models require that each sentence should be sense-tagged to annotate each word with supersenses before being translated. We adopt an integration strategy similar to that introduced by Xiong and Zhang (2014) to incorporate the MaxEnt classifier-based model into our SMT system. During decoding, once a new source word c is translated, we find its target phrase e according to word alignments that are kept in the phrase table. Then we compute the translation probability $p(e|C(c))$ via the equation (1) using the corresponding classifier. As to integrating the supersense embedding model, we load the pre-trained word sense embeddings to calculate the source phrase sense embeddings according to Eq. (4) when translating a sentence. We compute the similarity between a source phrase in a source sentence and the corresponding matched phrase from the phrase table using the following formula in order to select appropriate translation rules.

$$Sim(\overrightarrow{s_{ssrc}}, \overrightarrow{s_{tsrc}}) = \frac{\overrightarrow{s_{ssrc}} \bullet \overrightarrow{s_{tsrc}}}{||\overrightarrow{s_{ssrc}}|| \times ||\overrightarrow{s_{tsrc}}||} = \frac{\sum_i (a_i \times b_i)}{\sqrt{\sum_i {a_i}^2 \times \sum_i {b_i}^2}} \tag{11}$$

where s_{ssrc} is a phrase in a source sentence, s_{tsrc} is the same phrase in the phrase table, a_i and b_i are the value of ith dimension of their sense embeddings.

Given a source sentence $\{c_i\}_1^N$, We define the score of supersense embedding model as follows.

$$Score_{M_s} = \sum_{ssrc_i \in \Gamma} Sim(\overrightarrow{s_{ssrc_i}}, \overrightarrow{s_{tsrc_i}}) \tag{12}$$

where Γ is a set of source phrases which have translation rules in the phrase table.

6 Experiments

In this section, we conducted a series of experiments on English-to-Spanish translation using massive training data. With the trained supersense-based translation model, we would like to investigate the following two questions:

- Whether coarse-grained supersenses can improve translation quality.
- Whether supersense embeddings can play a role in lexical selection.

6.1 Setup

Our baseline is a state-of-the-art SMT system which adapts Bracketing Transduction Grammars (Wu, 1997) to phrasal translation and augment itself with a maximum entropy based reordering model (Xiong et al., 2006). Our training corpora are English-Spanish sentences from the Europarl parallel corpus (Koehn, 2005) consisting of 1.9M sentence pairs with 51M English words and 54M Spanish words. We ran GIZA++ on the training data in both directions and then applied the "grow-diag-final" refinement rule (Koehn et al., 2003) to obtain final word alignments. Our phrase table was generated according to the word-aligned data. As to the language model, we trained a separate 5-gram LM using the SRILM toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1996) on each subcorpus[4] and then interpolated them according to the corpus used for tuning.

We trained our MaxEnt classifiers with the off-the-shelf MaxEnt tool.[5] We performed 100 iterations of the L-BFGS algorithm implemented in the training toolkit on the collected training events from the sense-annotated data. We set the Gaussian prior to 1 to avoid overfitting.

[4]There are 12 subcorpora: commoncrawl, europarl, kde4, news2007, news2008, news2009, news2010, news2011, news2012, newscommentary, openoffice, un

The method used to learn supersense embeddings, word2vec, in this paper was implemented based on continuous bag-of-words model (Mikolov et al., 2013). We only varied vector dimensionality from 100 to 200 and set the value of threshold for occurrence of words to 0.00001. Default values of other parameters such as the training algorithm and the size of the window were all taken.

The QTLeap corpus[6] was divided into two parts equally to be used as our development set *batch1* and test set *batch2*. The corpus was composed by 4000 question and answer pairs in the domain of computer and IT troubleshooting for both hardware and software. This material was collected using a support service via chat, this implies that the corpus is composed by naturally occurring utterances produced by users while interacting with a service. Only interactions composed by one question and the respective answer were included in the corpus. We also divided our test set *batch2* into two parts equally ***batch2a*** and ***batch2q*** respectively. In other words, we used three test sets to verify the effectiveness of our proposed models. We adopted the case-insensitive BLEU-4 (Papineni et al., 2002) as evaluation metric and ran MERT (Och, 2003) three times to alleviate the instability. We reported average BLEU scores over the three runs as final results.

6.2 Results

Our first group of experiments are designed to investigate whether supersenses can be modeled like hidden senses using a MaxEnt classifier. We use the same experiment settings as Xiong and Zhang (2014) did. Especially, we also find that 10-word window is the most suitable window for extracting semantic information according to experiments. Table 3 shows the experimental results for the two SMT systems equipped with multiple MaxEnt classifiers trained on supersenses and hidden senses respectively.

We can easily find that resorting to a MaxEnt classifier, supersenses can also be integrated into the SMT system and achieve an improvement over the baseline, which is comparable to that obtained by hidden senses.

Inspired by the idea that distribution word representations can convey contextual information, we conduct our second group of experiments to investigate whether distributed supersense representations can be used to improve SMT. We are also concerned about the potential impact of the sense embedding dimensionality on the performance of the supersense embedding model. Hence, in addition to the different methods to represent source phrase supersense embeddings, we consider the dimension as 100 and 200 when training word supersense embeddings. Experimental results are listed in Table 4. From the table, we can observe that

	HSTM	38.20*	36.25	42.85
Merging	SSTM	38.64**	36.68**	43.17*
	HSTM	38.15*	36.29	42.95

Table 5: Results of using the dividing and merging method to obtain supersense embedding-based translation model (SSTM) vs. hidden sense embedding-based translation model (HSTM). **/*: significantly better than the baseline at $p < 0.01$ and $p < 0.05$ respectively.

- No matter which method we use to calculate source phrase supersense embeddings, the supersense embedding-based translation model is able to achieve an average of 0.7 BLEU points over the baseline on three test sets.
- When using the dividing method to calculate source phrase sense embeddings, the sense embedding dimension has a slight impact on the translation quality in terms of BLEU.
- On the contrary, when using the merging method to obtain source phrase supersense embeddings, training supersense embeddings with 100-dimension performs worse than 200-dimension on the test set. The BLEU score drops by 0.6 points on average. This may be because the merging method uses multiple supersense sequences to compute the final supersense embeddings (see Eq. (10)). The fluctuations caused by the dimensionality of embeddings may be amplified by the summation in Eq. (10).

Our final group of experiments is to study 1) whether hidden senses can be integrated into the SMT system in the way similar to supersense embeddings and 2) which kind of word senses can perform better. When using the dividing method to obtain source phrase hidden sense embeddings, we set the dimension value to 100 in which case supersense embeddings perform a little better than 200-dimension according to Table 4. As for the merging method, we set the dimension value to 200 to make an equitable comparison with supersenses. Table 5 shows the results. We find that supersense embedding-based model performs better than hidden sense embedding-based model in all cases. The reason for this may be that hidden senses have already encoded distributional information in themselves.

7 Conclusion

We have exploited coarse-grained supersenses which are semantic labels defined by WordNet to conduct high-level word sense disambiguation for SMT. After each source word in the training data is tagged with a supersense, we take two strategies to train our supersense-based translation models. One is utilizing a maximum entropy classifier to predict the target translation for a source word given its surrounding words and their corresponding supersenses. The other is taking advantage of a word2vec tool to learn supersense embeddings on corpus annotated with supersenses and then calculating the semantic similarity between phrases in source sentence and matched phrases from phrase table. The supersense-based translation model is integrated into a phrase-based SMT system.

We have conducted a series of experiments to validate the effectiveness of the proposed supersense-based translation models. Final experimental results show us that

- The supersense-based translation model is capable of improving translation quality significantly in terms of BLEU.
- When using a MaxEnt classifier to predict target translation for a source word given its surrounding semantic information, both supersenses and hidden senses perform well.
- When using distributed sense representations to build sense-based translation models, supersense embeddings perform better than hidden sense embeddings.

In the future, we would like to investigate new neural models to learn embeddings for a single word supersense as well as a supersense sequence. We are also interested in incorporating the relations of supersenses (i.e., high-level ontological concepts) for machine translation.

Abstract

Human-targeted metrics provide a compromise between human evaluation of machine translation, where high inter-annotator agreement is difficult to achieve, and fully automatic metrics, such as BLEU or TER, that lack the validity of human assessment. Human-targeted translation edit rate (HTER) is by far the most widely employed human-targeted metric in machine translation, commonly employed, for example, as a gold standard in evaluation of quality estimation. Original experiments justifying the design of HTER, as opposed to other possible formulations, were limited to a small sample of translations and a single language pair, however, and this motivates our re-evaluation of a range of human-targeted metrics on a substantially larger scale. Results show significantly stronger correlation with human judgment for HBLEU over HTER for two of the nine language pairs we include and no significant difference between correlations achieved by HTER and HBLEU for the remaining language pairs. Finally, we evaluate a range of quality estimation systems employing HTER and direct assessment (DA) of translation adequacy as gold labels, resulting in a divergence in system rankings, and propose employment of DA for future quality estimation evaluations.

1 Introduction

Although human evaluation of translation quality in theory provides the most meaningful assessment of machine translation (MT), achieving high levels of agreement between human assessors has proven challenging. For example, the annual Workshop on Statistical Machine Translation (WMT) provides large-scale human evaluation of systems, and reports inter-annotator agreement ranging from 0.260 (WMT-13) to 0.405 (WMT-15), with intra-annotator agreement not faring much better, from 0.407 (WMT-12) to 0.595 (WMT-15) (Callison-Burch et al., 2012; Bojar et al., 2013; Bojar et al., 2015).[1] Low agreement levels in human annotation cause challenges for tasks that require evaluation of MT output on the segment-level. For example, evaluation of MT quality estimation (QE) requires the comparison of system predictions of translation quality with segment-level human assessment. Automatic metrics, such as BLEU or TER, although fully repeatable, unfortunately lack the validity of human assessment and are well-known to suffer from bias in favour of translations that happen to be superficially similar to reference translations.

Part-automatic human-targeted metrics, however, are commonly employed as a substitute for human assessment on the segment-level, as they appear to provide a happy medium between fully automatic metrics, that lack the validity of human assessment, and human assessment that lacks reliability/reproducibility of automatic metrics. Human-targeted reference translations, each manually created by minimally post-editing the individual MT output translation to be assessed, remove the bias usually introduced by comparison with a generic reference. Subsequently an automatic component is applied to quantify the error now present between the MT output and its human-targeted reference.

[1]Agreement levels provided are average Kappa coefficients for all language pairs included in the main translation shared task.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3124–3134, Osaka, Japan, December 11-17 2016.

Although human-targeted metrics are indisputably more valid than their generic-reference counterparts, the scores they produce are nonetheless still partly automatic. Given the vast number of possible methods of comparing a given MT output with its (human-targeted) reference translation, it is necessary to provide evidence that any given choice of human-targeted metric provides the best formulaic substitute for human assessment.

As with fully automatic metrics, human-targeted metrics are themselves evaluated by strength of correlation with human assessment. For example, when the most widely applied human-targeted metric, human-targeted translation edit rate (HTER) was first proposed, Snover et al. (2006) reported that "HTER is more highly correlated to human judgments than BLEU or HBLEU" (p. 230), and hence, since 2006, it is HTER, as opposed to HBLEU, that is employed in MT as a human assessment substitute.

2 Relevant Work

HTER is generally regarded as a valid substitute for human assessment. In MT QE, for example, HTER scores are used to evaluate systems in large-scale shared tasks (Bojar et al., 2015; Graham, 2015). If a metric such as HTER is to be relied upon as a substitute for human assessment, it is important that trust in the metric is well-placed to avoid inaccuracies in empirical evaluations. For instance, Bojar et al. (2013) and Graham (2015) make the assumption that HTER provides a valid representation of translation quality and subsequently employ HTER scores as a gold standard representation when evaluating QE systems, ultimately leading to rankings for competing systems. If HTER scores do not in fact provide a valid representation of translation quality, however, system rankings are likely to be incorrect. On review of experiments that originally led to trust in HTER as a substitute for human assessment, a possible disparity emerges between the degree of trust placed in HTER and the limitations of original experiments. These limitations include:

- A sample of translations produced by two distinct MT systems, one of known *low-performance* and one known *high-performance* system;
- A single language pair (Arabic to English);
- A maximum of two human annotators per translation;
- Employment of human-targeted reference translations created by human post-editors coached to specifically minimize HTER scores as opposed to other possible formulations.

The degree to which general conclusions can be drawn from experiments should reflect the extent to which experiments were carried out, and the broad conclusions drawn that HTER has a strong correlation with human assessment is not ideal considering experiments were limited to a small number of translations produced by two MT systems and for a single language pair. Furthermore, translations sampled from systems that operate at the two extremes of performance, a known high quality system and a poorly performing one, risks exaggeration of correlation with human assessment.

In addition, it is possible that issues in relation to levels of inter-annotator agreement, common in other human evaluations, were also present in the human evaluation used in HTER experiments, as Snover et al. (2006) report that "... the four-reference variants of TER and HTER correlate with human judgments as well as – or better than – a second human judgment does" (p. 223). The fact that HTER scores correlated with the quality assessments of one human assessor more than those of another, highlights the likelihood that agreement between human annotators was low, although no precise agreement levels are reported. If, for example, the correlation of scores produced by a (part-automatic) metric, such as HTER, and human assessment scores provided by a given human assessor, Annotator$_a$, is stronger than the correlation between Annotator$_a$ and a second human annotator, Annotator$_b$, it follows that this latter correlation, between human assessments of the two distinct annotators cannot be all that high. Choosing to trust the annotations of Annotator$_a$ simply on the basis that those annotations yield a more favorable correlation with HTER is not justified. The fact that part-automatic metric scores correlate better with one human annotator than another is not evidence of how well the metric is performing, merely that the human evaluation employed is somewhat unstable.

Table 1: Initial human assessment of nine language pairs, sample taken from all WMT-13 translation task participating systems.

Finally, the comparison made between the correlation of HTER (with human assessment) and those of other possible formulations, such as HBLEU, was unfortunately biased in favour of HTER, as Snover et al. (2006) report "Annotators were coached on how to minimize the edit rate. The coaching given to the annotators in order to minimize HTER, consisted mostly of teaching them which edits were considered by TER. The annotators also consulted with each other during training to compare various techniques they found to minimize HTER scores" (p. 227). A clear bias was therefore introduced into the comparison of correlations achieved by HTER and other human-targeted metrics, such as HBLEU for example, by coaching post-editors specifically to reduce HTER scores. Although bias in favour of HTER was identified in Snover et al. (2006), reporting "It is possible that performance of HTER is biased, as the targeted references were designed to minimize TER scores rather than BLEU scores" (p. 228), this was not highlighted or reconsidered when reporting correlations and drawing conclusions about the superiority of HTER over other metrics.

In this paper, we repeat the original experiments to re-assess HTER as a human assessment substitute. In doing so, we vastly expand experimental settings relative to the limitations of the original, as follows:

- Data sets include translations sampled from the output of 131 MT systems, operating at all levels of performance;
- Correlations of HTER with human assessment are reported for nine language pairs;
- Evaluation is based on between 15 and 80 human assessments per translation – to overcome human annotator agreement issues;
- Human-targeted reference translations are created without any coaching.

3 Re-evaluating Human-Targeted Metrics

As in evaluation of fully automatic metrics, evaluation of human-targeted metrics is by correlation with human assessment. Like the original evaluation of HTER, our re-evaluation also operates on the segment-level, with the performance of different possible human-targeted metric formulations measured by correlation of metric scores with segment-level human assessment. To compute correlations for human-targeted metrics, two distinct human annotations of each translation are required.

Firstly, we require a human assessment rating of the quality of each translation in order to compute correlations of each human-targeted metric. Our evaluation additionally requires manually created post-editions of each original MT output translation. This human post-edit is employed as the human-targeted reference translation for computing human-targeted metric scores for translations. We firstly describe the methodology employed for human assessment, before providing post-editing details.

3.1 Human Assessment of Translation Adequacy

Overall in this work, human assessment was carried out for two distinct data sets, firstly a nine language pair data set to re-evaluate HTER and subsequently an English to Spanish data set (see Section 4.2). Below we describe human assessment of the nine language pair data set.

Human direct assessment (DA) of the adequacy of translations was collected by means of a 100-point continuous rating scale via crowd-sourcing. Large numbers of repeat human judgments for translations were collected on Amazon Mechanical Turk, by way of re-implementation and minor adaptation of

Graham et al. (2015).[2] Translations were sampled at random from all systems competing in WMT-13 translation task for Czech-to-English (CS-EN), German-to-English (DE-EN), Spanish-to-English (ES-EN), French-to-English (FR-EN), Russian-to-English (RU-EN), English-to-German (EN-DE), English-to-Spanish (EN-ES), English-to-French (EN-FR) and English-to-Russian (EN-RU). Human assessors rated the adequacy of translations in a monolingual human evaluation by comparing the meaning of the original generic human reference translation (rendered in gray) with a given MT output translation (rendered in black) by stating the degree to which they agree that:[3]

The text in black adequately expresses the meaning of the text in gray in English.

Quality control was applied by comparison of ratings provided by each Mechanical Turk worker for pairs of original and degraded translations hidden within HITs, where each pair contained an original MT output translation along with a degraded version of that translation. Ratings of workers who were not reliable (or at any point during the course of data collection became unreliable) in their ability to accurately distinguish between the adequacy of degraded and original system output translations were omitted from the final data set.

Between 15 and 80 (22.4 on average) human assessments of adequacy were collected per translation and combined into a mean score for a given translation, after standardization of scores based on the individual annotators mean and standard deviation rating. Table 1 shows numbers of human assessments collected contributing to mean adequacy scores for translations.

3.2 Human-Targeted Reference Translations

A human-targeted reference translation was created for every translation in the data set by a known-reliable volunteer post-editor native in the target language of the MT output in question. All human post-editors were unaware of the purpose of the post-editing work and experiments. Annotators were shown the reference and MT output with post-editing instructions as follows:[4]

**Making as few changes as possible **, correct the hypothesis segment to make it

(a) have the same meaning as the reference segment;

(b) grammatically correct.

3.3 HTER Re-evaluation Results

Table 2 shows correlations achieved by a range of human-targeted metric formulations with human assessment, including human-targeted versions of segment-level BLEU (Papineni et al., 2002; Koehn et al., 2007), TER (Snover et al., 2006), WER, PER and CDER (Leusch and Ney, 2008). Correlations with human assessment achieved by HTER are, for three of the nine language pairs we evaluate, below a Pearson correlation of 0.6. In addition, comparison of correlations achieved by HTER and HBLEU reveal a *higher* correlation achieved by HBLEU for five of the nine language pairs we evaluate.

As recommended by Graham et al. (2015), we test for significance of difference in dependent correlations using Williams test, as shown in Figures 1 and 2. For two language pairs, DE-EN and FR-EN, correlations achieved by HBLEU with human assessment are significantly stronger than those achieved by HTER, and for all other language pairs, the difference in correlation achieved by HBLEU and HTER is not statistically significant.

Table 2 also includes correlations achieved by all metrics with human assessment when the original generic reference is employed. As expected correlations of generic-reference metrics are in all cases substantially lower than that of their human-targeted counterparts.

3.4 Possibility of Reference Bias in Monolingual MT Assessment

As mentioned in Section 1, in automatic evaluation of MT reference bias is a known problem, as high quality MT output can be unfairly penalized simply due to a lack of superficial similarity with the generic

Table 2: Correlation of segment-level human-targeted metric scores with human assessment and correlations of raw metrics with human assessment for a random sample of translations from WMT-13 translation task system submissions

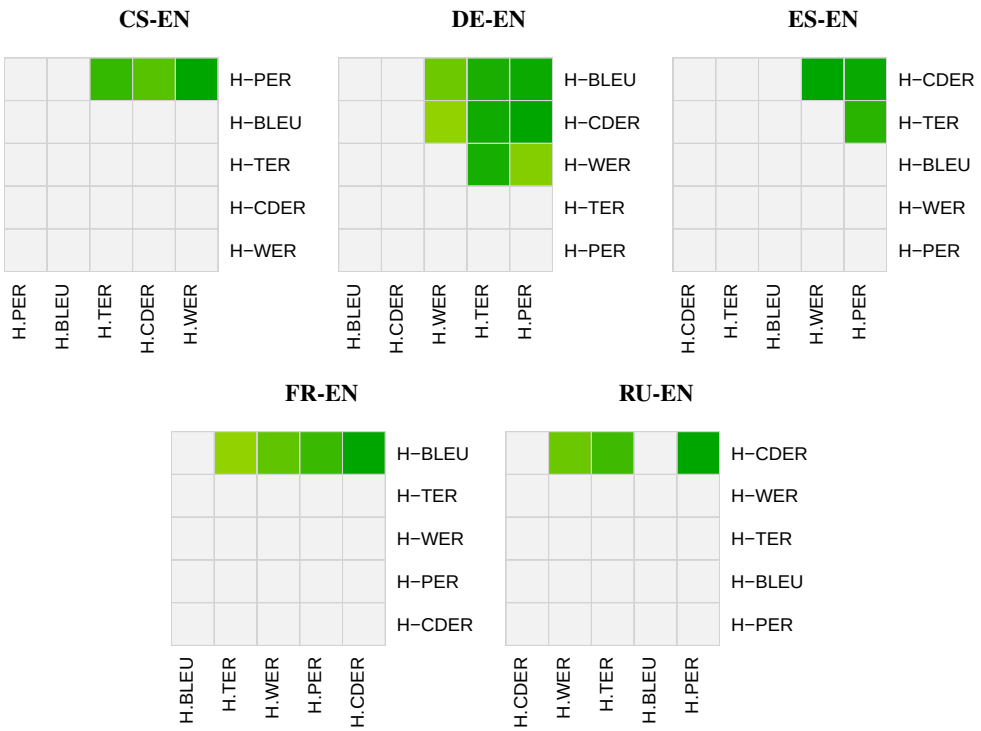

Figure 1: Significance test results (Williams test) of statistical significance of a difference in dependent correlations with human assessment for competing to-English human-targeted metrics; a green cell denotes a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column at $p < 0.05$.

reference translation. Although certainly not to the same extreme, human assessment of MT that employs a reference translation could incur similar reference bias. Graham et al. (2013) provide discussion on how reference bias could exist for direct assessment of translation adequacy, and, as a solution, propose inclusion of a separate reference-free fluency assessment, to provide a component of the evaluation that cannot be biased in any way by a reference translation.

However, it is inevitably the case that resources available to conduct human evaluation are limited, and therefore a trade-off exists between adding fluency assessments of translations and numbers of translations we can feasibly include. For example, in our earlier human evaluation of HTER, it would have been possible to allocate resources to assessment of the fluency of translations, in addition to adequacy, but this would have come at the cost of reducing the size of the test set by approximately one half. Therefore,

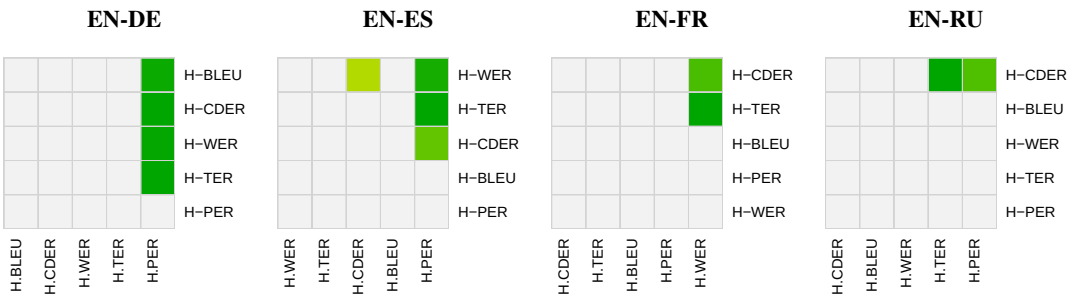

Figure 2: Significance test results (Williams test) of statistical significance of a difference in dependent correlations with human assessment for competing out-of-English human-targeted metrics; a green cell denotes a significant increase in correlation with human assessment for the metric in a given row over the metric in a given column at $p < 0.05$.

the decision to include fluency should be weighed against the degree to which reference bias is actually present in the adequacy evaluation. If there is strong reference bias, for example, it would be highly advisable to include both fluency and adequacy but for a smaller number of translations.

Fomicheva and Specia (2016) investigate bias in monolingual evaluation of MT and conclude reference bias to be a serious issue, with human annotators strongly biased by the reference translation provided. Their conclusion was based on estimation of confidence intervals for Kappa coefficients by means of an unconventional resampling technique, where samples used to estimate confidence intervals were smaller than the original sample size, drawn without replacement, and averaged; this diverges from standard methods of confidence interval estimation, such as bootstrap resampling. As a result, the reported confidence limits are unreliable, bringing their conclusions into question. We therefore consider it necessary to investigate the effect of reference bias with respect to the human evaluation we employ, to assess the likelihood of our own results with respect to the evaluation of HTER being contaminated by strong reference bias.[5]

Reference bias is the attribution of unfairly low scores to translations simply because they are not superficially similar to generic reference translations. In our evaluation of HTER, we employ DA adequacy scores by human assessment, where the MT output is compared to a generic reference translation. We will refer to DA scores collected in this way as $\text{DA}_{\text{gen-ref}}$. It is these gold standard $\text{DA}_{\text{gen-ref}}$ scores that potentially run the risk of introducing a strong reference bias into our evaluation of HTER.

At first, it might seem reasonable to attempt to measure this reference bias by comparison of $\text{DA}_{\text{gen-ref}}$ scores for translations with scores from an equivalent bilingual human evaluation, where the MT output is no longer compared to a reference translation, but is instead compared to the source language input and evaluated by a bilingual speaker. We refer to DA scores collected in this way as DA_{src}. However, in this case, DA_{src} scores could in fact include a different bias, one introduced by the fact that human assessors are now non-native in at least one of the required languages. To complicate things further, since non-native language skill levels will vary considerably from one human assessor to another, the degree of bias is likely to change considerably depending on particular language ability levels. Therefore, in addition to the potential of monolingual reference bias, we point out the real possibility in the case of DA_{src} of bias caused by reliance on bilingual human assessors not native in either the source or the target language. A comparison between DA_{src} and $\text{DA}_{\text{gen-ref}}$ scores for translations, therefore, would unfortunately not provide a reliable measurement of the monolingual reference bias, since such a comparison could be confounded by this additional bias.

Subsequently, we carry out a distinct comparison and motivate it as follows. Reference bias in $\text{DA}_{\text{gen-ref}}$ scores should cause unfairly low scores for only *some* translations, those that do not closely match generic reference translations but are in fact high quality translations. The difficulty in measur-

[5]This additional investigation was requested during peer review. Due to time limitations we only provide a preliminary investigation including a single language pair in this current publication. We hope to provide a more detailed study in the near future.

ing reference bias lies in separating the fair attribution of low scores to translations that do not closely match the reference and are *genuinely low quality* from those that also do not correspond closely to a given reference but nonetheless are in fact *high quality*. A comparison that would provide insight into the degree to which reference bias exists for $DA_{\text{gen-ref}}$ is one that compares $DA_{\text{gen-ref}}$ scores with those collected in a corresponding monolingual DA evaluation in which the surface similarity between MT output and reference translations is maximized for all translations in the test set. In this way, translations that have been unfairly penalized by $DA_{\text{gen-ref}}$ can be identified as having low $DA_{\text{gen-ref}}$ scores, when unfairly evaluated by comparison with a dissimilar generic reference, while at the same time achieving a high score when evaluated against a maximally similar reference translation. We therefore run DA with reference translations that have maximal surface similarity to MT output translations, by creating a human-targeted reference translation for each MT output.

3.4.1 DA with Source-Generated Human-Targeted References

In our earlier evaluation of HTER, human-targeted references were created by comparison with the generic reference. To guard against reference-bias being introduced in this current experiment, human-targeted references are now created without the use of the generic reference, instead by a bilingual examination of the original source language input and MT output only. We therefore employ a known-reliable bilingual native speaker of the source language with high fluency in the target language, as well as a known-reliable native speaker of the target language. In a first step, the bilingual post-edits the MT output, and in a second step, the post-edited MT output is checked for fluency in the target language by the monolingual in consultation with the bilingual to ensure human-targeted references remained faithful to the meaning of the source input.[6] We will refer to this additional set of DA scores as $DA_{\text{src-ht-ref}}$. In this way, translations that have been unfairly penalized by $DA_{\text{gen-ref}}$ can be identified as having low $DA_{\text{gen-ref}}$ scores, when unfairly evaluated by comparison with a dissimilar generic reference, while at the same time achieving a high $DA_{\text{src-ht-ref}}$ score when evaluated against a maximally similar reference translation.

3.4.2 Reference Bias in Monolingual MT Evaluation Experiment Results

Figure 3 (b) shows a scatter plot of $DA_{\text{src-ht-ref}}$ and $DA_{\text{gen-ref}}$ scores for our previous sample of RU-EN translations originally sampled from WMT-13. If a set of translations scored by $DA_{\text{gen-ref}}$ include reference bias, we would expect them to appear in the lower right quadrant of Figure 3 (b), as they will receive a low $DA_{\text{gen-ref}}$ score in combination with a high $DA_{\text{src-ht-ref}}$ score. As can be seen from the lower right portion of Figure 3 (b), only a small number of translations fall into the lower right quadrant, and the small number that do, all lie in very close proximity to neighboring upper-right and lower-left quadrants. Conversely, Figure 3 (a) shows the correspondence between $DA_{\text{src-ht-ref}}$ scores and the top-performing metric for that language pair, CDER,[7] where, in contrast, many translations, located in the lower right quadrant, receive an unfairly low CDER score while being scored highly by $DA_{\text{src-ht-ref}}$.

The lack of translations simultaneously receiving a low $DA_{\text{gen-ref}}$ score and high $DA_{\text{src-ht-ref}}$ score indicates that even though $DA_{\text{gen-ref}}$ employs a generic reference translation, scores are not strongly biased by the presence of this reference translation. This reinforces the validity of our human evaluation methodology, and should provide reassurance that in our direct assessment set-up, human assessors do in fact apply their human intelligence to the task, by reading a given translation and comparing its meaning to that of the generic reference, as instructed, as opposed to attributing scores to translations based on mere surface similarities between the MT output and generic reference translation.

4 Machine Translation Quality Estimation and Human-targeted Metrics

The now apparent lack of reliability of HTER as a valid substitute for human assessment raises doubts as to whether or not HTER scores should be relied upon as a gold standard representation for tasks such as QE, where the ultimate goal of systems is to predict translation quality. For example, previous evaluations of quality estimation systems have made the assumption that HTER provides a reliable human evaluation

[6] Post-editing guidelines are provided at `https://github.com/ygraham/direct-assessment/bilingual-postedit-guidelines`.

[7] Metric scores are standardized by the mean and standard deviation for ease of comparison.

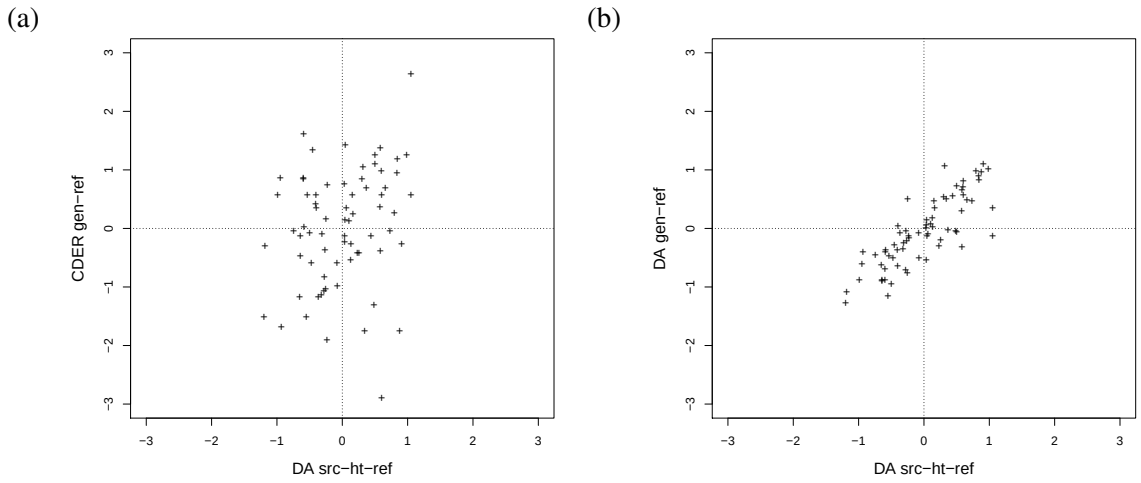

Figure 3: (a) Correspondence between DA scores collected by comparison with a source-generated human-targeted reference translation, DA src-ht-ref, where all translations benefit equally from close similarity to human-targeted references and automatic metric scores, CDER gen-ref, known to be biased by the generic reference and (b) the same instead compared to DA scores collected with comparison to generic reference translations, DA gen-ref. Lack of translations appearing in the lower right quadrant of (b) suggest DA human evaluation that employs a generic reference does not suffer from the strong reference bias known to be present in automatic metric scores (WMT-13 Russian to English).

substitute, but since we now know that HTER scores can be unrepresentative of translation quality, we rerun the previous evaluation provided by Bojar et al. (2013) and subsequently Graham (2015), instead employing DA human assessment as gold standard labels.

4.1 Human Annotation

Human-targeted reference translations were readily available in the WMT-13 shared task data set, while the human assessment method described in Section 3.1, was again applied to translations via crowdsourcing on Mechanical Turk, again applying strict quality control and computing mean scores for individual translations from a minimum of 15 human assessments. All human assessors who passed quality control by having significantly different scores for degraded versus genuine MT system output also showed no significant difference between mean rating scores for exact repeat translations.

Figure 4 (a) plots correspondence between HTER scores and human assessment, where the correlation of HTER with human assessment achieved is 0.678, almost at the same level as the strongest correlation in our nine-language pair evaluation. This data set therefore provides a best-case scenario for comparing differences in QE system rankings when HTER, as opposed to when human assessment, is employed as gold labels.

Before we compare QE system rankings, however, we carry out an analysis of a somewhat surprising relationship between HTER scores and human assessment for some translations shown in the scatter-plot in Figure 4 (a), where a number of translations appear to achieve a perfect HTER score of zero while at the same time cover a wide range of different human adequacy levels. Achieving a perfect HTER score means that the MT output was considered completely correct and required no post-editing whatsoever, so observing perfect HTER scores for translations that also receive low human assessment scores is a likely indication that something is amiss with either the post-editing carried out to create human-targeted references used to compute HTER scores or the human assessment.

Details of two example translations are provided in Figure 5. In Example 1, the source of error is the human post-editor (WMT-13 data set), since the MT output was in fact ungrammatical and despite this went uncorrected by the human post-editor, and this subsequently yielded an incorrect HTER score. Conversely, the error in Example 2 is caused by there being no direct translation of *straightforward* in Spanish and something unexpected subsequently taking place. Both the generic reference and the

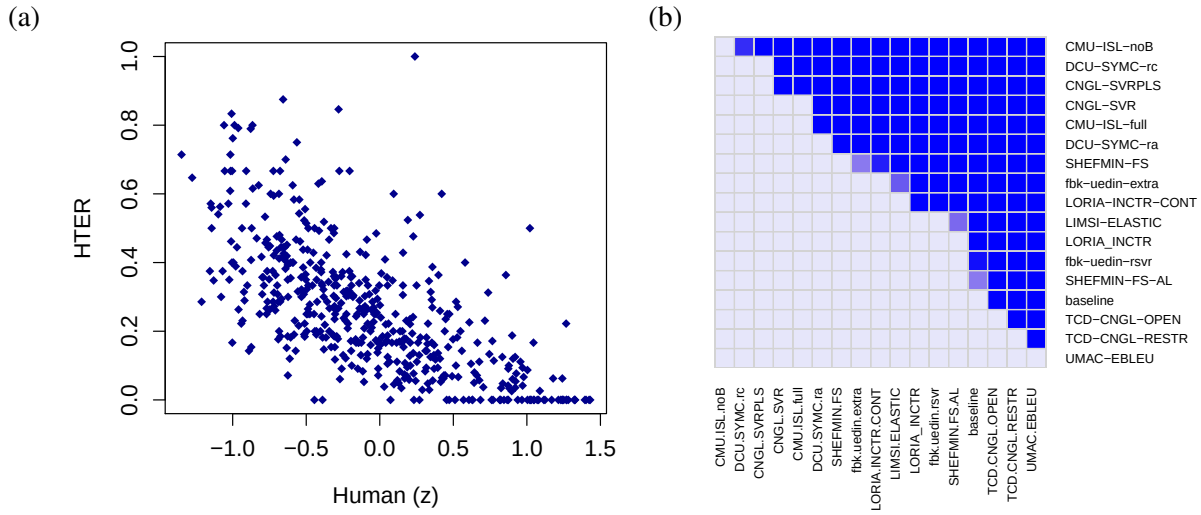

Figure 4: (a) Correspondence of HTER scores for translations in WMT-13 quality estimation Task 1.1 and human adequacy scores, and (b) significance test results (Williams test) of statistical significance of a difference in dependent correlations with human assessment for competing WMT-13 Task 1.1 quality estimation systems, a dark blue cell denotes a significant increase in correlation with human assessment for the QE system in a given row over the system in a given column at $p < 0.05$.

2.	source	A straightforward man			
	MT == HT ref.	Un hombre sencillo *A simple man*	0	−0.39	43%
	generic ref.	Un hombre sincero *A sincere man*			

Figure 5: Example translations with a perfect HTER score (according to WMT-13 QE data set) and range of human assessment scores, where *denotes text ungrammatical in Spanish; generic ref. = the generic reference displayed to human assessors; MT = the MT output or human-targeted reference (HT ref.) employed by HTER (the latter being one and the same for translations receiving a perfect HTER score).

MT output could both be considered correct translations of the source while at the same time each of their meanings diverges somewhat from the other. Since the generic reference is employed for human assessment, the translation receives a low human adequacy score, despite it being a good translation of the original. Although human assessment is more valid than part-automatic metric scores, neither method is entirely impervious to other sources of error, therefore.

4.2 Quality Estimation Results

Table 3 shows correlations of QE system predictions with gold labels, where the rank order of systems diverges considerably when gold labels take the form of HTER scores as opposed to human assessment.

Significance test results for differences in correlation with human assessment for each pair of competing systems are provided in Figure 4 (b), where a new distinct outright winner of the task is identified that significantly outperforms all others, when evaluated with human assessment, as CMU-ISL-noB.

	Human Assessment		HTER

Table 3: Pearson correlation of QE system predictions with HTER scores and correlation of system predictions with DA human adequacy scores for WMT-13 QE Task 1.1

The divergence in system rankings between evaluation of systems with HTER compared to DA indicates that even in the case that HTER correlates with human assessment to a relatively strong degree, 0.678, HTER is not a sufficient stand-in for human assessment. We subsequently recommend, where possible, employment of DA human assessment for evaluation of quality estimation systems, as it provides a valid human assessment without an automatic component, and has been shown to produce replicable sentence-level human assessment scores for translations (Graham et al., 2015).

5 Conclusion

Concerns were raised about the reliability of conclusions drawn in past experiments about HTER's superiority to other human-targeted metric formulations, and issues with respect to human post-editor coaching were highlighted as a source of bias, in addition to limited experiment settings. Subsequently, this motivated our re-evaluation of HTER extending to include a large number of systems across nine different language pairs. Results of our re-evaluation of HTER and several other possible metrics, including HBLEU, reveal significantly stronger correlations with human assessment for HBLEU compared to those achieved by HTER for two language pairs and no significant difference present in all other cases.

Further results showed correlations achieved by HTER may vary considerably across language pairs and in some cases are too low to provide a valid substitute for human assessment. As a test-case we replicated a previous quality estimation shared task and even when HTER scores correlate with human assessment at 0.678, they do not provide a valid human assessment substitute, with system rankings diverging considerably when DA human assessment is employed. We recommend DA human assessment for future evaluation of quality estimation.

Abstract

Although more additional corpora are now available for Statistical Machine Translation (SMT), only the ones which belong to the same or similar domains of the original corpus can indeed enhance SMT performance directly. A series of SMT adaptation methods have been proposed to select these similar-domain data, and most of them focus on sentence selection. In comparison, phrase is a smaller and more fine grained unit for data selection, therefore we propose a straightforward and efficient connecting phrase based adaptation method, which is applied to both bilingual phrase pair and monolingual n-gram adaptation. The proposed method is evaluated on IWSLT/NIST data sets, and the results show that phrase based SMT performances are significantly improved (up to +1.6 in comparison with phrase based SMT baseline system and +0.9 in comparison with existing methods).

1 Introduction

Large corpora are important for Statistical Machine Translation (SMT) training. However only the relevant additional corpora, which are also called in-domain or related-domain corpora, can enhance the performance of SMT effectively. Otherwise the irrelevant additional corpora, which are also called out-of-domain corpora, may not benefit SMT (Koehn and Schroeder, 2007).

SMT adaptation means selecting useful part from mix-domain (mixture of in-domain and out-of-domain) data, for SMT performance enhancement. The core task in adaptation is about how to select the useful data. Existing works have considered selection strategies with various granularities, though most of them only focus on sentence-level selection (Axelrod et al., 2011; Banerjee et al., 2012; Duh et al., 2013; Hoang and Sima'an, 2014a; Hoang and Sima'an, 2014b). There is a potential problem for sentence level adaptation: different parts of a sentence may belong to different domains. That is, it is possible that a sentence is overall out-of-domain, although part of it can be in-domain. Therefore a few works consider more granular level for selection. They build lexicon, Translation Models (TMs), reordering models or Language Models (LMs) to select fragment or directly adapt the models (Bellegarda, 2004; Deng et al., 2008; Moore and Lewis, 2010; Foster et al., 2010; Mansour and Ney, 2013; Carpuat et al., 2013; Chen et al., 2013a; Chen et al., 2013b; Sennrich et al., 2013; Mathur et al., 2014; Shi et al., 2015). One typical example of these methods is to train two Neural Network (NN) models (one from in-domain and the other from out-of-domain) and penalize the sentences/phrases similar to out-of-domain corpora (Duh et al., 2013; Joty et al., 2015; Durrani et al., 2015). As we know, Phrase Based SMT (PBSMT) mainly contains two models: translation model and LM, whose components are bilingual phrase pairs and monolingual n-grams. Meanwhile, most of the above methods enhance SMT performance by adapting single specific model.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3135–3145, Osaka, Japan, December 11-17 2016.

Instead of focusing on sentence selection or single model adaptation, we propose a phrase adaptation method, which is applied to both bilingual phrase pair and monolingual n-gram selection. It is based on a linguistic observation that the translation hypotheses of a phrase-based SMT system are concatenations of phrases from Phrase Table (PT), which has been applied to LM growing (Wang et al., 2014a; Wang et al., 2015). As a straightforward linear method, it is much efficient in comparison with NN based non-linear methods.

The remainder of this paper is organized as follows. Section 2 will introduce the connecting phrase based adaptation method. The size of adapted connecting phrase will be tuned in Section 3. Empirical results will be shown in Section 4. We will discuss the methods and conduct extension experiments in Section 5. The last section will conclude this paper.

2 Connecting Phrase based Adaptation

Suppose that two phrases '*would like to learn*' and '*Chinese as second language*' are in the in-domain PT. In decoding, these two phrases may be connected together as '*would like to learn Chinese as second language*". The phrases '*would like to learn Chinese*' or '*learn Chinese as second language*' may be outside in-domain PT/LM, but they may possibly be in out-of-domain PT/LM. Traditionally their translation probabilities are only calculated by the combination of probabilities from in-domain PT/LM. For the proposed methods, the translation probabilities of connecting phrases from out-of-domain corpus are estimated by real corpus directly. If we can add these connecting phrases with their translation probabilities, which may be useful in decoding, into in-domain bilingual (together with source part phrases) PT or monolingual LM, they may help improve SMT.

Note that connecting phrases are generated from in-domain PT, it is necessary to check if these in-domain connecting phrases actually occur in out-of-domain PT/LM. Connecting phrases can occur in decoding by combining two phrases from in-domain PT.

Let w_a^b be a phrase starting from the a-th word and ending with the b-th word, and $\gamma w_a^b \beta$ be a phrase including w_a^b as a part of it, where γ and β represent any word sequence or none. An i-gram phrase $w_1^k w_{k+1}^i$ $(1 \leq k \leq i-1)$ is a connecting phrase[1] (Wang et al., 2014a), if

1) w_1^k is right (rear) part of one phrase γw_1^k in the in-domain PT, and

2) w_{k+1}^i is left (front) part of one phrase $w_{k+1}^i \beta$ in the in-domain PT.

For example, let '*a b c d*' be a 4-gram phrase, it is a connecting phrase if at least one of the following conditions holds:

1) 'γ *a*' and '*b c d* β' are in phrase table, or

2) 'γ *a b*' and '*c d* β' are in phrase table, or

3) 'γ *a b c*' and '*d* β' are in phrase table.

For a phrase pair (F, E) in out-of-domain PT, there are four cases: a) Both F and E, b) either F or E, c) only F, d) only E are/is connecting phrase(s). We empirically evaluate the performance of these four cases and the results show that a) gains the highest BLEU, so it is adopted at last. For an n-gram LM, we only consider target side information.

3 Adapted Phrase Size Tuning

A lot of connecting phrases are generated in the above way. We propose two methods to rank these phrases and only the top ranked ones are added into in-domain PT/LM.

[1]We are aware that connecting phrases can be applied to three or more phrases. Experimental results show that using more than two connecting phrases cannot further improve the performance, so only two connecting phrases are applied.

3.1 Occurring Probability based Tuning

The potential Occurring Probability (OP) of a source phrase $P_{op}(F)$ and $P_{op}(E)$ are defined as,

$$P_{op}(F) = \sum_{k=1}^{p-1}(\sum_{\beta} P_s(\beta f_1^k) \times \sum_{\gamma} P_s(f_{k+1}^p \gamma)),$$

$$P_{op}(E) = \sum_{k=1}^{q-1}(\sum_{\beta} P_t(\beta e_1^k) \times \sum_{\gamma} P_t(e_{k+1}^q \gamma)),$$

respectively, where P_s (for source phrase f_1^p) or P_t (for target phrase e_1^q) is calculated using source or target monolingual LM trained from in-domain corpus.

The $P_{op}(F, E)$ of a connecting phrase pair (F, E) in SMT decoding is defined as $P_{op}(F) \times P_{op}(E)$. $P_{op}(F, E)$ is used to rank connecting phrase pairs. For target LM, only $P_{op}(E)$ is used to rank connecting n-gram (Wang et al., 2014a).

3.2 NN based Tuning

The basic hypothesis of NN based adaptation is: two NN models (translation model as NNTM or LM as NNLM), one from in-domain and one from out-of-domain are trained. Taking NNTM as example, for a phrase pair (F, E) relevant with in-domain ones, the translation probabilities $P_{in}(E|F)$ by $NNTM_{in}$ should be larger and $P_{out}(E|F)$ by $NNTM_{out}$ should be lower. This hypothesis is partially motivated by (Axelrod et al., 2011), which use bilingual cross-entropy difference to distinguish in-domain and out-of-domain data.

The translation probability of a phrase-pair is estimated as,

$$P(E|F) = P(e_1, ..., e_q|f_1, ..., f_p), \tag{1}$$

where f_s ($s \in [1, p]$) and e_t ($t \in [1, q]$) are source and target words, respectively. Originally,

$$P(e_1, ..., e_q|f_1, ..., f_p) = \prod_{k=1}^{q} P(e_k|e_1, ..., e_{k-1}, f_1, ...f_p). \tag{2}$$

The structure of NN based translation model is similar to Continuous Space Translation Model (CSTM) (Schwenk, 2012). For the purpose of adaptation, the dependence between target words is dropped[2] and the probabilities of different length target phrase are normalized. For an incomplete source phrase, i.e. with less than seven words, we set the projections of the missing words to zero. The normalized translation probability $Q(E|F)$ can be approximately computed by the following equation,

$$Q(E|F) \approx \sqrt[q]{\prod_{k=1}^{q} P(e_k|f_1, ...f_p)}. \tag{3}$$

Finally, the minus $D_{minus}(E|F)$ is used to rank connecting phrase pairs from mix-domain PT,

$$D_{minus}(E|F) = Q_{in}(E|F) - Q_{in}(E|F). \tag{4}$$

where $Q_{in}(E|F)$ and $Q_{in}(E|F)$ are corresponding probabilities from in-domain and out-of-domain NNTMs.

For monolingual n-gram tuning, two NNLMs (in and out) are trained, and

$$D_{minus}(E) = Q_{in}(E) - Q_{out}(E), \tag{5}$$

[2]We have also empirically compared the performance of using NN with target word dependence and the results are not that positive.

where $Q_{in}(E)$ and $Q_{out}(E)$ are corresponding probabilities from in-domain and out-of-domain NNLMs. $D_{minus}(E)$ is used for n-gram ranking.

Beside for connecting phrases size tuning, this NN[3] based method can also be applied to phrase adaptation directly, which is similar as other NN based adaptation methods, such as (Duh et al., 2013) for sentence selection and (Joty et al., 2015) for joint model adaptation. In addition, the translation probabilities of connecting phrases calculated by NN can also be used to enhance SMT, and the experimental results will be shown in Section 5.4.

3.3 Integration into SMT

The thresholds of P_{op} and D_{minus} are tuned using development data. Selected phrase pairs are added into the in-domain PT. Because they are not so useful as the in-domain ones, a penalty score is added. For in-domain phrase pairs, the penalty is set as 1; for the out-of-domain ones the penalty is set as e (= 2.71828...). Other phrase scores (lexical weights et. al.) are used as they are. This penalty setting is similar to (Bisazza et al., 2011). Penalty weights, together with all of existing score weights, will be further tuned by MERT (Och, 2003). The phrase pairs in re-ordering model are selected using the same way as PT. The selected monolingual n-grams are added to the original LM, and the probabilities are re-normalized by SRILM (Stolcke, 2002; Stolcke et al., 2011).

4 Experiments

4.1 Data sets

The proposed methods are evaluated on two data sets. 1) IWSLT 2014 French (FR) to English (EN) corpus[4] is used as in-domain data and dev2010 and test2010/2011 (Niehues and Waibel, 2012), are selected as development (dev) and test data, respectively. Out-of-domain corpora contain Common Crawl, Europarl v7, News Commentary v10 and United Nation (UN) FR-EN parallel corpora[5]. 2) NIST 2006 Chinese (CN) to English corpus[6] is used as in-domain corpus, which follows the setting of (Wang et al., 2014b) and mainly consists of news and blog texts. Chinese to English UN data set (LDC2013T06) and NTCIR-9 (Goto et al., 2011) patent data are used as out-of-domain bilingual (Bil) parallel corpora. The English patent data in NTCIR-8 (Fujii et al., 2010) is also used as additional out-of-domain monolingual (Mono) corpus. NIST Eval 2002-2005 and NIST Eval 2006 are used as dev and test data, respectively.

IWSLT FR-EN	Sentences	Tokens
in-domain	178.1K	3.5M
out-of-domain	17.8M	450.0M
dev	0.9K	20.1K
test2010	1.6K	31.9K
test2011	1.1K	21.4K
NIST CN-EN	**Sentences**	**Tokens**
in-domain	430.8K	12.6M
out-of-domain (Bil)	8.8M	249.4M
out-of-domain (Mono)	33.7M	1.0B
dev (average of four)	4.4K	145.8K
test (average of four)	1.6K	46.7K

Table 1: Statistics on data sets ('B' for billions).

[3]NN based methods have been applied to a series of NLP tasks, such as Chinese word segmentation and parsing (Cai and Zhao, 2016; Zhang et al., 2016).

[5]http://statmt.org/wmt15/translation-task.html

[6]http://www.itl.nist.gov/iad/mig/tests/mt/2006/

4.2 Common Setting

The basic settings of IWSLT-2014 FR to EN and NIST-06 CN to EN phrase based translation baseline systems are followed. 5-gram interpolated KN (Kneser and Ney, 1995) LMs are trained. Translation performances are measured by case-insensitive BLEU (Papineni et al., 2002) with significance test (Koehn, 2004) and METEOR (Lavie and Agarwal, 2007). MERT (Och, 2003) (BLEU based) is run three times for each system and the average BLEU/METEOR scores are recorded. 4-layer CSTM (Schwenk, 2012) are applied to NN translation models: phrase length limit is set as seven, shared projection layer of dimension 320 for each word (that is 2240 for seven words), projection layer of dimension 768, hidden layer of dimension 512. The dimensions of input/output layers for both in/out-of-domain CSTMs follows the size of vocabularies of source/target words from in-domain corpora. That is 72K/57K for IWSLT and 149/112K for NIST. Since out-of-domain corpora are huge, part of them are resampled (resample coefficient 0.01 for IWSLT and NIST).

Several related existing methods are selected as baselines[7]: Koehn and Schroeder (2007)'s method for using two (in and out-of-domain) TMs and LMs together, entropy based method for TM (Ling et al., 2012) and LM (Stolcke, 1998) adaptation (pruning), (Duh et al., 2013) for NNLM based sentence adaptation, (Sennrich, 2012) for TM weights combination, and (Bisazza et al., 2011) for TM fill-up. In Table Tables 2 and 3, 'in-domain', 'out-of-domain' and 'mix-domain' indicate training all models using corresponding corpora, 'in+NN' indicates applying NN based adaptation directly for all phrases, and 'in+connect' indicates adding all connecting phrases and n-grams to in-domain PT and LM, respectively. For tuning methods, 'in+connect+OP/NN' indicates tuning connecting phrase pairs and n-grams using Occurring Probability (OP) and NN, respectively. Only the best preforming systems (for both the baselines and proposed methods) on development data are chosen to be evaluated on test data.

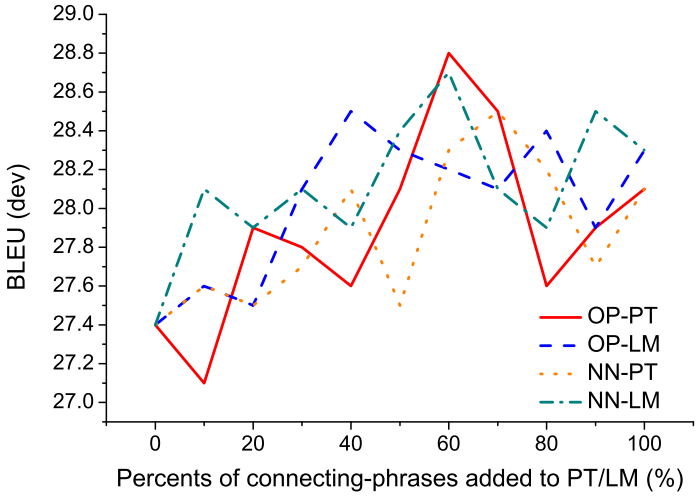

Figure 1: Connecting phrases size tuning on IWSLT.

4.3 Results and Analysis

For all ranked connecting phrase pairs and n-grams, we empirically add different sized (top) parts of them into PT/LM for size tuning. Figure 1 shows performances of the proposed tuning methods on IWSLT development data set. The results show that adding connecting phrases can enhance SMT performance in most of cases. Meanwhile, the tuned connecting phrases, which are parts of the whole, gain more BLEU improvement. They are considered as the most useful connecting phrases and evaluated on the test data sets.

[7]We are aware that there are various SMT adaptation works such as (Deng et al., 2008; Hoang and Sima'an, 2014a; Joty et al., 2015). However, there does not exist a commonly used evaluation corpus for this task, and either detailed implementations or experimental settings are absent for most published works.

Methods	PT Size	LM Size	BLEU test10	METEOR test10	BLEU test11	METEOR test11
in-domain	9.8M	7.9M	31.94	34.07	29.16	32.34

Table 3: NIST-06 CN-EN Results.

Tables 2 and 3 shows that directly using 'out-of-domain' or 'mix-domain' data will cause SMT performances decrease in comparison with 'in-domain' data. Adding connecting phrases will enhance SMT performances and the proposed tuning method can further increase SMT performances significantly (up to +1.6 BLEU in IWSLT task and +1.1 in NIST task) and outperform the existing methods (up to +0.9 BLEU in IWSLT task and +0.7 in NIST task). The NN method performs better as a tuning method than as a direct adaptation method.

5 Discussions

5.1 Individual Model Analysis

Most of the existing methods focus on single model adaptation, however the proposed connecting phrase method can be applied to both TM and LM. So it seems a little unfair to compare the existing methods with our methods. To compare with them in a more fair way, we show the performance of individual model in Tables 4 and 5 for IWSLT tasks. Similar as the previous experiments, only the best performing system on development data of each method is evaluated on the test data.

Methods	LM Size	BLEU test10	BLEU test11
in-domain	7.9M	31.94	29.16
out-of-domain	497.4M	31.01	27.42
mix-domain	503.1M	32.23	28.42
Koehn's method	N/A	32.34	29.10
entropy method	146.1M	32.31	29.24
Duh's method	271.0M	32.65	29.18
in+NN	156.2M	32.66	29.38
in+connect	133.8M	32.78	29.32
in+connect+OP	53.5M	**32.95**	29.45
in+connect+NN	80.3M	32.56	**29.78**

Table 4: IWSLT FR-EN results on LM adaptation.

Methods	PT Size	BLEU test10	BLEU test11
in-domain	9.8M	31.94	29.16
out-of-domain	759.0M	28.62	24.56
mix-domain	765.4M	29.56	26.78
Koehn's method	N/A	31.97	29.21
entropy method	247.8M	32.43	28.73
Sennrich's method	765.4M	32.41	29.67
Bisazza's method	765.4M	32.24	29.35
in+NN	296.8M	32.31	29.63
in+connect	184.5M	32.87	29.48
in+connect+OP	122.0M	**33.05**	29.77
in+connect+NN	141.3M	32.73	**29.89**

Table 5: IWSLT FR-EN results on TM adaptation.

As shown in Tables 4 and 5, the proposed methods outperform existing methods in individual model performance (up to +0.3 BLEU in LM task and +0.6 BLEU in TM task for test10 and +0.5 BLEU in LM task and +0.2 BLEU in TM task for test11). Another observation is that adding out-of-domain data into

TM hurt SMT system more seriously than LM (-0.9 BLEU in LM task versus -3.4 BLEU in TM task for test10 and -1.7 BLEU in LM task versus -4.6 BLEU in TM task for test11).

5.2 Manual Example

A few adapted phrase examples of IWSLT FR-EN task are in Table 6. For NN based method (direct apply NN in adaptation), some phrases with similar meaning are adapted, such as *third world countries* and *developing countries*. For connecting phrase method, phrases which are combination of phrases are adapted, such as *the reason* and *why I like* form *the reason why I like*.

Methods	Source Phrases	Original Target Phrases	Adapted Phrases
NN	*les pays en voie de développement*	*1. developing countries* *2. the developing countries* *3. all developing countries*	*1. developing countries* *2. third world countries* *3. countries in the developing world*
Connect	*la raison pour laquelle je tiens*	*1. the reason I want* *2. why I like* *3. I therefore wish*	*1. the reason why I like* *2. the reason I want* *3. the reason I would like*

Table 6: Some examples of adapted phrases, which are ranked by translation probabilities.

5.3 Efficiency Comparison

Table 7 shows the adaptation time of each method[8] on IWSLT task. The proposed methods show significant advantage over others, and NN based methods are very time consuming.

Methods	Adaptation Time
entropy method	12 hours
Duh's method	7 days
Bisazza's method	6 hours
in+NN	10 days
in+connect	**2 hours**
in+connect+OP	3 hours
in+connect+NN	3 days

Table 7: Efficiency comparison (CPU time) on IWSLT.

5.4 Adding NN Probabilities

As mentioned in Section 3.2, NN can be used to predict the translation probabilities of bilingual phrase pairs and the occurring probabilities of monolingual n-grams. The minus D_{minus} between in-domain NN probabilities Q_{in} and out-of-domain NN probabilities Q_{out} are used to judge whether a phrase (pair) is similar to the in-domain ones. Meanwhile, these in-domain NN probabilities Q_{in} themselves are also useful information. In the previous sections, the adapted phrase pairs are added into original PT or LM with their own probabilities. In this subsection, Q_{in} of adapted and original phrases are also adopted in SMT decoding. That is, $Q_{in}(E|F)$ is added as a feature for adapted and original phrase pairs in PT and $Q_{in}(E)$ of adapted and original n-grams are interpolated with n-gram LM probabilities.

The results in Table 8 show that the NN feature can enhance SMT performance slightly. Although this is not our main contribution, it shows the NN method cannot only be applied to phrase pair and n-gram adaptation, but also to probability estimation.

[8] Koehn and Schroeder (2007) is only for model combination, so we do not compare with it.

Methods	PT Size	LM Size	BLEU without Q_{in}	BLEU with Q_{in}
in-domain	9.8M	7.9M	31.94	32.34
in+NN	296.8M	156.2M	32.54	32.48
in+connect	184.5M	133.8M	33.26	33.45
in+connect+OP	122.0M	53.5M	33.53	**33.67**
in+connect+NN	141.3M	80.3M	32.91	33.12

Table 8: IWSLT FR-EN Results.

6 Conclusion

In this paper, we propose a straightforward connecting phrase based SMT adaptation method. Two model size tuning methods, NN and occurring probability are proposed to discard less reliable connecting phrases. The empirical results in IWSLT French to English and NIST Chinese to English translation tasks show that the proposed methods can significantly outperform a number of the existing SMT adaptation methods in both performance and efficiency. We also show some empirical results to discuss where the SMT improvements come from by individual model and manual example analysis.

Abstract

We present a new Bayesian HMM word alignment model for statistical machine translation. The model is a mixture of an alignment model and a language model. The alignment component is a Bayesian extension of the standard HMM. The language model component is responsible for the generation of words needed for source fluency reasons from source language context. This allows for untranslatable source words to remain unaligned and at the same time avoids the introduction of artificial NULL words which introduces unusually long alignment jumps. Existing Bayesian word alignment models are unpractically slow because they consider each target position when resampling a given alignment link. The sampling complexity therefore grows linearly in the target sentence length. In order to make our model useful in practice, we devise an auxiliary variable Gibbs sampler that allows us to resample alignment links in constant time independently of the target sentence length. This leads to considerable speed improvements. Experimental results show that our model performs as well as existing word alignment toolkits in terms of resulting BLEU score.

1 Introduction

Word alignment is one of the basic problems in statistical machine translation (SMT). The IBM models were originally devised for translation by Brown et al. (1993). Later, when SMT started to employ entire phrases instead of single words (Koehn et al., 2003), the IBM models were repurposed as word alignment models. The alignments they produce guide the phrase extraction heuristics that are used in many modern SMT systems.

There are several extensions of the classical IBM models that try to weaken their independence assumptions. Notably, Vogel et al. (1996) introduced Markovian dependencies between individual alignment links. Those links were treated as independent events in IBM models 1, 2 and 3. The model of Vogel et al. (1996) can be viewed as a Hidden Markov Model (HMM) in which the hidden Markov Chain induces a probability distribution over latent alignment links. Besides weakening the independence assumptions of the simpler IBM models, the HMM alignment model has the additional benefit of being tractable. This means that expectations under the HMM aligner can be computed exactly using the forward-backward algorithm. These expectations are then used in the Baum-Welch algorithm (Baum et al., 1970) to compute parameter updates for the model. Crucially, the Baum-Welch algorithm is a special case of the EM algorithm and thus guaranteed to never decrease the model's likelihood at each parameter update (Dempster et al., 1977).

Tractability and convergence (at least to a local optimum) are clear advantages of the HMM aligner over IBM models 3 to 5 which are all intractable. In practice, hill-climbing heuristics are employed to approximate expectations in these more complex models. Unfortunately, all convergence guarantees of the learning algorithm are lost this way.

A major problem for the HMM aligner is the handling of NULL words.[1] The NULL word is a special

[1]The original work of Vogel et al. (1996) did not use NULL words and instead aligned *all* source words. Later work by Och and Ney (2003) and Liang et al. (2006) has shown that using NULL words to allow for unaligned words improves performance.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3146–3155, Osaka, Japan, December 11-17 2016.

lexical item that is hypothesised to stand at the beginning of every target (English) sentence. Since in word alignment the source (French) side is generated given the target side, the NULL word is used to generate source words that do not have lexical translations on the target side. Such untranslatable words are often idiosyncratic to the source language. Examples are prepositions such as *de* in French. The translation of the English *orange juice* is *jus **d'** orange*. In that case the (clitic) preposition *de* would be generated from the NULL word on the English side. For the HMM alignment model the NULL word is troublesome since it stands in the 0^{th} English position and thus induces unusually long jumps which have to be captured by the jump distribution of the HMM.

In this work we present a Bayesian HMM aligner that does not make use of artificial NULL words. Instead, untranslatable source words are generated from the words preceding them. This way, our proposed model only needs to account for lexically motivated alignment links. Moreover, since our model is a hierarchical Bayesian model we can bias it towards inducing sparse lexical distributions. This in turn leads to significantly better translation distributions (Mermer and Saraçlar, 2011). Moreover, we can even perform inference on the model's hyperparameters, freeing us of having to choose arbitrary prior distributions.

Existing Bayesian word aligners are often too slow to be useful in practice. We overcome this problem by designing an auxiliary variable Gibbs sampler that reduces sampling complexity by an order of magnitude. We also provide a formal proof that this sampler works correctly.

We provide several detailed experiments which show that our model performs on par with or better than standardly used alignment toolkits in terms of BLEU score.

Notation Throughout this paper we will denote random variables (RVs) by upper case Roman letters. If we want to express the probability of a specific outcome for the RV X we write $P(X = x)$. If we want to leave the value of X underspecified, we simply write $P(x)$. We abbreviate a sequence of RVs X_1 to X_n as X_1^n and a sequence of outcomes x_1 to x_n as x_1^n. We also distinguish notationally between probability mass functions (pmfs) and probability density functions (pdfs). We denote pmfs by $P(\cdot)$ and pdfs by $p(\cdot)$. Finally, we use v_F and v_E to denote the French (source) and English (target) vocabulary sizes.

2 The HMM Word Alignment Model

The HMM model of Vogel et al. (1996) defines a joint distribution over alignments and source words given a target sentence.[2] The source words are observed as part of the parallel corpus whereas the alignments are hidden. An alignment consists of as many alignment links as there are source words. Unlike the IBM models 1 and 2, which assume independence between alignment links, the HMM model assumes a first-order Markov dependency between them. This means that each alignment link depends on its predecessor.

We define random variables E ranging over the target vocabulary $\mathcal{E}$, variables F ranging over the source vocabulary $\mathcal{F}$, and variables A modelling alignment links. We use F_j for the variable associated with the source word occupying position j in the source sentence f_1^m. Consequently, A_j is the random variable for the alignment link associated with position j. This random variable ranges over word positions in the target sentence e_0^l, where 0 is a special position occupied by the hypothetical NULL word. Finally, we use e_{a_j} to denote the target word that position j is aligned to. We can then express the likelihood of the HMM model for a single sentence pair as shown in Equation 1.

$$P(f_1^m|e_0^l) = \prod_{j=1}^{m} \sum_{i=0}^{l} P(A_j = i|a_{j-1}) P(f_j|e_i) \tag{1}$$

Here, the Markovian dependency of the alignment links is captured by a distribution over *alignment jumps*. The distance between the current and the previous link can be thought of as a jump from one position to the next. The jump width is then given by $i - i'$ where i is the current value of A_j and i'

[2]The extension to a corpus of parallel sentences is trivial because independence between sentence pairs is assumed. To keep the notation simple we describe all models on the sentence level.

is the value of the previous alignment link A_{j-1}. The distribution over alignment jumps is then simply $P(A_j = i|A_{j-1} = i') = P(i - i')$. In practice, we set a_0 to a special start token, so as to provide a conditioning event for the first alignment decision.

A severe problem for the HMM alignment model is the handling of NULL words. If we did not treat alignments to the NULL position in a special way, those alignments would distort the alignment distribution because they induce unusually long jumps. To solve this problem, we introduce a special jump value for NULL alignments.[3] This has the effect that jumps to and from NULL are modelled explicitly and behave just like other jump values. On the other hand, if the preceding alignment is an alignment to NULL, the distribution over jumps becomes uniform. This is because when jumping from NULL a special jump value gets invoked that does not depend on the position that the next jump leads to. This behaviour obviously restricts the expressive power of the model somewhat but provides a clean handling of NULL alignments.

The parameters of the standard HMM of Vogel et al. (1996) are estimated through likelihood maximization. Here, we extend their model with prior distributions over parameters. This means that we are turning it into a Bayesian model. The parameters of the alignment HMM are categorical parameters of the following distributions:

- A distribution over the source lexicon for each target word. We call this the translation distribution and use Θ_e as a variable over the corresponding parameter vector.
- A distribution over alignment jumps. We call this the alignment distribution and use Θ_a as a variable over the corresponding parameter vector.

Since the model's distributions are categorical, we impose (symmetric) Dirichlet priors on their parameters. The Dirichlet is a standard choice in this case as it is conjugate to the categorical.[4] The variables in the Bayesian HMM aligner are thus generated as follows:

$$A_j|a_{j-1} \sim \theta_a \qquad \Theta_a \sim \mathrm{Dir}(\alpha)$$
$$F_j|e_{a_j} \sim \theta_{e_{a_j}} \qquad \Theta_e \sim \mathrm{Dir}(\beta)$$

We describe how to do inference in this model in Section 4.

3 An HMM Aligner with a Language Model Component

Our model is a mixture between a Bayesian HMM aligner and a Bayesian source language model. It differs from the Bayesian HMM aligner of Section 2 in that the language model component is the one responsible for generating source words from (source) context when those do not have a target translation. These are the words that would otherwise be aligned to NULL under the IBM models and our own Bayesian HMM (Section 2).

Formally, we extend the Bayesian HMM alignment model with binary choice variables Z which we are used to indicate collocations. There is one such variable for each source position, thus Z_j is the choice variable for position j. We use this variable as an indicator for whether the language model is used. Thus, if $Z_j = 1$, the source word f_j is generated from f_{j-1}. Otherwise, if $Z_j = 0$, f_j is generated from the target word it is aligned to (e_{a_j}).

Since our model is Bayesian, we put priors on all parameters. In particular, the translation parameters (θ_e), language model parameters (θ_f) and jump parameters (θ_a) are drawn from Dirichlet distributions with parameter vectors α, β and γ. The binary choice variables Z only have one parameter q_f which depends on the previous source word and follows a Beta distribution with parameters s and r. Since it is hard to guess reasonable values for the parameters s and r, we further assume that they are independently drawn from a Gamma distribution whose shape and rate parameters we set to 1. This extra level of hierarchy frees us from having to choose arbitrary values for s and r. Empirically, it also improves the performance of our model.

[3] Conceptually, we add a categorical event TONULL and another FROMNULL to the distribution over alignment jumps.

[4] Conjugacy in this case means that the posterior over parameters will again be a Dirichlet. This has the advantage that we can analytically integrate with respect to the posterior.

To better understand our model, we formulate a generative story:

- Draw values for s and r independently from $\mathrm{Gamma}(1, 1)$
- Generate q_f from $\mathrm{Beta}(s, r)$ for each source word f
- Draw values for θ_a, θ_e and θ_f from their respective Dirichlet priors
- For each source position j
  1. Generate an alignment link a_j conditional on a_{j-1}
  2. Choose a value for Z_j conditional on the previous source word f_{j-1}
     (a) If $Z_j = 0$, generate source word f_j from target word e_{a_j}
     (b) If $Z_j = 1$, generate source word f_j from source word f_{j-1}

In terms of variable generation we have to adjust the model description from Section 2. For reasons of clarity, we condition all variables only on those events that they depend on.

$$
\begin{aligned}
S &\sim \mathrm{Gamma}(1,1) & R &\sim \mathrm{Gamma}(1,1) \\
Z_j|f_{j-1} &\sim \mathrm{Bernoulli}(q_{f_{j-1}}) & Q_f &\sim \mathrm{Beta}(s,r) \\
A_j|a_{j-1} &\sim \mathrm{Cat}(\theta_a) & \Theta_a &\sim \mathrm{Dir}(\alpha) \\
F_j|a_j, Z_j = 0, e_{a_j} &\sim \mathrm{Cat}(\theta_{e_{a_j}}) & \Theta_e &\sim \mathrm{Dir}(\beta) \\
F_j|a_j, Z_j = 1, f_{j-1} &\sim \mathrm{Cat}(\theta_{f_{j-1}}) & \Theta_f &\sim \mathrm{Dir}(\gamma)
\end{aligned}
$$

Our model as described above defines a joint distribution over French words, collocation and alignment variables and parameters given an English sentence and the hyperparameters.

4 Inference

In this section we derive a Gibbs sampler for our collocation-based model (Section 3). The sampler for the Bayesian HMM with NULL words (Section 2) follows from that. We also describe how to sample the hyperparameters of the Beta prior on the collocation distributions.

4.1 Dirichlet Predictive Posterior

Let us first establish a general useful fact about the Dirichlet distribution.[5] Let us call the posterior Dirichlet parameter vector η.[6] Then the posterior predictive distribution for a categorical outcome x is given by the following integral:

$$P(x|\eta) = \int P(x|\theta)p(\theta|\eta)d\theta = \int \theta_x p(\theta|\eta)d\theta \; . \tag{2}$$

Here, we use θ_x to denote the categorical parameter for outcome x. Note that the last integral in Equation (2) is in fact equal to the expectation of θ_x under $\mathrm{Dir}(\eta)$. It is well known that for a k-dimensional Dirichlet distribution this expectation is $\mathbb{E}[\theta_x|\eta] = \frac{\eta_x}{\sum_{i=1}^{i=k} \eta_i}$. Thus, the predictive posteriors for the alignment and collocation variables after integrating over the categorical or Beta parameters take the form of this expectation.

4.2 Gibbs Sampling the Hidden Variables

Since we are only interested in the assignments of the alignment and collocation variables, we integrate over the model parameters θ_e, θ_a, θ_f and q_f. This gives us a collapsed Gibbs sampler.

In general, a Gibbs sampler resamples one variable at a time while conditioning on the current assignments of all other variables. In our case we are interested in resampling A_j and Z_j. This means that we

[5] This fact immediately carries over to the Beta distribution which can be viewed as a 2-dimensional Dirichlet distribution.

[6] Since the categorical is in the exponential family and the Dirichlet is conjugate to it, the posterior Dirichlet parameter η is simply the sum of the prior Dirichlet parameter (which we will call ϵ here) and the sufficient statistics of the categorical likelihood. In our concrete case, these sufficient statistics are simply the number of times an outcome has been observed in the data. Let us denote these counts by $c(x)$ for an outcome x. Thus, for this outcome x, we have $\eta_x = \epsilon_x + c(x)$.

will need to derive posterior predictive distributions for these variables. Let us first deal with the posterior predictive for the collocation variables where we assume the Beta parameters r and s as given. To ease notation we introduce the set $\mathcal{C} = \{r, s, \alpha, \beta, \gamma\}$ which contains all remaining (hyper-)parameters. We use $x_{\neg j}$ to denote the set of all outcomes x except the j^{th} one. We also introduce the function $c(\cdot)$ as a (conditional) count function for an outcome across the entire corpus, excluding the j^{th} such outcome if necessary. Proportionality in the following equations comes about because we eliminate normalization constants that do not depend on the value of the variable that we sample.

$$\begin{aligned} P(Z_j = 0 | z_{\neg j}, a_1^m, f_{\neg j}, e_1^l, \mathcal{C}) &\propto P(Z_j = 0 | f_{j-1}, s, r) \times P(f_j | a_j, e_{a_j}, \beta) \\ &= \frac{c(z = 0 | f_{j-1}) + r}{c(f_{j-1}) + r + s} \times \frac{c(f_j | e_{a_j}) + \beta}{c(e_{a_j}) + v_F \beta} \\ &\propto (c(z = 0 | f_{j-1}) + r) \times \frac{c(f_j | e_{a_j}) + \beta}{c(e_{a_j}) + v_F \beta} \end{aligned} \tag{3}$$

$$\begin{aligned} P(Z_j = 1 | z_{\neg j}, a_1^m, f_{\neg j}, e_1^l, \mathcal{C}) &\propto P(Z_j = 1 | f_{j-1}, s, r) \times P(f_j | f_{j-1}, \gamma) \\ &= \frac{c(z = 1 | f_{j-1}) + s}{c(f_{j-1}) + r + s} \times \frac{c(f_j | f_{j-1}) + \gamma}{c(z = 1 | f_{j-1}) + v_F \gamma} \\ &\propto (c(z = 1 | f_{j-1}) + s) \times \frac{c(f_j | f_{j-1}) + \gamma}{c(z = 1 | f_{j-1}) + v_F \gamma} \end{aligned} \tag{4}$$

When resampling the alignment variables, we need to distinguish between the two cases where the collocation variable is active or not. In case the collocation variable is switched off, inference for the alignment variable is similar to that in the Bayesian HMM aligner. The crucial difference, however, is that in the standard case, the values of the alignment variable range from 0, the NULL position, to the target sentence length l. In our model, however, the possible values for the alignment variable start at 1 as there is no NULL position.

$$\begin{aligned} P(a_j | Z_j = 0, a_{\neg j}, f_1^m, e_1^l, \mathcal{C}) &\propto P(a_j | a_{j-1}, \alpha) \times P(a_{j+1} | a_j, \alpha) \times P(f_j | e_{a_j}, \beta) \\ = \frac{c(a_j - a_{j-1}) + \alpha}{\sum_{i=1}^{l} (c(i - a_{j-1}) + \alpha)} &\times \frac{c(a_{j+1} - a_j) + \alpha}{\sum_{i=1}^{l} (c(a_{j+1} - i) + \alpha)} \times \frac{c(f_j | e_{a_j}) + \beta}{c(e_{a_j}) + v_F \beta} \\ &\propto (c(a_j - a_{j-1}) + \alpha) \times (c(a_{j+1} - a_j) + \alpha) \times \frac{c(f_j | e_{a_j}) + \beta}{c(e_{a_j}) + v_F \beta} \end{aligned} \tag{5}$$

Again, let us point out that the predictive posterior in (5) is the one we use for inference in the Bayesian HMM model described in Section 2 with difference that the alignment positions include 0 in that case.

If the collocation variable is switched on, i.e. if the j^{th} French word is generated from its predecessor, there is no lexical influence on the alignment posterior and the new link is simply sampled from the alignment distribution.

$$\begin{aligned} P(a_j | Z_j = 1, a_{\neg j}, f_{\neg j}, e_1^l, \mathcal{C}) &\propto P(a_j | a_{j-1}, \alpha) \times P(a_{j+1} | a_j, \alpha) \\ = \frac{c(a_j - a_{j-1}) + \alpha}{\sum_{i=1}^{l} (c(i - a_{j-1}) + \alpha)} &\times \frac{c(a_{j+1} - a_j) + \alpha}{\sum_{i=1}^{l} (c(a_{j+1} - i) + \alpha)} \\ &\propto (c(a_j - a_{j-1}) + \alpha) \times (c(a_{j+1} - a_j) + \alpha) \end{aligned} \tag{6}$$

At this point it is important to note that the naïve Gibbs sampler described here considers all target positions as candidate alignment points for a given source position j. This means that the time it takes to re-sample an alignment link grows linearly with the length of the target sentence. In practice this makes the sampler unpractically slow. We address this problem in the following section.

4.3 Sampling Alignments Efficiently

We are interested in sampling from $P(a_j|a_{\neg j}, \mathcal{C})$, where we conflate all other variables in $\mathcal{C}$ to avoid clutter. Note that we know $P(a_j|a_{\neg j}, \mathcal{C})$ up to a normalisation constant, thus sampling requires evaluating Equation 5 (or 6) for all $1 \leq i \leq l$. Naturally, this procedure runs in time proportional to $O(l)$. In this section we present an auxiliary variable sampler that brings this down to constant time.

The idea is to evaluate $P(a_j|a_{\neg j}, \mathcal{C})$ only for assignments in a subset of target positions.[7] This subset must include at least 2 candidates and it must be such that it contains the current assignment of the variable we are resampling. That is, if we let $\left(a_{\neg j}^{(t)}, a_j^{(t)}\right)$ denote the current state of the Markov chain, then we need to select $a_j^{(t)}$ as well as at least one random candidate from the remaining available positions $\{1, \ldots, l\} \setminus \{a_j^{(t)}\}$. We denote a selection of target positions by a vector $k \subseteq \{0,1\}^l$ such that $k_i = 1$ signifies that i is a reachable candidate. Then, once a selection is made, we sample the next state of the Markov chain, i.e. $\left(a_{\neg j}^{(t)}, a_j^{(t+1)}\right)$, from a distribution proportional to $P(A_j^{(t+1)} = i|a_{\neg j}^{(t)}, \mathcal{C}^{(t)}) \times k_i$. Note that, under this distribution, only selected positions have non-zero probability. This makes sampling the next state run in constant time independent of the target sentence length.

Formally, this is a case of sampling by data augmentation (Tanner and Wong, 1987). Let K be a random variable taking values in $\mathcal{K} \subset \{0,1\}^l$. We interpret an assignment of K as a random selection of at most l target positions. We define the joint distribution $P(a_j, k|a_{\neg j}, \mathcal{C}) = P(a_j|a_{\neg j}, \mathcal{C}) \times P(k|a_j, a_{\neg j})$, where we take the conditional $P(k|A_j = i, a_{\neg j}) = \frac{k_i}{\sum_{k' \in \mathcal{K}} k'_i}$ to distribute uniformly over all selections in $\mathcal{K}$ that contain i. This guarantees that the current state of the Markov chain is part of the selection, a condition necessary for irreducibility. Then, the conditional $P(A_j = i'|k, a_{\neg j}, \mathcal{C})$ follows directly:

$$P(A_j = i'|k, a_{\neg j}, \mathcal{C}) \propto P(A_j = i'|a_{\neg j}, \mathcal{C}) \times P(k|A_j = i', a_{\neg j}) \propto P(A_j = i'|a_{\neg j}, \mathcal{C}) \times k_{i'} \quad (7)$$

Claim If $\mathcal{K}$ includes at least all subsets of size 2 where one of the elements is the previous state of the Markov chain, then the transition kernel $\kappa(i'|i) = \sum_{k \in \mathcal{K}} P(i'|k) \times P(k|i)$ is strictly positive for every $i, i' \in \{1, \ldots, l\}$ and, therefore, the resulting Markov chain is Harris ergodic.

Proof.

$$\kappa(i'|i) = \sum_{k \in \mathcal{K}} P(i'|k) \times P(k|i) = \sum_{k \in \mathcal{K}} \frac{P(i') \times P(k|i')}{P(k)} \times P(k|i) = P(i') \sum_{k \in \mathcal{K}} \frac{\frac{k_{i'}}{\sum_{k' \in \mathcal{K}} k'_{i'}} \times \frac{k_i}{\sum_{k' \in \mathcal{K}} k'_i}}{P(k)} \quad (8)$$

In the last term of Equation 8, $P(i')$ is strictly positive because $i' \in \{1, \ldots, l\}$ by construction, and the sum is strictly positive when $\mathcal{K}$ includes at least one subset containing both i and i'. This is why we can start the candidate set with $\{a_j^{(t)}\}$ and enlarge it by sampling uniformly from $\{1, \ldots, l\} \setminus \{a_j^{(t)}\}$ without replacement. We need to do it at least once, but we can also repeat it a fixed number of times. □

The complete algorithm consists of 2 simulations, $K^{(t+1)} \sim P(\cdot|a_j^{(t)}, a_{\neg j}^{(t)})$ and $A_j^{(t+1)} \sim P(\cdot|k^{(t+1)}, a_{\neg j}^{(t)}, \mathcal{C}^{(t)})$, each feasible in isolation. With this improved sampler we can resample alignment links in constant time whereas the naïve sampler would require time linear in target sentence length. It is easy to see that to resample all alignment links in a source sentence with m words, the naïve sampler would take time $O(l \times m) \approx O(l^2)$, whereas our improved auxiliary variable sampler does the same in $O(l)$. This improvement makes our model competitive with maximum-likelihood models.

4.4 Sampling of the Beta Parameters

The parameters s and r of the Beta distribution which serves as a prior on the decision variables are random variables in our model. Since there is no easily computable conjugate distribution for these parameters, we can not integrate them out analytically. Instead, we choose to approximate the integral

[7] Recall that l is the target sentence length.

through repeated sampling of these variables. Since both these variables take on values in the positive reals, we impose a Gamma prior on them as described in Section 3.

There are several ways of sampling variables in non-conjugate Bayesian models. Here we use slice sampling (Neal, 2003) as it is fast and easy to implement. The idea of slice sampling is that we augment our sampling distribution with an auxiliary variable U such that the marginal distribution of S (or R) stays unchanged.[8] Simulation then follows by Gibbs sampling, whereby we sample U conditioned on S, and S conditioned on U in turn. It can be shown that, with conditionals as shown in (9), the transition kernel underlying this Gibbs sampling procedure is Harris ergodic (Neal, 2003). Thus, the procedure is not only correct but also very efficient as we only sample from uniform distributions.

$$p(u|s) = \frac{\mathbb{1}(u < p(s))}{p(s)} \qquad p(s|u) \propto \begin{cases} 1 & \text{if } p(s) \geq u \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

The posterior that we slice sample from is simply proportional to the product of likelihood and prior of the Beta distribution: $p(s|f_1^m, z_1^m, r) \propto P(z_1^m|f_1^m, s, r) \times p(s)$.

Notice that the conditions in Equation (9) guarantee that at least the current point will be in the slice. We will therefore always be able to obtain a new sample. Intuitively, slice sampling works because the marginal distribution $p(s)$ stays unchanged.

4.5 Decoding

After we have taken a number of samples, we are ready to decode. We use a version of maximum marginal decoding (Johnson and Goldwater, 2009) in which we assign to each source position j the target position that was most often sampled as a value for A_j. If most of the time the collocation variable Z_j was active, however, we leave that source position unaligned.

5 Experiments and Results

All experiments were run using the Moses phrase-based system (Koehn et al., 2007) with lexicalized reordering. In order to speed up our experiments we used cube pruning with a pop limit of 1000 in both tuning and evaluation. Symmetrised alignments were obtained with the `grow-diag-final-and` heuristic.

Data We used the WMT 2014 news commentary data[9] to train our models and the corresponding dev (`newstest2013`) and test (`newstest2014`) sets for tuning and evaluation. We use all available monolingual data to train 5-gram language models with KenLM (Heafield, 2011).

Models We report results for the Bayesian HMM described in Section 2 (BHMM) and our collocation-based model described in Section 3 (BHMM-Z). To enable comparison with standard alignment toolkits, we also report results with Giza++ and fastAlign (Dyer et al., 2013). Finally, we make a comparison with the collocation-based IBM2 model of Schulz et al. (2016) (BIBM2-Z).

Hyperparameters The hyperparameters of our model were set to $\beta = \gamma = 0.0001$ to obtain sparse lexical distributions. For the jump prior we chose $\alpha = 1$, not giving preference to any particular distribution. The same choices apply for the BIBM2-Z. However, that model does not employ hyperparameter inference and we therefore set $s = 1, r = 0.01$. Finally, the BHMM uses the same parameters as the previous two models, except those associated with the collocation variable.

All samplers were run for 1000 iterations without burn-in and samples were taken after each 25^{th} iteration. The initial state was chosen to be the Viterbi decoding of IBM model 1. For our auxiliary variable sampler we select exactly 2 candidates, thus making inference as fast as possible. Giza++ and fastAlign were run under their standard parameter settings. For Giza++ this means that we ran EM for IBM model 1 and the HMM (5 iterations each) and for IBM models 3 and 4 (3 iterations each). Since

[8] In the following exposition we will describe the resampling of S and assume a fixed value r. Resampling R works analogously with a fixed value s.

[9] `http://statmt.org/wmt14/translation-task.html`

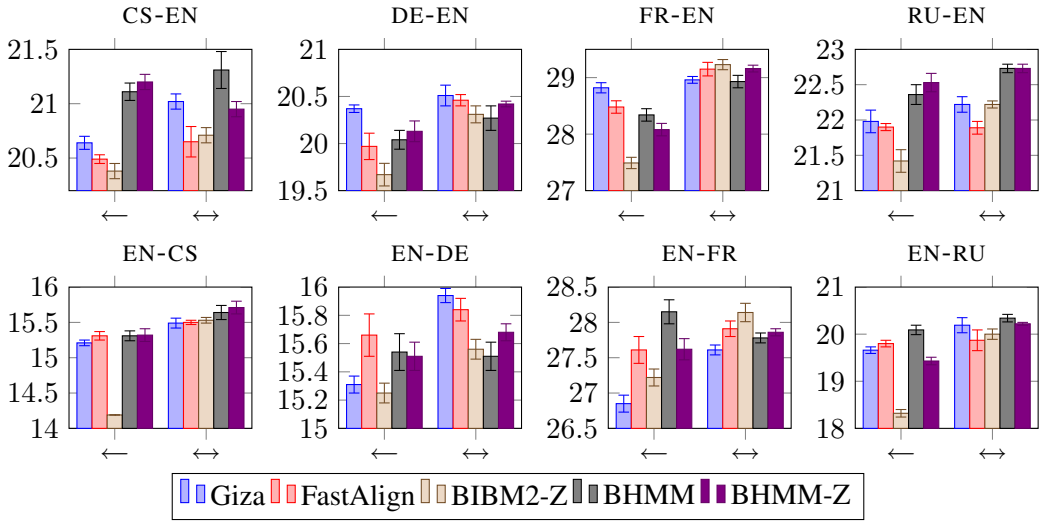

Figure 1: BLEU scores for each translation direction trained on (←) directional (condition on target and generate source) and (↔) symmetrised alignments (`grow-diag-final-and`). Observe that the plots are on different scales. This means that results cannot directly be compared across plots.

the maximum likelihood HMM is incorporated in the Giza++ pipeline, we do not report separate results for it.

Results Figure 1 shows translation quality results in terms of BLEU for different aligners, where BHMM is the Bayesian HMM (Section 2) and BHMM-Z is our novel collocation-based model (Section 3). Furthermore, BIBM2-Z is the model of Schulz et al. (2016). To account for optimiser instability (MERT in this case), we plot average and standard deviation across 5 independent runs. Note that our Bayesian models perform mostly on par with maximum-likelihood models. In the directional case, our Bayesian models lose to Giza++ only in DE-EN by a very slim margin. Except for EN-DE (symmetrised) our models are never worse than fastAlign. Moreover, our models perform notably well on Czech and Russian outperforming the maximum-likelihood models. Finally, except for EN-FR (directional), our collocation-based BHMM-Z improves upon the more basic BHMM. It also often improves upon the BIBM2-Z. That model is only better on the symmetrised English-French data where it outperforms all other models.

We also analysed the number of alignment links that our systems set. It is noteworthy that the Bayesian HMM with NULL words consistently sets much fewer links than all other systems. Taking BHMM as baseline other models set additionally (on average across languages and translation direction) 39.5% (our collocation-based model), 39.2% (Giza++), and 36.2% (fastAlign) more links. Setting more links constrains phrase extraction heuristics more and leads to smaller phrase tables. Empirically, the phrase tables of the collocation-based model are roughly three times smaller than those of the Bayesian HMM. Thus, the collocation-based system is at an advantage here.

Finally, in terms of speed, Giza++ takes on average (across languages and translation directions) 202 minutes on 2 CPUs, while BHMM and BHMM-Z take respectively 81 and 267 minutes in 1 CPU.[10] The slower performance of BHMM-Z in relation to BHMM is not per se due to the sampling of collocation variables, but rather due to hyperparameter inference (see Section 4.4).

6 Related Work

There are several extensions of the classical IBM models. Dyer et al. (2013) use a log-linear model for the distortion distribution. While they keep the independence assumptions for alignment links, they bias

[10]The run times for our models include the computation of the initial state of the sampler with IBM model 1. The run time of the sampler itself is thus slightly lower than the reported times. Also notice that due to its highly optimised posterior computations, fastAlign finishes in under 10 minutes on average.

their model to preferably align positions which are close to each other. Using standard results for series, they manage to make the posterior computations in their model extremely fast.

Another interesting extension of the HMM alignment is presented in Zhao and Gildea (2010) who added a fertility distribution to the HMM. This made posterior computations in their model intractable, however, they avoided the use of heuristics and instead approximated the posterior using MCMC.

The idea of using Bayesian inference together with a Gibbs sampler for word alignment was first presented for IBM model 1 by Mermer and Saraçlar (2011). They also gave a more detailed analysis of their method and extended it to IBM model 2 in Mermer et al. (2013). The model presented here is also similar in spirit to Schulz et al. (2016) who proposed to use a language model component together with an alignment model. However, they used IBM models 1 and 2 as alignment components.

Apart from the present work, the only other work on Bayesian word alignment that we know of that performed as well as or better than Giza++ was presented in Gal and Blunsom (2013). These authors reformulated IBM models 1-4 as hierarchical Pitman-Yor processes. While their models are highly expressive, the Gibbs sampler based on Chinese Restaurant processes that they used is very slow and thus their models are unfortunately not useful in practice.

7 Discussion and Future Work

We envision several useful extensions of our model for the future. Firstly, we plan to turn the language model distribution into a hierarchical distribution. We plan to use either a hierarchical Dirichlet process or Pitman-Yor process for this. The advantage of this technique is that information about untranslatable source words can be shared across preceding source words. Sampling from such a distribution using a Chinese Restaurant Process is potentially time-consuming. However, we are confident that we can maintain a good speed if we apply our auxiliary variable technique and employ efficient samplers as described by Blei and Frazier (2011).

Since our model aligns many words and thus restricts the amount of phrases that can be extracted, it may also be a good alignment model for hierarchical phrase-based SMT. We plan to apply our model to this scenario in the future.

The code used in our experiments is freely available at `https://github.com/philschulz/Aligner`.

Abstract

We present an approach for learning to translate by exploiting cross-lingual link structure in multilingual document collections. We propose a new learning objective based on structured ramp loss, which learns from graded relevance, explicitly including negative relevance information. Our results on English-German translation of Wikipedia entries show small, but significant, improvements of our method over an unadapted baseline, even when only a weak relevance signal is used. We also compare our method to monolingual language model adaptation and automatic pseudo-parallel data extraction and find small improvements even over these strong baselines.

1 Introduction

Typically, parameters of an SMT system are learned on a small parallel data set from the domain or genre of interest. However, while many multilingual data sets, especially in the realm of user-generated data, contain document-level links, sentence-parallel training data are not always available. A small number of sentences can be manually translated for in-domain parameter tuning, but this ignores most of the available multilingual resource. Monolingual language model adaptation via concatenation or interpolation is one viable solution which makes use of the target side part of a collection (see e.g. Koehn and Schroeder (2007) or Foster and Kuhn (2007)). Additionally, there are several approaches to automatic parallel data extraction from cross-lingual document-level links, such as Munteanu and Marcu (2005)'s work on news data, or more recent work on Wikipedia by Wołk and Marasek (2015), and on websites by Smith et al. (2013). We argue that these approaches work well if the cross-lingual links are a strong signal for parallelism, but fail if the signal linking documents across languages is weaker. We propose a method for tuning sparse lexicalized features on large amounts of multilingual data which contain some cross-lingual document-level relevance annotation. We do so by re-formulating the structured ramp loss objective proposed by Chiang (2012) and Gimpel and Smith (2012) to incorporate graded and negative cross-lingual relevance signals. Using translation of Wikipedia entries as a running example, we evaluate the efficacy of our method along with the traditional approaches on a manually created in-domain test set. We show that our method is able to produce small, but significant, gains, even if only a weak relevance signal is used.

Section 2 explains our learning objective and cost function. In Section 3 we describe the construction of our training and evaluation data, including pseudo-parallel data extraction. Section 4 contains details of our experimental setup and presents our experimental results. Section 5 concludes the paper.

2 Learning from graded relevance feedback

2.1 Learning objectives

We work within a scenario where we want to learn the parameters of an SMT system, but have no in-domain reference translations available. What we have, is a large collection of source and target language documents and a signal telling us that some target documents are *more relevant* to a source document

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3156–3166, Osaka, Japan, December 11-17 2016.

than others. For example, in the multilingual Wikipedia, cross-lingual documents can be connected in different ways. First, a link exists between two documents if they are connected by an interlanguage link (we call this a *mate* relation). This is a very strong relevance signal. Second, a more indirect link exists between a source language document and a target language document if the target language document is connected to the source language document's mate by a hyperlink (we call this a *link* relation). This is a weaker relevance signal. A cross-lingual mate is more relevant to an input document than a document that is only linked to by the mate. In turn, this linked document is more relevant to the input than a document that has no direct link to the mate. Any Wikipedia document is more relevant than a document from a different data set. We write relevance as $d_1 \succ_{\mathbf{f}} d_2$ ("d_1 is more relevant to $\mathbf{f}$ than d_2"). Another example of graded relevance information, which has been used in information retrieval, occurs in multilingual patent collections, where patent documents can be in a "family" relation if they contain publications of the same patent, or be related to a lesser degree, if a target document is cited by a source document's family patent. Of course, other notions of relevance are conceivable, e.g. by document similarity, and we plan to further investigate such notions in future work.

In order to incorporate graded relevance information, we modify the structured ramp loss objective by Gimpel and Smith (2012) to also include negative relevance information. Ramp loss based SMT tuning methods as presented by Gimpel and Smith (2012) and Chiang (2012) usually try to find parameters that separate a "good" hypothesis with respect to the reference from one that is "bad" with respect to the same reference. Goodness and badness are measured by an external cost function, or a cost function combined with the model prediction. Equation 1 shows one version of the structured ramp loss ("ramp loss 3"/equation 8 from Gimpel and Smith (2012)):

$$L_{Gimpel}(\mathbf{F};\theta) = \sum_{\mathbf{f}\in\mathbf{F}} \underbrace{-\max_{\mathbf{e}}(\text{score}(\mathbf{e};\theta) - \text{cost}(\mathbf{e}))}_{\text{hope derivation}} + \underbrace{\max_{\mathbf{e}}(\text{score}(\mathbf{e};\theta) + \text{cost}(\mathbf{e}))}_{\text{fear derivation}} \quad (1)$$

where $\mathbf{F} = \{\mathbf{f}_1, \mathbf{f}_2 \ldots \mathbf{f}_n\}$ is a finite set of input examples, θ refers to the model parameters and $\mathbf{e}$ is a translation hypothesis; $\text{score}(\mathbf{e};\theta)$ is the log-linear model score of the hypothesis, which is proportional to the dot product between the feature vector associated with the hypothesis and the weight vector; $\text{cost}(\mathbf{e})$ is a cost function, which measures the quality of the current hypothesis. Usually, this function is some per-sentence approximation of the BLEU score against one or more reference translations. Following Chiang (2012)'s terminology, this loss tries to maximize the distance between a *hope* derivation – which has high model score and low cost – from a *fear* derivation – which has high model score, but high cost.

We define two training objectives which are variations of this loss function, but which incorporate positive and negative relevance information. Our intuition is that instead of trying to separate *hope* and *fear* with respect to the same reference, we try to separate a hypothesis that has high model score and low cost with respect to a relevant document from one that has high model score and low cost with respect to a document that is irrelevant. Our first objective is given in Equation 2:

$$L_{ramp_1}(\mathbf{F};\theta) = \sum_{\mathbf{f}\in\mathbf{F}} \underbrace{-\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) - \text{cost}(\mathbf{e},d^+_{\mathbf{f}}))}_{\text{hope derivation w.r.t. } d^+} + \underbrace{\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) - \text{cost}(\mathbf{e},d^-_{\mathbf{f}}))}_{\text{hope derivation w.r.t. } d^-} \quad (2)$$

In this objective, $\text{cost}(\mathbf{e},d) \in [0,1]$ is the cost of a hypothesis $\mathbf{e}$ with respect to a document d. d^+ and d^- are documents, such that $d^+ \succ_{\mathbf{f}} d^-$. Unlike L_{Gimpel}, this loss tries to separate two different hope derivations. One potential weakness of L_{ramp_1} is that it treats d^+ and d^- completely independently. This could lead to very similar hypotheses being selected, if there exist hypotheses that have low cost in both d^+ and in d^-. To solve this issue, we propose a second modification of the loss.

In the second variant we define "good" and "bad" hypotheses as those which have the largest *difference* between the cost with respect to d^+ and d^-, i.e. hypotheses that best distinguish d^+ from d^-. This leads to the following objective given in Equation 3.

$$L_{ramp_2}(\mathbf{F};\theta) = \sum_{\mathbf{f}\in\mathbf{F}} \underbrace{-\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) - (\text{cost\_diff}(\mathbf{e},d^+_{\mathbf{f}},d^-_{\mathbf{f}}))}_{\text{derivation with lowest cost}(d^+)\textit{ and }\text{highest cost}(d^-)} + \underbrace{\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) - (\text{cost\_diff}(\mathbf{e},d^-_{\mathbf{f}},d^+_{\mathbf{f}}))}_{\text{derivation with lowest cost}(d^-)\textit{ and }\text{highest cost}(d^+)} \quad (3)$$

where cost_diff is defined as

$$\text{cost\_diff}(\mathbf{e},d_1,d_2) = \text{cost}(\mathbf{e},d_1) - \text{cost}(\mathbf{e},d_2) \quad (4)$$

Note that with the above definition of cost_diff, equation 3 can be reformulated as

$$L_{ramp_2}(\mathbf{F};\theta) = \sum_{\mathbf{f}\in\mathbf{F}} \underbrace{-\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) - \text{cost\_diff}(\mathbf{e},d^+_{\mathbf{f}},d^-_{\mathbf{f}}))}_{\text{hope derivation}} + \underbrace{\max_{\mathbf{e}}(\text{score}(\mathbf{e},\mathbf{f};\theta) + \text{cost\_diff}(\mathbf{e},d^+_{\mathbf{f}},d^-_{\mathbf{f}}))}_{\text{fear derivation}} \quad (5)$$

which is identical to the original structured ramp loss (Equation 1), but still allows to include positive and negative relevance signals via the cost function. We apply a linear scaling operation to squash our new cost function to return values between 0 and 1.

2.2 Implementation and learning

Parallelized stochastic subgradient descent. Algorithm 1 shows our learning procedure. Optimization is done using stochastic subgradient descent (SSD) as proposed for ramp loss by Keshet and McAllester (2011). In order to be able to train on thousands of documents, we use the method described in Algorithm 4 of Simianer et al. (2012), which splits training data into shards (line 1 in Algorithm 1), trains one epoch on each shard (line 3 to 12), and then applies feature selection by ℓ_1/ℓ_2 regularization (line 13) before starting the next epoch.

Sampling. For each training example, we first sample a document pair (d^+, d^-) (line 6). The *sample()* procedure draws documents d^+ from a set of relevant documents D^+ and d^- from a set of "contrast documents", D^-, according to some cross-lingual relevance signal. In our experiments, we first use random sampling. We also try out a weighted sampling strategy, if the relevance signal is weaker. In this case, we want to sample a document more frequently from D^+, if it is more similar to the input document. We calculate cross-lingual document similarity by using document representations from bilingual word embeddings. The embeddings are learned from the aligned parallel training corpus using the Bilingual Skip-gram model of Luong et al. (2015).[1] Document representations are computed by averaging over all word representations in the document, weighted by the inverse document frequencies of the words. Cosine similarity is used to measure similarity between the current source document and the documents in D^+. We use weighted reservoir sampling (Efraimidis and Spirakis, 2006) to draw a document weighted by its similarity to the current source document. The contrast document d^- is drawn randomly from D^-, but is re-drawn if d^- is more similar to the input then d^+.

Search. In lines 7 and 8 we identify the "good" and "bad" hypotheses h^+ and h^- by running *search()*. Most tuning algorithms use k-best lists to approximate the search space over possible translation hypotheses. However, k-best lists cover only a very small portion of the possible hypothesis space and often contain very similar hypotheses. Since we may not have a strong enough signal to differentiate between those hypotheses, we also experiment with using the entire search space, which in hierarchical phrase-based translation can be represented by a packed hypothesis forest, or hypergraph. In this scenario, *search()* amounts to finding the Viterbi derivation after annotating the translation hypergraph

Algorithm 1 SSD

Require: input X, epochs T, initial weights w_0, cost function $cost$, document collection D^+, D^-, stepsize η, regularization strength C, number of shards S

1: $\{X_1 \dots X_S\} \leftarrow$ make_shards(S, X) ▷ Create shards for parallel training
2: **for** $t = 1$ to T **do**
3: **for** $s = 1$ to S parallel **do**
4: $w_{s,t-1}^{(0)} \leftarrow w_{t-1}$
5: **for** $i = 1$ to $|X_s|$ **do**
6: $(d^+, d^-) \leftarrow$ sample$(X_s^{(i)}, D^+, D^-)$ ▷ Sample relevant and irrelevant document
7: $(h^+, h^-) \leftarrow$ search$(X_s^{(i)}, w_{s,t-1}^{(i-1)}, cost, d^+, d^-)$ ▷ Find hope and fear
8: $w_{s,t-1}^{(i)} \leftarrow w_{s,t-1}^{(i-1)} + \eta(\phi(h^+) - \phi(h^-)) - \eta C(\frac{w_{s,t-1}^{(i-1)} - w_0}{|X|})$ ▷ Update weights
9: **end for**
10: $w_{s,t} \leftarrow w_{s,t-1}^{(|X|)}$
11: **end for**
12: $w_t \leftarrow$ select$(w_{1,t} \dots w_{S,t})$ ▷ Select features by ℓ_1/ℓ_2 regularization
13: **end for**

edges with the cost for each edge. This requires a cost function which decomposes over edges, as will be detailed in section 2.3. We run experiments both using a k-best lists and the full search space.

Finally, the weights are updated in line 9 by adding the negative subgradient multiplied by learning rate η and a regularization term which is obtained from adding $C\frac{1}{2|X|}\|(w - w_0)^2\|$ to the ramp loss objective.

2.3 Cost function

So far, we have not yet specified the cost function. Usually, $1 - psBLEU(\mathbf{e}, \mathbf{r})$ is used as a cost function, where $\mathbf{r}$ is a reference translation and $psBLEU$ is a per-sentence approximation of the $BLEU$ score. Since we do not have reference translations as feedback, we need to use a cost function that will evaluate the quality of a hypothesis with respect to a relevant document. Like BLEU we use average n-gram precision. Unlike BLEU, we cannot use reference length to control the length of the produced translation. Our solution is to use the source length, multiplied by the average source-target length ratio r which can be empirically determined on the training set.

For *k*-best training, where we can evaluate complete sentences, we use average *n*-gram precision:

$$\mathrm{nprec}(\mathbf{e}, \mathbf{f}, d) = \frac{1}{N}\sum_{n=1}^{N} \frac{\sum_{u_n} c_{u_n}(\mathbf{e}) \cdot \delta_{u_n}(d)}{\sum_{u_n} c_{u_n}(\mathbf{e})} \cdot min(1, \frac{r \cdot |\mathbf{e}|}{|\mathbf{f}|})$$

where N is the maximum *n*-gram size, u_n are *n*-grams present in $\mathbf{e}$, $c_{u_n}(\mathbf{e})$ counts the occurrences of u_n in $\mathbf{e}$ and $\delta_{u_n}(d)$ returns 1 if u_n is present in document d and 0 otherwise. The second term is the brevity penalty. As a cost function, this becomes $1 - \mathrm{nprec}$. BLEU uses the geometric mean to account for the exponentially decaying precision, as n increases. When calculating per-sentence BLEU, we might face the problem of zero-precision, as n increases. Since BLEU is measured over a corpus and not over a sentence, the case of zero-values was not taken into consideration. A common solution to this is count smoothing. We use the arithmetic instead of the geometric mean, since it avoids the problem of zeros, and will return the same ranking as the geometric mean.

When training on hypergraphs, we are facing the problem that *n*-gram precision is not edge-decomposable. For our hypergraph experiments, we tried the simplest possible approach, which is to compute nprec at edge level:

$$\mathrm{nprec}(\mathbf{e}, \mathbf{f}, d) = \sum_{\bar{e} \in \mathbf{e}} \mathrm{nprec}(\bar{e}, \bar{f}, d)$$

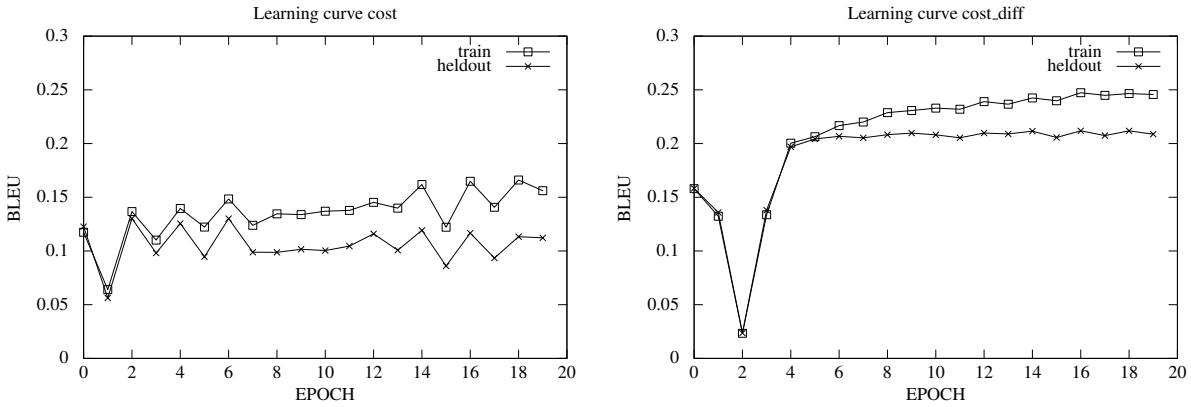

Figure 1: Learning curves on training and heldout data when training on references. The left side uses the loss from equation 2, the right side uses the loss from equation 3.

In order to test the proposed loss and cost functions, we look at how they perform in a case, where we are learning translation model weights from a perfect signal, i.e. reference translation. Instead of sampling d^+ from a set of relevant documents D^+ , we use the reference translation of input $\mathbf{f}_i$. For the contrast set d^-, we sample another sentence from the target side of the training data. We train on 500-best lists for 20 epochs. We conduct this experiment on the IWSLT evaluation data, using IWSLT tst2010 for training and tst2013 for evaluation. The model is trained on out-of-domain data in the same way as the model described in 4.1. Figure 1 shows learning curves for L_{ramp_1} which uses cost and L_{ramp_2} which uses $\mathrm{cost\_diff}$. We found $\mathrm{cost\_diff}$ to perform much better than cost on both train and heldout data. Why does cost do so much worse? Remember, that in this scenario we select two *hope*-derivations. What is more, we only select them from a small k-best list (500 translations). With the $\mathrm{cost\_diff}$ function we are required to choose hypotheses that *distinguish* most between d^+ and d^-. This will select a h^- that is far away from the reference (similar to a *fear* derivation). While with cost, there is no guarantee that h^- will differ from h^+.

3 Data preparation and extraction

3.1 Initial Wikipedia data set

Wikipedia is internally structured by cross-lingual links and inter-article links. We use the German-English WikiCLIR collection by Schamoni et al. (2014), along with their definition of cross-lingual relevance levels: A target language document has relevance level 3 if it is the cross-lingual mate of an input document. It is assigned relevance level 2, if there is a bidirectional link relation between the cross-lingual mate and the document. WikiCLIR contains a total of 225,294 mate relations with 1 average German mate per English document, and over 1.7 million bidirectional link relations, with on average 8.5 links per English document. We use the link information provided by WikiCLIR, but we work with the full Wikipedia documents rather than WikiCLIR's abbreviated queries.

3.2 Automatic sentence alignment

The cross-lingual mate relation in Wikipedia is a strong indicator for parallelism. However, Wikipedia entries in different languages are not necessarily translations of each other, but can be edited independently. In order to find parallel sentences, we use an automated extraction method. We do this for three purposes:

1. To identify nearly parallel document pairs for the construction of a clean in-domain evaluation set without having to rely on manual translation.

2. To examine whether bidirectional links provide a strong enough signal for extracting pseudo-parallel training data.

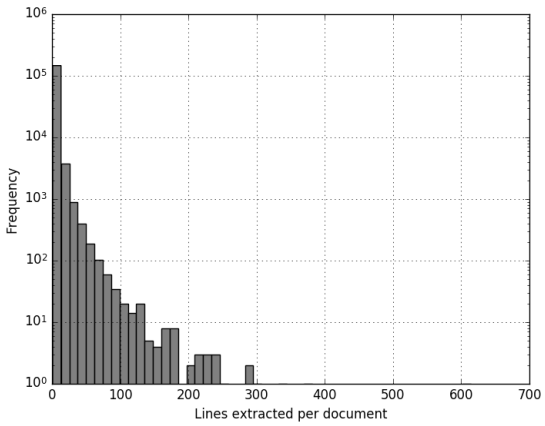

Figure 2: Number of documents (y-axis, on log-scale) from which n lines were extracted (x-axis).

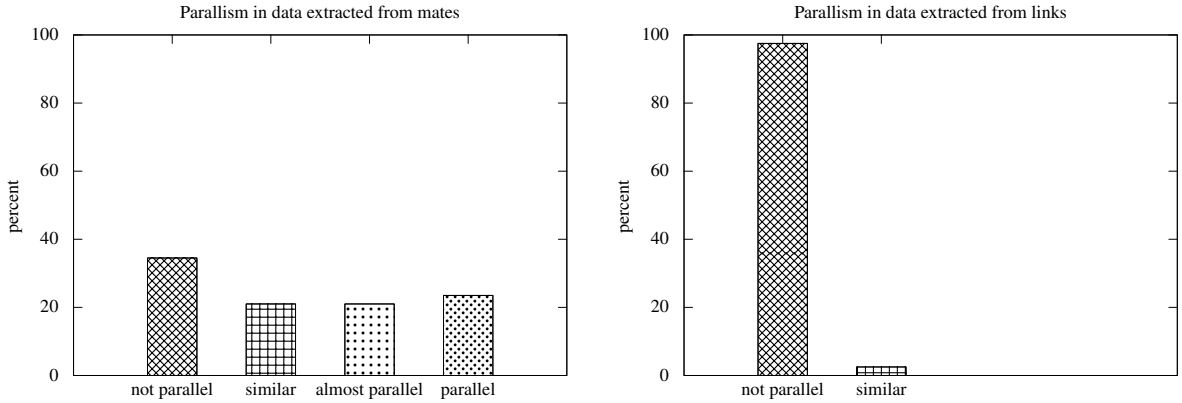

Figure 3: Sentence aligner precision for mates and links.

3. To compare our method to automatic parallel data extraction based on relevance annotation.

We use the modified `yalign` method described by Wołk and Marasek (2015) for pseudo-parallel data extraction.We adapt their software to handle the WikiCLIR format. `yalign` requires a bilingual dictionary with translation probabilities. Following Wołk and Marasek (2015), we use a lexical translation table created from the TED parallel training data[2] as our bilingual dictionary. We filter the dictionary for punctuation and numerals and discard all entries whose lexical translation probability is smaller than 0.3.

Figure 2 shows the frequency histogram of the number of extracted lines per document pair for document pairs with a mate relation. For most document pairs, only a single sentence pair was extracted. However, there were a few document pairs that yielded several hundred sentence pairs. In total, 533,516 sentence pairs were extracted.

Figure 3 shows our evaluation of `yalign`'s precision for the mate and link relations. We manually evaluated a sample of 200 automatically aligned sentence pairs. The sentence pairs were annotated using four categories: "fully parallel", "almost parallel" – this category contains sentence pairs that have parallel segments, with other segments missing from the aligned part, "similar" – for sentence pairs that have similar content or wording but differ factually –, and "non parallel". While 65.5% of sentence pairs from the mate relation were similar or parallel, the link relation yielded only 2.6% sentence pairs that were at least similar. We conclude that the bidirectional link relation is too weak to extract useful pseudo-parallel data.

Table 1: Wikipedia development and test documents.

3.3 Evaluation data construction

To construct our in-domain evaluation data, we sorted all automatically aligned documents by the number of aligned sentences up to a limit of 10,000 sentences. We then selected eight documents for manual alignment, discarding other document pairs which appeared to have been machine-translated, only contained few parallel sentences, or consisted of lists of proper names. During manual alignment, we also fixed sentence splitting errors and removed image captions and references. We split the documents into two groups of four, making sure to keep the sets diverse. Table 1 shows the two sets of extracted documents. They are topically diverse, similar in length, and contain a considerable percentage of parallel sentences.

4 Experiments

4.1 Out-of-domain translation system

Our baseline English-German translation system is trained on 2.1 million sentence pairs (61/59 million English/German tokens) from the Europarl v7[3] corpus (1.78 million sentence pairs), the News Commentary v10[4] corpus (200K sentence pairs) and the MultiUN v1[5] corpus (150K sentence pairs). Word alignments are computed using MGIZA++[6], alignments are symmetrized using the `grow-diag-final-end` heuristic. A 4-gram count-based language model is estimated from the target side of the training data using `lmplz` (Heafield et al., 2013). All experiments use the hierarchical phrase-based decoder `cdec` (Dyer et al., 2010). Hierarchical phrase rules are extracted using `cdec`'s implementation of the suffix array extractor by Lopez (2007) with default settings. Our baselines use 21 decoder features (7 translation model features, 2 language model features, 7 pass through features, 3 arity penalty features, word penalty and glue rule count features), which are implemented in `cdec`. Feature weights are optimized on the WMT Newstest 2014 data set (3003 sentence pairs) using the pairwise ranking optimizer `dtrain`[7]. We run `dtrain` for 15 epochs with the hyperparameters k-best size=100, loss-margin=1, and a learning rate of $1e^{-5}$. The final weights are averaged over all epochs. Performance of our baseline system (*baseline 1*) is given in the first row of Table 2.

4.2 Translation model and language model adaptation

For translation model (TM) adaptation we add the automatically extracted pseudo-parallel Wikipedia data (see Section 3) to our baseline training data and re-train the translation model. For language model (LM) adaptation, we sample 500,000 sentences from the German Wikipedia data, which we add to the out-of-domain language model data to re-build a combined 4-gram language model. Both language model and translation model adaptation boosted performance. Rows 1 and 3 in Table 3 show BLEU

scores for an LM-adapted model (*baseline 2*) and a model with both LM and TM adaptation (*baseline 3*). The good performance of TM adaptation leads to the conclusion that if there is a strong signal for potential parallelism like in the Wikipedia data, automatic pseudo-parallel data extraction works well.

4.3 Learning from Wikipedia mates and links

We train our method on 10,000 input sentences sampled from the English WikiCLIR documents. Each input sentence is annotated with a document identifier in order to sample positive and negative examples. The relevant document collection D^+ includes all German documents which are linked to an English document by a mate or bidirectional link relation. For the contrast documents D^- we use the News Commentary corpus, split into documents. In a pre-processing step, we extract n-grams up to order 3 from each document, which we need to calculate n-gram precision. We also experimented with a larger training set of 200,000 input sentences but found no significant improvement. All experiments use the same 21 features as the baseline, keeping those weights fixed, but train sparse lexicalized features (rule identifiers, rule source and target bigrams and lexical alignment features described in Simianer et al. (2012)) in parallel on 10 shards, followed by an ℓ_1/ℓ_2 feature selection step which keeps at most 100,000 features. We use a constant learning rate of $\eta = 1e^{-4}$ and regularization strength $C = 1$. Experiments were run for up to 20 epochs and performance on the heldout *set1* was used as an early stopping criterion.

Table 2 reports BLEU scores on *set2*, when our model is trained on an unadapted baseline model (*baseline 1*). Significance tests were conducted by `multeval` (Clark et al., 2011). While training on k-best lists produced a small incremental gain, training on hypergraphs improved up to 0.6 BLEU over the baseline. Both cost and cost_diff produced an improvement over the baseline, however, cost_diff performed slightly better. As expected, using the strongest signal, the cross-lingual mate relation, worked best. When only the link relation was used, only the experiment with the weighted sampling strategy produced a significant improvement. Figure 4 shows learning curves over epochs on heldout *set1* for

Experiment	%BLEU *set2*
baseline 2 (LM adaptation)	13.62
hypergraph-train (mates, cost_diff)	13.93* (+0.31)
baseline 3 (LM and TM adaptation)	14.96
hypergraph-train (mates, cost_diff)	15.17* (+0.21)

Table 3: Results for training on Wikipedia with adapted model. * indicates a significant difference to the baseline at a significance level of 0.05.

training on mates and links (both with random sampling).

Table 3 shows results for training on mates with an adapted baseline model. In both experiments, there was a small, yet significant, improvement over the adapted model, showing that additional information can be learned from the relevance signal.

Examples. To give a better impression what is learned by our method, Table 4 contains some example translations from *baseline 1* and the best adapted model from Table 2. Spans in which our model performed better are marked in **boldface**. *Example 1* shows that our model fixed word order mistakes made by the baseline, such as "Apartheid zionistischen", which is fixed to "zionistischen Apartheid". The same is true for the proper name and attribution "Thomas Michael Hamerlik (CDU)" in *Example 2*. Both examples suggest that by training on Wikipedia documents, which include frequent parentheses, quotations and named entities, our model becomes better at handling these types of phrases. *Example 3* is interesting, because in this case the baseline produced an idiomatic, rather informal translation for "postponed indefinitely" ("auf den Sankt - Nimmerleins - Tag verschoben") which would be correct in a spoken language context but strange to use in a Wikipedia article, while our model produced the correct translation ("auf unbestimmte Zeit verschoben").

5 Conclusion and future work

In this paper we have presented a new objective for learning translation model parameters from graded and negative relevance signals. Using Wikipedia translation as an example, we were able to achieve significant improvements over an unadapted baseline. As expected, a stronger relevance signal produced larger gains, but we were able to produce small, but significant, improvements, even when learning only from indirect links. We compare our method to baselines that use monolingual data to adapt the language model or rely on strong parallelism signals to adapt the translation model. Our approach was able to yield a small gain even when combined with these strong baselines.

It is worth mentioning that our approach is not restricted to Wikipedia data, but could be applied to other large multilingual collections where cross-lingual relevance information can be extracted. For example, cross-lingual mates could be extracted for multilingual patent corpora through patent family relations (i.e. versions of the same patent submitted to different patent organizations). In addition, weaker links are given by the international patent classification system, or by citations between patents. Another application scenario could be social media data which use the same hashtags across languages. If no explicit signals are available, or if they are not strong enough, one could also use unsupervised document similarity metrics or cross-language information retrieval techniques to detect relevant documents in a target language collection and use these documents as positive examples. We plan to explore these directions in the future.

Since our general learning setup and objective is agnostic about the type of translation system we also plan to apply it to neural machine translation.

Universal Reordering via Linguistic Typology

Abstract

In this paper we explore the novel idea of building a single *universal* reordering model from English to a large number of target languages. To build this model we exploit typological features of word order for a large number of target languages together with source (English) syntactic features and we train this model on a *single combined* parallel corpus representing all (22) involved language pairs. We contribute experimental evidence for the usefulness of linguistically defined typological features for building such a model. When the universal reordering model is used for preordering followed by monotone translation (no reordering inside the decoder), our experiments show that this pipeline gives comparable or improved translation performance with a phrase-based baseline for a large number of language pairs (12 out of 22) from diverse language families.

1 Introduction

Various linguistic theories and typological studies suggest that languages often share a number of properties and that their differences fall into a small set of parameter settings (Chomsky, 1965; Greenberg, 1966; Comrie, 1981). While this intuition has influenced work on multilingual parsing (Zeman and Resnik, 2008; McDonald et al., 2011), it has found less practical use in other areas of natural language processing, such as the task of machine translation. In machine translation, significant word order differences between languages often constitute a challenge to translation systems. Word order differences are frequently given special treatment, such as in the case of preordering (Xia and McCord, 2004; Neubig et al., 2012; Stanojević and Sima'an, 2015, inter alia), which is a technique heavily used in practice as a means to improve both translation quality and efficiency. In preordering, word order is predicted based on manually created rules or based on statistical models estimated on word-aligned training data exploiting only source language features. This approach works well for some language pairs, however it usually demands a separate, dedicated preordering model for every source-target language pair, trained on a word-aligned corpus specific for the particular language pair.

But if the similarities and differences between languages can indeed be captured with a small set of features, as linguistic theory suggests, then it seems more expedient to try to benefit from the similarities between target languages in the training data, which is not possible when training a separate preordering model for every new target language. Ideally, the word-aligned data obtained for various target languages should be combined to train a single, *universal* reordering model with a single set of features. The questions addressed in this paper are (1) could a linguistically inspired universal reordering model show any promising experimental results and (2) how can such a universal reordering model be built?

For building an effective universal reordering model, we need access to a resource that describes the similarities and differences between (target) languages in a small set of properties. The World Atlas of Language Structures (Dryer and Haspelmath, 2013), WALS, is a major resource which currently specifies the abstract linguistic properties of 2,679 languages.[1] In this paper we explore the use of the

[1] http://wals.info/languoid

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3167–3176, Osaka, Japan, December 11-17 2016.

linguistically defined WALS features for a broad range of target languages and show that these features have merit for building a single, universal reordering model. The universal reordering model is based on a feed-forward neural network which is trained to predict the target word order given source syntactic structure and all available WALS parameter settings for each of the 22 target languages involved. By training the feed-forward neural network on the WALS-enriched data from a broad range of target languages, we enable the universal reordering model to both learn how much to trust the WALS parameters and to exploit possible interactions between them for different target languages. When the universal reordering model is followed by *monotone translation* (no reordering inside the decoder), our experiments show that this pipeline gives comparable or improved translation performance to a Moses baseline with standard distortion settings, for a large number of language pairs. This suggests that typological target language features could play a key role in building better, more general preordering models, which have, heretofore, been trained solely on source sentences and word alignments, but had no access to other target-side information.

We believe that the experiments presented in this paper have both theoretical and practical implications. Firstly, they show the utility and provide empirical support for the value of linguistic typology. Secondly, they enable building more compact preordering models that should generalize to a broad set of target languages and which potentially apply for the low resource setting where no or little parallel data is available for a specific target language.

2 Related Work

The most basic usage of linguistic knowledge in preordering is in restricting the search space of possible reorderings by using syntactic parse trees. Earlier work was done mostly on constituency trees (Khalilov and Sima'an, 2012; Xia and McCord, 2004) while more recent versions of preordering models mostly use dependency trees (Lerner and Petrov, 2013; Jehl et al., 2014). Preordering in syntax-based models (whether dependency or constituency) is done on the local level where for each constituent (or head word) the classifier decides how the children (or dependent words) should be reordered.

Employing classifiers to make local decisions on each tree node is one machine learning approach to solving this problem. An alternative to employing machine learning techniques is the use of linguistic knowledge that can in some cases give clear rules for the reordering of children in the tree. An early example of rule-based preordering is by Collins et al. (2005), who develop linguistically justified rules for preordering German into English word order. Similar in spirit but much simpler is the approach of Isozaki et al. (2010), who exploit the fact that Japanese word order is in large part the mirror image of English word order—the heads of constituents in English are in final position while in Japanese they are in initial position. Preordering English sentences into Japanese word order thus only involves two simple steps: (1) Finding the parse tree of the English sentence (the authors used HPSG derivations) and (2) moving the head of each constituent to the initial position. However, this approach does not seem to scale up easily because manually encoding reordering rules for all the world's language pairs would be a rather difficult and very slow process.

In contrast to manually encoding rules for language pairs, we could use similarities and differences between target languages encoded in existing *typological databases* of structural properties of the world's languages, e.g., the World Atlas of Language Structures, WALS (Dryer and Haspelmath, 2013). Therefore, the challenge taken up in the present work is how to exploit typological databases such as WALS to guide the learning algorithm into making the right decisions about word order. So if, for instance, a feature indicates that the target language follows VSO (verb-subject-object) word order, then the preordering algorithm should learn to transform the English parse tree from SVO into a VSO tree. Using typological features like these in a machine learning system for preordering constitutes a compromise between knowledge-based (rules) and data-driven (learning) approaches to preordering.

Researchers in linguistic typology have produced various initiatives to collect typological data in a centralized and structured format out of which WALS is the most comprehensive one. We briefly discuss WALS in Section 3. WALS has been used before in computational linguistics, e.g., by Östling (2015) who performed a typological study of word order based on a corpus of New Testament translations in 986

Table 1: WALS features potentially relevant to determining word order.

languages. This study found that the word order typology created from such data and the information in WALS show a high level of agreement. Finally, Bisazza and Federico (2016) survey word reordering in machine translation and categorize languages based on their WALS features. In the present work, we make novel use of linguistic typological features from WALS for building a universal reordering model.

3 Linguistic Typology

The field of linguistic typology studies the similarities and distinguishing features between languages and aims to classify them accordingly. Among other areas, the World Atlas of Language Structures describes general properties of each language's word order. Overall, WALS contains 192 features, but not all features are relevant to determining word order. Many WALS features deal with phonology, morphology or lexical choice: Feature 129A, for example, describes whether the language's words for "hand" and "arm" are the same. Hence, for simplicity's sake we pre-select the subset of WALS features potentially relevant to determining word order and describe this subset in the following. Table 1 provides an overview of these features, along with an indication of the relative frequency distribution of each of their values over all languages in WALS.

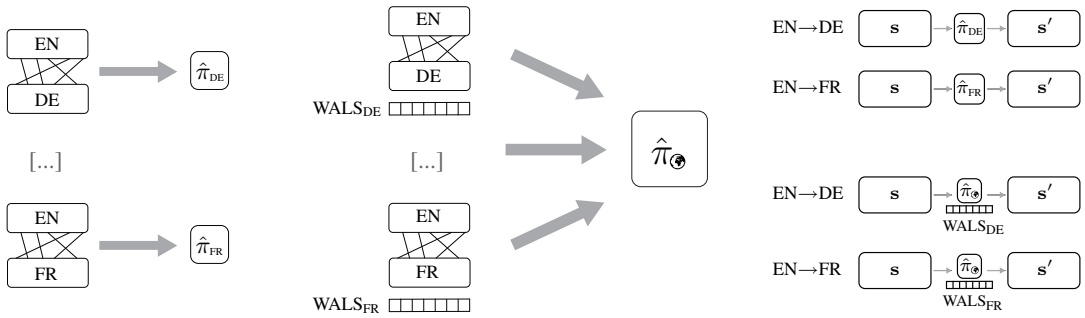
One of the most common ways to classify languages is according to the order of the subject, the object and the verb in a transitive clause. Accordingly, a number of WALS features describe the order of these elements. WALS Feature 81A classifies languages into 6 dominant clause-level word orders. For languages such as German or Dutch, which do not exhibit a single dominant clause-level order, Feature 81B describes 5 combinations of two acceptable word orders. Additionally, two features describe whether the verb precedes the subject (82A) and whether the verb precedes the object (83A). The position of adjuncts in relation to the object and the verb are described in Feature 84A and the internal structure of adpositional phrases is described in Feature 85A, which specifies whether the language uses pre-, post- or inpositions. Finally, the following properties describe the order of words in relation to nouns: Feature 86A specifies the position of genitives (e.g. *the girl's cat*), Feature 87A the position of adjectives (e.g. *yellow house*), Feature 89A the position of numerals (e.g. *10 houses*) and Feature 90A the position of relative clauses (e.g. *the book that I am reading*) in relation to the noun.

4 Universal Reordering Model

Our universal reordering model uses a preordering architecture similar to the (non-universal) preordering model of De Gispert et al. (2015), which in turn is based on the authors' earlier work on logistic regression and graph search for preordering (Jehl et al., 2014).

4.1 Basic Preordering Model

In this neural preordering model, a feed-forward neural network is trained to estimate the swap probabilities of nodes in the source-side dependency tree. The learning task is defined as follows: How likely is it that two nodes *a* and *b* are in the linear order (a, b) or (b, a) in the target language? Preordering then consists of finding the best sequence of swaps according to this model. While De Gispert et al. (2015)



(a) Basic preordering training. (b) Universal reordering model training. (c) Applying the models.

Figure 1: Training and application of basic preordering models and the universal reordering model.

use a depth-first branch-and-bound algorithm to find the best permutation, we use the k-best version of this algorithm and minimize the resulting preordering finite-state automaton to produce a lattice of word order choices (Daiber et al., 2016).

Model estimation Training examples are extracted from all possible pairs of children of the source dependency tree node, including the head itself. The crossing score of two nodes a and b (a precedes b in linear order) and their aligned target indexes A_a and A_b is defined as follows:

$$\mathrm{cs}(a, b) = |\{(i, j) \in A_a \times A_b : i > j\}|$$

A pair (a, b) is swapped if $\mathrm{cs}(b, a) < \mathrm{cs}(a, b)$, i.e. if swapping reduces the number of crossing alignment links. Training instances generated in this manner are then used to estimate the order probability $p(i, j)$ for two indexes i and j. The best possible permutation of each node's children (including the head) is determined via graph search. The score of a permutation π of length k consists of the order probabilities of all possible pairs:

$$\mathrm{score}(\pi) = \prod_{1 \le i < j \le k | \pi[i] > \pi[j]} p(i, j) \cdot \prod_{1 \le i < j \le k | \pi[i] < \pi[j]} 1 - p(i, j)$$

De Gispert et al. (2015) use a feed-forward neural network (Bengio et al., 2003) to predict the orientation of a and b based on 20 source features, such as the words, POS tags, dependency labels, etc.[2]

Permutation lattices To find the sequence of swaps leading to the best overall permutation according to the model, the score of a permutation is obtained by extending a partial permutation π' of length k' by one index i (Jehl et al., 2014). This score can be efficiently computed as:

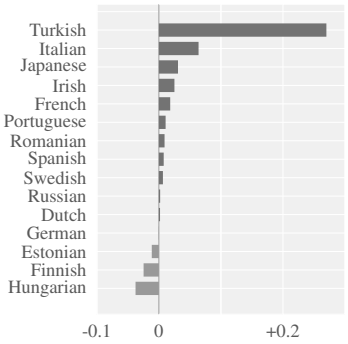
$$\mathrm{score}(\pi' \cdot \langle i \rangle) = \mathrm{score}(\pi') \cdot \prod_{j \in V | i > j} p(i, j) \cdot \prod_{j \in V | i < j} 1 - p(i, j)$$

Instead of extracting the single-best permutation, we use the *k*-best extension of branch-and-bound search (van der Poort et al., 1999). The resulting k-best permutations are then compressed into a minimal deterministic acceptor and unweighted determinization and minimization are performed using OpenFST (Allauzen et al., 2007).

4.2 Estimating a Universal Reordering Model

The universal reordering model differs from the basic neural preordering model in terms of features and training data collection. Differences in training data collection and application are illustrated in Figure 1.

[2]Full set of features: words, word classes, dependency labels, POS tags, coarse POS tags, word and class of the left-most and right-most child token, and the tokens' distance to their parent.



(a) Absolute 1-best Kendall τ improvements.

(b) N-best permutation quality on manually and autom. aligned data.

Figure 2: Intrinsic quality of word order predictions (improvement over source word order).

In addition to the source features used in the standard neural preordering model (cf. Section 4.1), we add a feature indicating the source word order of the two tokens, as well as the type of end-of-sentence punctuation. We then add WALS features 37, 46, 48, 52–57, 61, 66–69 and 81–97. WALS features are represented by their ID and the value for the current target language (e.g. "WALS_87A=Adj-Noun" or "WALS_87A=Noun-Adj"). For the most basic word order features (81, 82 and 85–91), we additionally add a feature indicating if the order of the node pair agrees with the order specified by the WALS feature.[3]

While the training data for a standard preordering model consists of source sentences and their target-language order retrieved via word alignments, the training data for the universal reordering model is comprised of training examples from a large number of language pairs. Because of the diversity of this data, special care has to be taken to ensure a balanced dataset. We use an equal number of sentences from each language-specific training subcorpus. Additionally, we reduce class imbalance by further randomly shuffling the source tokens when creating training instances. This ensures a balanced distribution of classes in the training data. The distribution of the two classes is 84.5%/15.5% in the original and 50.1%/49.9% in the randomized dataset.

4.3 Intrinsic Evaluation

We use NPLM (Vaswani et al., 2013) to train a feed-forward neural network to predict the orientation of two nodes a and b based on the features described in Section 4.2. The network consists of 50 nodes on the input layer, 2 on the output layer, and 50 and 100 on the two hidden layers. We use a learning rate of 0.01, batch sizes of 1000/64 and perform 60 training epochs, ensuring convergence of the log-likelihood on a validation set.

Preordering data The training data for the universal reordering model consists of a combined corpus of 30k sentence pairs each from the Tatoeba corpus (Tiedemann, 2012) for French, German, Japanese, Portuguese, Russian, and Spanish as well as 100k sentence pairs each from the OpenSubtitles 2012 corpus (Tiedemann, 2012) for Spanish, Portuguese, Italian, Danish, Romanian, Swedish, French, Greek, Russian, Polish, Arabic, Hebrew, Hungarian, Czech, Finnish, Icelandic, Dutch, Slovak, Chinese, German and Turkish. Word alignments for all corpora were produced using MGIZA (Och and Ney, 2003) using *grow-diag-final-and* symmetrization and performing 6, 6, 3 and 3 iterations of IBM M1, HMM, IBM M3 and IBM M4 respectively. To evaluate the model, we also use sets of manually word-aligned sentence for the following language pairs: En–Ja (Neubig, 2011), En–De (Padó and Lapata, 2006), En–It (Farajian et al., 2014), En–Fr (Och and Ney, 2003), En–Es and En–Pt (Graça et al., 2008).

Quality of word order predictions Figure 2a shows the intrinsically measured quality of the predictions by the universal reordering model. We use Kendall τ (Kendall, 1938) to measure the correlation

[3]Example for WALS feature 87A=Adj-Noun: $f(a,b) = \begin{cases} \text{"W87A:ab"} & \text{if } a = \text{adj} \wedge b = \text{noun} \\ \text{"W87A:ba"} & \text{if } a = \text{noun} \wedge b = \text{adj} \end{cases}$

Table 2: Properties of training data from the 2012 OpenSubtitles corpus.

between the predicted word order and the *oracle* word order determined via the word alignments. Figure 2a plots absolute Kendall τ improvement over the original, i.e. unreordered, source sentence for the single best permutation for a number of language pairs. The three worst-performing target languages in Figure 2a, Estonian, Finnish and Hungarian, are all morphologically rich, indicating that additional considerations may be required to improve word order for languages of this type. Figure 2b shows the quality of n-best permutations of the universal reordering model for both manually and automatically word-aligned sentence pairs. This table allows two observations: Firstly, the evaluation of word order quality using automatic alignments shows good agreement with the evaluation using manually word-aligned sentences, thus highlighting that automatic alignments should suffice for this purpose in most cases. Secondly, we can observe that for all datasets presented in this table little is gained from increasing the number of extracted permutations beyond 100 predictions. We therefore apply a maximum number of 100 permutations per sentence in all experiments presented in the rest of this paper.

5 Translation Experiments

To evaluate the universal reordering model in a real-world task, we perform translation experiments on various language pairs. As a baseline system, we use a plain phrase-based machine translation system using a distortion-based reordering model with a distortion limit of 6. When applying the universal reordering model, we produce a lattice from each sentence's best 100 word order permutations. This lattice is then passed to the machine translation system and no additional reordering is allowed. During training, we choose the source sentence permutation closest to the gold word order determined via the word alignments (lattice silver training; Daiber et al., 2016). The word alignments for the preordered training corpus are then recreated from the original MGIZA alignments and the selected permutation.[4]

Translation experiments are performed with a phrase-based machine translation system, a version of Moses (Koehn et al., 2007) with extended lattice support.[5] We use the basic Moses features and perform 15 iterations of batch MIRA (Cherry and Foster, 2012). To control for optimizer instability, we perform 3 tuning runs for each system and report the mean BLEU score for these runs (Clark et al., 2011). As a baseline we use a translation system with distortion limit 6 and a distance-based reordering model. For each language pair, a 5-gram language model is estimated using *lmplz* (Heafield et al., 2013) on the target side of the parallel corpus.

5.1 Evaluating on a Broad Range of Languages

In order to test the ideas presented in this paper, we evaluate our model on a broad range of languages from various language families. While doing so, it is important to ensure that the results are not skewed by differences in the corpora used for training and testing each language pair. We therefore build translation systems from the same corpus and domain for every language pair. We use the 2012 OpenSubtitles corpus[6] (Tiedemann, 2012) to extract 800,000 parallel sentences for each language pair, ensuring that every sentence pair contains only a single source sentence and that every source sentence contains at least 10 tokens. For each language pair, 10,000 parallel sentences are retained for tuning and testing. We use English as the source language in all language pairs. Table 2 summarizes properties of the data

[4]To keep the experiments manageable, we opted not to re-align the preordered training corpus using MGIZA. Re-alignment often leads to improved translation results, therefore we are likely underestimating the potential preordered translation quality.

Table 3: Translation experiments with parallel subtitle corpora.

used in these experiments. Apart from the average sentence length and the number of training examples, we report Bilingual Head Direction Entropy, BiHDE (Daiber et al., 2016), which indicates the difficulty of predicting target word order given the source sentence and its syntactic analysis. The language pairs in Table 2 are sorted by their BiHDE score, meaning that target languages whose word order is more deterministic are listed first. For each language pair, we train four translation systems:

Baseline The baseline system is a standard phrase-based machine translation system with a distance-based reordering model, a distortion limit of 6, and a maximum phrase length of 7.

Gold The gold system provides an indication for the upperbound achievable translation quality using preordering. In this system, the tuning and test sets are word-aligned along with the training portion of the corpus and the word alignments are then used to determine the optimal source word order. While this system provides an indication for the theoretically achievable improvement, this improvement may not be achievable in practice since not all information required to determine the target word order may be available on the source side (e.g. morphologically rich languages can allow several interchangeable word order variations). Apart from the source word order, the gold system is equivalent to the Baseline system.

No WALS As a baseline for our preordering systems, we create a translation system that differs from our universal reordering model only in the lack of WALS information. The preordering model is trained using the standard set of features described in Section 4.1 with only a single additional feature: the name of the target language. As in the WALS system, this system is applied by generating a minimized lattice from the 100-best permutations of each sentence and restricting the decoder's search space to this lattice. This system therefore isolates two potential sources of improvement: (1) improvement due to restricting the search space by the source dependency tree and (2) improvement from the preordering model itself, independent of the typology information provided by WALS.

WALS The WALS system applies the universal reordering model introduced in Section 4.2. For each language pair, the preordering model is provided with the target language and all the WALS features available for this language. The MT system's search space is then restricted using the minimized lattice of the 100-best word order permutations for each sentence and no additional reordering within the MT decoder is allowed.

The results of the translation experiments using the OpenSubtitles corpora are presented in Table 3. BLEU scores for the No WALS, WALS and Gold systems are reported as absolute improvement over the Baseline system (Δ BLEU). Over the three tuning runs performed for each system, we observe minor variance in BLEU scores (mean standard deviations: Baseline 0.04, No WALS 0.05, WALS 0.05, Gold 0.07), thus we report the mean BLEU score for each system's three runs.

While performing monotone decoding (i.e., allowing no reordering on top of the input lattice), the universal reordering model (WALS) enables improvements or comparable performance for the majority

Table 4: Translation experiments with varying training data and domains.

of the language pairs we evaluated while the No WALS system performs worse for most language pairs. This suggests that the improvements are not due to the neural preordering model or the lattice-based translation alone, but that the WALS information is crucial in enabling these results.

5.2 Influence of Domain and Data Size

While the experiments using the subtitle corpora presented in the previous section allow a fair comparison of a large number of language pairs, they also exhibit certain restrictions: (1) all experiments are limited to a single domain, (2) the source sentences are fairly short, and (3) to ensure consistent corpus sizes, a limited number of 800k sentence pairs had to be used. Therefore, we perform an additional set of experiments with data from different domains, longer sentences and a larger number of sentence pairs.

To train the translation systems for these experiments, we use the following training data: For En–It, En–Es and En–Pt, we train systems on Europarl v7 (Koehn, 2005). En–Hu uses the WMT 2008 training data,[7] En–Tr the SETIMES2 corpus (Tiedemann, 2009). Tuning is performed on the first 1512 sentences of newssyscomb2009+newstest2009 (En–It), newstest2009 (En–Es), newsdev2016 (En–Tr), newstest2008 (En–Hu), and the first 3000 sentences of news commentary v11 (En–Pt). As test sets we use the rest of newssyscomb2009+newstest2009 (En–It), newstest2013 (En–Es), newstest2016 (En–Tr), newstest2009 (En–Hu), and the first 3000 sentences of news commentary v11 not used in the dev set (En–Pt). All datasets are filtered to contain sentences up to 50 words long, and tokenization and truecasing is performed using the Moses tokenzier and truecaser. Statistics about each dataset and the dataset's domains, as well as translation results for the baseline system and the universal reordering model are summarized in Table 4. The results indicate that despite the longer sentences and different domains, the universal reordering model performs similarly as in the experiments performed in Section 5.1.

Our intrinsic evaluation (Section 4.3) as well as the extrinsic evaluation on a translation task (Section 5) indicate that a universal reordering model is not only feasible but can also provide good results on a diverse set of language pairs. The performance difference between the No WALS baseline and the universal reordering model (cf. Table 3) further demonstrates that the typological data points provided by WALS are the crucial ingredient in enabling this model to work.

6 Conclusion

In this paper, we show that linguistics in the form of linguistic typology and modern methods in natural language processing in the form of neural networks are not rivaling approaches but can come together in a symbiotic manner. In the best case, combining both approaches can yield the best of both worlds: the generalization power of linguistic descriptions and the good empirical performance of statistical models. Concretely, we have shown in this paper that it is possible to use linguistic typology information as input to a preordering model, thus enabling us to build a single model with a single set of model parameters for a diverse range of languages. As an empirical result, our findings provide support for the adequacy of the language descriptions found in linguistic typology. Additionally, they open the way for more compact and universal models of word order that can be especially beneficial for machine translation between language pairs with little parallel data. And finally, our results suggest that target-language typological features could play a key role in building better preordering models.

Abstract

We present a novel fusion model for domain adaptation in Statistical Machine Translation. Our model is based on the joint source-target neural network (Devlin et al., 2014), and is learned by fusing in- and out-domain models. The adaptation is performed by backpropagating errors from the output layer to the word embedding layer of each model, subsequently adjusting parameters of the composite model towards the in-domain data. On the standard tasks of translating English-to-German and Arabic-to-English TED talks, we observed average improvements of +0.9 and +0.7 BLEU points, respectively over a competition grade phrase-based system. We also demonstrate improvements over existing adaptation methods.

1 Introduction

The quality of machine translation systems is sensitive to the domain of the training data. More data, but out-of-domain data, may not be best suited and could even be harmful for specific translation tasks such as translating TED talks (Cettolo et al., 2014), patents (Fujii et al., 2010) and educational content (Guzmán et al., 2013). This is because of the difference in stylistic variations, vocabulary choices and word sense ambiguities across genres. *Domain adaptation* aims at finding the optimal point, that maximizes on the useful information available in the out-domain data, in favor of the in-domain data, while preventing it from degrading the performance of the system. This is either done by selecting a subset from the out-domain data, which is closer to the in-domain data (Matsoukas et al., 2009; Moore and Lewis, 2010), or by re-weighting the probability distribution in favor of the in-domain data (Foster and Kuhn, 2007; Sennrich, 2012).

Recently, there has been a growing interest in deep neural networks (DNNs) and word embeddings with application to numerous NLP problems. The ability to generalize and to better capture non-local dependencies gives edge to the neural models over their traditional counter-part. Several researchers have also attempted to employ DNNs for domain adaptation in SMT. Duh et al. (2013) and Durrani et al. (2015) used DNNs for data selection. Joty et al. (2015) proposed a DNN-based adaptation model for SMT that regularizes the loss function with respect to the in-domain model.

In this paper, we propose a deep fusion approach to domain adaptation for SMT. We use the Neural Network Joint Model (NNJM) proposed by Devlin et al. (2014) as our base model. However, rather than training the model on a plain concatenation of in- and out-domain data or a weighted concatenation (Joty et al., 2015), we first train in- and out-domain NNJM models, and then learn a composite model by readjusting their parameters through backpropagating errors from the output layer to the word embedding layer of each model. The intuition behind learning the models separately, is to learn in-domain model parameters without contaminating them with the out-domain data. In a variant of our model, we restrict backpropagation to only the outermost hidden layer and adjust only the final layer combination weights. The composite model is used as a feature during decoding, where it can help assigning higher scores to the hypotheses that represent lexical choices and patterns preferred by the in-domain data.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 3177–3187, Osaka, Japan, December 11-17 2016.

We evaluated our model on a standard task of translating TED talks for English-to-German and Arabic-to-English language pairs. Compared to baseline NNJM models trained on a concatenation of in- and out-domain data, our model achieves an average improvement of up to 0.9 BLEU points. The most relevant to our work are the NDAM model of Joty et al. (2015) and the *fine-tuning* method of Luong and Manning (2015). The NDAM model uses data dependent regularization in the NNJM model to weight training instances, while training the model on the concatenated data. The fine-tuning method first trains the NNJM on the concatenated data, then runs a few additional epochs on the in-domain data to tune the model towards in-domain. We found our method to outperform both the NDAM and fine-tuning methods. We also carried experiments against phrase-table weighting methods such as instance weighting (Sennrich, 2012), and phrase-table fill-up combination (Bisazza et al., 2011) and found our approach to outperform these. Our approach is complementary and the gains obtained were found to be additive on top of phrase-table adaptation and MML-based data-selection (Axelrod et al., 2011).

The remainder of this paper is organized as follows. Section 2 briefly describes neural network joint model. Section 3 describes our fusion model for domain adaptation. Section 4 presents results and analysis. Section 5 gives an account on the related work and Section 6 concludes the paper.

2 Neural Network Joint Model

Neural models are quickly becoming the state-of-the-art in machine translation. The ability to generalize and better capture non-local dependencies gives them edge over traditional models. The two most prevalent approaches are to use NNs as a feature inside SMT decoder (Vaswani et al., 2013; Devlin et al., 2014), or as an end-to-end translation system (Luong et al., 2015; Bahdanau et al., 2015; Sennrich et al., 2016) designed as fully trainable model of which every component is tuned based on training corpora to maximize its translation performance. Our work falls in the former category and extends NNJM.

The NNJM model learns a feed-forward neural network from augmented streams of source and target sequences. For a bilingual sentence pair (S, T), NNJM defines a conditional probability distribution:

$$P(T|S) \approx \prod_{i=1}^{|T|} P(t_i|t_{i-1} \dots t_{i-n+1}, \mathbf{s_i}) \tag{1}$$

where, $\mathbf{s_i}$ is an m-word source window for a target word t_i based on the one-to-one alignment between T and S. This is essentially an $(m+n)$-gram bilingual language model originally proposed by Bengio et al. (2003). As shown in Figure 1, each input word in the context has a D dimensional vector representation in the shared embedding layer $E \in \mathbb{R}^{|V_i| \times D}$, where V_i is the input vocabulary; E is considered as a model parameter to be learned. The context of the sequence is represented by a concatenated vector $\mathbf{x_n} \in \mathbb{R}^{(m+n-1)D}$, which is then passed through non-linear hidden layers to learn high-level abstract representations. The output layer defines a `softmax` over the output vocabulary V_o:

$$P(y_n = k|\mathbf{x_n}, \theta) = \frac{\exp\ (\mathbf{w}_k^T \mathbf{z_n})}{\sum_{m=1}^{|V_o|} \exp\ (\mathbf{w}_m^T \mathbf{z_n})} \tag{2}$$

where $\mathbf{z}_n = \phi(\mathbf{x_n})$ defines the non-linear transformations of $\mathbf{x_n}$ through one or more hidden layers, and $\mathbf{w}_k$ are the weights from the outermost hidden layer to the output layer. By setting m and n to be sufficiently large, NNJM can capture long-range cross-lingual dependencies between words. The maximum (log) likelihood objective of the model can be written as:

$$J(\theta) = \sum_{n=1}^{N} \sum_{k=1}^{|V_o|} y_{nk}\ log\ P(y_n = k|\mathbf{x_n}, \theta) \tag{3}$$

where, $y_{nk} = I(y_n = k)$ is an indicator variable (i.e., y_{nk}=1 when y_n=k, otherwise 0).

A major efficiency bottleneck of NNJM is to surmount the computational cost involved in training the model and applying it for MT decoding. Devlin et al. (2014) proposed two tricks to speed up computation in decoding. The first one is to pre-compute the hidden layer computations and fetch them directly as

needed during decoding. The second technique is to train a *self-normalized* NNJM to avoid computation of the softmax normalization factor (i.e., the denominator in Equation 2) in decoding. However, self-normalization does not solve the computational cost of training the model. In the following, we describe a method that addresses this issue.

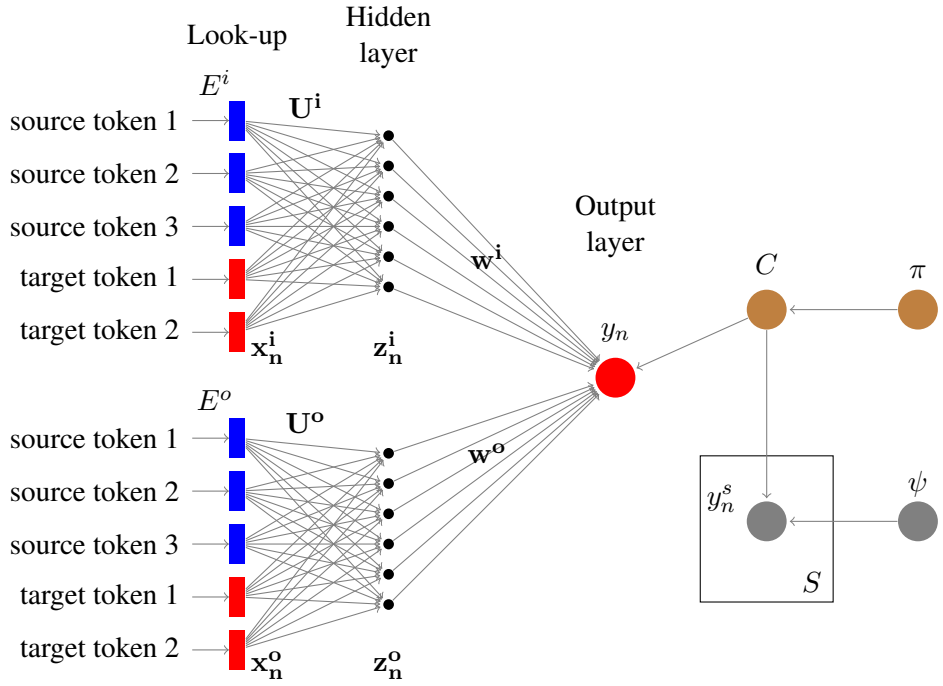

Figure 1: Fusion of two simplified neural network joint models with noise contrastive loss. For illustration, we use 3-gram target words (i.e., 2-words history) and a source context of size 3. The output y_n is shown as a single categorical variable (scalar) as opposed to the traditional one-hot vector representation.

Noise Contrastive Estimation: Like other deep neural models, optimization in NNJM is performed using first-order online methods, such as stochastic gradient ascent (SGA) with standard *backpropagation* algorithm. Unfortunately, training NNJM could be impractically slow using the standard maximum likelihood objective (Eq. 3), because for each training instance $(\mathbf{x_n}, y_n)$, the softmax output layer (Eq. 2) needs to compute a summation over all words in the output vocabulary.

One way to avoid this repetitive computation is to use Noise contrastive estimation or NCE (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012), which adds S noise samples (see Figure 1) for each training instance by sampling from a known noise distribution (e.g., `unigram`). NCE is then defined as such to discriminate a *true* instance from a *noisy* one. Let $C \in \{0, 1\}$ denote the class of an instance with $C = 1$ indicating *true* and $C = 0$ indicating *noise*. NCE maximizes the following conditional log likelihood:

$$J(\theta) = \sum_{n=1}^{N} \Big[log[P(C = 1|y_n, \mathbf{x}_n, \theta)] + \sum_{m=1}^{M} log[P(C = 0|y_n^m, \mathbf{x}_n, \psi)] \Big], \quad (4)$$

which can be simplified as $J(\theta) = \sum_{n=1}^{N} \sum_{k=1}^{|V_o|} \Big[\; y_{nk} \; log \; \sigma_{nk} + \sum_{s=1}^{S} y_{nk}^s \; log \; \psi_{nk} \; \Big]$, where $\sigma_{nk}{=}\exp(\mathbf{w}_k^T \mathbf{z_n})$ is the unnormalized score and $\psi_{nk}{=}P(y_n^s = k|\mathbf{x}_n, \psi)$ is the noise distribution; y_{nk} and y_{nk}^s are indicator variables indicating the true output and the noise sample, respectively. NCE reduces the number of computations needed at the output layer from $|V_o|$ to $S + 1$, where $S << |V_o|$.

3 Neural Fusion Models

The NNJM model trained from a simple concatenation of large and diverse multi-domain data with in-domain data could be sub-optimal, because the resulting probability distribution can diverge from the

target domain hurting the system performance. The goal in domain adaptation is to restrict this drift while still making the best use of the available data. Joty et al. (2015) recently proposed a weighted concatenation approach using data dependent regularizations in the loss function. While it helps, their approach does not fully prevent out-domain data from contaminating the model parameters.

3.1 Fusion Models

We take a different approach of learning in- and out-domain models separately, then fusing them together by readjusting their parameters towards in-domain data.

Fusion Model-I: Let θ^i and θ^o be the parameter sets of the trained in- and out-domain NNJMs, respectively. We combine the two models by redefining the `softmax` output layer (Eq. 2) as follows:

$$P(y_n = k|\mathbf{x_n^i}, \mathbf{x_n^o}, \theta^i, \theta^o) = \frac{\exp\ ([\mathbf{w}_k^i, \mathbf{w}_k^o]^T [\mathbf{z}_n^i, \mathbf{z}_n^o])}{\sum_{m=1}^{|V_o|} \exp\ ([\mathbf{w}_m^i, \mathbf{w}_m^o]^T [\mathbf{z}_n^i, \mathbf{z}_n^o])}$$

where $[\mathbf{w}_k^i, \mathbf{w}_k^o]$ is the concatenation of the output layer weights of in-domain and out-domain models; similarly, $[\mathbf{z}_n^i, \mathbf{z}_n^o]^T$ is the concatenation of the activations at the outermost hidden layer of the two models. Figure 1 demonstrates the fusion process with two simplified NNJMs: (*i*) the in-domain NNJM parameterized by $\theta^i = [E^i, U^i, W^i]$, and (*ii*) the out-domain NNJM parameterized by $\theta^o = [E^o, U^o, W^o]$.[1]

We train this model on the in-domain data using backpropagation on the NCE objective, where each participating model uses its own noise distribution. The errors (i.e., gradients) of the objective with respect to the final layer weight vectors $\mathbf{w}_j^d$ are:

$$\nabla_{\mathbf{w}_j^d} J(\theta) = \sum_{n=1}^{N} \Big[(y_{nj} - \sigma_{nj}) \mathbf{z}_n^d \Big] \tag{5}$$

where $d \in \{i, o\}$ in the superscript denotes the domain, $y_{nj} = I(y_n = j)$ is an indicator variable, and $\sigma_{nj} = \exp(\mathbf{w}_j^T \mathbf{z_n^d})$ is the unnormalized score in the output. We train the model by backpropagating these errors from the output layer of the neural network to the word embedding layer (i.e., look-up layer) of each model. Therefore, all the parameters of the participating models (i.e., E, U and W) are fine-tuned on the in-domain data. Such training yields adjusted models that are collectively optimized for the target in-domain data.

Fusion Model-II: A variation of the above model is to tune only the final layer combination weights $[\mathbf{w}_k^i, \mathbf{w}_k^o]$, which can be achieved by restricting the backpropagation only to the outermost hidden layer of the neural network models. This model is faster to train than the above model but could suffer from limited representation power.

3.2 Interpolation

Another approach we explored is to combine in- and out-domain NNJM models through linear interpolation. This approach has been extensively tried out in the literature to interpolate phrase-translation models (Foster and Kuhn, 2007). Several metrics such as tf/idf, LSA or perplexity have been employed for weighting. Here we interpolate multiple NNJM models instead. The mixture weights are computed by optimizing perplexity on the in-domain tuning set[2] using a standard EM-based algorithm as described below:

Model Weighting by EM: Let $\theta_d \in \{\theta_1, \ldots \theta_D\}$ represent an NNJM model trained on domain d, where D is the total number of domains. The probability of a sequence $\mathbf{x}_n$ can be written as a mixture of D probability densities, each coming from a different model:

[1] Although we define the fusion for two NNJM models, this can be easily generalized to multiple models.

[2] The tuning-set is required to be word-aligned and then converted into an augmented streams of source and target strings (for NNJM) to compute model-wise perplexities.

$$P(\mathbf{x}_n|\theta,\lambda) = \sum_{d=1}^{D} P(\mathbf{x}_n|z_n = d, \theta_d)\ \lambda_d$$

where $P(\mathbf{x}_n|z_n = d, \theta_d)$ represents the probability of $\mathbf{x}_n$ assigned by model θ_d, and the mixture weights λ_d satisfy $0 \leq \lambda_d \leq 1$ and $\sum_{d=1}^{D} \lambda_d = 1$. In our setting, $\theta = \{\theta_1, \ldots \theta_D\}$ is known, and we can use EM to learn the mixture weights. The expected complete data log likelihood is given by:

$$E[L(\lambda)] = \sum_{n=1}^{N}\sum_{d=1}^{D} r_{nd}\ log\left[P(\mathbf{x}_n|z_n = d, \theta_d)\lambda_d\right]$$

where $r_{nd} = P(z_n = d|\mathbf{x}_n, \theta_d, \lambda_d^{t-1})$ is the responsibility that domain d takes for data point n given the mixing weight in the previous step λ_d^{t-1}. In the E-step, we compute r_{nd} and we update λ in the M-step. More specifically:

E-step: Compute $r_{nd}^t = \frac{\lambda_d^{t-1} P(\mathbf{x}_n|z_n=d,\theta_d)}{\sum_{d'=1}^{D} \lambda_{d'}^{t-1} P(\mathbf{x}_n|z_n=d,\theta_{d'})}$

M-step: Update $\lambda_d^t = \frac{1}{N}\sum_{n=1}^{N} r_{nd}^t$

Once we have learned the relative weights of the models based on the in-domain tuning data, we can linearly interpolate the models as:

$$P_{nnjm}(T|S) \approx \prod_{i=1}^{|T|}\sum_{d} \lambda_d P(t_i|t_{i-1}\ldots t_{i-n+1}, \mathbf{s_i}, \theta_d)$$

An alternative way to combine the models is through log-linear interpolation by optimizing weights, directly on BLEU, along with other features inside of the SMT pipeline.

Note that both fusion and linear interpolation have the same number of parameters, which is the sum of the size of the base models. In fusion, we readjust all the parameters of the base models (or just the output layer weights in fusion-II), where in linear interpolation, we only learn their mixing weight.

4 Experiments

Data: We experimented with the data made available for the translation task of the International Workshop on Spoken Language Translation IWSLT (Cettolo et al., 2014). We used TED talks as our in-domain ($\approx$ 177K sentences) corpus. For Arabic-to-English, we used the multiUN ($\approx$ 3.7M sentences) (Eisele and Chen, 2010) as our out-domain corpora. For English-to-German, we used data made available ($\approx$ 4.4M sentences) for the 9^{th} Workshop on Machine Translation[3] as our out-domain data. Language models were trained on all the available monolingual data (English: $\approx$ 287.3M and German: $\approx$ 59.5M sentences). Machine translation systems were tuned on concatenation of the dev- and test2010 and evaluated on test2011-2013 datasets. We used *Farasa* (Abdelali et al., 2016) to tokenize Arabic and the default *Moses* tokenizer for English-and German. All data was truecased. See Table 1 for data sizes.

NN Training: The NNJM models were trained using the NPLM[4] toolkit (Vaswani et al., 2013) with the following settings: a target context of 5 words and an aligned source window of 9 words. We restricted source and target side vocabularies to the 20K and 40K most frequent words in the in-domain data.[5] The word vector size D and the hidden layer size were set to 150 and 750, respectively. Training was done using SGD with NCE using 100 noise samples and a mini-batch size of 1000. All models were trained for 15 epochs. Training NN models is expensive.[6] In the interest of time, we therefore reduced the NN

[3]http://www.statmt.org/wmt14/translation-task.html

[4]http://nlg.isi.edu/software/nplm/

[5]Less frequent words are mapped to `unk` class if they were found in the in-domain data or $\texttt{unk}_o$ otherwise. Please refer to (Joty et al., 2015) for how the vocabularies from in-domain and out-of-domain are mapped.

[6]Training model with the whole corpus requires roughly 12 days of wall-clock time (18 hours/epoch) to train NNJM models on our machines (on a Linux Ubuntu 12.04.5 LTS running on a 16 Core Intel Xeon E5-2650 2.00Ghz and 64Gb RAM). We ran a baseline experiment with all the data and did not find it better than the system trained on randomly selected subset.

Table 1: Statistics of the English-German and Arabic-English training corpora in terms of Sentences and Tokens (represented in millions). ep = Europarl, cc = Common Crawl, un = United Nations

training to a subset of 1 million sentences containing all the in-domain data and a random selection of sentences from the out-domain data.

Machine Translation Settings: We trained a Moses system (Koehn et al., 2007), with the settings described in (Birch et al., 2014): a maximum sentence length of 80, Fast-Aligner for word-alignments (Dyer et al., 2013), an interpolated Kneser-Ney smoothed 5-gram language model (Heafield, 2011), lexicalized reordering model (Galley and Manning, 2008), a 5-gram operation sequence model (Durrani et al., 2013) and other defaults. We used k-best batch MIRA (Cherry and Foster, 2012) for tuning. Arabic OOVs were transliterated using unsupervised transliteration module (Durrani et al., 2014) in Moses.

Baselines: Baseline MT systems were trained by simply concatenating all the data. We included NNJM model trained on a plain concatenation of the data as a feature in our baseline system. In the adapted systems, we either replaced it with the NDAM models trained on weighted concatenation, or with our fusion models (NFM*), where models are trained independently and adjusted towards in-domain data or by interpolating them linearly (EM-weighting) or log-linearly. We also tried the approach of Luong and Manning (2015) by *Fine Tuning* baseline model towards in-domain data (i.e., by training the neural network model for additional epochs on in-domain data). We trained for 10 more epochs.

Phrase-table Adaptation: We also compared performance of our models against state-of-the-art model adaptation techniques available in Moses. Rather than training the MT systems on concatenated data, we train phrase-tables from in- and out-domain data separately and combine them through *Linear Phrase-table Interpolation*, *Instance Weighting* and *Fill-up* methods.[7]

Data Selection: Finally, we compared our system against MML-filtering (Axelrod et al., 2011), although this technique falls in the array of data-selection methods unlike our method which is a model weighting technique. We selected 0%, 2.5%, 5%, 10%, 20%, 40% and 100% out-domain data, and trained MT systems by concatenating the selected data with the in-domain data. The optimal thresholds were found to be 20% and only 5% in English-German and Arabic-English[8] respectively.

Comparing with Neural Model Weighting: The first row in Table 2 shows results for the baseline system, which includes NNJM trained on plain concatenation. The next set of rows show results for systems, where the NNJM model is adapted using weighted concatenation (NDAM), by interpolating (linearly or log-linearly) in- and out-domain models, by fine tuning the baseline model by running epochs on in-domain data only. This method gave significantly better results on the English-German task, but was not found effective in the Arabic-English direction. Next rows show results of our neural fusion

[7] Word alignment is still carried on the concatenated data.

[8] Sajjad et al. (2013) selected 3% of the UN data in their best competition grade system.

Table 3: Comparing with Translation Model Adaptation Techniques – Linear Interpolation and Instance Weighting (Senrich 2012), Fill-up Method (Bisazza et al. 2011), NFM = Neural Fusion Model

models (NFM*). Our models significantly[9] outperformed the baseline system and were also found better than other neural adapted models. We found that our model gets higher weights than the baseline NNJM model (0.054 compared to 0.047 in En-De and 0.043 compared to 0.040 in Ar-En) in MERT training.

Fusion Model-I (NFM-I), which performs deeper fusion (i.e., till the embedding layer) worked better than Fusion Model-II (NFM-II), where backpropagation is restricted only to the out-most hidden layer, showing that there is an additional value in doing a deeper fusion.

Comparing with Phrase-table Weighting: Next we compare our model with the domain adaptation methods available in Moses (See Table 3). Here instead of adapting the NNJM model, we perform adaptation on translation-tables, by interpolating in- and out-domain phrase-tables, through instance weighting or through fill-up method. Instance weighting method gave best improvements among the lot, however, our fusion model outperform these methods in both language pairs and in most of the test-sets. Additional experiments combining phrase-table adaptation and fusion model found gains to be additive in Arabic-to-English language pair. But no further improvements were observed in English-to-German, except for test2011.

Comparing with Data Selection: In Table 4 we experiment with MML-based filtering and probe whether our model can also improve on top of data selection. Firstly, selecting no out-domain data degrades the English-to-German system. On the contrary, the Arabic-to-English system substantially improves. This shows that general domain data is useful for English-to-German and much of the out-domain data (UN corpus) used in these experiments is harmful in the case of Arabic-to-English. In comparison, data selection was found to be less useful in the case of English-to-German. But we found

[9] $p < 0.05$ using bootstrap resampling (Koehn, 2004), with 1000 samples.

Table 4: Comparing with MML (Axelrod et al 2011)

that using our fusion model instead of baseline NNJM in either system still gave improvements (+0.5 and +0.3 in English-German and Arabic-English, respectively).

5 Related Work

Previous work on domain adaptation in MT can be broken down broadly into two main categories namely *data selection* and *model adaptation*.

Data selection has shown to be an effective way to discard poor quality or irrelevant training instances, which when included in an MT system, hurts its performance. Selection based methods can be helpful to reduce computational cost when training is expensive and also when memory is constrained. Data selection was done earlier for language modeling using information retrieval techniques (Hildebrand et al., 2005) and perplexity measures (Moore and Lewis, 2010). Axelrod et al. (2011) further extended the work of Moore and Lewis (2010) to translation model adaptation by using both source- and target-side language models. Duh et al. (2013) used a recurrent neural language model instead of an ngram-based language model to do the same. Translation model features were used recently by (Liu et al., 2014; Hoang and Sima'an, 2014) for data selection. Durrani et al. (2015) performed data selection using operation sequence model and NNJM models.

An alternative to completely filtering out less useful data is to minimize its effect by down-weighting it. It is more robust than selection since it takes advantage of the complete out-domain data with intelligent weighting towards the in-domain. Our work falls in this line of research. Matsoukas et al. (2009) proposed a classification-based sentence weighting method for adaptation. Foster et al. (2010) extended this by weighting phrases rather than sentence pairs. Other researchers have carried out weighting by merging phrase-tables through linear interpolation (Finch and Sumita, 2008; Nakov and Ng, 2009) or log-linear combination (Foster and Kuhn, 2009; Bisazza et al., 2011; Sennrich, 2012) and through phrase training based adaptation (Mansour and Ney, 2013). Chen et al. (2013) used a vector space model for adaptation at the phrase level. Every phrase pair is represented as a vector, where every entry in the vector reflects its relatedness with each domain.

Other work on domain adaptation includes but not limited to studies focusing on topic models (Eidelman et al., 2012; Hasler et al., 2014), dynamic adaptation without in-domain data (Sennrich et al., 2013; Mathur et al., 2014) and sense disambiguation (Carpuat et al., 2013).

6 Conclusion and Future Work

We presented a deep fusion model based on the neural network joint model (NNJM) of Devlin et al. (2014). The model is learned by fusing in- and out-domain NNJM models into a composite model by adjusting their parameters in favor of the in-domain data. When used as a feature during decoding, our model obtains statistically significant improvements on top of a competition grade phrase-based baseline system. We also showed improvements compared to previous adaptation methods. Further gains were obtained when our models were combined with existing methods. Although this study focused on fusing multiple neural models for domain adaptation in phrase-based SMT, the central idea can be adopted in the end-to-end NMT systems (Bahdanau et al., 2015), where the goal will be to fuse multiple NMT systems. We intend to explore this idea in our future work.

Abstract

Being able to induce word translations from non-parallel data is often a prerequisite for cross-lingual processing in resource-scarce languages and domains. Previous endeavors typically simplify this task by imposing the one-to-one translation assumption, which is too strong to hold for natural languages. We remove this constraint by introducing the Earth Mover's Distance into the training of bilingual word embeddings. In this way, we take advantage of its capability to handle multiple alternative word translations in a natural form of regularization. Our approach shows significant and consistent improvements across four language pairs. We also demonstrate that our approach is particularly preferable in resource-scarce settings as it only requires a minimal seed lexicon.

1 Introduction

Bilingual lexica provide word-level semantic equivalence information across languages, and prove to be valuable for a range of cross-lingual natural language processing tasks (Och and Ney, 2003; Levow et al., 2005; Täckström et al., 2013, *inter alia*). As building bilingual lexica from parallel corpora has been solved by word alignment (Och and Ney, 2003), researchers have turned their attention to non-parallel corpora. Accompanied by a small seed lexicon, non-parallel corpora are usually the only resources available in resource-scarce languages and domains, making the task of bilingual lexicon induction both important and challenging. A variety of statistical methods have been proposed to induce bilingual lexica from non-parallel data (Rapp, 1999; Koehn and Knight, 2002; Fung and Cheung, 2004; Gaussier et al., 2004; Haghighi et al., 2008; Ravi and Knight, 2011; Vulić et al., 2011; Vulić and Moens, 2013a; Vulić and Moens, 2013b; Dong et al., 2015). With the surge of word embeddings trained by neural networks, recent approaches that learn bilingual word representations from non-parallel data for bilingual lexicon induction have also shown promise (Mikolov et al., 2013b; Vulić and Moens, 2015).

However, none of the existing methods explicitly considers multiple alternative translation, i.e., the phenomenon that one source language word may have multiple possible translations in the target language. For example, the (romanized) Chinese word "*qiche*" can be translated to "car" or "automobile" in English, while the English word "car" can mean "*qiche*" or "*chexiang*" (railway carriage) in Chinese. Although prevalent among natural languages (Resnik and Yarowsky, 1999), multiple alternative translation is basically ignored by prior bilingual lexicon inducers; instead, they typically impose the one-to-one translation assumption (Vulić and Moens, 2013b) for simplicity. This represents a major drawback of existing bilingual lexicon induction approaches.

There has been one study that shows potential for tackling this issue. It introduces the Earth Mover's Distance (EMD) (Zhang et al., 2016). Given learned bilingual word embeddings, the EMD is used as a post-processing step to match vocabularies cross-lingually, which can be interpreted as word translation. Unlike the traditional K nearest neighbors leaving the determination of the number of translation proposals K to the user, the EMD automatically determines the list of translation candidates for each source word.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3188–3198, Osaka, Japan, December 11-17 2016.

Figure 1: An illustration of bilingual word embeddings for translating from (romanized) Chinese to English. Arrows indicate translations, and solid ones are correct. (a) The nearest neighbor incorrectly translates "*chexiang*" to "automobile", and does not allow finding "car" as the other translation of "*qiche*". (b) The Earth Mover's Distance translates correctly. It associates words with weights, as indicated by the sizes of the shapes.

In this work, we propose to bring the EMD's capability to training. Intuitively, as the EMD in the post-processing step is able to connect a source word with multiple target word translations, it can play a more important role during training by driving the word vectors of these mutual translations to be closer. We therefore expect that the bilingual word embeddings learned this way will be more suitable for encoding multiple alternative translation by harnessing the power of the EMD. Our experiments validate the effectiveness of this strategy. A summary of our contributions is as follows:

- We introduce the Earth Mover's Distance into the training of bilingual word embeddings, and interpret it as a natural form of regularization for the overall learning objective (Section 3).
- We demonstrate significant and consistent performance improvement from our strategy across four language pairs (Sections 6.1 and 6.2).
- We investigate the effect of the number of seed word translation pairs, and find our approach to be most appealing with few seeds, in line with typical resource-scarce scenarios (Section 6.3).

2 Background

As an embedding-based approach to bilingual lexicon induction, the model consists of matrices $W^{\mathrm{S}} \in \mathbb{R}^{D \times V^{\mathrm{S}}}$ and $W^{\mathrm{T}} \in \mathbb{R}^{D \times V^{\mathrm{T}}}$, which pack up D-dimensional word embeddings of source and target languages with vocabulary sizes V^{S} and V^{T}, respectively. After training, these bilingual word embeddings are supposed to properly lie in the D-dimensional space that encodes cross-lingual semantic equivalence. To build a bilingual lexicon, or equivalently, to translate a source word into the target language, the nearest neighbor is typically employed to retrieve the target word embedding that is closest to the source word embedding.

The nearest neighbor has its limitations, as argued by Zhang et al. (2016). For one thing, the retrieval operation is inherently local (Figure 1(a)). Instead, they introduce the Earth Mover's Distance (EMD), which offers to match two sets of points with minimum total cost. For the word translation task, bilingual word embeddings can be naturally viewed as two sets of points. Therefore, given bilingual word embeddings, the EMD can perform word translation by providing optimal vocabulary-level matching in a holistic fashion (Figure 1(b)). This is achieved via the following optimization program:

$$\begin{aligned} &\min_{T} \sum_{t=1}^{V^{\mathrm{T}}} \sum_{s=1}^{V^{\mathrm{S}}} T_{ts} C_{ts} \\ &s.t.\ T_{ts} \geq 0 \\ &\quad \sum_{s=1}^{V^{\mathrm{S}}} T_{ts} \leq f_t^{\mathrm{T}}, t \in \{1, ..., V^{\mathrm{T}}\} \\ &\quad \sum_{t=1}^{V^{\mathrm{T}}} T_{ts} = f_s^{\mathrm{S}}, s \in \{1, ..., V^{\mathrm{S}}\} \end{aligned} \tag{1}$$

where C_{ts} defines the cost of matching the target word w_t^{T} and the source word w_s^{S} (illustrated by the distance between words in Figure 1), and f_t^{T} (resp. f_s^{S}) is the weight associated with w_t^{T} (resp. w_s^{S}) (illustrated by the sizes of the shapes in Figure 1(b)). The weights are chosen to be the number of times a word appears in the corpus. Once the linear program is solved, the matrix T stores the matching information between source and target vocabularies. This cross-lingual matching can be interpreted as translation. For example, a non-zero T_{ts} can be seen as evidence to translate the source word w_s^{S} to the target word w_t^{T}.

Besides the vocabulary-level matching, the EMD program brings an additional benefit. As mentioned in Section 1, it automatically retrieves multiple translations for a source word as long as the program finds it appropriate (cf. Figure 1). In the following section, we will strengthen this desirable capability by bringing the EMD program from a post-processing step to the training phase.

3 Approach

In typical scenarios, resources available to bilingual lexicon inducers include non-parallel corpora $\mathcal{C}^{\mathrm{S}}$ and $\mathcal{C}^{\mathrm{T}}$, and a seed lexicon $\mathbf{d}$. In order to utilize these resources to train bilingual word embeddings, a straightforward idea is to devise a learning objective that combines a monolingual term and a seed term.

The monolingual term $\mathcal{J}_{\mathrm{mono}}$ is responsible for explaining regularities in corpora $\mathcal{C}^{\mathrm{S}}$ and $\mathcal{C}^{\mathrm{T}}$. Since the two corpora are non-parallel, $\mathcal{J}_{\mathrm{mono}}$ consists of two monolingual submodels that are independent of each other:

$$\mathcal{J}_{\mathrm{mono}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}\right) = \mathcal{J}_{\mathrm{mono}}^{\mathrm{S}}\left(W^{\mathrm{S}}\right) + \mathcal{J}_{\mathrm{mono}}^{\mathrm{T}}\left(W^{\mathrm{T}}\right). \tag{2}$$

As the common practice (Gouws et al., 2015), we choose the well established skip-gram model (Mikolov et al., 2013a) for our monolingual term.

The seed term $\mathcal{J}_{\mathrm{seed}}$ encourages embeddings of word translation pairs in a seed lexicon $\mathbf{d}$ to move near, which can be achieved via a L_2 regularizer:

$$\mathcal{J}_{\mathrm{seed}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}\right) = -\sum_{\langle s,t\rangle \in \mathbf{d}} \left\|W_s^{\mathrm{S}} - W_t^{\mathrm{T}}\right\|^2, \tag{3}$$

where $s \in \left\{1, ..., V^{\mathrm{S}}\right\}$ and W_s^{S} is the s-th column of W^{S} (i.e. the embedding of the s-th source word w_s^{S}), and notations are similar for the target side.

However, as shown in our experiment, a simple linear combination of the monolingual term and the seed term is insufficient to provide satisfactory performance. We propose to introduce the Earth Mover's Distance into the training phase, as an additional term in the learning objective:

$$\mathcal{J}_{\mathrm{EMD}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}, T\right) = -\sum_{t=1}^{V^{\mathrm{T}}}\sum_{s=1}^{V^{\mathrm{S}}} T_{ts}C_{ts} \tag{4}$$

with constraints

$$\begin{gathered} T_{ts} \geq 0 \\ \sum_{s=1}^{V^{\mathrm{S}}} T_{ts} \leq f_t^{\mathrm{T}}, t \in \left\{1, ..., V^{\mathrm{T}}\right\} \\ \sum_{t=1}^{V^{\mathrm{T}}} T_{ts} = f_s^{\mathrm{S}}, s \in \left\{1, ..., V^{\mathrm{S}}\right\} \end{gathered}. \tag{5}$$

Note that, unlike the post-processing case (1), the ground distance matrix C is now parametrized by bilingual embeddings W^{S} and W^{T}, and therefore adjustable during training.

Putting everything together, we arrive at our overall learning objective to maximize:

$$\mathcal{J}\left(W^{\mathrm{S}}, W^{\mathrm{T}}, T\right) = \mathcal{J}_{\mathrm{mono}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}\right) + \lambda_{\mathrm{s}}\mathcal{J}_{\mathrm{seed}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}\right) + \lambda_{\mathrm{e}}\mathcal{J}_{\mathrm{EMD}}\left(W^{\mathrm{S}}, W^{\mathrm{T}}, T\right) \tag{6}$$

with constraints (5) inherited from the EMD. The hyperparameters λ_{s} and λ_{e} control the relative weighting of the terms. In this form, we can naturally view the EMD term as a regularizer that can potentially

drive the embedding space to be more suitable for inducing bilingual lexica, especially multiple alternative word translation pairs.

The joint maximization of the overall learning objective (6) is clearly non-convex. In order to take advantage of the efficient solver specialized for the EMD program, we propose an alternating optimization procedure:

1. Fix W^{S} and W^{T}, and optimize with respect to T. This reduces to the usual linear EMD program with fixed ground distance, and the optimization can be achieved with the existing solver.

2. Fix T, and optimize with respect to W^{S} and W^{T}. Now the optimization can be easily achieved with stochastic gradient ascent.

4 Implementation

In this section, we describe details of a practical implementation of our approach.

4.1 Optimization

In our overall learning objective (6), unlike the other two, the EMD term $\mathcal{J}_{\mathrm{EMD}}$ requires an alternating optimization procedure. In order to allow each term to contribute to the learning process, we follow these steps. First, in each pass of the corpus (i.e. an epoch) the monolingual term $\mathcal{J}_{\mathrm{mono}}$ and the seed term $\mathcal{J}_{\mathrm{seed}}$ are optimized with asynchronous stochastic gradient ascent (Gouws et al., 2015). Then, we proceed to optimize the EMD term $\mathcal{J}_{\mathrm{EMD}}$ with the alternating optimization procedure. In Step 2 of the procedure, we take M gradient ascent steps. This hyperparameter is related to λ_{e}, as they jointly affect the strength of the EMD regularization. We are inclined to take small and many gradient ascent steps, so we fix $M = 10,000$ and tune λ_{e} on the validation set. Finally, the learning rate is decayed linearly at the end of each epoch.

4.2 Adding Context Vectors

In the previous section, we have presented our model with word vectors W^{S} and W^{T} as the parameters. In reality, each word is associated with a context vector as well (Mikolov et al., 2013c). While the usual representation of a word for evaluation is simply a word vector, some authors have suggested adding the context vector (Pennington et al., 2014; Levy et al., 2015). Previously this means a simple post-processing step during evaluation, but in our setting we can bring the trick to training. Specifically, using Euclidean distance as the ground distance, we would have parametrized C_{ts} in the EMD term (4) as

$$C_{ts} = \left\| W_t^{\mathrm{T}} - W_s^{\mathrm{S}} \right\|. \tag{7}$$

Considering the context vectors U^{S} and U^{T}, we now reformulate the ground distance as

$$C_{ts} = \left\| \left(W_t^{\mathrm{T}} + U_t^{\mathrm{T}}\right) - \left(W_s^{\mathrm{S}} + U_s^{\mathrm{S}}\right) \right\|. \tag{8}$$

This modification affects both steps in the alternating optimization procedure. In addition, the seed term also encourages corresponding context vectors to be close.

5 Experimental Setup

5.1 Data

In our experiments, the tested systems induce bilingual lexica from Wikipedia comparable corpora[1] on four language pairs: Chinese-English, Spanish-English, Italian-English, and Japanese-Chinese. Following (Vulić and Moens, 2013a), we retain only nouns that occur at least 1,000 times in our corpora.[2] For the Chinese side, we first use OpenCC[3] to normalize characters to be simplified, and then perform

[1] http://linguatools.org/tools/corpora/wikipedia-comparable-corpora

[2] For Spanish-English and Italian-English, the cut-off frequency is 3,000 for a comparably-sized vocabulary.

# with multiple alternative translation	661	1,293	1,338	513

Table 2: Statistics of the test sets obtained by processing the gold standard lexica in the same way as (Zhang et al., 2016). A good portion of the test instances come with multiple alternative translation in the ground truth.

Chinese word segmentation and POS tagging with THULAC[4]. The preprocessing of the English side involves tokenization, POS tagging, lemmatization, and lowercasing, which we carry out with the NLTK toolkit[5] for the Chinese-English pair. For Spanish-English and Italian-English, we choose to use TreeTagger[6] for preprocessing, as in (Vulić and Moens, 2013a). For the Japanese corpus, we use MeCab[7] for word segmentation and POS tagging. The statistics of the preprocessed corpora is given in Table 1.

5.2 Seed Word Translation Pairs

We build our seed lexicon in a way similar to (Vulić and Moens, 2013a). First, we ask Google Translate[8] to translate the source side vocabulary. Then the translations in the target language are queried again in the reverse direction to translate back to the source language, and those that don't match with the original source words are discarded. This helps to ensure the quality of the translations. Finally, a translation pair is discarded if the target word falls out of our target vocabulary. We then take the most frequent S translation pairs as the seed lexicon. We vary S in our experiment to examine the effect of the seed lexicon size.

5.3 Evaluation Method

The limiting factor that prevents us from experimenting with truly resource-scarce language pairs is the unavailability of gold standard lexica for evaluation. Our focus on multiple alternative translation raises a higher demand that the gold standard lexica should include multiple possible translations for source words. For Chinese-English, we use Chinese-English Translation Lexicon Version 3.0[9] as the gold standard. For Spanish-English and Italian-English, we access Open Multilingual WordNet[10] through NLTK. For Japanese-Chinese, we use an in-house lexicon that meets our need. We reserve 10% of each gold standard lexicon for validation, and the remaining 90% for testing. We list test set statistics for each language pair in Table 2.

Following (Zhang et al., 2016), our evaluation metrics include accuracy A, precision P, recall R, and F_1 score. Accuracy is traditionally reported for the bilingual lexicon induction task, but it does not reflect the handling of multiple translations. This evaluative tradition also proves the lack of attention for multiple alternative translation. Therefore, we will be primarily looking at F_1 score in our experiments.

Ours	0.3686	0.3452	0.4111

Table 4: F_1 scores for three language pairs with 100 seed word translation pairs.

5.4 Baselines

We compare our approach to two baselines:

1. Statistics-based (STAT) (Gaussier et al., 2004).

2. Monolingual and seed terms (MONO+SEED).

The first baseline (STAT) is the traditional statistics-based approach, conventionally considered the standard approach to bilingual lexicon induction (Gaussier et al., 2004). It represents each word with a vector that encodes association strength between the word and seed words. We use a smoothed version of positive pointwise mutual information (PPMI) (Turney and Pantel, 2010) as the monolingual association measure.

The second baseline (MONO+SEED) is our system without the EMD term (i.e. $\lambda_{\mathrm{e}} = 0$). Comparison with it allows us to observe the effectiveness of the EMD term.

As we focus on multiple alternative translation but existing methods do not address it, we post-process the baselines by the EMD procedure (Zhang et al., 2016) to grant them the desired capability for a fair comparison with our approach.[11]

5.5 Hyperparameters

Our approach inherits hyperparameters from the monolingual skip-gram model, and includes term weights λ_{s} and λ_{e}. We set these hyperparameters based on tuning on the validation set, and observe little performance difference as long as they lie within a reasonable range. The monolingual hyperparameters are set as follows: embedding size D is 40; window size is 5; 5 negative samples; subsampling threshold is 10^{-5}; initial learning rate is 0.02; 20 training epochs. The statistics-based baseline uses a window size of 5 as well. The seed term weight λ_{s} is set to 0.01, and the EMD term weight λ_{e} is 0.0001.

6 Results

6.1 Performance on Chinese-English

We first report experimental results on Chinese-English lexicon induction with 100 seed word translation pairs, as shown in Table 3. We observe significant performance gains over both baselines, as measured by all evaluation metrics. In particular, comparing our approach with the MONO+SEED baseline highlights the effectiveness of introducing the EMD program into the training phase. As for training time, our approach takes about 4 hours, compared to 2 hours of MONO+SEED, due to the introduction of the EMD regularization.

[11] We found EMD post-processing to be generally superior to nearest neighbors, in line with (Zhang et al., 2016).

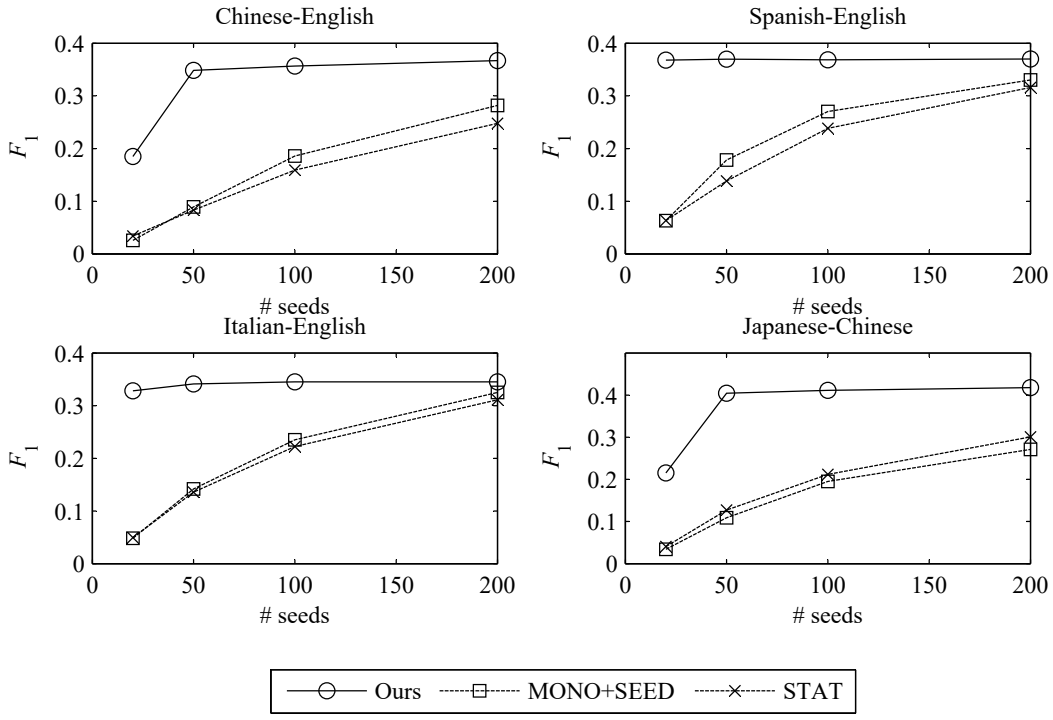

Figure 2: F_1 scores for the four language pairs with varying number of seed word translation pairs.

6.2 Performance on Other Language Pairs

We next experiment with the other three language pairs, i.e., Spanish-English, Italian-English, and Japanese-Chinese. The tested systems are provided with 100 seed word translation pairs as well. We only report the resulting F_1 scores in Table 4, as the other evaluation metrics exhibit similar trends. Relative to Chinese-English, these three language pairs should be more closely related. Nevertheless, the improvements of our method remain large, regardless of language pairs. The consistent performance signifies the generalizability of our approach across different language pairs.

6.3 Effect of Seed Lexicon Size

In this section, we investigate how the number of seed word translation pairs may affect the performance of the bilingual lexicon inducers. We vary the seed lexicon size in $\{20, 50, 100, 200\}$. Figure 2 shows the F_1 scores of the tested systems for the four language pairs. We observe that our system always attains high performance for the closely related language pairs Spanish-English and Italian-English, even when the seeds are as few as 20. For the more distant language pairs Chinese-English and Japanese-Chinese, 50 seeds suffice. In contrast, a limited number of seeds considerably degrades the performance of the baseline systems. Therefore, our system is particularly appealing in realistic resource-scarce scenarios for its minimal requirement for a seed lexicon, which is labor-intensive to compile.

6.4 Qualitative Analysis

In order to obtain a clearer view of the difference between the tested systems, we probe into the embeddings trained by them through a few examples. The Chinese-English translations in Table 5 imply that embeddings trained by our method appear superior. Although the two baselines may output more translations than our system, they often miss the correct ones, as shown by the examples of "*shan*" and "*jianzhu*". These translation differences should be eventually attributed to the quality of the underlying bilingual word embeddings, and in turn to the performance of the systems.

	STAT	MONO+SEED	Ours
qiche	good maker	**automobile** competitor customer luxury	**car** **automobile** **auto**
shan	palm flat waterfall dune barley chestnut citrus	middle part	**hill** **mountain**
jianzhu	architecture monument	foundation interior brick onwards	**building**

Table 5: English translations of three (romanized) Chinese words by the tested systems. The correct translations are in bold. The number of translations in each cell varies because it is automatically determined by the EMD program.

7 Related Work

Following its monolingual counterpart (Mikolov et al., 2013c, *inter alia*), bilingual word representation learning has attracted considerable attention. However, most of the works require parallel data as the cross-lingual signal (Zou et al., 2013; Chandar A P et al., 2014; Hermann and Blunsom, 2014; Kočiský et al., 2014; Gouws et al., 2015; Luong et al., 2015; Coulmance et al., 2015), making them unsuitable for bilingual lexicon induction. Although a few exceptions exist (Mikolov et al., 2013b; Faruqui and Dyer, 2014; Lu et al., 2015; Vulić and Moens, 2015; Shi et al., 2015; Gouws and Søgaard, 2015; Wick et al., 2016; Ammar et al., 2016), they lack a mechanism to deal with the multiple alternative translation prevalent cross-lingually.

The multiple alternative translation across languages is rooted in the polysemy of words within languages. In the monolingual setting, word sense disambiguation stands with a long line of research (Agirre and Rigau, 1996, *inter alia*). Since the advent of word representation learning, there have been some attempts to learn multiple vectors for a word, each dedicated to a single sense of the word, and therefore known as "sense embedding".

Existing sense embeddings can be roughly divided into two categories, depending on whether external resources are utilized. For those that do not rely on external resources, their main idea is to employ unsupervised methods like clustering to differentiate between multiple senses (Reisinger and Mooney, 2010; Huang et al., 2012; Neelakantan et al., 2014; Tian et al., 2014; Li and Jurafsky, 2015). For those that do, they typically retrofit existing word vectors to sense inventories (Jauhar et al., 2015; Rothe and Schütze, 2015), or use the resources to obtain a word sense disambiguation system, and then use it to disambiguate words, so that word representation learning methods can be applied (Chen et al., 2014; Iacobacci et al., 2015). An exception is the work of (Guo et al., 2014). Their external resource is parallel data. They observe that different senses of a word usually have different translations, so disambiguation can be thus achieved.

However, no prior research has shown how to connect sense embeddings cross-lingually, unless multilingual lexical ontologies exist (Camacho-Collados et al., 2015). For bilingual lexicon induction, where only non-parallel data and a seed lexicon are available, it is unclear whether sense embeddings can address multiple alternative translation.

Our work complements (Zhang et al., 2016): Their work applies the Earth Mover's Distance to the post-processing of fixed bilingual word embeddings to retrieve word translation, while ours strives to

train better bilingual word embeddings with the EMD. In addition, we also explore the feasibility of using the EMD for bilingual lexicon induction from non-parallel data. In computer vision, there have been a few works that experiment with trainable ground distance in the EMD program (Wang and Guibas, 2012; Zen et al., 2014). However, they require supervision to properly guide the training. With supervision, their EMD program can stand alone to fit training data, while in our approach the EMD shows up as a regularizer in the learning objective. Besides, their models fully parametrize the ground distance as optimizable variables, whereas our model treats it as the Euclidean distance with adjustable word vectors.

8 Conclusion

In this paper, we look into multiple alternative translations prevalent across natural languages, which are largely neglected in previous bilingual lexicon induction research. We propose to introduce the Earth Mover's Distance into the training of bilingual word embeddings as a natural form of regularization. We provide strong empirical results for four language pairs to demonstrate the effectiveness of our approach. Furthermore, we discover that our method remains reliable with rather few seed word translation pairs, unlike the baselines exhibiting performance degradation. This advantage of our approach is particularly desirable in realistic resource-scarce settings.

What Makes Word-level Neural Machine Translation Hard: A Case Study on English-German Translation

Abstract

Traditional machine translation systems often require heavy feature engineering and the combination of multiple techniques for solving different subproblems. In recent years, several end-to-end learning architectures based on recurrent neural networks have been proposed. Unlike traditional systems, Neural Machine Translation (NMT) systems learn the parameters of the model and require only minimal preprocessing. Memory and time constraints allow to take only a fixed number of words into account, which leads to the out-of-vocabulary (OOV) problem. In this work, we analyze why the OOV problem arises and why it is considered a serious problem in German. We study the effectiveness of compound word splitters for alleviating the OOV problem, resulting in a 2.5+ BLEU points improvement over a baseline on the WMT'14 German-to-English translation task. For English-to-German translation, we use target-side compound splitting through a special syntax during training that allows the model to merge compound words and gain 0.2 BLEU points.

1 Introduction

In the field of machine translation, traditional methods depend on a careful design of useful features obtained by analyzing linguistic properties of the translation tasks. Inspired by recent success of methods that learn vector representation of words from large corpora in an unsupervised way, Devlin et al. (2014) have shown that word representations learned by neural language models can be effectively used as components in a complex translation system. By contrast, *Neural Machine Translation (NMT)* models are end-to-end learning systems that tune model parameters so that the desired output sentence is generated for a given input sentence of arbitrary length with minimal processing steps such as tokenization. Most of recently proposed NMT models are based on the encoder-decoder framework (Sutskever et al., 2014; Cho et al., 2014), where a source sentence is mapped into a fixed-size vector that preserves both the syntactic and semantic structure of the source sentence, from which a decoder starts with generating a sequence of words in a target language. Bahdanau et al. (2015) extend the vanilla encoder-decoder NMT framework by adding a small feed-forward neural network which learns which word in the source sentence is relevant for predicting the next word in the target sequence. It has been shown that the performance of such *soft-attention* NMTs stays consistent as the sequence length increases.

Although NMT models have been applied successfully to translation tasks, it is still challenging to handle *out-of-vocabulary (OOV)* words because only a small number of words are considered to reduce computational overhead. All words not in the vocabulary are assigned to a single special token, e.g., $\langle$UNK$\rangle$ in our case. In order to address the OOV problem, Jean et al. (2015) further extend the model of Bahdanau et al. (2015) with importance sampling so that it can hold a larger vocabulary without increasing training complexity. Luong et al. (2015) address the OOV problem by looking up unknown words in an automatically generated dictionary, and use an external word aligner to map words in the target sequence to ones in the source sequence.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3199–3208, Osaka, Japan, December 11-17 2016.

Regarding OOV words, a fundamental problem of NMT models that take words as inputs is that having a larger vocabulary cannot be a solution for morphologically rich languages such as German and Czech due to the proliferation of word forms resulting from the addition of affixes to word stems. This means that even though we include millions of words in the vocabulary, quite a significant ratio of words remains unknown tokens. We will discuss such properties of German in Section 3.

Therefore, instead of using words as only inputs and outputs, there have been several approaches which take into account more fine-grained units such as characters. Based on the fact that rare words are often composed of frequent words, Sennrich et al. (2016) build a vocabulary of subunits instead of words and view a sentence as a sequence of subunits. Such a vocabulary typically includes meaningful linguistic units, e.g., prefixes, suffixes and frequent stems, but it may also include less meaningful units because the vocabulary building process solely relies on their frequencies. While learning directly from characters of both source and target sentences is interesting since the OOV problem is not an issue anymore, it is more difficult and time-consuming to train such models (Ling et al., 2015). As a compromise, (Luong and Manning, 2016) propose a hybrid model that uses both words and characters. Similarly, (Chung et al., 2016) suggest the use of a character-level decoder which takes words or subunits as inputs but outputs character sequences.

According to the recent developments in NMT, it is highly likely that fine-grained units enable us to get better neural translation models. In this paper we, hence, explore the problems that are typically encountered by word-level neural translation systems, how we can avoid such problems and what remains problematic. We will start with a brief explanation of the word-level NMT architecture proposed by (Bahdanau et al., 2015) in the next section.

2 Background: Neural Machine Translation

Consider that we have a pair of a source sentence and its translation in the target language, e.g., (*Wie geht es dir?*, *How are you?*) when translating German sentences to English. If a word is treated as an atomic unit of translation, we can define both source and target sentences as a sequence of words such that $\boldsymbol{x} = \{x_j\}_{j=1}^{Tx}$ and $\boldsymbol{y} = \{y_i\}_{i=1}^{Ty}$ where T_x is the number of words in the source sentence and T_y is that of the target words. The goal of learning translation models can be expressed as maximizing the joint probability $p\left(\boldsymbol{y}|\boldsymbol{x}\right)$ of the target words $\boldsymbol{y} = \{y_1, \cdots, y_{T_y}\}$ conditioned on the source words $\boldsymbol{x} = \{x_1, \cdots, x_{T_x}\}$. We can factorize it into a product of conditional probabilities of a single target word:

$$p\left(\boldsymbol{y}|\boldsymbol{x}\right) = \prod_{i=1}^{T_y} p\left(y_i|\boldsymbol{y}_{<i}, \boldsymbol{x}\right) \tag{1}$$

where $\boldsymbol{y}_{<i} = \{y_1, \cdots, y_{i-1}\}$ denotes a set of words preceding a word at position i in the target sentence. Each conditional $p(y_i|\boldsymbol{y}_{<i}, \boldsymbol{x})$ can be defined in a parameterized form by

$$p(y_i = k|\boldsymbol{y}_{<i}, \boldsymbol{x}) = \frac{\exp(s_{ik})}{\sum_{v=1}^{V} \exp(s_{iv})} \tag{2}$$

where s_{ik} is a score for predicting the k-th word in the target vocabulary as a word at position i. Since in most cases T_x and T_y are variable across sentence pairs as well as $T_x \neq T_y$ in a single pair of sentences, we use the *encoder-decoder* architecture, also known as *sequence-to-sequence* learning (Sutskever et al., 2014; Cho et al., 2014; Bahdanau et al., 2015), where two RNNs are trained jointly to handle such variable inputs and outputs. Using the encoder-decoder RNNs the score s_{ik} can be defined by $s_{ik} = f\left(y_{i-1}, \mathbf{h}_i, \mathbf{c}_i\right)$. One RNN, the so-called *encoder*, computes the hidden state $\overline{\mathbf{h}}_j$ of a source word x_j given previous hidden state as $\overline{\mathbf{h}}_j = \text{RNN}_{enc}(\mathbf{x}_j, \overline{\mathbf{h}}_{j-1})$ where $\mathbf{x}_j$ is vector representation of a word x_j. Similarly, we obtain a hidden state $\mathbf{h}_i$ to be used for predicting y_i using the other, so-called *decoder* RNN as $\mathbf{h}_i = \text{RNN}_{dec}\left(\mathbf{y}_{i-1}, \mathbf{h}_{i-1}, \mathbf{c}_i\right)$ where $\mathbf{c}_i = \sum_{j=1}^{T_x} \alpha_{ij} \overline{\mathbf{h}}_j$ s.t. $\sum_j \alpha_{ij} = 1$ is a context vector, which is a weighted sum of input hidden states. Moreover, we also learn the *attention weights* $\alpha_{ij} = f_{att}\left(\mathbf{h}_{i-1}, \overline{\mathbf{h}}_j\right)$. The decoder's initial hidden state $\mathbf{h}_0$ is initialized by the encoder, e.g., using the last

POS/NE	German		English	
	Coverage	Ratio	Coverage	Ratio

hidden state $\overline{\mathbf{h}}_{T_x}$ of the source sentence $\boldsymbol{x}$ while we can set the initial hidden state of the encoder $\overline{\mathbf{h}}_0 = \mathbf{0}$. For further details, see (Bahdanau et al., 2015).

Given a corpus of N training examples $\mathcal{D} = \{(\boldsymbol{x}^{(n)}, \boldsymbol{y}^{(n)})\}_{n=1}^{N}$, we can iteratively update the model parameters θ by using the gradient of the negative log-likelihood given by

$$\frac{\partial}{\partial\theta}\mathcal{L}(\theta;(\boldsymbol{x}^{(n)},\boldsymbol{y}^{(n)})) = -\sum_{i=1}^{T_y^{(n)}}\frac{\partial}{\partial\theta}s_{ik} - \mathbb{E}_{v\sim\mathcal{V}}\left[\frac{\partial}{\partial\theta}\exp(s_{iv})\right]. \quad (3)$$

As computational complexity of Equation (3) grows linearly in the size of the vocabulary $\mathcal{V}$, it is often the case that tens of thousands of the most frequent words are included in the vocabulary.

3 What is Behind the Out-of-Vocabulary Problem?

In the experimental results of (Jean et al., 2015), we can see that a larger vocabulary does not bring us the performance improvement when the target language is German while English to French translation benefits from the use of a larger vocabulary. This tells us that a larger vocabulary might not be an effective solution to the OOV problem, at least, when we translate into German. To look into the reasons, let us consider what type of words are treated as OOV words and how often such words appear in the corpus. To be more precise, we collect the most frequent $30,000$ words from a large corpus, i.e., the training set being used in our experiments. Then we calculate the following two scores for each of part of speech (POS) and named entity (NE) tags with respect to OOV words as follows

$$\text{coverage(tag)} = \frac{\text{\# of words with } \textit{tag} \text{ in vocabulary}}{\text{\# of words with } \textit{tag}}, \qquad \text{ratio(tag)} = \frac{\text{\# of words with } \textit{tag}}{\text{\# of words}}.$$

For POS and NE tagging, we use the Stanford NLP suite[1].

The results are summarized in Table 1, where we merge the different tagsets for German and English into common tags to make them comparable. In particular, all different types of adjectives fall into a single *ADJ* tag. The ratio refers to the frequency in the test set, e.g., 20.50% for *NN* means that 20.50% of the words in unseen data are nouns. As can be seen in the table, NEs in all forms, i.e., I-PER, I-ORG and I-LOC, are poorly covered. This is intuitively obvious because a fixed-size vocabulary cannot contain the names of all people, places, or organizations. NEs also appear frequently, i.e., 5% of all unknown words are NEs. The coverage of numbers (*CARD*) is also suboptimal, with the English vocabulary covering 92.01% while the German vocabulary covers only 87.62%. For numbers as well as for NEs this may not be a problem per se because OOV words can be copied from the source sentence using the alignment model.

[1] http://stanfordnlp.github.io/CoreNLP

The biggest gap of coverage of a tag set between English and German can be seen for nouns (*NN*). English features a coverage of 93.25% while German covers only 68.73%. The reason for this is most likely due to an interesting property of the German language: compound words. In German, new words can be created by concatenating two or more words.

Interestingly, it is hard to get 95% of German words covered by a vocabulary of even 1M words in contrast to English. Figure 1 shows coverage of words in the test set as a function of vocabulary size. Unless German compound words are split, coverage of German is lower than that of English by $3 \sim 8\%$ depending on the vocabulary size. Splitting compound words enables to cover German words in the test set as much as English ones as the vocabulary size increases.

4 Dealing with Compound Words

Compounds are words (more precisely, lexemes) consisting of more than one stem. Compounding is found in many languages, including Dutch, Finnish, and German. To build a compound word, two or more words are joined resulting in a longer word. For example, the German compound word *Apfelkuchen* is produced by concatenating *Apfel* (apple) and *Kuchen* (pie). Yet in German, it needs to be explicitly added to the vocabulary while its corresponding term, *apple pie*, is likely to be already included in the vocabulary extracted from a large English corpus. As Germanic languages such as German have a high number of compound words, we explore the methodology of compound splitting for German being both on the source and target side, referred to as *compound splitting* and *compound merging*, respectively.

4.1 Compound Splitting

Compound splitters often employed in the literature generally fall into one of two categories (Fritzinger and Fraser, 2010; Popović et al., 2006): *corpus-driven* and *linguistic*. The former is based on word frequencies calculated on a training corpus, the best split being selected among the candidates. The latter splits words through linguistic analysis e.g., by using a morphological analyzer. Hybrid approaches are possible, and corpus-driven splitters found in practice often contain some additional rules instead of relying solely on corpus statistics. Likewise, while it is possible to split words based solely on the output of a morphological analyzer, a splitter may take word frequencies into account.

In this work, we consider the following two splitters:

1. The compound splitter developed by Weller and Heid (2012), herein referred to as *IMS splitter*, is based on the corpus-driven approach by Koehn and Knight (2003). We compute a frequency list of lemmatized words using TreeTagger (Schmid, 1994; Schmid, 1995) on the WMT14 training data as well as a frequency list of words with respect to their POS tag.[2] These two lists are used to improve the performance of the IMS splitter. Different splitting possibilities are ranked by the geometric mean of the frequencies $(\prod_{i=1}^{n} \text{freq}(p_i))^{\frac{1}{n}}$ where p_i are the parts of the respective splittings and n the number of parts. An exemplary output of this splitter can be found in Table 2, which shows different ways to split a word along with the scores for this particular split.

2. Fritzinger and Fraser (2010) studied compound splitters in terms of their effectiveness in statistical machine translation (SMT) systems and propose a hybrid approach that uses corpus statistics as well as a morphological analyzer. Hence, we will refer to this splitter as *hybrid splitter*. Based on split points provided by the morphological analyzer *Smor*, word frequencies from a large training corpus are consulted. Smor is a finite-state based morphological analyzer concerned with the word formation of German, i.e., inflection, derivation, and compounding. By employing a hybrid approach, only linguistically motivated splittings (provided by Smor) are performed according to the frequency lists on the training corpus, hence reducing the number of incorrect splits. For example, The word *Durchschnittsauto* (*standard car*) is split into *Durchschnitt Auto* instead of *Durch Schnitt Auto*. The word *Durchschnitt* has a one-to-one relation with the English word *average*, but is itself a compound word.

[2] We switched to TreeTagger from the Stanford Tagger because of its substantially faster processing speed.

Table 2: Exemplary output of the IMS splitter.

Compound	Split Compound	Score
kühleinrichtung	kühl_ADJ einrichtung_NN	869.3
	kühlen_V einrichtung_NN	251.4
	kühleinrichtung_NN	6.0
gezeitenkraftwerk	gezeiten_NN kraft_NN werk_NN	984.9
	gezeiten_NN kraftwerk_NN	324.44
	gezeitenkraft_NN werk_NN	243.6
	gezeitenkraftwerk_NN	33.0

Another important aspect when talking about compound splitting is the concept of *filler letters*. When a new word is formed through the use of compounding, sometimes filler letters are inserted between two compounds. For German, these filler letters are usually *s, en, n, er, and es*. For example, the German word *Jahresverpflichtung* is made from the words *Jahr* (year) and *Verpflichtung* (commitment), and between these two words the infix *es* is inserted. The easiest way to deal with this issue is to maintain a list of filler letters and a set of rules for testing whether a compound ends with one of them, in which case these filler letters can be removed. Indeed, the IMS splitter uses exactly this type of rules to provide proper splits. The hybrid splitter does not need an explicit definition of filler letters because this knowledge is already encoded in the morphological analyzer Smor.

For the inverse task of translating from English to German, it is not so clear what filler letters should be used because filler letters are needed for reconstructing a correct compound word from its individual elements.

4.2 Compound Merging

When compounds occur on the target side it is necessary to join individual compound elements together. We can deal with this problem by inserting special syntax into the training corpus that eases the process of compound merging. For example, instead of encoding the word *Autofahrer* (car driver) as *Auto* and *Fahrer*, we can encode it as *Auto @@ Fahrer*. By doing so, we hope the model will produce such connection markers in the decoder, which can then easily be joined during postprocessing. This also solves the problem of filler letters for German being on the target side, because filler letters can be encoded using this special syntax as well. For instance, the word *Kraftverkehrsverband* is made of up the words *Kraft*, *Verkehr*, and *Verband* and can be encoded as *Kraft @@ Verkehr @s@ Verband*.

This process has also been proposed by (Williams et al., 2015) using the hybrid splitter by (Fritzinger and Fraser, 2010). We argue that this special syntax can also be produced by a much simpler corpus-driven splitter such as the IMS splitter. Hence, we modified the IMS splitter to output these filler letters between compound words. This modification applies to all compound splitters simply by comparing the splitter's output with its input and extracting filler letters using a regular expression.

5 Experimental Setup

This section describes the foundations of our experiments. In particular, we address preprocessing, which is an important part of the machine learning pipeline, and the setup of our NMT training.

5.1 Dataset & Preprocessing

Our models were trained on the data provided by the 2014 Workshop on Machine Translation (WMT). Specifically, we used the Europarl v7, Common Crawl, and News Commentary corpora. Our development set corresponds to the data in the *newstest2013* files while the test set is given by *newstest2014*.[3] We use Moses' tokenizer[4] and filter out noisy sentences, written in a different language, using a language detection tool.[5]

[3] We use cleaned test sets.

[4] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl

[5] https://github.com/shuyo/language-detection

Since some of the German sentences in the training set were made available before the German orthography reform of 1996, we converted such words to conform to the new spelling rules. For instance, the following rules were used: (muß ⟶ muss), (Phantasie ⟶ Fantasie), (Bestelliste ⟶ Bestellliste), (essentiell ⟶ essenziell) and (geschrieen ⟶ geschrien). Note that this spelling conversion does not affect the development and test sets because no occurrences of words written in the old style were present.

5.2 Training Details

Our NMT implementation is based on the neural network framework `Blocks`[6] (van Merriënboer et al., 2015). While it may be advisable to try different hyperparameters, an elaborate tuning of the RNNs was not practical given that it took about one week to train a single hyperparameter configuration for machine translation on the WMT data set on our hardware. Therefore, we chose the same set of hyperparameters as in (Bahdanau et al., 2015) except for the size of the vocabularies. To be more specific, we set the dimensionality of word vectors to 640, the number of hidden units in GRU-RNN to $1,000$, the maximum sequence length during training to 50, the mini-batch size to 80, and the number of words in both source and target vocabularies to $30,000$. We did not use weight noise regularization or dropout. We also randomly shuffled the training data using a constant seed for all our experiments so that different models are trained on the same order of the data set.

We trained our models on a NVIDIA Tesla K20 and Titan Black GPU. Since our data set contains nearly 4 million instances, a single epoch corresponds to around $48,000$ iterations. Depending on the model, the best score on the development set was usually achieved at around $400,000$ to $500,000$ iterations, or 8 to 10 epochs, or 5 to 7 days. At every checkpoint, $15,000$ iterations in our experiments, we computed the bilingual evaluation understudy (BLEU) score (Papineni et al., 2002), the Metric for Evaluation of Translation with Explicit ORdering (METEOR) (Banerjee and Lavie, 2005) and the translation error rate (TER) (Snover et al., 2006) to monitor the progress of the model on the development set.

6 Experiments

In this section, we present the results for the experiments we conducted with the setup explained in the previous sections. We will first show that German to English translation works considerably better than English to German (Section 6.1), and then try to analyze this observation in more depth (Section 6.2).

6.1 Effect of Compound Splitting and Joining

Table 3 shows the performance of three models on the test set for both translation directions. All our models produce cased outputs. Nonetheless, BLEU scores are given for evaluation performed before and after lowercasing predictions and reference sets.

For English to German, both compound splitters contribute to the improvements of NMT models across all measures except for TER although the gap of the performance between the models is negligible. However, for German to English translation, we can observe huge gains by using the corpus-based compound words splitting method, outperforming the baseline by 2.7 BLEU$^{\text{uncased}}$, 3.3 METEOR, and -0.6 TER. While the use of compound splitters enables to achieve significant performance improvement in terms of BLEU and METEOR, only marginal improvement was observed in TER. This implies that splitting German compound words results in more number of correct n-grams in English whereas it has no significant impact on word ordering. See more details of three metrics in (Birch and Osborne, 2011). Note that German word order can differ from that of English due to separated verb prefixes and long-range movement of verbs in German.

When inspecting the output of both splitters, we noticed that the hybrid/linguistic splitter is more likely to produce a correct splitting. However, the corpus-based splitter provides better results for NMT. This contradiction has also been observed by (Fritzinger and Fraser, 2010) for phrase-based SMT. Corpus-driven methods tend to split more aggressively. For instance, consider the word *überall* which may get split into *über* and *all* by the corpus-driven approach due to these two words appearing very frequently. Conversely, the linguistic splitter is unlikely to split this word.

[6] `https://github.com/mila-udem/blocks`

Table 3: Results of compound split for German words using either a corpus-based splitter or hybrid corpus-based/linguistic-motivated one. Scores in subscripts are on the development set.

Translation Direction	Model	↑ BLEU$^{\text{uncased}}$	↑ BLEU$^{\text{cased}}$	↑ METEOR$^{\text{uncased}}$	↓ TER$^{\text{uncased}}$
English → German	Baseline	$19.21_{19.6}$	$18.79_{19.11}$	$39.40_{39.00}$	$63.40_{61.70}$
	Hybrid Split	$19.34_{19.58}$	$18.95_{19.10}$	$39.90_{39.10}$	$63.70_{62.20}$
	Corpus-based Split	$19.41_{20.22}$	$18.99_{19.78}$	$40.30_{39.80}$	$64.40_{62.10}$
German → English	Baseline	$21.72_{23.30}$	$20.91_{22.36}$	$26.50_{27.90}$	$58.80_{58.70}$
	Hybrid Split	$22.30_{23.55}$	$21.37_{22.50}$	$27.30_{28.40}$	$60.00_{59.30}$
	Corpus-based Split	$24.42_{24.89}$	$23.41_{23.75}$	$29.80_{30.30}$	$58.20_{57.80}$

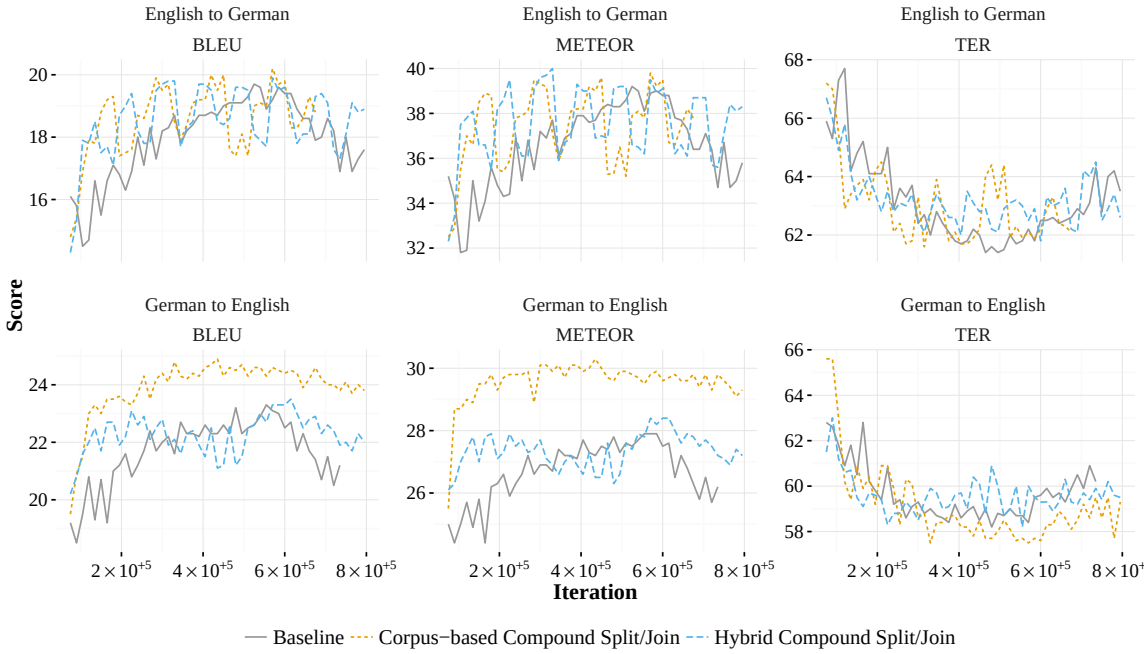

Figure 2: Performance of NMT models handling compound words differently on the development set.

The explanation for a translation system performing better with aggressive splits could be that the system can recover from words that are split too much. This is especially applicable to NMT, where the problem of OOV words leads to many compound words not found in the vocabulary. Hence, the performance hit by unsplit words that may lead to OOV words is larger than the performance hit produced by overaggressive splitting.

We believe that the reason why compound splitting works much better for English than for German is that the vocabulary coverage for English is well above the coverage of German. As noted in Section 3, we found that only 68.73% German nouns are covered when encoding a text corpus using a fixed vocabulary of size $30,000$, whereas English nouns are covered at a ratio of 93.25%. This motivated our experiment that contains a compound splitter. Before we started training a NMT model with compound split data, we first explored the effects of compound splitting in terms of word coverage on the test data. For this analysis, we used the IMS splitter. Our results, which can be seen in Figure 1, confirm that word coverage for German dramatically increases when compound splitting is applied. Another possible reason is that if a compound word at the source side is split into multiple words, the NMT model described in Section 2 is able to learn alignments between English words and multiple subwords of the compound word. We think that this is also related to why the frequency-based vocabulary construction method improves the performance of NMT models (Sennrich et al., 2016).

6.2 Difficulties When Translating into German

When German is on the target side, the model successfully produces the special syntax we used that allows us to concatenate compound words as a postprocessing step (cf. Section 4.2). A translation produced by this model looks as follows:

Source Sentence	The darker the meat, the higher the **pH value**.
Reference Sentence	Je dunkler das Fleisch, desto höher der **ph-Wert**.
Baseline Model	Je dunkler das Fleisch, desto höher der **pH**.
Split/Join Model	Je dunkler das Fleisch, desto höher der **pH @-@ Wert**.
Split/Join Model (merged)	Je dunkler das Fleisch, desto höher der **pH-Wert**.

The translation produced by the model for the phrase *pH value* is *pH @-@ Wert* and can be concatenated by the use of a regular expression. This seems to work even with longer compound words, as shown by the following example:

Source Sentence	A total of four **road safety inspections** were carried out.
Reference Sentence	Insgesamt seien vier **Verkehrsschauen** durchgefhrt worden.
Baseline Model	Insgesamt wurden vier ⟨**UNK**⟩ durchgefhrt.
Split/Join Model	Es wurden insgesamt vier **Straße @n@ Verkehr @s@ Inspektionen** durchgefhrt.
Split/Join Model (merged)	Es wurden insgesamt vier **Straßenverkehrsinspektionen** durchgefhrt.

In this case, the baseline model fails to translate the phrase altogether resulting in an unknown word. For readers not familiar with German, all sentences are correct translations for the source sentence when we disregard the unknown word, i.e., the baseline model and the split model differ in structure, but both are correct, and the split join model is more precisely in translating the word for road safety inspection.

Another interesting observation is that the performance in terms of BLEU fluctuates wildly as splitting is applied. We compared the translation output between iterations showing favorable performance and iterations with a lower BLEU score. We found that sentences were often restructured causing the performance to drop. An example of this restructuring may look as follows:

Source Sentence	However, the new rules put in place will undoubtedly make it more difficult to exercise the right to vote in 2012 .
Reference Sentence	Allerdings werden die neu eingeführten Regeln im Jahr 2012 zweifellos die Ausübung des Wahlrechts erschweren .
Split/Join Model, Iteration 450000	Mit den neuen Regeln wird es zweifellos schwieriger sein, das Wahlrecht im Jahr 2012 auszuüben .
Split/Join Model, Iteration 465000	Die neuen Regeln werden jedoch zweifellos die Ausübung des Wahlrechts für 2012 erschweren .

The system output at iteration $450,000$ in this example receives 35.29 BLEU points, whereas the output at iteration $465,000$ receives 71.43 BLEU points. This discrepancy can be explained with the fact that BLEU as an evaluation measure favors sentences with more n-gram matches. The model's output at iteration $450,000$ receives a 4-gram match for the phrase *zweifellos die Ausübung des Wahlrechts erschweren*, whereas the other model's output does not. Please do note that both outputs are perfect translations of the source sentence and would be evaluated similarly by a human evaluator.

7 Conclusion

In this work, we presented why word-level NMT models have trouble with OOV words and explained why such problems arise. Based on the analysis about the OOV problem, we obtained substantial improvements of 2.7 BLEU points for German to English translations by splitting German compound words on the source side. We also applied compound splitting when German was on the target side by modifying the compound splitter's output to contain special syntax that can later be used to create compound words from their individual components. While we obtained only a modest improvement of 0.2 BLEU, our proposed method is able to merge German words on the target side, allowing us to generate correct target sentences.

Abstract

We address the problem of inducing word alignment for language pairs by developing an unsupervised model with the capability of getting applied to other generative alignment models. We approach the task by: *i)* proposing a new alignment model based on the IBM alignment model 1 that uses vector representation of words, and *ii)* examining the use of similar source words to overcome the problem of rare source words and improving the alignments. We apply our method to English-French corpora and run the experiments with different sizes of sentence pairs. Our results show competitive performance against the baseline and in some cases improve the results up to 6.9% in terms of precision.

1 Introduction

Statistical machine translation systems usually break the translation task into two or more subtasks and an important one is finding word alignments over a sentence-aligned bilingual corpus (Brown et al., 1990). One of the common approaches to find word alignment, uses a generative translation model that produces a sentence in one language given the sentence in another language. Most SMT systems use an implementation of the IBM alignment models (Brown et al., 1993). These models use expectation maximization (EM) algorithm in training and only require sentence-aligned bilingual texts. Inducing word alignment from bilingual texts requires large amount of sentence-aligned parallel data which is not available for most of the language pairs. It also causes more problems for rare words which are the key parts of the sentences, but at the same time, are less frequent and therefore have a more biased probability distribution (Moore, 2004).

This paper deals with the alignment task for the rare words by proposing a new alignment model based on the low-dimensional representations of the words. We explore the effect of replacing words with their vector space embeddings in IBM Alignment Model 1. In this model, instead of using a conditional multinomial distribution (to generate a target word $t_i \in T$ given a source word $s_i \in S$), we use a conditional Gaussian distribution and generate a d-dimensional word embedding $V_{t_i} \in \mathbb{R}^d$ given s_i. We then propose a method to **improve the alignments for rare words** by using their similar words and updating their distributions.

The advantages of this model are: *i)* It uses monolingual word embedding which has more available training data; *ii)* By using the extracted knowledge from monolingual data, it has better results in low-resource word alignment tasks; *iii)* The Gaussian model can be applied to all generative alignment models by replacing the conditional distribution, and thus getting even better results.

2 Related Works

2.1 Word Embeddings

Recent works on word embedding show improvements in capturing semantic features of the words (Mikolov et al., 2013; Pennington et al., 2014). Since the word alignment task requires a form of statistics or comparison between words from the source and the target languages, a good translation model

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3209–3215, Osaka, Japan, December 11-17 2016.

can result in better alignments. Bilingual word embedding models like (Zou et al., 2013; Søgaard et al., 2015) train vectors for words in both languages in the same vector space, Hence a translation model can be made by these embeddings and it can be really useful for the task of word alignment. Despite the advantages of bilingual embedding models, to achieve a good performance by these models and building more informative vector representations for words, a large amount of data is required, which is not available in low-resource language pairs. On the other hand, providing a good monolingual corpus for most of the languages needs less effort and building a model that mostly uses monolingual data is more reasonable.

2.2 Alignment Model

IBM alignment models such as model 1, usually have problems with aligning rare words (Moore, 2004). In a sentence pair (S, T), for a target word $t \in T$ and two source words $s, s_{rare} \in S$ when s_{rare} is a rare word and s is a normal word, the translation model will more likely generate $p(t|s_{rare}) > p(t|s)$, and therefore most of the target words will align to s_{rare}. The reason for this problem is the rare word s_{rare} has co-occurrence with only a few target words and it increases the conditional probabilities for those target words. If a source word s which is similar to s_{rare} exists and has co-occurrence with more target words, those target words could be used to improve the distribution of s_{rare}.

There were proposed methods to overcome the problem of low-resource languages based on using different word alignment methods and combining the results like in (Xiang et al., 2010). We try to provide a combination of alignments to get better performance for the rare words.

3 Vector Model

In this section, we develop a conditional model $p(t|s)$ that, given a source word s, assigns probabilities to a target word t using a conditional Gaussian distribution. We explain the required modifications needed in IBM alignment model 1 for using word embedding and briefly review the EM algorithm in this model. We then present the method to use the similar words for updating the distributions of each word and improving the alignment results. The embedding of word $w \in W$ will be written as $\mathbf{v}_w \in \mathbb{R}^d$. The proposed model will be called the *Vector Model*.

3.1 Alignment Model

The IBM alignment models use a translation model in the form of conditional probability $p(t|s)$. In a similar way to (Lin et al., 2015), given a source word $s \in S$, instead of the probability of the target word $t \in T$, the probability of a vector representation $\mathbf{v}_t \in \mathbb{R}^d$ of the word can be calculated. Correspondingly, each source word $s \in S$ is represented by mean μ_s and covariance matrix Σ_s:

$$\begin{aligned} p(t|s) &= p(\mathbf{v}_t|\mu_s, \Sigma_s) \\ &= \frac{\exp\left(\frac{-1}{2}(\mathbf{v}_t - \mu_s)^T \Sigma_s^{-1}(\mathbf{v}_t - \mu_s)\right)}{\sqrt{(2\pi)^d |\Sigma_s|}} \end{aligned} \tag{1}$$

In this model, vector representations are only used for target words and source words are replaced with distributions in the target language vector space.

3.2 EM Algorithm

The EM algorithm should have some modifications to update the Gaussian distributions. The expectation step is similar to the original model. For all sentence pairs (S, T):

$$\forall s \in S, t \in T :$$

$$count(t|s) += \frac{p(t|s)}{\sum_{s' \in S} p(t|s')} \tag{2}$$

$$total(s) += \frac{p(t|s)}{\sum_{s' \in S} p(t|s')} \tag{3}$$

The new conditional probabilities are calculated in the maximization step and for making means and covariances for the source words, these probabilities are used as weights for weighted averaging of the vectors:

$$p(t|s) = \frac{count(t|s)}{total(s)} \tag{4}$$

$$\forall s : \mu_s = \frac{1}{\sum_t p(t|s)} \sum_t p(t|s)\mathbf{v}_t \tag{5}$$

$$\forall s : \Sigma_s = \frac{1}{\sum_t p(t|s)} \sum_t p(t|s)(\mathbf{v}_t - \mu_s)(\mathbf{v}_t - \mu_s)^T \tag{6}$$

In the initialization of the EM algorithm, for all pairs of words, the probability $p(t|s)$ is equal to 1. Therefore, the distributions of source words are made based on their co-occurrences with the target words, which is a similar situation to initialization of the IBM model 1.

3.3 Using Similar Words for Improvement

The proposed model in §3.1 only uses word embedding in the target vector space and each source word corresponds to a distribution. As discussed in §2.2, the distributions of the rare source words will be biased to a small set of target words.

For each source word s, similar source words to s can be found using the cosine similarity between their corresponding vectors. We call the top *k* similar words to each word s, the neighbors of s and represent it as $(N_k(s))$. A weight will be given to each neighbor based on the cosine similarity with the source word:

$$\forall x \in N_k(s) : w_s(x) = \frac{sim(s,x)}{\sum_{x' \in N_k(s)} sim(s,x')} \tag{7}$$

where $w_s(x)$ is the similarity weight of the neighbor word x to the word s and $sim(x,y)$ is the cosine similarity of $\mathbf{v}_x$ and $\mathbf{v}_y$.

In order to use the neighbors for updating the distributions of source words, in the maximization step of the EM algorithm, calculation of the means and covariances will have additional steps:

$$\forall s : \mu_s = \lambda\mu_s + (1-\lambda) \sum_{s' \in N_k(s)} w_s(s')\mu_{s'} \tag{8}$$

$$\forall s : \Sigma_s = \lambda\Sigma_s + (1-\lambda) \sum_{s' \in N_k(s)} w_s(s')\Sigma_{s'} \tag{9}$$

where λ is the linear interpolation parameter and it should be estimated.

4 Experiments

4.1 Data

The language pair used for all the experiments is English-French. The test set is a word-aligned bilingual corpus that contains 447 sentence pairs (Och and Ney, 2000b). Using larger data sets can result in better learning for the model, and in order to create corpora with different sizes, we appended more parallel sentences from the training set to the test data (Note that the proposed model is unsupervised and it does not use the gold alignment in the training). We created corpora with different sizes of sentence pairs and the experiments use these corpora.

For creating the word embeddings, we used the tool word2vec[1] (Mikolov et al., 2013). For the input, we used the English sentences and the French sentences separately and created two sets of vectors. The number of dimensions for vectors was set to 200.

[1] https://code.google.com/p/word2vec/

The models are evaluated using the Alignment Error Rate (AER) and using both possible and sure alignment links. The baseline model is IBM model 1 which has the same learning method and is the most similar model to the proposed one. For making the IBM alignments, the tool Giza++ was used (Och and Ney, 2000a). We believe that the same kind of improvement to this baseline can be achieved by other generative models like IBM Models, by applying the proposed model in this paper.

4.2 Number of Iterations

To see the improvement of the model in each iteration, the 1K corpus is used. Figure 1 illustrates the performance of our vector model compared to IBM model for different number of iterations.

As can be seen from the Figure 1, the proposed vector model has better performance during all iterations of the training and it seems that 5 iterations for training is suitable for both vector model and the IBM model. Therefore, for the rest of the experiments, the models will train for 5 iterations.

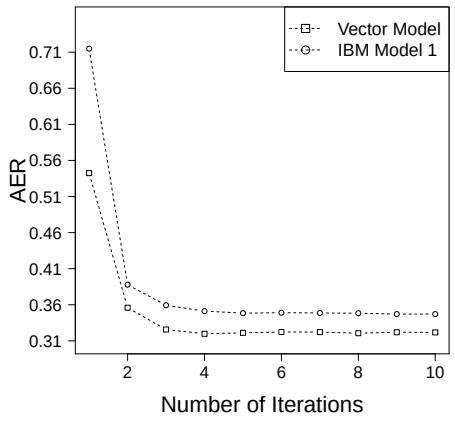

Figure 1: AER as a function of the number of iterations.

4.3 Estimation of the Parameter Lambda

To find the best value for the parameter λ, we used the 1k corpus. The AER is evaluated for different values of λ. Figure 2 shows that the best performance can be achieved by the value 0.4.

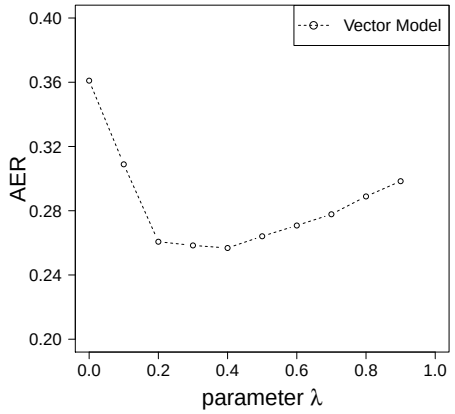

Figure 2: AER of Vector model based on the value of λ.

4.4 Number of Neighbors

To see the improvement with using different number of neighbors for updating the source words, we used the 1k corpus and changed the number of neighbors used for updating the distributions. In this experiment, for the parameter λ we used the value 0.4.

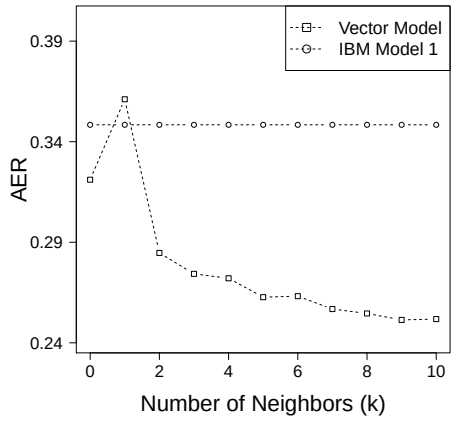

Figure 3: AER based on the number of neighbors.

Figure 3 illustrates the improvement of AER by using more neighbors for updating the distributions. The improvement is up to 9.7% in AER. The results are not improving significantly with more than 7 neighbors, and for the next experiments, the parameter k will be set to 7.

4.5 Size of the Corpus

This experiment is for evaluating the performance of the model based on the size of the corpus. In this experiment, the three models: *a)* IBM model 1, *b)* Vector model using 7 neighbors and *c)* Vector model with no neighbors are trained on the corpora with five different sizes 1k, 5k, 10k, 20k and 100K.

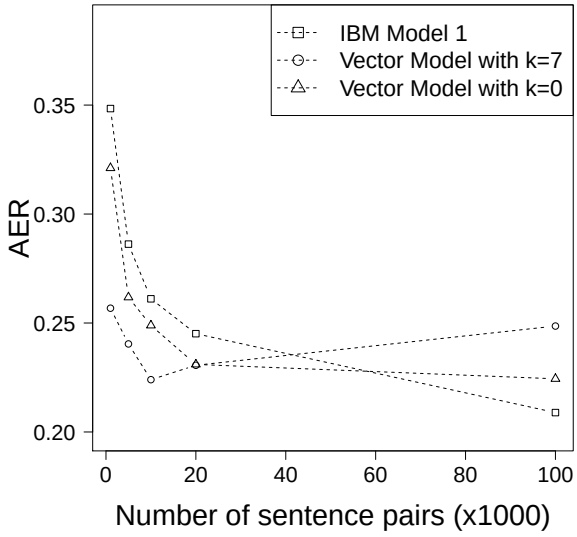

Figure 4: AER of Vector model and baseline based on the size of corpus.

Figure 4 illustrates that the two proposed models are outperforming the baseline for small data sizes. It also shows that the performance of the vector model with 7 neighbors is promising in small corpora

which is useful for low-resource languages. When the size of the corpus grows, the vector model gets to a certain threshold and will stop improving. Using the vector representations for making the translation model can be a good method for small corpora, but in a large corpus, making the probability model is far better than the approximation of the same model.

4.6 Precision on Rare Words

The last experiment is for evaluating the performance of the model based on the precision of the alignments of the rare words. As a definition for rare words, in this experiment, we call a word to be rare if it appears less that 20 times in the corpus. The precision of the alignment for the rare words is calculated by this formula:

$$precision = \frac{\#\text{of correct alignments for rare words}}{\#\text{of alignments for rare words produced by the model}} \tag{10}$$

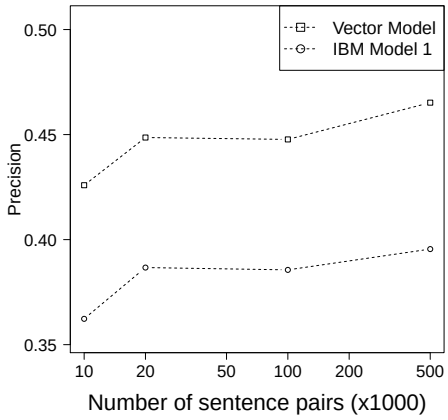

Figure 5: Precision of the Vector model and baseline on rare words based on the size of the corpus.

As shown in Figure 5, the proposed method produces better alignments for the rare words on all different sizes of the corpora.

5 Conclusion

We presented an unsupervised method to find word alignments for language pairs that uses monolingual word embeddings. We then, studied the usage of neighbors for improving the word alignment which made the model more useful for small corpora. We showed that the proposed method finds better alignments for the rare words and outperforms the baseline on different sizes of the corpora. Using the neighbors improved the performance of the model for rare words up to 6.9% compared to the baseline. The proposed Vector model has the capability of being applied to other generative alignment models which is not studied yet. Our work could be extended to other IBM models in the future works.

Abstract

Measuring the information content of news text is useful for decision makers in their investments since news information can influence the intrinsic values of companies. We propose a model to automatically measure the information content given news text, trained using news and corresponding cumulative abnormal returns of listed companies. Existing methods in finance literature exploit sentiment signal features, which are limited by not considering factors such as events. We address this issue by leveraging deep neural models to extract rich semantic features from news text. In particular, a novel tree-structured LSTM is used to find target-specific representations of news text given syntax structures. Empirical results show that the neural models can outperform sentiment-based models, demonstrating the effectiveness of recent NLP technology advances for computational finance.

1 Introduction

Information has economic value because it allows individuals to make choices that yield higher expected payoffs than they would obtain from choices made in the absence of information. A major source of information is text from the Internet, which embodies news events, analyst reports and public sentiments, and can serve as a basis for investment decisions. Measuring the information content of text is hence a highly important task in computational finance. For investors such as venture capitals, information content should reflect a firm's intrinsic value, or potential of future growth. However, measuring the information content of text can be challenging due to uncertainties and subjectivity. Fortunately, for public companies, the stock price can be used as a metric. Our goal is thus to leverage such data on public companies to train a model for measuring the information content of news on arbitrary companies.

Finance theory suggests that stock prices reflect all available information and expectations about the future prospects of firms (Fama, 1970). Based on this, empirical studies in economics and finance literature have exploited statistical methods to investigate how stock returns react to a particular news or event, which is called *event studies* or *information content effect* (Ball and Brown, 1968). A standard analysis is to measure the *cumulative abnormal return* (CAR) of a firm's price over a period of time centered around the event date (termed the *event window*) (MacKinlay, 1997). Conceptually, a daily *abnormal return* represents the performance of a stock that varies from the expectation, normally triggered by an event, and can be positive or negative depending on whether the stock outperforms or underperforms the expected return. A CAR is the sum of all abnormal returns in an event window, formally described in Section 2.

We study how news affects a public firm's CAR for training a model to measure the information content of arbitrary financial news. It is worth noting that this is different from predicting a firm's stock price movements, which aims at maximizing trading profits. Rather, we investigate whether NLP techniques can assist the understanding of an event's economic value. In finance literature sentiment signals have been used as a standard linguistic feature for representing information content (Tetlock, 2007). We build a baseline using frequency-based features derived from sentiment words to represent news text. However, sentiment polarities are subjective and may not fully represent the message conveyed in news text. For example, event information is also influential in determining a firm's stock price.

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 3216–3225, Osaka, Japan, December 11-17 2016.

To address this, we propose a deep neural model to better present news. A typical way of modeling a sentence is to treat it as a sequence and input the sequence to a long short-term memory (LSTM; (Hochreiter and Schmidhuber, 1997) model, which is capable of learning semantic features automatically. However, information may present different impact to individual firms and therefore, we need a way to represent information conveyed in a news sentence depending on a specific firm. We propose a novel Tree-LSTM which incorporates contextual information with target-dependent grammatical relations to embed a sentence. Because of the target-dependent feature of the proposed embedding model, the representation of a sentence varies from firm to firm.

We train our information content measurement model with news text collected from Reuters Business & Financial News[1]. Results show that the proposed model yields significant improvements over a baseline sentiment-based model. Different from existing event studies which focus on predefined events or firms (Davis et al., 2012), our model is general to various news and firms; and one can measure the effect of information content of news on any companies, including private companies.

The contribution of this paper is two-fold:

- First, we show that the information content of news text can be measured automatically. Our results demonstrate the effectiveness of state-of-the-art NLP techniques in computational finance, and introduce *information content effect* in finance to the ACL community. Given the ubiquitous and instantaneous nature of electronic text, text analytics is an obvious approach for information content analysis.
- Second, we design a novel target-dependent Tree-LSTM-based model for representing news sentences. To our knowledge, this is the first open-domain information content effect prediction system using machine learning and NLP technologies.

2 Cumulative Abnormal Return

Formally, the *abnormal return* of a firm j on date t is the difference between the *actual return* R_{jt} and the *expected return* $\hat{R_{jt}}$. $\hat{R_{jt}}$ can be an estimated return based on an asset pricing model, using a long run historical average, or it can be the return on an index, such as the Dow Jones or the S&P 500 during the same period. For example, suppose that a firm's stock price rose by 3%, and the market index increased by 5% over the same period. If the stock is expected to perform equally to what the market does, namely 5%, the stock yielded an abnormal return of -2% even though the firm's actual return is positive.

The *cumulative abnormal return* (CAR) of a firm j in an n-day event window is defined as the sum of abnormal returns of each day:

$$CAR_{jn} = \sum_{t=1}^{n} (R_{jt} - \hat{R_{jt}}) \quad (1)$$

The event window is normally centered at the event date and only trading days are considered in a window. The CARs before and after the event date mimic possible information leaks and delayed response to the information, respectively. Depending on the span of an event window, CARs provide analysts with short- and long-term information about the impact of an event on a stock's price. The most common event window found in research is a three-day window (-1, 1) where an event is centered at day 0 (Tetlock, 2007; Davis et al., 2012), and the corresponding CAR is denoted as CAR_3.

In this paper we model the effect of a news release on a firm's CAR_3. If a news release occurs during trading hours, day 0 is the news release date; otherwise, day 0 is the next trading period. As prior research demonstrates that there is no significant difference between a modeled expected return and the market return for a short-term event window (Kothari and Warner, 2004), we compute the expected return $\hat{R_{jt}}$ by the return of the equally-weighted market index including all the stocks on NYSE, Amex and NASDAQ.

3 Information Content Prediction

Our goal is to estimate the polarity of information content $y \in \{0$: negative effect, 1: positive effect$\}$ given a sentence s in which a target firm is mentioned. Assume that there is an embedding model that

[1] http://www.reuters.com/finance

maps a sentence to a feature vector $g \in \mathbb{R}^{d_g}$. The probability of positive information content effect is defined as:

$$p(y = 1|s) = softmax(W_p g + b_p) \tag{2}$$

W_p and b_p are parameters. We build two methods to obtain g from text, one being a traditional method in the finance literature (Section 4) and the other being a novel neural network (Section 5).

It is possible that there is more than one sentence, $\langle s_1, s_2, \ldots, s_m \rangle$, mentioning a firm of interest in the same event window. In this case, a neural attention mechanism adapted from Bahdanau et al. (2014) is utilized to synthesize the corresponding information embeddings $\langle g_1, g_2, \ldots, g_m \rangle$. To compute the attention vector, we define:

$$u^{(i)} = v^T tanh(W_u g_i) \qquad a^{(i)} = softmax(u^{(i)}) \qquad g' = \sum_{i=1}^{m} a^{(i)} g_i \tag{3}$$

where v and W_u are learnable parameters. $u^{(i)}$ is the score of how much attention should be put on g_i, and $a^{(i)}$ is the normalized score. The final synthetic feature vector g' substitutes for g in Equation 2 to predict the effect.

4 Sentiment-based Representation

A growing body of finance research literature examines the correlation between financial variables, such as stock returns and earning surprises, and the sentiment of corporate reports, press releases, and investor message boards (Li, 2010; Davis et al., 2012), most of which are based on purpose-built sentiment lexicon. A commonly used source is the list compiled by Loughran and McDonald (2011),[2] which consists of 353 positive words and 2,337 negative words. As a baseline we follow prior literature (Mayew and Venkatachalam, 2012) and represent the information content of a sentence based on counts derived from the lexicon of Loughran and McDonald. The feature vector consists of raw frequency counts and sentence length-normalized values of positive words, negative words, and the difference of positives and negatives. In addition, the sentence length is also considered.

5 Deep Neural Representation

As mentioned in the introduction, it is useful to model news information content beyond their sentiment signals. Deep learning has shown being effective in automatically inducing features that capture semantic information over nature language sentences. To verify the relative effectiveness of deep neural models, we first build a baseline neural network model using a popular LSTM structure (Section 5.1) and then develop a novel syntactic tree-structured LSTM that is sensitive to specific target entities (Section 5.2).

5.1 Bidirectional LSTM

A popular way of modeling a sentence s is to represent each word by a vector $x \in \mathbb{R}^{d_x}$ (Mikolov et al., 2013), and sequentially input its word vectors $\langle x_1, x_2, \ldots, x_{|s|} \rangle$ to a long short-term memory (LSTM; Hochreiter and Schmidhuber (1997)) model, which is a form of recurrent neural network (RNN; Pearlmutter (1989)). We take a variation of LSTM with *peephole connections* (Gers and Schmidhuber, 2000), which uses a *input gate* i_t, a *forget gate* f_t and a *output gate* o_t in the same memory block to learn from the current cell state. In addition, to simplify model complexity, we adopt coupled i_t and f_t (Cho et al., 2014). The following equations show how the LSTM *cell state* c_t and the *output* of the memory block h_t are updated given *input* x_t at time step t:

$$\begin{aligned} i_t &= \sigma(W_1 x_t + W_2 h_{t-1} + W_3 c_{t-1} + b_1) & c_t &= f_t \otimes c_{t-1} + i_t \otimes tanh(W_7 x_t + W_8 h_{t-1} + b_3) \\ f_t &= 1 - i_t & h_t &= o_t \otimes tanh(c_t) \\ o_t &= \sigma(W_4 x_t + W_5 h_{t-1} + W_6 c_t + b_2) \end{aligned} \tag{4}$$

The W terms are the weight matrices (W_3 and W_6 are diagonal weight matrices for peephole connections); the b terms denote bias vectors; σ is the logistic sigmoid function; and $\otimes$ computes element-wise multiplication of two vectors.

[2] http://www.nd.edu/~mcdonald/Word_Lists.html

A deep LSTM is built by stacking multiple LSTM layers, with the output memory block sequence of one layer forming the input sequence for the next. At each time step the input goes through multiple non-linear layers, which progressively build up higher level representations from the current level. In our information embedding models, we embody a deep LSTM architecture with 2 layers.

One of our baseline information embedding models is a bidirectional LSTM model (Graves et al., 2013), called *BI-LSTM*, consisting of two 2-layer LSTMs running on the input sequence in both forward and backward directions yielding vectors $\langle \overrightarrow{h_1}, \overrightarrow{h_2}, \ldots, \overrightarrow{h_{|s|}} \rangle$ and $\langle \overleftarrow{h_{|s|}}, \overleftarrow{h_{|s|-1}}, \ldots, \overleftarrow{h_1} \rangle$, respectively. We exclude stopwords and punctuations from each sentence. The final model outputs the information embedding g by concatenating the final outputs of the two LSTMs, namely $\overrightarrow{h_{|s|}}$ and $\overleftarrow{h_{|s|}}$.

5.2 Dependency Tree-LSTM

A syntactic approach for modeling a sentence s is to use a tree-structured LSTM (Tree-LSTM), embedding the parse tree of a sentence (Le and Zuidema, 2015; Tai et al., 2015; Zhu et al., 2015; Miwa and Bansal, 2016). Our hypothesis is that dependency relations between words convey a certain level of information content. For example, a dependency parser can tell *Facebook* is the subject which did the action *acquired* to the object *Whatsapp* in the sentence *Facebook acquired Whatsapp*. We parse sentences with ZPar (Zhang and Clark, 2011)[3] and adopt the N-ary Tree-LSTM of Tai et al. (2015) with peephole connections to run on a binarized dependency-based parse tree.

For the specific task, we leverage the structure of a binary Tree-LSTM, and develop a novel way to represent a dependency relation between two words using this structure (Section 5.2.1). We propose an algorithm to transform a dependency parse tree to a binary tree, where leaf nodes are words and internal nodes are dependency relations, so that the transformed tree can be embedded using binary Tree-LSTM (Section 5.2.2). Finally we explain how the task of information content effect measurement can benefit from the target-dependent feature of the proposed binarization algorithm (Section 5.2.3).

5.2.1 Binary Tree-LSTM for Dependency Arcs

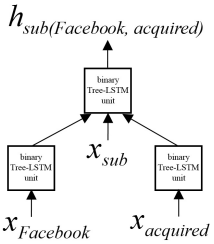
Similar to the LSTM memory block described in Section 5.1, a binary Tree-LSTM unit (Tai et al., 2015) takes *input* x_t at time step t and updates its *cell state* c_t and the *output* of the memory block h_t controlled by *input gate* i_t, *forget gate* f_t and *output gate* o_t. However, instead of depending on only one previous memory block as in a sequential LSTM model, a binary Tree-LSTM unit takes two children units, namely left (l) and right (r), into consideration. In this case, there are two forget gates f_t^l and f_t^r for the left and right children, respectively, so that information from each child can be selectively incorporated. The unit activations are defined by the following set of equations:

$$
\begin{aligned}
i_t &= \sigma(W_9 x_t + \sum_{D\in\{l,r\}} (W_{10}^D h_{t-1}^D + W_{11}^D c_{t-1}^D) + b_4) \\
f_t^l &= \sigma(W_{12} x_t + \sum_{D\in\{l,r\}} (W_{13}^D h_{t-1}^D + W_{14}^D c_{t-1}^D) + b_5) \\
f_t^r &= \sigma(W_{15} x_t + \sum_{D\in\{l,r\}} (W_{16}^D h_{t-1}^D + W_{17}^D c_{t-1}^D) + b_6) \\
o_t &= \sigma(W_{18} x_t + \sum_{D\in\{l,r\}} W_{19}^D h_{t-1}^D + W_{20} c_t + b_7) \\
c_t &= \sum_{D\in\{l,r\}} f_t^D \otimes c_{t-1}^D \\
&\quad + i_t \otimes tanh(W_{21} x_t + \sum_{D\in\{l,r\}} W_{22}^D h_{t-1}^D + b_8) \\
h_t &= o_t \otimes tanh(c_t)
\end{aligned}
\tag{5}
$$

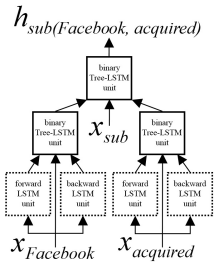
The above binary Tree-LSTM model was proposed to represent binary-branching constituents (Tai et al., 2015). In this paper, however, we show that it can be used to represent dependency arcs. For example, given the subject dependency arc *sub* between *acquired* (head) and *Facebook* (dependent), Figure 1a illustrates the bottom-up information propagation in a binary Tree-LSTM model, where x_{sub}, $x_{acquired}$ and $x_{Facebook}$ are vector representations of *sub*, *acquired* and *Facebook*, respectively. The output of the last unit $h_{sub(Facebook,acquired)}$ is the dependency embedding of *sub(acquired, Facebook)*. We call this model *LEX-TLSTM*.

Miwa and Bansal (2016) incorporate bidirectional LSTMs into the input of a Tree-LSTM unit by concatenating x_i, $\overrightarrow{h_i}$ and $\overleftarrow{h_i}$ so that contextual information of individual words can be considered. Instead

[3]We use the default English dependency parser model available at https://github.com/frcchang/zpar/releases/tag/v0.7.5



(a) Lexical input.



(b) Contextual input.

Figure 1: Binary Tree-LSTM models.

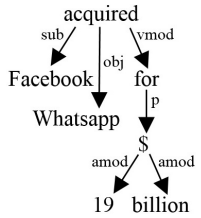
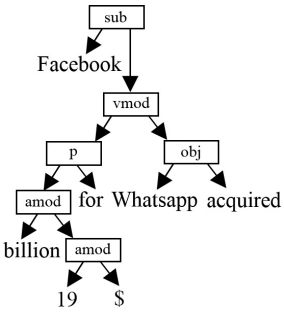
Output: binarized dependency tree T_b
$T_b \leftarrow NewBinaryTree$
$T_b.root \leftarrow Binarize(n, T_d)$
Function *Binarize(n, T_d)*
  if T_d.*HasNoDep(n)* **then**
    return n
  end
  if T_d.*HasParent(n)* **then**
    $p \leftarrow T_d.GetParent(n)$
    $btn \leftarrow NewBinaryTreeNode$
    $btn.dep \leftarrow T_d.RemoveDep(p, n)$
    $btn.LChild \leftarrow Binarize(n, T_d)$
    $btn.RChild \leftarrow Binarize(p, T_d)$
    return btn
  end
  if T_d.*HasChild(n)* **then**
    $c \leftarrow T_d.GetOneChild(n)$
    $btn \leftarrow NewBinaryTreeNode$
    $btn.dep \leftarrow T_d.RemoveDep(n, c)$
    $btn.LChild \leftarrow Binarize(c, T_d)$
    $btn.RChild \leftarrow Binarize(n, T_d)$
    return btn
  end

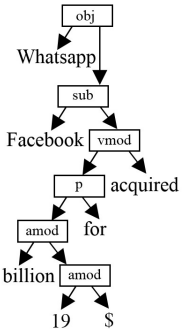
Algorithm 1: Dependency tree Binarization



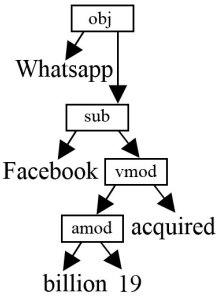
(a) Dependency parse tree.



(b) Binarized dependency tree using the root word *acquired* as the target.



(c) Target dependent tree using *Whatsapp* as the target.



(d) Remove stopwords and punctuations from tree (c).

Figure 2: A dependency parse tree and its binarized versions given different targets.

of inputting the three vectors as a whole into a Tree-LSTM unit, we treat forward and backward 2-layer LSTM units as the left and right children, respectively, while inputting a word vector as shown in Figure 1b, which we refer as *CTX-TLSTM*.

5.2.2 Binarized Dependency Tree

Figure 2a shows the dependency parse tree of the tokenized sentence *Facebook acquired Whatsapp for $ 19 billion*, where the root word is at *acquired* and head words are at the upper ends of dependency branches. To adapt a dependency parse tree to a binary Tree-LSTM model, Algorithm 1 presents a recursive algorithm to binarize a dependency parse tree given a target word.

The algorithm starts from a given target word and creates a binary tree node to represent a dependency relation between the target word and another word, with the dependent and head placed at the left and right children, respectively. The rule for selecting the dependency relation is that the dependency with the target's head is considered first followed by that of the target's dependents. In addition, we sort the dependents of a target word in a way that left context words are always in front of right context words, and both of the left and rigth context words are ordered by the distance to the target word in descending order. For instance, the sorted dependent list of *acquired* in the example is $\langle$*Facebook*, *for*, *Whatsapp*$\rangle$. After deciding a dependency relation to binarize, the head and dependent words become targets of the algorithm to expand the binary tree recursively until all the dependency relations are transformed. After the transformation, a binarized tree has words at leaf nodes, and each internal node represents a dependency relation as shown in Figure 2b.

5.2.3 Target Dependent Tree-LSTM

Recall that our objective is to model the information content effect on a target firm mentioned in a sentence. In the previous example, a bidirectional model would output only one representation for the sentence no matter what the target firm is. In contrast, the proposed tree transformation algorithm outputs different binarized trees when different targets are given. Figure 2b and Figure 2c show the binarized trees using *Facebook*[4] and *Whatsapp* as targets, respectively. As in BI-LSTM, we remove stopwords and punctuations from a tree. Figure 2d demonstrates the result after removing *for* and *$* from Figure 2c. When one child is ignored, the current node is replaced by the other child.

When applying a binary Tree-LSTM model on a binarized dependency tree, information is propagated from the bottommost leaf nodes to the topmost dependency node (e.g. sub in Figure 2b), and the final output h is treated as the information embedding g. As the proposed binarization algorithm tends to leave the target at the top of the binary tree, information effectively flows from context to the target firm. For a binary Tree-LSTM model running on a target-dependent tree, we add the prefix *TGT-* to the model identification; otherwise the target is the root word defined by the parser, and *RT-* is prefixed to the model identification.

5.3 Training

We pre-train skip-gram embeddings (Mikolov et al., 2013) of size 100 on a collection of Bloomberg financial news from October 2006 to November 2013, and the size of the trained vocabulary is 320,618. In addition, firm names and an UNK token for representing any words out of the vocabulary are added to the vocabulary, having an initial embedding as the average of the pre-trained word vectors. The word embeddings are fine-tuned during model training, with dropout (Srivastava et al., 2014) using a probability of 0.5 to avoid overfitting. The other hyperparameters for our models along with dependency type representations are initialized according to the method of Glorot et al. (2010)

For sequential LSTMs we use a 2-layer structure with inputs of size 100 and outputs of size 200. For Tree-LSTM models, only one layer is exploited, and the input and output dimensions are the same as that of sequential LSTMs.

Training is done by maximizing the conditional log-likelihood of the target effect category for 15 iterations. The parameters are optimized by stochastic gradient descent with momentum (Rumelhart et al., 1988) using an initial learning rate of 0.005, with L2 regularization at strength 10^{-6}. Every 1,000 training examples the parameters are evaluated on the development set by the macro-averaged F-score, and those achieving the highest value are kept.

6 Experiments Settings

Data: We collect publicly available financial news from Reuters from October 2006 to December 2015. Instead of taking a whole news article or simply a news title into consideration, we target the section of text which appears in the HTML 'class' attribute of 'focus paragraph' of Reuters news articles. This is invariably the first paragraph of such articles, which provide additional detail to the information contained in the article's title. For example, the focus paragraph of the news titled *Exclusive: Target gets tough with vendors to speed up supply chain* (4 May 2016, 12:22pm EDT) is:

Discount retailer Target Corp (TGT.N) is cracking down on suppliers as part of a multi-billion dollar overhaul to speed up its supply chain and better compete with rivals including Wal-Mart Stores Inc (WMT.N) and Amazon.com Inc (AMZN.O).[5]

As *Target Corp*, *Wal-Mart Stores Inc* and *Amazon.com Inc* are mentioned in the paragraph, we assume that the information content of the paragraph affects CAR_3 of these three firms. We ignore focus paragraphs that do not contain any names of U.S.-based, publicly listed firms. Finally, text are grouped per firm per event date, and for each group a CAR_3 is computed accordingly. This yields 22,317 instances, 5,848 of which have information gathered from more than one news. A total of 1,330 firms are covered

[4]Targeting at *acquired* and *Facebook* happen to have the same binarized tree.

TGT-LEX-TLSTM	0.63	0.63
TGT-CTX-TLSTM	**0.64**	**0.66**

Table 2: AUCs of different embedding methods.

	+CAR_3	-CAR_3	+CAR_3 >+2%	-CAR_3 <-2%
Sentiment-based	0.53	0.55	0.59	0.58
BI-LSTM	0.58	0.58	0.66	0.63
TGT-CTX-TLSTM	**0.63**	**0.62**	**0.70**	**0.68**

Table 3: Final AUCs.

in our data. We randomly select 1,000 and 2,000 instances as development and test sets, respectively, and the rest are used for training. The numbers of positive and negative CAR_3 examples in the training, development and test sets are fairly balanced, as shown in Table 1.

Evaluation Metric: Although the task of information content effect prediction is a binary classification problem, we do not evaluate our models using the accuracy metric because the data are automatically aligned and some CAR_3 values may not reflect the information correctly. Instead, we evaluate the performance of the models by the area under the precision-recall curve (AUC), where *precision* is the fraction of retrieved positive/negative effect instances that really have positive/negative impact, and *recall* is the fraction of positive/negative effect instances that are retrieved.

6.1 Development Experiments

Table 2 summarizes AUCs of both positive and negative effect predictions on the development set for models using different embedding methods. First, the deep neural embedding approaches outperform the conventional sentiment-based representation widely exploited in finance research. This shows that deep neural models are stronger in capturing news information on and beyond sentiment signals. Second, compared with the sequential embedding strategy, namely BI-LSTM, those Tree-LSTM based (TLSTM) dependency embeddings perform better, demonstrating the benefit of syntactic information. Finally, the information content prediction can benefit from the target-dependent tree transformation (TGT) compared with that using the root word (RT). In addition, the performance of target-dependent models can be improved by incorporating an input word embedding (LEX) with its contextual information (CTX). It is worth noting that the main improvement comes from using the neural feature representation instead of the sentiment word statistics.

6.2 Final Results

Table 3 gives the AUCs for the baseline sentiment-based representation, the sequential embedding BI-LSTM, and the targeted dependency tree method TGT-CTX-TLSTM evaluated on the test set. TGT-CTX-TLSTM outperforms the other baselines, and the improvements between models are statistically significant ($p \leq 0.05$).

One possible application of the proposed model is the use as a security recommender in the financial domain. Thus we apply the model to instances with $|CAR_3| > 2\%$, namely information with high impact. A total of 1,021 instances in the test set pass this threshold. As shown in Table 3 the proposed model achieves AUCs of 0.7 and 0.68 on +CAR_3 and -CAR_3, respectively. The results not only show the robustness of our model compared to the baselines but also demonstrate its applicability.

To demonstrate the attention mechanism for weighing individual news, Table 4 shows three sets of news, each of which consists news from the same event window and mentioning a specific firm. Both the CAR_3 and the predicted effect probability for each event window are given, and the modeled weight is shown in front of each news, which meets human expectations. For example, one would expect that the news of Wal-Mart Stores Inc missing its profit expectation is more influential than that of being capable of paying shopping using smartphones at Wal-Mart, as shown in the first news group.

- Target: Wal-Mart Stores Inc; CAR_3: -4.7%; TGT-CTX-TLSTM: 0.21
  - 0.95 Wal-Mart Stores Inc's (WMT.N) full-year profit may miss analysts' expectations as growth slows in its international markets, pressuring the company even as its U.S. discount stores continue to prosper.
  - 0.05 A group of big retailers that includes Wal-Mart Stores Inc, Target Corp and Japan's 7-Eleven is developing a mobile payment network, adding to the proliferation of options that let consumers pay with smartphones.
- Target: Oshkosh Corp; CAR_3: 9.8%; TGT-CTX-TLSTM: 0.81
  - 0.66 Activist investor Carl Icahn offered to buy all the outstanding shares of Oshkosh Corp (OSK.N) Thursday for a 21-percent premium to the U.S. truckmaker's closing price on Wednesday, sending its shares to their highest in more than a year.
  - 0.34 Truck maker Oshkosh Corp (OSK.N) advised its shareholders on Thursday to take no action related to activist investor Carl Icahn's offer to buy all outstanding shares in the company for $32.50 each.
- Target: Sony Corp; CAR_3: -2.3%; TGT-CTX-TLSTM: 0.27
  - 0.86 Sony Corp stuck with its full-year profit forecast after slashing its outlook for TV sales, confident that other units will perform better than earlier anticipated to offset additional losses in the unit.
  - 0.14 Japan's biggest technology conglomerates reported quarterly results, with weak TV demand a common theme at both Sony Corp and Sharp Corp.

Table 4: Learned weights for different news.

7 Related Work

Our work is related to research that applies NLP techniques on financial text to predict stock prices and market activities. In terms of corpora, financial news (Leinweber and Sisk, 2011; Xie et al., 2013; Luss and d'Aspremont, 2015; Ding et al., 2015), firm reports (Kogan et al., 2009; Li, 2010; Lee et al., 2014; Qiu et al., 2014) and web content, such as tweets (Bollen et al., 2011; Vu et al., 2012) and forum posts (Das and Chen, 2007; Gilbert and Karahalios, 2010) have been studied. In terms of linguistic features, existing work can be classified into tree major categories: bag-of-words (Kogan et al., 2009; Lee et al., 2014; Qiu et al., 2014), sentiment-based (Das and Chen, 2007; Li, 2010; Bollen et al., 2011; Vu et al., 2012; Luss and d'Aspremont, 2015), and information-retrieval-based (Schumaker and Chen, 2009; Xie et al., 2013; Ding et al., 2015) methods. Our work falls into the category of information retrieval-based features by exploiting syntax information derived from a dependency parser. However, different from the aforementioned work, our goal is not to predict stock prices but to measure the economic value of news information content.

The proposed Tree-LSTM based model for automatically representing syntactic dependencies is in line with recent research that extends the standard sequential LSTM in order to support more complex structures, such as Grid LSTM (Kalchbrenner et al., 2015), Spatial LSTM (Dyer et al., 2015), and Tree-LSTM (Le and Zuidema, 2015; Tai et al., 2015; Zhu et al., 2015; Miwa and Bansal, 2016). We consider the information content prediction as a semantic-heavy task and demonstrate that it can benefit significantly from a novel target-specific dependency Tree-LSTM model.

8 Conclusion

We showed that the impact of information in news release can be predicted using a firm's CAR, and that a proposed target-depend Tree-LSTM model, incorporating contextual information with syntax dependencies, is more effective in representing information content in news text compared to the classic bidirectional LSTM model and a baseline sentiment-based representation. The proposed model can serve as a security assessment tool for financial analysts, and benefit more comprehensive financial models and studies.

Abstract

Truly effective and practical educational systems will only be achievable when they have the ability to fully recognize deep relationships between a learner's interpretation of a subject and the desired conceptual understanding. In this paper, we take important steps in this direction by introducing a new representation of sentences – Minimal Meaningful Propositions (MMPs), which will allow us to significantly improve the mapping between a learner's answer and the ideal response. Using this technique, we make significant progress towards highly scalable and domain independent educational systems, that will be able to operate without human intervention. Even though this is a new task, we show very good results both for the extraction of MMPs and for classification with respect to their importance.

1 Introduction

Over the last few decades, technology has provided us many powerful tools that have completely changed our daily routines. However, one crucial area where technology has yet to have the significant impact suggested by its true promise is in education. Most students around the world have been learning in the same manner for decades. Nevertheless, in the past few years technology has started to increase its role in the learning process and has begun improving the effectiveness of students and instructors. Several groups are developing tools or systems with the goal of improving the feedback provided to students and instructors, assessing students' understanding of a concept, and facilitating their self-guided learning.

Intelligent Tutoring Systems (ITSs) were created with the goal of improving learning through real-time and personalized feedback for students (Graesser et al., 2001; Rosé et al., 2003; Makatchev et al., 2004; Pon-Barry et al., 2004). ITSs need to be able to interpret complex student responses and improve their feedback as they process more questions and responses, but essentially all existing systems require skilled developers to write new rules or train new classifiers for each additional question. Generally, an ITS only provides feedback to students, and when they do provide feedback to instructors, it is typically just high-level information regarding the correctness of the answer. Much of the prior work in this area originated in educational assessment systems (Mitchell et al., 2002; Sukkarieh et al., 2003; Nielsen et al., 2009). Most such systems investigate similarity or entailment relationships between a learner's answer and the reference answer, and then communicate a score to the teacher.

More recently, a new type of educational technology has emerged with the goal of increasing student engagement in classrooms (Paiva et al., 2014). Classroom Engagement Systems (CES) are meant to replace audience response (clicker) systems (Duncan, 2006; Fies and Marshall, 2006) by allowing students to construct answers to free-response questions. Unlike an ITS, the main goal of a CES is to facilitate teacher-student interaction. However, the system Paiva and associates present has some notable weaknesses: the analysis is strictly lexical, all content words are treated with equal importance, and only a small number of student responses are chosen as representatives.

The lack of tools to precisely identify the importance of concepts in the reference answer without manual intervention for each question, and the lack of tools to analyze the nature of a student's response,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3226–3236, Osaka, Japan, December 11-17 2016.

Q: Explain how mass is different than weight.

RA: Mass tells you how much matter an object has. Weight tells you how gravity affects the mass and it changes when gravity changes.

Reference Answer MMPs:		**Student Answer** MMPs:
1. Mass tells you how much matter an object has.^{P}	$\Longleftarrow$	1. Mass is the amount of matter an object holds.
2. Weight tells you how gravity affects the mass.^{P}		2. Weight is how heavy/light something is.
3. Weight changes when gravity changes.^{S}	$\Longleftarrow$	3. Weight gets heavier in higher gravity.

Figure 1: MMP Overview. **P** refers to a primary MMP while **S** denotes a secondary MMP. The entailment symbol signifies that the student understood that MMP.

again without manual coding per question, are significant weaknesses in existing educational technology. To that end, this paper takes important steps to address those weaknesses, introducing methods that will enable educational systems to effectively analyze deep semantic relationships between a learner's answer and a reference answer. Our primary contributions are:

- We introduce the concept of Minimal Meaningful Propositions (MMP), a decomposition of text, such as a question's answer, into the set of propositions that individually represent single minimal claims or arguments that cannot be further decomposed without losing contextual meaning, and taken as a whole represent the entire meaning of the text.
- We present a computational method for breaking text down into its MMPs.
- We present a method, features and categories to classify a reference answer's MMPs, which will allow educational systems to ensure feedback is focused on the most pertinent points.

MMPs are extracted from the reference answer to enable a thorough comparison between it and a student's response in order to diagnose which concepts were understood, misunderstood, or omitted from the response, as well as to determine the importance of those concepts. The research described in this paper will represent a strong foundation for the next generation of fully automated scoring systems. A complete example showing how MMPs are useful is given in Figure 1. Here we show a question, the reference answer, its MMPs, the student answer MMPs and their entailment relations. As can be seen, the student fails to address primary MMP 2 from the reference answer. However, the student successfully understood the concepts expressed in MMPs 1 and 3.

The final outcome of this approach to analyzing student responses will open a variety of new possibilities for fully automated educational systems. For instance, it will support: improved dynamic analysis of student answers to novel questions, the ability to focus on the most important conceptual misunderstandings, the means to provide meaningful feedback to instructors regarding the classroom understanding of concepts, and a construct for more effectively grouping similar answers either for realtime classroom analysis or for assessment purposes. This will allow such systems to be flexible enough to adapt to individual student and teacher needs and to various pedagogical methods. MMPs could also be an effective level of analysis in a wide variety of other NLP applications such as summarization, translation and more general textual entailment. In the following sections we describe the MMP concept and present our methods and results for MMP Extraction and MMP Classification.

2 Related Work

The goal of our work is not only to research means to better assess students' answers in a classroom environment, but also to research tools for more effective and constructive feedback regarding overall understanding of a subject. Although we are the first to introduce the concept of Minimal Meaningful Proposition, other works in the literature have had relatively similar goals (Burrows et al., 2015).

C-rater, a scoring engine developed by ETS, grades a student's answer to assessment questions (Leacock and Chodorow, 2003). C-rater recognizes paraphrases of a set of reference answers to determine wether the student's answer is correct. Although much of the work done by c-rater has been automated in the past years (Sukkarieh and Stoyanchev, 2009), it still requires an appropriate set of responses that have

Data	#Questions	Answ. Words/Question	#MMP	MMP/Q	Primary	Secondary	Extraneous	Redundant
Train	208	25.5	826	4.0	676 (81.8%)	100 (12.1%)	41 (4.9%)	9 (1.0%)
Test	109	22.1	383	3.5	323 (84.3%)	45 (11.7%)	12 (3.1%)	3 (0.7%)
Total	317	24.3	1209	3.8	999 (82.6%)	145 (11.9%)	53 (4.3%)	12 (0.9%)

Table 1: MMP counts and the average length of the reference answers in words.

already been holistically scored by trained raters.[1] In contrast, our approach is fully automated and can be used in a dynamic setting to recognize the focused relationships between a specific reference answer proposition and the student's response. MMPs are also classified for importance in a fully automated, domain-independent fashion using general linguistic features extracted from the reference answer, the question, and their interrelationships.

Another approach with a similar goal is entailment of semantic facets (Nielsen et al., 2009). Here, rather than checking whether the student's answer is a paraphrase of the reference answer as a whole, the authors break the target conceptual knowledge down into fine-grained *facets*, derived roughly from the typed dependencies in a parse of the reference answer. This might allow pinpointing the facet of the reference answer that the student misunderstood at a very fine-grained level, but unlike Minimal Meaningful Propositions, facets are often not *meaningful* without much more context. Hence, entailment of a semantic facet could be misleading with regard to student understanding.

Other related concepts have been introduced in text summarization, question answering and dialog generation. For example, *Elementary Discourse Units* (EDUs), developed for discourse segmentation, are defined as minimal non-overlapping textual spans representing units of discourse. EDUs are generally used as a precursor to identifying relationships between discourse segments. Previous work extracting EDUs has proposed rule-based approaches (Polanyi et al., 2004), classification of discourse boundaries (Soricut and Marcu, 2003; Subba and Di Eugenio, 2007; Afantenos et al., 2010) and sequence labeling (Hernault et al., 2010). However, in contrast with MMPs, EDUs are not necessarily either minimal or meaningful – for example, conditionals required for *meaningful* interpretation of a proposition are not included in the same EDU as their consequent, and a "minimal" discourse unit text span can often be broken into multiple finer-grained *minimal* propositions.

Nenkove and Passonneau (2004) introduced the *Summary Content Unit* (SCU) as a key component of the Pyramid evaluation method for multi-document summarization. SCUs are defined as semantically-motivated, sub-sentential units of variable length and emerge from the annotation of multiple human summaries for the same input. Previous work extracts SCUs manually (Nenkova and Passonneau, 2004; Nenkova et al., 2007) or uses topic modeling to match topics with manually-extracted SCUs (Hennig et al., 2010). However, to the best of our knowledge, there is no model for automatically constructing SCUs. Another important difference is the input data being used. SCUs are extracted from multiple, well-structured human summaries; whereas, MMPs emerge from a single version of a potentially poorly-structured answer. A review of SCUs also finds that, while they are *meaningful*, they are not necessarily *minimal* – many SCUs are syntactically complex and would be divided into multiple MMPs.

3 Data Description

The data used in our experiments consists of 317 questions that were asked in real science classes from middle school. Each question comes with the teacher's reference answer, which was decomposed into MMPs by two graduate students (from education and science major) and adjudicated by a third (from Education and Linguistics). Each of the first two annotators labeled the data independently and the adjudicator decided the correct label among the existing annotations.

The first stage of the annotation was identifying the MMPs in the instructors' reference answers. Annotators were provided guidelines for restating a reference answer as its corresponding set of minimal meaningful propositions, or distinct stand-alone claims, and given several guiding examples.

The second stage of the annotation process was to classify the MMPs into one of the following classes:

[1] https://www.ets.org/research/topics/as_nlp/written_content/

1. *primary*: fundamental to answering question
2. *secondary*: relevant but not integral to answer – often clarify or qualify a primary MMP
3. *extraneous*: unnecessary or minimally relevant to the question
4. *redundant*: contain information directly or indirectly provided by the question

As can be seen in Table 1, 1209 MMPs were annotated in total, with an average of 3.8 MMPs per answer. 999 MMPs were annotated as primary, 145 as secondary, 53 as extraneous and 12 as redundant. Training and test sets were created by randomly splitting the questions (2/3 in training and 1/3 in test).

4 Minimal Meaningful Propositions

Consider a sentence to be comprised of a set of related propositions. We define an MMP as a *proposition* that cannot be broken down into finer-grained propositions (it is *minimal*) and still be interpretable without further context (it is *meaningful* on its own). A sentence usually contains more than one MMP. Note that the MMPs only state explicit propositions, not any implications, presuppositions, or entailments. Moreover, in our case, an MMP should relate to the question in a way or another, when treated independently. The goal of the present work is to automatically extract MMPs from a question's reference answer and classify them according to their importance. The example below is a real question and reference answer asked in a classroom, and its human-extracted MMPs.

Q: How did Rutherford figure out that atoms are mostly empty space, and that the nucleus is positive?

RA: He used gold foil hammered about an atom thick, and placed radium in a lead lined box that emitted positive alpha particles towards the gold foil.

MMPs:

1. Rutherford used gold foil with the thickness of an atom.
2. Rutherford placed radium in a lead lined box.
3. The lead lined box emitted positive alpha particles towards the gold foil.

Extracted MMPs can contain information that was initially spread out over the sentence. These finer-grained propositions allow us to separate the different pieces of information expected from a student and classify their importance. An educational system that successfully uses MMPs will be able to tell the teacher which concepts were understood, contradicted, or omitted by the students.

5 MMP Extraction

A high level summary of the MMP extraction process is as follows. First, in the learning phase, we learn the unique set of syntactic patterns covering all of the gold-standard human generated MMPs. Then, in the application or testing phase, we process sentences recursively, on each call extracting the MMP associated with the longest matching pattern learned from the training set and recursively processing the remainder of the sentence. If part of the sentence remains and no further patterns match, the remainder forms the final MMP. The details of this process follow.

In the *learning* phase, the algorithm learns structural templates from a shallow parse (i.e., chunks) of the gold-standard MMPs in the training data. These templates will be used to extract MMPs from test set answers. Figure 2 shows an MMP and the structure extracted. Table 2 shows the most frequent structures in the dataset. The frequencies follow a Zipfian distribution, with the five most common structures covering almost 50% of the MMPs.

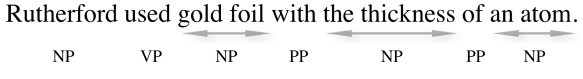

Figure 2: MMP Structure

Rank	Structure	%
1	*NP, VP, NP*	19.5
2	*NP, VP, NP, PP, NP*	11.3
3	*NP, VP, PP, NP*	8.5
4	*NP, VP*	7.6
5	*NP, PP, NP, VP, NP*	2.6

Table 2: Most Frequent MMP Structures

In the *test* phase, the algorithm first splits the answer into sentences, which it parses using Stanford CoreNLP (Manning et al., 2014). Then conjunctions are automatically pre-processed to: replace enu-

	F_1-score			BLEU score			
	Avg. P	Avg. R	F_1	1-grams	2-grams	3-grams	4-grams
MMP Extraction	**0.725**	**0.552**	**0.627**	**0.569**	**0.495**	**0.360**	**0.172**
Predicates Baseline	0.437	0.375	0.404	0.290	0.229	0.160	0.107
Sentence Baseline	0.438	0.449	0.443	0.377	0.315	0.246	0.154

Table 3: MMP Extraction Results

merations with a single base phrase type, and split conjoined SVO (i.e., Subject Verb Object) structures into separate sentences, replicating the subject and verb as appropriate.

Then, for each sentence, the algorithm finds the longest structure matching a pattern learned during training. If the matching pattern only covers a portion of the sentence, the algorithm extracts that portion as an MMP and recursively processes the unmatched portion of the sentence. If any base phrases remain unmatched when the recursion bottoms out, they become the final MMP. Due to the nature of the algorithm, our method is generalizable to different questions types or domains.

Given our example question **Q** in Section 4, the automatically extracted MMPs are:

1. He used gold foil hammered about an atom thick.
2. Placed radium in a lead lined box.
3. Emitted positive alpha particles towards the gold foil.

As can be seen, the automatically extracted MMPs are very similar to the human-generated examples. The major difference being the missing subject in the last 2 MMPs, which we will address in future work.

5.1 Results

To evaluate the performance, we compared the set of system-generated MMPs with the gold standard for each question. We pre-processed both system-generated and gold-standard MMPs to remove stop words and stemmed the remaining words using the Porter Stemmer. We report the Precision, Recall and F_1-score as well as the BLEU score. Precision is computed as the number of matching words divided by the total number of words in the system-generated MMP. Recall is the number of matching words divided by the total number of words in the gold-standard MMP. The BLEU score, introduced in (Papineni et al., 2002), is a highly-adopted method for automatic evaluation of machine translation systems. BLEU is based on a modified computation of *precision*, using the number of matching n-grams. It ranges from 0 to 1, with values closer to 1 representing more similar texts. Using different values of n, we can measure different aspects of the evaluation, *adequacy*: n = 1-2, and *fluency*: n = 3-4.

MMP-level metric values are based on a greedy iterative alignment of system-generated and gold-standard MMPs, where on a given iteration the algorithm aligns, processes, and then removes the pair with the highest F_1-score (or BLEU score). MMP-level values are averaged to get a question-level value, and finally, Table 3 presents the average over all questions.

For comparison we also computed two baselines. The *Sentence Baseline* is a method in which every sentence of the reference answer is treated as an MMP. In the *Predicates Baseline*, we build an MMP for every predicate in a sentence. Using SENNA (Collobert et al., 2011), we then identify the predicate's arguments and attach them to the MMP. As can be seen, the method that we propose, *MMP Extraction*, significantly outperforms the two baselines, achieving an F_1-score of 0.627 and showing that the pattern matching approach generalizes well on new, unseen questions. The precision is higher than the recall, meaning that the system generated MMPs are shorter than the human-generated ones.

The BLEU score achieved for different n-gram sizes are also considerably higher than the baselines'. The *adequacy* scores, unigrams and bigrams, are fairly high for this new task. As we increase the number of consecutive words to be scored, the score drops. This is a normal behavior for tasks where different solutions to a problem exist without any compromises. When using the BLEU metric to score the *fluency*, trigrams and 4-grams, it is strongly recommended that you have more than one reference solution or, in our case, human-annotated MMPs. When a single reference solution exists, as in our case, substantially lower values are expected (Papineni et al., 2002). For comparison, in a translation task, on a test corpus of about 500 sentences, a human translator scored 0.346 against four references and scored 0.257 against

two references, when $n = 4$ (Papineni et al., 2002).

5.2 Error Analysis

Some of the most common errors occurring in the extraction phase are associated with the subjectivity of the task. Consider the following reference answer and its system-generated MMPs:

RA: *Once light reaches our eyes, signals are sent to our brain and our brain deciphers the information in order to detect the appearance, location and movement of objects.*

1. Light reaches our eyes.
2. Signals are sent to our brain.
3. Brain deciphers the information.
4. In order to detect the appearance, location and movement of objects.

First, in the human-annotated set of MMPs, 1 and 2 are joined into a single proposition: *When light reaches our eyes, signals are sent to our brain*. The annotators believed that the two pieces of information were too dependent to be separated. On the other hand, the system found two different claims and therefore, extracted two propositions. In addition, the fourth MMP generated by the system is dependent on the context and thus, not very good. The annotators broke this piece of text into three different MMPs, one for each element detected by the brain. In future, we plan to solve this issue using the semantic roles of constituents. We will also include coreference resolution to improve detecting agents.

Other errors made by the system can be fixed by including more syntactic and semantic information. For example, in a student response where the object does not immediately follow the predicate, our algorithm can get confused, and in some cases will not include the object as part of the MMP. In future work, we will check the validity of verb usages in an external resource such as VerbNet (Schuler, 2005), which will help us distinguish, for example, between transitive and intransitive verbs.

6 MMP Classification

Given a question, reference answer and its MMPs, our goal is to identify the importance of each MMP with respect to the question. We follow a supervised approach to classify MMPs as *primary, secondary, redundant* or *extraneous*. Many of the features the classifier uses to determine this importance compare the MMPs to the question. Hence, in preparation for feature extraction, we pre-process the question to eliminate unnecessary information and identify its key concepts. We then extract a number of features and train a classifier to predict labels for each MMP.

6.1 Question Pre-processing

Questions often include instructions to guide students on issues unrelated to content (e.g. *answer in $\leq$ 2 sentences*). An analysis of such text revealed it can provide unnecessary errors to our model. Therefore, we filtered out text matching patterns indicative of such instructions. Three cases were explored:

Hints. We filtered out sentences starting with the keyword *hint*, if the hint was unrelated to other question content (e.g. Why do models change over time? *Hint: think about why your idea changed.*). The hint sentence was deemed related if the Pointwise Mutual Information (PMI) between any of its words and those of the rest of the question exceeded a threshold of $T = 0.28$, which was learned from annotated word pairs (*related* vs. *not related*) from the training data. In the example above, the hint was removed, since no relationship was found with the preceding sentence.

Punctuated Instructions. While analyzing the training data, several additional patterns indicating content-independent instructions were discovered. For example, in the question: *"Using the tables, describe how you know the object is accelerating."*, the instruction *using the tables* is unrelated to understanding the core *object acceleration* concept. In a substantial number of patterns, the instructions were delimited by punctuation, as in this case. Rules were developed to detect and filter out these punctuation-delimited content-independent instructions.

Parentheticals. Parenthesized text often includes important abbreviations, definitions or examples, but it can also contain content-independent instructions. Based on analysis of the training data, we wrote rules to filter out parentheticals that: 1) contain imperative statements: *... (Do not touch your eyes!)*, 2)

start with negation: *What gives an atom its VOLUME (not its mass)?*, or 3) do not contain a noun, since this is highly correlated with instructions: *... the dependent variable (what we measure).*

6.2 Key Concept Identification

We identify a subset of the key concepts in the question for use in feature extraction. Specifically, we focus on concepts identifiable using part-of-speech tags and grammatical dependency relations, which covers the vast majority of key concepts. Generally key concepts are expressed as nouns, but many are also expressed as adjectives (*Explain what* homogeneous *means*) or gerunds (*Explain what* weathering *means*). The most common dependency types associated with key concepts are: adjectival modifiers (`amod`), noun compound modifiers (`nn`), and copulas (`cop`). However, we only consider dependency word pairs that are collocations as determined by applying the *Likelihood Ratio* statistic, using word counts from a large corpus consisting primarily of *Gigaword* (Graff and Cieri, 2003). If a dependency pair is not a collocation only constituent words matching previous selection criteria are used (e.g., since the dependency concept *equal forces* is not a collocation, only *forces* is retained). Given the question: *What evidence can indicate if a change is physical?*, the system identifies the key concepts: *evidence* and *physical change*.

6.3 Classification

To classify MMPs, we follow a supervised approach, training Random Forests on features indicative of the classes. However, since the original data lacks of *redundant* MMPs (see Table 1), we enriched the *training* data by adding 64 manually generated examples. Following the patterns in the training data, we created redundant MMPs by using information already stated in the question or paraphrasing parts of it.

Feature Engineering. Using information from the training data, we manually designed features based on the question, the MMPs, the reference answer, and the relations between them. From all the features explored, we chose the set that performed best in 10-fold cross-validation (10xCV) on training data. The final set of features is described in Table 4.

Note that two versions of the question were considered in this process: the original question (Q) and a version based strictly on its interrogative and imperative sentences (Q′). Various types of features were explored: 1) *features derived from the question representation* – $\{1, 2, 4\}$, 2) *semantic features* – $\{5, 18, 25, 27\}$, 3) *syntactic features* – $\{6, 7, 8, 9\}$, 4) *features focused on mismatches between the MMP and question* – $\{20, 21, 26\}$ and 5) *features focused on overlapping information* – $\{3, 10, 13, 14, 15\}$.

QUESTION FEATURES

1.	Q contains structures similar to *"tell me what you know"*.
2.	Q has only one concept.
3.	Q has only one concept and it appears in MMP.
4.	Q has only one MMP attached.
5.	Q′'s concepts have hyponyms/hypernyms in MMP. (Fellbaum, 1998)
6.	Q′'s subject is lemma in MMP.
7.	Q′'s subject is concept in MMP.
8.	Q′'s subject is subject in MMP.
9.	Q′'s predicate appears in MMP.

MMP FEATURES

10.	#overlapping lemmas between MMP and Q, excluding stop words.
11.	max PMI of MMP words (not in Q) and Q words.
12.	min PMI of MMP words (not in Q) and Q words.
13.	all MMP words appear in Q.
14.	all MMP words appear in a Q's sentence.
15.	all MMP words appear in a Q's interrogation.
16.	at least one MMP concept addressed by Q.
17.	MMP's predicate occurs in Q.
18.	MMP's predicate has hyponyms/hypernyms in Q.
19.	MMP's subject is subject in an answer sentenceaddressing Q.
20.	MMP provides a reason, although Q did not ask for it.
21.	MMP provides more information than required by Q.
22.	MMP is relevant for Q.
23.	the current MMP embeds other MMP.
24.	MMP's subject in Q′'s concepts.
25.	MMP's subject relates to Q′'s concepts using hyponymy or PMI.
26.	MMP's subject not in Q′, but refers to previous MMPs.
27.	max similarity score between MMP and Q′'s sentences.

Table 4: Description of Features

6.4 Results and Discussion

We report Precision, Recall and F_1-score per class, using both a *strict* evaluation, based on adjudicated labels, and a *relaxed* evaluation, where the system is credited for matching either annotator's label. The results from 10xCV on the training data are presented in Table 5. As can be seen, *primary* and *redundant* are the best performing classes – they follow more recognizable patterns than the others. Whereas, *secondary* is the worst performing class. The vast majority of system errors on the *secondary* class are

predictions of *primary*. Similarly, in analyzing the human annotation disagreements for MMPs adjudicated as *secondary*, the confusion was with *primary* in the vast majority of the cases – discriminating between *secondary* and *primary* is hard for humans as well as the system. This suggests there is more of a continuum between *primary* and *secondary* rather than a sharp decision boundary. This will be explored further in future work.

While the increase in the F_1-score for the *relaxed* evaluation is more than 6% for *secondary*, when viewed as a relative reduction in the error rate, the increase is considerable for all classes, ranging from 10% to 27%. This provides further motivation for a future investigation into the similarity in the errors in system and human judgements. Despite challenges, the high system F_1-score demonstrates the feasibility of the task and the promise of the system.

Next, we compare the performance to the majority class baseline, where each instance is classified as *primary*. Table 6 reports the weighted F_1-score achieved on both the test set and in 10xCV on training. The proposed approach outperforms the baseline in both scenarios. Our method shows an improvement of almost 16% in 10xCV compared with the baseline. Employing the *relaxed* evaluation, our performance is higher than the baseline with almost 16% on 10xCV and 7% on the *test* set.

The system outperformed the baseline under all scenarios (Table 6). It shows a slight improvement on test, even though the baseline results are 12% higher on test than on training. This difference in the baseline is due to the addition of redundant MMPs to the training data, as detailed earlier.

	Strict Matching			Relaxed Matching		
Classes	P	R	F_1	P	R	F_1
Primary	0.840	0.970	0.900	0.884	0.976	0.927
Secondary	0.675	0.250	0.365	0.835	0.303	0.429
Redundant	0.875	0.662	0.753	0.856	0.797	0.810
Extraneous	0.882	0.365	0.517	0.950	0.514	0.588

Table 5: Training Set 10xCV Results

	Training 10xCV		Test	
System/Approach	Strct F_1	Rlxd F_1	Strct F_1	Rlxd F_1
Proposed Approach	**0.810**	**0.857**	**0.815**	**0.876**
Majority Class	0.653	0.701	0.770	0.804

Table 6: System weighted F_1-score vs. Baseline

Ablation study. To assess the contribution of different categories of features, we performed an ablation study. Table 7 reports the weighted F_1-score when training on *all* of our features, and when training on all features except the specified set. The final column shows the increase in the error after removing the feature set, as a percent of 0.185 – the error when training on all features.

All feature categories have a substantial contribution to the results. The features derived from *Mismatching Information* between the question and MMP are especially useful – their removal results in a 21% relative increase in the error. The *secondary* and *extraneous* classes suffer the largest increase in error when *Mismatching Information* is not leveraged. This is logical since the *extraneous* information is not directly related to the question and *secondary* MMPs are optional and less directly tied to the question than *primary* MMPs. *Semantic features* have the second largest impact. While they help all classes, the greatest impact is on *primary* and *secondary* classes. MMPs with these classes contain highly relevant information for the question and the semantic features help identify indirect semantic relationships between parts of the MMP and the question. *Syntactic features* also have a positive contribution, especially for the *redundant* class. This is likely due to a more regular pattern in the mapping between components of a redundant MMP and the syntactic structure of the question. The *Question Representation features* also make a substantial contribution, particularly in classifying *primary*, *secondary* and *extraneous* MMPs. For example, if the question contained a single key concept and the MMP did not address it, the MMP is probably *extraneous*; whereas, if the MMP is strongly related to the key concept, then it is likely *primary* or *secondary*.

Feature Category *Removed*	**Wtd F_1**	**RIE%**
None (trained on *all* features)	0.815	–
Syntactic Features	0.800	8
Question Features (Q)	0.794	11
Question Representation Features	0.790	14
Semantic Features	0.787	15
Mismatching Information	0.776	21

Table 7: Feature ablation: weighted F_1 with *relative* percent increase in error (RIE) on Test

7 Conclusion

This work has resulted in three notable contributions. First, we introduced the concept of Minimal Meaningful Propositions and discussed how it can enhance feedback and accuracy in applications such as educational assessment. Second, we described an effective method for automatically extracting MMPs. The results of this approach were shown to be considerably higher than two meaningful baselines (0.184 absolute improvement on F_1 over a better baseline – 33% error reduction), validating the approach. Third, we successfully classified MMPs with respect to their importance, achieving a weighted F_1-score of 0.815 on the test set. This will enable applications, such as ITS, to respond appropriately based on different types of MMPs. This work introduces a new fully automated, domain-independent foundation for analyzing students' free responses, at a level of granularity that is appropriate for contextual comparison. The corpus described in this paper is publicly available for research purposes and represents a substantial contribution to multiple NLP sub-communities. This will quicken the pace of much related research. The annotated corpus along with the annotation guidelines will be available from the H*i*LT Lab Resources webpage.[2]

Abstract

News portals, such as Yahoo News or Google News, collect large amounts of documents from a variety of sources on a daily basis. Only a small portion of these documents can be selected and displayed on the homepage. Thus, there is a strong preference for major, recent events. In this work, we propose a scalable and accurate First Story Detection (FSD) pipeline that identifies fresh news. In comparison to other FSD systems, our method relies on relation extraction methods exploiting entities and their relations. We evaluate our pipeline using two distinct datasets from Yahoo News and Google News. Experimental results demonstrate that our method improves over the state-of-the-art systems on both datasets with constant space and time requirements.

1 Introduction

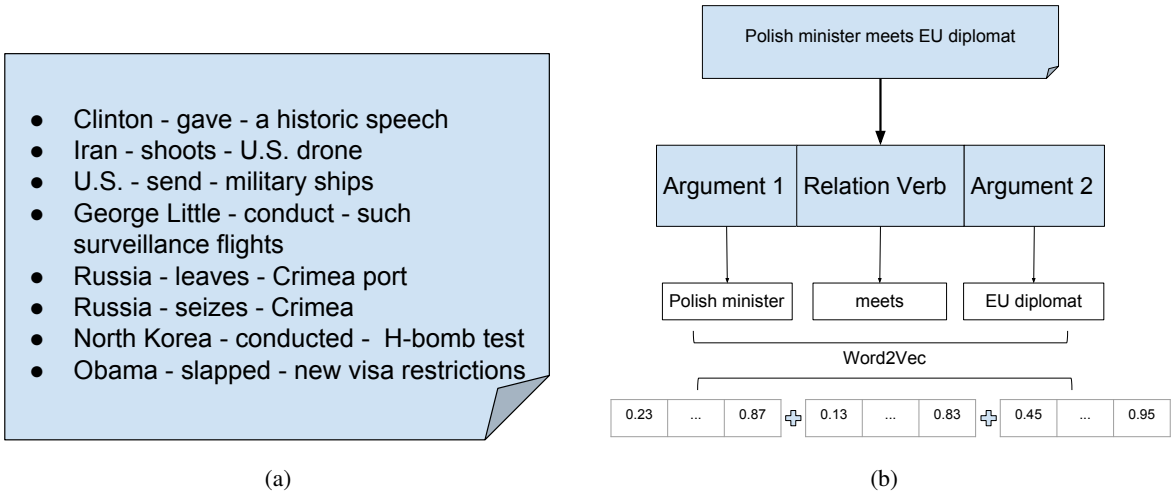
First Story Detection (FSD) is the task of detecting the first document about a new event given a stream of documents (Allan et al., 1998; Allan et al., 2000a). The task is also known as New Event Detection (NED). The problem appears in several real-world applications where news stories are accumulated and presented to users in near real-time. A FSD system should be accurate, scalable, and process a stream of articles in a single pass. The output of such a system is very valuable to news portals such as Yahoo News, Google News, since the rapid detection of a new event is crucial for the service reputation. FSD is a very challenging, if not impossible, task for human operators, since it requires inspecting millions of documents per day. As a result, accurate, automatic solutions are very desirable.

The majority of the FSD systems in the literature attempt to classify a document as a first story if the document differs significantly from those published before and thus may describe a new event. This is accomplished usually in two steps. In the first step, the nearest neighbor of a new document in the previous document stream is identified. In the second step, the similarity between the new document and its nearest neighbor is considered in order to decide if it is a first story or not. In this methodology, the selection of an appropriate similarity metric and the selection of an informative document representation are essential. As a result many different metrics have been studied in the literature, such as the cosine similarity (Petrović et al., 2012), the KL-Divergence (Karkali et al., 2013), and the named entities overlap (Kumaran and Allan, 2004). So far, terms and entities occurring in a document have been the main representation units, boiling down the task to detecting documents with novel terms and entities in a stream.

We believe that existing approaches under-utilize the semantic information present in news articles, specifically, actions performed by entities, or interactions that happened between a pair of entities. These actions and interactions are essential, since they describe events, around which a news story revolves. Our hypothesis is that often the same entities and terms may appear in documents that describe different events – sometimes related – leading to false negatives. For example, when North Korea conducted the hydrogen bomb test in January of 2016, the U.N. security council called for an emergency meeting. This resulted in two different events in news streams in the following order: (1) North Korea conducted the H-bomb test, (2) the U.N. announced a meeting about North Korea. The articles about the two events have a very similar term and entity distribution. Nevertheless, the extracted relations about North Korea and the U.N. differ in the two story lines. For the first story line, relations such as "N.Korea - concerns - U.N." are detected while for the second story line relations such as "U.N. - announces - meeting about North Korea" are present.

Motivated by this observation, we propose to utilize relations between entities when deciding if an article should be classified as a first story. For this purpose, we define a relation as an entity-action-entity triplet (see Figure 1a)

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers,
pages 3237–3244, Osaka, Japan, December 11-17 2016.



(a) (b)

Figure 1: (a) Relations extracted from different news articles. (b) Our proposed relation representation.

describing events and sub-events of a story. In addition, we rely on a distributed representation to represent our relation triplets in order to overcome lexical variation.

To the best of our knowledge, our approach is the first one to integrate relations between entities in a FSD system. Our experiments demonstrate that our system improves the detection error trade-of (DET) on a Yahoo News dataset by up to 29.6% compared to the best unsupervised system and up to 17.3% compared to the best supervised system. At the same time, we show that the space and time requirements remain constant over time suggesting that the method is suitable for very high volume streams.

The contributions of this work can be summarized as follows:

- We build an efficient, stream-based pipeline for detecting fresh news that uses traditional term similarity metrics amplified by relation and entity similarity information
- We propose a novel approach to model a document as a set of named entities and their relations.
- We make annotation and preprocessing tools as well as preprocessed datasets available [1].

The rest of the paper is organized as follows. In Section 2, we briefly describe related work on FSD, as well as recent advances in relation extraction. Section 3 follows with the description of our system. First, we provide details of a basic scalable FSD system. Then, we describe our proposed entity-relation document model and present our system in detail. In Section 4, we describe the evaluation procedure, the datasets, and the systems we compared with. In Section 5, we provide experimental results and analysis. Section 6, concludes the paper.

2 Related Work

First Story Detection has been extensively studied in the literature. One of the best-performing FSD systems proposed was UMASS (Allan et al., 2000b). This system retrieves the nearest neighbour of a new document. Then the system calculates a novelty score for the new document as the cosine distance, using incremental TF-IDF weighted vectors, to its nearest neighbor. This score is used to decide if it is a first story or not. In a work proposed by (Stokes and Carthy, 2001), the authors use two distinct document representations when searching for the nearest neighbor while on (Brants et al., 2003) the authors use different TF-IDF models per document category during the search. All these approaches leverage primarily statistical information about terms found in a document.

The same principle was extended in (Kumaran and Allan, 2005) where the authors incorporated information about entities, topics and also used a supervised classifier to perform the detection. In this work, we also use features that exploit the named entities. However, we extend the entity usage by capturing also the way that the entities interact.

The above approaches are not designed to scale with massive streams. Efficient first story detection was recently studied by (Petrović et al., 2010) where the authors proposed a constant time and space solution. They redesign UMASS (Allan et al., 2000b) utilizing a locality sensitive hashing (LSH) multi-index and apply the system on the Twitter stream. We deploy the same algorithm in our system for scalability. The (Petrović et al., 2010) system was also implemented in (McCreadie et al., 2013) as a storm topology that is able to process the Twitter Firehose in

[1] Supplementary paper material available at: `https://bitbucket.org/npan1990/firststory-annotator`

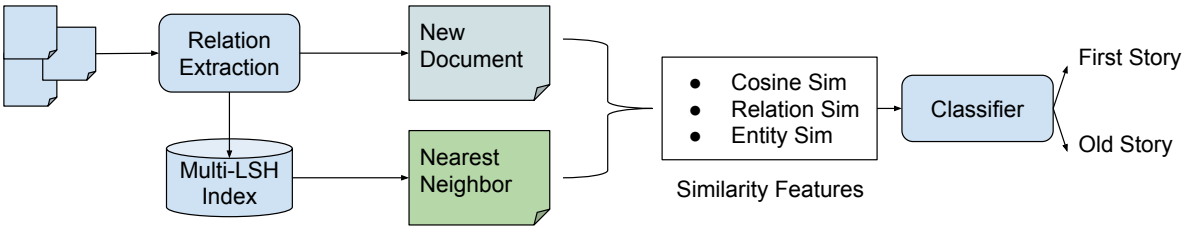


Figure 2: The First Story Detection pipeline we propose.

real-time using 70 processing units according to the author claims. On the same direction, the authors in (Karkali et al., 2013) develop an efficient approach that completely avoids the nearest neighbor identification by defining the novelty of a document as the novelty of its terms.

In addition, (Petrović et al., 2012) provides an extension of the system described in (Petrović et al., 2010) that addresses the synonymy problem by expanding the term vectors with paraphrases. The new system yielded a 13% improvement in detection error trade-of without significantly increasing the computational complexity. In our work we also address the synonymy problem, but from a different perspective through Word2Vec (Mikolov et al., 2013).

The method that we propose highly depends on a robust relation extraction mechanism. Since we are interested in generic relations independent of a predefined taxonomy, we rely on an open information extraction system. These systems detect open domain relations by self-training over a massive corpus (Banko et al., 2007) or heuristic rules (Fader et al., 2011; Etzioni et al., 2011; Schmitz et al., 2012). They allow the development of very scalable systems. The relations extracted often have a generic format of two arguments that are connected by a verb (see Figure 1a). In our work, we use OpenIE 4.1 (Etzioni et al., 2011) the successor of ReVerb (Fader et al., 2011), Ollie (Schmitz et al., 2012) and TextRunner (Banko et al., 2007).

3 The Proposed First Story Detection Pipeline

We design and implement a novel pipeline to solve the FSD task. In this section, we describe the main aspects of our pipeline. We begin by describing the basic approach and a scalable extension that uses locality sensitive hashing in Section 3.1. Then, in Section 3.2, we describe a holistic document representation based on relations and a similarity function that compares documents using this representation. Finally, in Section 3.3, we present how we identify first stories using various similarity features and a supervised classifier.

3.1 A Basic First Story Detection Pipeline

A generic pipeline for detecting first stories consists of two basic steps. In the first step, as soon as a new document arrives, the nearest neighbor is identified. In the second step, a similarity function is considered in order to measure how similar the new document is to its nearest neighbor and decide if it is a new story. This basic design was first instantiated by the UMASS system described in (Allan et al., 2000b). It uses cosine similarity and incremental TF-IDF document vectors and achieved state-of-the-art performance during the topic detection and tracking challenge (Fiscus and Doddington, 2002). Subsequently it was improved along two axes: (i) improved scalability by exploiting approximate nearest neighbor techniques, proposed by (Petrović et al., 2010), that use locality sensitive hashing, (ii) improved accuracy by addressing the synonymy problem through exploiting syntactic paraphrases (Petrović et al., 2012).

Our approach follows the basic First Story Detection paradigm. The main novel aspects of the pipeline we propose are: (i) New features are extracted improving the resolution of the similarity function. These features exploit the **relations** between the entities that appear in a document and we show how they can be obtained and incorporated in a novel similarity measure between documents. (ii) The various similarity features extracted are given to a supervised classifier that learns how to combine them, and decides if a new document is a new story. Our complete First Story Detection pipeline is illustrated in Figure 2.

3.2 Entity-Relation Document Representation

In this section, we describe how we model the entities and their relations in a document. In addition, we propose Relation Similarity (RelSim), a metric for comparing two documents in terms of their named entities and their relations. Our technique uses state-of-the-art relation extraction algorithms that extract the relationship between two arguments in a 3-tuple format (see Figure 1a).

Simplifying the Relations

The relation arguments are n-grams and in many cases consist of large text chunks or even sub-clauses. However,

these large text chunks add noise to the relations and rarely reappear on other documents making relation comparison a difficult task. For that reason, we employ a set of simplification heuristics in order to convert large relation arguments to small n-grams. Here is a summary of the rules:

- We require the first relation argument to contain a simple named entity. If it does, then the argument is replaced by the named entity.
- We require that the second relation argument is not a sub-clause. If it is we remove the relation.
- If the second argument contains a named entity the argument is replaced by the named entity. If it contains more than one named entities the relation is split into multiple relations.
- From the second relation argument we keep only the nouns and the adjectives.
- From the relationship verbs we keep only the core verb that expresses the action. Modals and auxiliary verbs are removed.

During the relation extraction, we also extract the named entities along with their types[2]. We keep only the named entities of type *Person*, *Location*, and *Organization*. In many cases, we observed that an entity was mentioned explicitly only once in the text, and then was referenced implicitly through pronouns in later sentences. So, after we have identified the entities and their types, we propagate them to the following sentences while replacing the pronouns (e.g. He-met-Putin translates to Obama-met-Putin).

Relation Representation

The UMASS system represents the documents as TF-IDF weighted vectors. However, in order to compare documents in terms of their relations we need a relation-oriented representation.

Definition 1 Relation: *A relation is defined as a 3-tuple* $r = (arg1, action, arg2)$. arg1 *is the main entity or actor of the relation.* arg2 *is the recipient of that action (e.g. Putin - meets - Obama) or a preposition that describes the action (Obama - landed - Thursday). The action is a simple verb.*

Definition 2 Bag of Relations: *The relation set* $R_d = \{r_1, \ldots, r_{|R_d|}\}$ *for a document d.*

In many cases the actor of a relation could have multiple textual representations or surface forms (e.g. Obama, Barack Obama, President of US). In addition, multiple relation verbs could express the same action. For example, the relations $r_1 = (A, proposes, X)$ and $r_2 = (A, suggests, X)$ have probably the same semantic meaning. Thus, we decided to exploit Word2Vec, a technique described in (Mikolov et al., 2013) that learns a vector representation for words. All the three relation parts were converted into their corresponding vectors. If the representation of a n-gram (e.g. "U.S. President") was not directly available we used the average vectors of the n unigrams. The resulting three vectors are concatenated to a large vector. The concatenated vector of a relation $r_1 = (A, meets, X)$ will be different than the concatenated vector of the relation $r_2 = (X, meets, A)$. Under this technique, similar relations will have a similar vector representation addressing this way the synonymy problem. The procedure is also illustrated in Figure 1b.

Comparing documents using relations

So far we have described how to represent a document as a set of simplified relations. However, it is unclear how to compare two documents using their relations. Thus, we propose Relation Similarity (RelSim), a metric that compares semantically two documents using their named entities and relations.

Assume that we have two documents d_1 and d_2 that we need to compare, each with its relations R_{d1} and R_{d2}, respectively. For each relation $r_i \in R_{d1}$ the method $simRD(r_i, d_2)$ returns a relation score rs_i that is equal to the cosine similarity with the most similar relation $r_j \in R_{d2}$. While searching for the most similar relation from d_2, $SimRD(r_i, d_2)$ also checks the distance to the inverse of the relation r_i. This decision was taken since in some cases, a relation r_i may be expressed in a reverse form on the document we compare. For example, the inverse relation of $r_i = (Obama, meets, Putin)$ is the relation $r'_i = (Putin, meets, Obama)$. The method $SimRD(r_i, d_2)$ is defined on Equation 1.

The document to document similarity $SimDD(d_1, d_2)$ is the average relation score rs_i for every relation $r_i \in R_{d1}$ with the document d_2 and is defined on Equation 2. Since $SimDD(d_1, d_2)$ is not a symmetric function it is not suitable for a similarity metric. The final relation similarity $RelSim(d_1, d_2)$ defined on Equation 3 is the metric we use to compare two documents in terms of their relations. It is important to note that the computational complexity of RelSim is $O(|R_{d1}| * |R_{d2}|)$. However, the relations identified per document are on average only 10 with a standard deviation of 9. Thus, the computational complexity of RelSim won't affect the system scalability.

$$SimRD(r_i, d_2) = \max_{r_j \in R_{d2}} (max(Cos(r_i, r_j), Cos(r'_i, r_j))) \quad (1)$$

$$SimDD(d_1, d_2) = \frac{sum_{r_i \in R_{d1}}(SimRD(r_i, d_2))}{|R_{d1}|} \quad (2)$$

Feature	LSH-RelFSD	LSH-RelEntFSD
$CosSim(d, d_n)$	✓	✓
$RelSim(d, d_n)$	✓	✓
$EntOverlap(d, d_n)$	✗	✓
$RelEntOverlap(d, d_n)$	✗	✓

Table 1: The similarity features between d and d_n used by our methods.

$$RelSim(d_1, d_2) = \frac{SimDD(d_1, d_2) + SimDD(d_2, d_1)}{2} \quad (3)$$

3.3 Entity-Relation FSD

We only focused on extracting relations from news articles, simplifying them and using them as a distance metric for document comparison. Having these ingredients, in this section we describe how to use the relation similarity (*RelSim*) discussed above in order to perform first story detection. We present two supervised approaches, *LSH-RelFSD* and *LSH-RelEntFSD*, that address the FSD task as a binary classification problem. The first uses as features the cosine similarity and the relation similarity between and new document d and its nearest neighbor d_n. The latter uses also entity similarity features. The classifier we use, since the method is supervised, is a Logistic Regression. The features used for a new document d and its nearest neighbor d_n are presented on Table 1. CosSim is the term cosine similarity employed also by UMASS. RelSim is the similarity function described in the previous section. EntOverlap is the overlap of the entities that appear on the documents and RelEntOverlap is the overlap of the entities present in the relations.

4 Evaluation Setup

In this section we describe our evaluation framework. We provide details about the datasets, the annotation process, the system configuration, and the pipeline parameters.

4.1 Datasets

We decided to evaluate the scalability and accuracy of our FSD pipeline on three datasets: (1) A Yahoo News dataset (D1) under the category "Politics and Government" that we created using an event-guided annotation procedure described in (Petrović et al., 2012). In order to simplify the annotation process for the dataset (D1) we implemented a user-friendly web interface, which allows the easy labelling of the documents in terms of events. We make the tool available[3]. This dataset consists of 652 documents, 89 are first stories and 563 are non first stories. (2) A Google News dataset (D2) that was proposed in (Karkali et al., 2013). This dataset consists of 2006 documents about "Technology" where 1491 are annotated as first stories and 515 are annotated as non first stories. Clearly, the datasets (D1) and (D2) have different label distributions. (3) A much larger synthetic dataset (D3) of $106,000$ documents from Yahoo News is used in order to evaluate the scalability of our method. However, this dataset is not annotated and thus is not used for evaluating the accuracy.

4.2 System Instantiation

In order to compare our system with existing state-of-the-art systems, we implemented to the best of our ability the following systems: (i) LSH-UMASS by (Petrović et al., 2010) and (ii) PAR-UMASS by (Petrović et al., 2012). (Karkali et al., 2013) define several measures to evaluate the novelty of a document's terms; we use here the ones they suggest that perform best for the content, namely (iii) NTD, (iv) NBD, (v) NBU. (vi) CS-NE-Top suggested by (Kumaran and Allan, 2005). LSH-UMASS, PAR-UMASS and CS-NE-Top are similar to our method in that they also initially detect the nearest neighbor of a new document. LSH-UMASS uses the incremental TF-IDF weighted term vectors while PAR-UMASS expands the vectors according to a pool of syntactic paraphrases. CS-NE-Top uses the similarity of the term, the entity and the non-entity (topic) vectors and similarly to our technique uses a classifier in order to combine the multiple similarity features.

LSH-UMASS, LSH-RelFSD and LSH-RelEntFSD use locality sensitive hashing as described in (Petrović et al., 2010), to efficiently identify the nearest neighbor. The required multi-LSH index parameters were set to $K = 5$ and $L = 20$ which result in missing a nearest neighbor of distance 0.3 with probability $\delta = 0.025$. The maximum LSH bucket size was set to 1000. For the PAR-UMASS system paraphrases available online[4] with Precision more than 0.4 are used. For NBU, NTD, and NBD we set the required parameter N to 60.

(a) Dataset (D1)

(b) Dataset (D2)

Figure 3: FSD systems comparison in terms of Precision, Recall and F-Measure.

4.3 System Description

We preprocessed our dataset (D3) on a large commercial Hadoop Cluster. The preprocessing was implemented via a Pig script in order to effectively allocate the required resources and run the Map-Reduce job. The job took less than 2 hours to extract the necessary metadata for the January 2016 dataset (D3). Datasets (D1) and (D2) are much smaller than (D3), and the preprocessing was done on a single machine. For evaluating our pipeline accuracy and performance we used a 4-core Intel i7 CPU with 32GB of RAM.

4.4 Evaluation Metrics

In order to evaluate the FSD task we used Precision, Recall, and F-Measure. Datasets (D1) and (D2) are fully labeled, so it is possible to calculate the above metrics averaged over the two classes. Also, a commonly used metric for FSD is the detection error trade-off (DET) score. DET score is defined in Equation 4 and depends on the probability of missing a first story P_{miss} and the probability of a false alarm P_{fa} for a specific threshold τ. For each system we find the threshold τ that minimizes P_{fa} and P_{miss} and achieves the lowest DET score DET_{min}. The costs of a false alarm and missing a first story C_{fa} and C_{miss} are set to 1.0, P_{target} is set to 0.5 similarly to (Karkali et al., 2013). All the evaluation metrics are calculated under 5-fold stratified cross validation.

$$DET = C_{miss} * P_{miss} * P_{target} + C_{fa} * P_{fa} * (1 - P_{target}) \quad (4)$$

5 Experimental Results and Discussion

5.1 First Story Detection Performance

In Figure 3a, we present the performance of various FSD systems on the Yahoo News dataset (D1). Clearly, the systems that incorporate entity or relation information have a significant advantage on this dataset. LSH-RelEntFSD achieves a F-Measure of .73 and CS-NE-Top, which comes second, achieves a F-Measure of .70. LSH-RelFSD and NBU systems that follow on this dataset achieve a F-Measure of .65. In terms of Precision, LSH-RelEntFSD and CS-NE-Top report .67 and .64 while their Recall is .81 and .77 respectively. The rest of the systems score F-Measure values between .40 and .61.

In Figure 3b, we present the performance on the Google News dataset (D2). LSH-RelEntFSD achieves the best performance with a F-Measure of .57. CS-NE-Top and LSH-RelFSD that follow both report a F-Measure of .55. The systems LSH-UMASS and PAR-UMASS that come next achieve a F-Measure of .54. The Precision and the Recall for LSH-RelEntFSD is $\sim$ .57. The remaining systems report F-Measure values up to .52.

The results for the DET_{min} evaluation metric are shown in Table 2. The best performance on both datasets is achieved by LSH-RelEntFSD and CS-NE-Top. On the Yahoo news dataset (D1) our LSH-RelEntFSD system achieves a 17.3% improvement over the state-of-art supervised system CS-NE-Top and a 29.6% improvement over the best unsupervised system NBU. On the Google news dataset (D2), LSH-RelEntFSD achieves a 4.4% improvement in the DET_{min} score over the best unsupervised system.

The improvement in Det_{min} score is statistically significant for the dataset (D1) at the $p < 0.05$ level using a paired t-test. However, for dataset (D2) all methods perform close to the best method (LSH-RelEntFSD) and so the results are not statistically significant. To understand our results in (D2) we explored the nature of this dataset in more detail and discovered that the dataset contains many non-news articles, such as product descriptions, reviews as well as personal opinions. The impact is two-fold: firstly, incorporating entity and relation information on these articles is not as important as in dataset (D1) about "Politics and Government" where many named entities

Method	$Det_{min}(D1)$	$Det_{min}(D2)$
LSH-UMASS	.35	.45
PAR-UMASS	.36	.45
NBU	.27	.5
NTD	.62	.5
NBD	.42	.47
CS-NE-Top	.23	.44
LSH-RelFSD	.27	.44
LSH-RelEntFSD	**.19**	**.43**

Table 2: Det_{min} scores for the Yahoo (D1) and Google (D2) datasets.

participate and interact. In addition, we discovered that for several of the articles in (D2), in particular among those that are reviews, descriptions or opinions, there is significant ambiguity whether they should have been classified as new stories or not. This clearly impacts the performance of all the techniques.

Our proposed pipeline outperforms all the methods used on both datasets. This strengthens the conclusion that a linear classifier that combines multiple similarity features is essential in order to effectively address the task at hand. The supervised system CS-NE-Top is the closest competitor reporting similar performance as LSH-RelEntFSD on dataset (D2) while LSH-RelEntFSD outperforms CS-NE-Top on dataset (D1) by 17.3%. This improvement results mainly from taking into account the entity relations in addition to the entity and term similarity features.

5.2 Space and Time requirements

Since our system should be able to process hundreds of thousands or even millions of documents per day we ensure that the algorithm's time and space requirements do not increase as the stream progresses. Figure 4 illustrates the processing time required per document on the large Yahoo News dataset (D3). Clearly, it shows that the processing time per document remains steady over time and it is less than $20ms$ on average. This result suggests that the processing time per document does not grow with the stream time making the method suitable for high volume streams. The four large spikes on the figure are caused due to the memory allocation and cleaning operations performed by the Java virtual machine. In addition, the memory usage is also steady and did not exceed $18GB$ of which $7GB$ were required by the Word2Vec model.

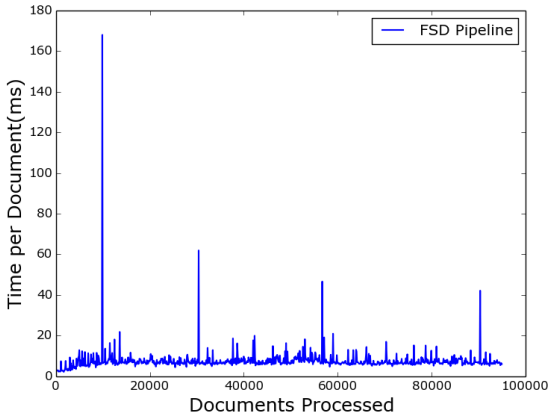

Figure 4: Processing time per document.

6 Conclusions

In this work, we proposed a scalable first story detection pipeline that exploits relations between entities in order to deduce the freshness of a document. To the best of our knowledge, our approach is the first one to integrate relations between entities in a FSD system. We proposed a novel document representation based on relation triplets and described a similarity function on that representation. The positive results on two datasets provide evidence that incorporating relation information helps to detect new events. Another advantage of our method is that it addresses indirectly the synonymy problem through the usage of Word2Vec in the relation representation. Finally, we demonstrated that our system is scalable with constant space and time requirements by investigating the behaviour on a large dataset.

Textual complexity as a predictor of difficulty of listening items in language proficiency tests

Abstract

In this paper we explore to what extent the difficulty of listening items in an English language proficiency test can be predicted by the textual properties of the item text. We show that a system based on multiple text complexity features can predict item difficulty for several different item types and for some items achieves higher accuracy than human estimates of item difficulty.

1 Introduction

Many language proficiency tests measuring listening or reading comprehension consist of multiple questions or "items" of varying complexity. For simpler items, finding the correct answer may be easy even for relatively low-proficiency speakers while other, more difficult, items require higher levels of proficiency. In addition, multiple sets of items or "forms" are usually created for large-scale language tests to reduce the possibility that the test takers are already familiar with a particular item. In order to be fair to all test takers, such forms need to be comparable in terms of difficulty of the items they contain. Therefore item difficulty is a crucial parameter for every new item added to the test. In test theory, item difficulty is defined by the proportion of the test takers who answer the item correctly (Holland and Thayer, 1985). This value can be estimated empirically by a pilot study before the item is used in an actual test. However, reliable estimates of item difficulty require a substantial amount of test taker responses. There are also concerns about item exposure, especially if an item is to be used in a high-stakes test.

In this study we consider an automated system for item difficulty prediction that can help obtain quick estimates of item difficulty for new items and assist test developers in creating items of varying complexity while retaining form comparability. The novel contribution of this study is the application of the state-of-the-art findings related to predicting the difficulty of spoken texts to predicting the difficulty of listening items in a language proficiency test.

Listening comprehension items often consist of a recorded passage followed by a printed or recorded multiple choice question related to this passage. Several studies have investigated the factors that affect the difficulty of such listening and reading test items. Previous work on item difficulty prediction (Boldt and Freedle, 1996; Freedle and Kostin, 1996; Nissan et al., 1995; Rupp et al., 2001) identified three types of variables that affect item difficulty. The first category are the variables related to the text such as its length or information density. The second group of variables consider various properties of the question, for example, the number of negatives in correct and incorrect responses ("distractors") to the question or lexical overlap between the correct and incorrect responses. Finally, the last group of variables considers interaction between the text and the question, for example, what kind of information a test taker needs to extract from the text to provide the correct answer. In these studies a relatively small number of features from all of these groups were moderately predictive of item difficulty with an R^2 around 0.3. More recently, Hoshino and Nakagawa (2010), Susanti et al. (2016), and Beinborn et al. (2014) developed item difficulty prediction systems for other types of items such as those contained in Cloze tests or vocabulary tests. They used features that assess (a) the difficulty of a passage, (b) the difficulty of a correct answer,

Proceedings of COLING 2016, the 26th International Conference on Computational Linguistics: Technical Papers, pages 3245–3253, Osaka, Japan, December 11-17 2016.

and (c) the similarity between the correct answer and the distractors, but the detailed implementation of features and the performance in predicting item difficulty substantially varied across different studies. These studies were also conducted on relatively small numbers of items and test takers.

While previous studies found that all three categories of features were predictive of item difficulty, many of the features were designed for particular item types and therefore required new features to be developed for new item types. In this study, we use a large corpus of items to investigate whether item difficulty can be estimated using a large pool of more general text complexity features that can be applicable across a wide range of items. In contrast to previous studies such as Beinborn et al. (2014), which were generally limited to items comprised of short texts, some item-types in this study assess the understanding of relatively long texts, and this further motivates our use of generic text complexity features in the item difficulty prediction.

Compared to the relatively limited number of studies on item difficulty, there exists extensive research on the factors that affect ESL reading and listening comprehension as well as automated text difficulty prediction systems for spoken and written texts. Mature automated text difficulty prediction systems (Landauer et al., 1998; Sheehan et al., 2013) are already available and have been used operationally to evaluate reading materials selected for use in instruction and assessment. For listening materials, a comprehensive list of features known to affect a spoken text difficulty has been recently provided by Bloomfield et al. (2010) who classified these features along four dimensions: length, complexity, organization, and auditory features. Moreover, many studies explored individual features. Thus syntactic complexity and vocabulary difficulty features have been found to have a strong and consistent effect on reading and listening comprehension (Blau, 1990; Nissan et al., 1995). For the auditory dimension, speaker accent, disfluencies, audio quality (background noise), and speaking rate were found as important factors (Blau, 1990; Brindley and Slatyer, 2002). Based on these findings, Kotani et al. (2014) and Yoon et al. (2016) developed fully automated spoken text difficulty prediction systems and reported promising performances.

Of the four dimensions identified by Bloomfield et al. (2010), the auditory dimension of the items in this study was generally held almost constant since acoustic characteristics such as speaker accent, speaking rate, and audio quality were closely monitored during the original recording. As a result, they were very homogenous. Therefore, we focused on the first three dimensions: length, complexity and organization of the item text, and we explored whether these can predict item difficulty as measured empirically.

This study focuses on the following aspects:

- We use a set of generic text complexity features for four largely different item-types.
- We use a large set of items with an objective item difficulty index estimated by students' performance from a large scale language proficiency test.
- We provide further insight about the relationship between item difficulties and passage difficulties.

2 Data and methodology

2.1 Corpus of listening items

We used a large collection of listening items from an international English language proficiency test. The corpus comprised four types of multiple choice items listed here in increasing order of complexity:

- Picture description (*PD*): Test takers are presented with a picture and four recorded statements. Their task is to select the statement that best describes the given picture.
- Dialogue completion (*DC*): Test takers hear a question or a statement and several possible responses. Their task is to choose which response is the most appropriate.
- Conversation (*C*): Test takers listen to a conversation between two speakers and answer a series of printed questions about the content of the conversation.

- Monologue (*M*): Test takers listen to a recording of a monologue (e.g., announcement or advertisement) and answer a series of printed questions about the content of the recording.

Compared to *PD* and *DC*, the *C* and *M* items have a more complex structure. For these two item types the items are clustered into testlets or sets with three items per testlet. All items in the same testlet refer to a common listening passage (conversation or monologue). The listening passages in *C* and *M* items are also much longer than in *PD* and *DC* items; the number of words ranged from 41 to 174 and the mean was 97.17. *C* and *M* item are further classified into gist items that assess understanding of the central idea and detail items that assess understanding of details.

The total number of items used in this study is presented in Table 1. The items were included in 154 operational test forms administered from 2009 to 2013 to two groups of test takers referred to hereafter as Group A and Group B. Both groups included English language learners, but the two groups took test in different countries. The number of test takers for each admin was around 30,000 on average, and the minimum number of test takers was 3,599.

Group	Total	*PD*	*DC*	*C*	*M*
Group A	5092	520	1569	1501	1502
Group B	6436	671	2011	1872	1882
Both	1694	165	511	504	514
Total	9834	1026	3069	2869	2870

Table 1: The number of items of different types across the two populations

2.2 Item difficulty indicators

2.2.1 EQDelta

The difficulty of each item was estimated by delta. It is computed by Eq. 1,

$$\Delta = 13 - 4Z_p \tag{1}$$

where p is the proportion of the test taker population who answered the item correctly and Z_p is the Z value corresponding to a given p value in the standard normal distribution (Holland and Thayer, 1985).

Thus on the delta scale, the higher delta values denote more difficult items. In the testing program, the observed deltas obtained from different test forms were equated to a common scale, so that the equated deltas can be compared across test forms. These empirically obtained equated deltas ("EQDelta") were used as a response variable in our study.

The descriptive statistics of item difficulty are shown in Table 2. The means of different item-types ranged from 11.54 to 13.08.

Group	Item-type	Minimum	Maximum	Mean	Std. Deviation
Group A	*PD*	6.50	17.20	11.54	2.21
	DC	7.50	16.50	12.36	1.43
	C	8.50	16.70	12.99	1.32
	M	9.00	17.30	13.08	1.33
Group B	*PD*	6.20	17.50	11.94	2.14
	DC	7.70	17.30	12.45	1.45
	C	8.40	16.80	12.75	1.42
	M	7.60	17.00	12.88	1.44

Table 2: Descriptive statistics of EQDelta

2.2.2 Item sequence

The Equated Deltas can only be computed after the item has been administered to a certain number of test takers. When creating new items, test developers rely on their experience and prior understanding of item difficulty drivers to vary the difficulty of the items. This predicted difficulty is generally used to sequence the items within each form in increasing order of difficulty. Note that the relationship between the item sequence and item difficulty is less direct for *C* and *M* items where several items are combined in sets. In this case the placing of the items in the form are determined by the overall difficulty of the whole set and therefore item order is a less useful indicator of the perceived difficulty of individual items within each set. Nonetheless in the absence of other criteria, item sequence can be used as a proxy for expert human estimate of item difficulty, a useful benchmark for the automated system for item difficulty prediction.

2.3 Text complexity features

In order to obtain text features, we used an automated text complexity prediction system, *TextEvaluator* (Sheehan et al., 2013; Sheehan et al., 2014; Napolitano et al., 2015). *TextEvaluator* is a fully automated system which was created to assess the complexity of reading passages for both native and non-native speakers including the complexity of reading items in English Language proficiency tests (Chen et al., 2015).

TextEvaluator generates 339 raw features based on vocabulary lists and various NLP technologies such as tagging and automated parsing. The features were designed to measure the degree of complexity along the four dimensions: vocabulary, syntax, cohesion, and discourse. These features can be categorized into the follow subgroups:

- Academic Vocabulary (vocabulary): features in this dimension measure the proportion of academic vocabulary in the text. e.g., the frequency of academic words normalized by text length
- Concreteness (vocabulary): features in this dimension measure the degree of concreteness of the text by aggregating concreteness rating of each word in the text.
- Word unfamiliarity (vocabulary): features in this dimension measure the difficulty of vocabulary used in the text. e.g., the frequency of rare words normalized by text length
- Syntactic Complexity (syntax): features in this dimension measure the complexity of grammatical structures used in the text. e.g., the average frequency of long sentences, and average number of words per sentence.
- Cohesion (cohesion): this dimension includes two different types of features (cohesion): frequency of content word overlap and frequency of casual conjuncts.
- Argumentations (cohesion): this dimension includes two features: the frequency of concessive and adversative conjuncts
- Conversational style (discourse): features in this dimension measure the proportion of words related to conversational text (e.g., conversational verbs, communication verbs, and contractions)
- Degree of narrativity (discourse): features in this dimension calculate the frequency of expressions related to narrativity (e.g., frequency of past tense verbs and frequency of 3rd person singular pronouns.)

TextEvaluator analyzed the features of the entire item: the audio, the question, and the options for item types *PD* and *DC*. For item types *C* and *M*, which consist of an audio stimulus share between the three items and 3 items consisting of a question related to this stimulus and possible responses, *TextEvaluator* extracted separate sets of features for the the stimulus and for each item.

Item	Group A			Group B		
	IS	TC	V	IS	TC	V
PD	0.40	0.49	0.41	0.58	0.52	0.47
DC	0.44	0.40	0.33	0.40	0.40	0.28
C	0.09	0.24	0.16	0.22	0.27	0.19
M	0.22	0.33	0.29	0.20	0.26	0.19

Table 3: Model performance (Pearson's r between predicted and observed EQDelta) based on item sequence (IS), all text complexity features (TC) and vocabulary features only (V) for two populations of test takers

2.4 Experiment design

The goal of the experiment was to evaluate how well *TextEvaluator* features can predict EQDelta for each item. For a benchmark we used the system which predicts the EQDelta based on a single feature: the position in which the item appears in the form, which to some degree reflects the estimate of item complexity assigned to the item by test developers[1].

We built separate models for each of the two populations and four different item types. For *C* and *M* items, which consisted of both recorded propmt and printed questions, we trained 3 types of models: the complexity of a recorded passage only, the complexity of printed questions only, and both sets of features.

For each group, the data were randomly split into training (50%), development (25%) and evaluation (25%) partitions. For *C* and *M* items the partitions were created so that the items related to the same stimulus were always in the same partition. The models were trained on the training set, fine-tuned using evaluations on the development set and finally evaluated on held-out evaluation set.

We used 9 regressors available via SKLL package (Blanchard et al., 2016) to map either the item sequence or the text complexity features to the EQDelta. These included ordinary least squares linear regression, LASSO regression, decision tree regression, elastic net, k-neighbours regression, stochastic gradient descent regression, linear and non-linear support vector regressions and random forest regression. The model performance was evaluated by correlation between predicted and observed EQDelta on new data.

3 Results

The analysis of model performance on the development set showed that for *TextEvaluator* features random forest regressor consistently outperformed other learners. All classifiers produced similar results for the benchmark system based on item sequence. Therefore for consistency we used random forest regressor for both benchmark and complexity-based models.

3.1 Item sequence benchmark

The dependency between item sequence and its empirically established difficulty varied between the item types (see Table 3). Item sequence was the strongest predictor of item difficulty for the two simpler items, *PD* and *DC*, with r varying between 0.40 and 0.58. As expected, the performance was noticeably lower for *C* and *M* (r between 0.09 and 0.22) since these items are combined into sets and sequenced by the overall difficulty of the sets. These patterns were observed for both populations.

3.2 Text complexity

We first looked at the performance of the models based on text complexity of the whole item presented to the test taker. For *PD* and *DC* the complexity features were computed on the script of the recorded item text. For items *C* and *M* these models contained features computed for the recorded passage and printed questions.

[1]For items that have been used in several forms we average both EQDelta and item position across these forms

Item type	Group A		Group B	
	IS	TC	IS	TC
PD	0.50	0.42	0.42	0.42
DC	0.45	0.44	0.34	0.32
C	0.08	0.31	0.20	0.32
M	0.18	0.29	0.12	0.26

Table 4: Model performance (Pearson's r between predicted and observed EQDelta) based on item sequence (IS) and Text complexity (TC) on the held-out evaluation set

The performance of the complexity-based models generally followed the same pattern as was previously observed for sequence-based models: the correlation between predicted and observed items decreased from simpler to more complex items with r around 0.4-0.5 for *PD* items and r around 0.24-0.33 for *M* and *C*.

When compared to human benchmark, for *PD* and *DC* items the models based on text complexity produced similar results. At the same time, the complexity of the text for *C* and *M* items was a better predictor of item difficulty than the item sequence benchmark.

In order to further investigate the relationship between item type and item difficulty prediction, we analyzed the distribution of EQDelta using training data partition.

If EQDelta was not normally distributed for a certain item type (e.g., with a skew towards easy or difficult items), it may have increased the difficulty of the automated prediction and decreased the correlation between predicted difficulty and EQDelta. However, we did not find such tendency; all item types showed a normal distribution. We also found that EQDeltas for *PD* item type were more widely distributed than other items. The standard deviation was approximately 1.4 times greater than for the other item types. This wider distribution of EQDeltas may contribute to higher performance of the automated system for *PD* item type.

Finally, we explored what features contributed most to the final prediction by computing the variable importance for each feature (Breiman, 2001). We found that for all item types the most highly ranked features were related to the lexical content of the item text. These 26 features covered three aspects of vocabulary: first, vocabulary diversity measured as type-to-token ratio in item text. Second, the difficulty of vocabulary in the item text as measured by the frequency of the words in different corpora; Third, the concreteness and imageability of the text (Sheehan et al., 2013). Table 3 shows the performance of all models considered in this study.

3.3 Model performance on the evaluation set

Our analysis of system performance on the development set reported in the previous sections showed the best performance was achieved by the system based on all text complexity features and random forest regressor. We therefore evaluated the performance of these final models on the held-out evaluation set that had not been used for any other analyses.

The results were consistent with what was observed on the development set. These are presented in Table 4.

3.4 Comparison between recorded and printed parts of the item

Two types of items in our study, *C* and *M*, consisted of a listening passage shared between different items within a testlet and printed questions unique for each item. For these two item types we compared performance of text complexity features computed on different parts of the items. *C* and *M* items infer the test takers' understanding of the listening passage. Therefore we initially hypothesized that the text complexity of a common listening passage would be a strong predictor of the item difficulty. However, the empirical results did not support this.

For both populations for the *C* items the performance of the models based on the listening passage was slightly better than the one based on the printed question. There was further improvement from

combining the two parts of the items. At the same time for *M* items the performance of the model based on the listening passage was substantially lower than that of the model based on the printed question. There also was only a very little improvement when the listening passage was added to printed question. These results are presented in Table 5.

Type	Item part	Group A	Group B
C	Listening passage	0.20	0.22
C	Printed question	0.18	0.17
C	Both	0.24	0.27
M	Listening passage	0.19	0.12
M	Printed question	0.30	0.24
M	Both	0.33	0.26

Table 5: Baseline performance (Pearson's r) for models based on different parts of complex items

4 Discussion

In this paper we explored to what extent the text complexity of the item text can be used to predict item difficulty. We compared text complexity-based prediction system to the benchmark system based on item sequence, which we treated as an indication of test developer intuition about item difficulty.
